Stroke

Anne M. Woodson

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define stroke, or cerebrovascular accident, and briefly describe the causes, incidence, and impairments and disabilities that can result from stroke.
2. Describe the continuum of care for individuals recovering from stroke, including the interdisciplinary team, the various settings for care, and the phases of recovery and intervention.
3. Describe methods for evaluating areas of occupation, performance skills and client factors of patients recovering from stroke.
4. Suggest goals and methods for treatment to improve the occupational performance and performance skills and client factors of patients recovering from stroke.
5. Analyze the effectiveness of occupational therapy intervention in improving a patient's quality of life and adjustment to life with stroke.

Stroke, or cerebrovascular accident (CVA), describes a variety of disorders characterized by the sudden onset of neurological deficits caused by vascular injury to the brain. Vascular damage in the brain disrupts blood flow, limits oxygen supply to surrounding cells, and leads to brain tissue death or infarction. The mechanism, location, and extent of the lesion determine the symptoms and prognosis for the patient. This chapter focuses on patients with stroke, but nonvascular brain trauma or disease, such as gunshot wounds or tumors, may manifest many of the same neurological deficits and may be treated similarly.

CAUSATION

Strokes are usually classified by the mechanism and location of the vascular damage. The two broad causes are ischemia and hemorrhage. Ischemic strokes result from a blockage of a cerebral vessel and can further be categorized as caused by thrombosis or embolism. Thrombosis is the stenosis or occlusion of a vessel, usually as a result of atherosclerosis. This occlusion is typically a gradual process, often with preceding warning signs, such as transient ischemic attack (TIA). An embolism is dislodged platelets, cholesterol, or other material that forms at another location, travels in the bloodstream, and blocks a cerebral vessel. Ischemic strokes are the most common type, accounting for about 87% of strokes (American Stroke Association, 2011).

Hemorrhagic strokes result from a rupture of a weakened cerebral blood vessel. In such strokes, blood accumulates outside of the vascular space and compresses surrounding brain tissue. Hemorrhagic strokes are either intracerebral (bleeding into the brain itself) or subarachnoid (bleeding into an area surrounding the brain). Aneurysms and arteriovenous malformations are the most common types of weakened blood vessels causing hemorrhagic strokes (American Stroke Association, 2011). Hemorrhagic strokes are less common (an estimated 13% of strokes), but they result in a higher mortality rate than ischemic strokes (Roger et al., 2011).

Location of Involvement

Most lesions are either anterior circulation strokes, which present signs and symptoms of hemispheric dysfunction, or posterior circulation strokes, which display signs and symptoms of brainstem involvement (Simon, Greenberg, & Aminoff, 2009). Another distinction related to location of CVA is whether the lesion results from large-vessel or small-vessel disease. Thrombosis occurs most often in the large cerebral blood vessels. Small-vessel, or lacunar, strokes are very small infarctions that occur only where small arterioles branch off the larger vessels (National Institutes of Health, 2011).

INCIDENCE

Stroke is the third leading cause of death in the United States and a leading cause of chronic disability among adults. Of the estimated 795,000 persons who have first or recurrent

CVAs in the United States each year, approximately two-thirds survive, bringing the number of stroke survivors in the U.S. population at any one time to over nine million (American Stroke Association, 2011). Stroke is the most common neurological diagnostic category among patients seen by occupational therapists (National Board for Certification in Occupational Therapy, 2008). The projected aging of the U.S. population is expected to raise the incidence of stroke, because about two-thirds of all strokes occur in those older than age 65 years (National Institutes of Health, 2011).

MEDICAL MANAGEMENT

Acute stroke care focuses on determining the cause and site of the stroke, preventing progression of the lesion, reducing cerebral edema, preventing secondary medical complications, and treating acute neurological symptoms (Bartels, 2011). Techniques of diagnostic imaging, including computed tomography (CT) and magnetic resonance imaging (MRI), can distinguish ischemic from hemorrhagic lesions and define their location, size, and vascular territory (National Institutes of Health, 2011).

In acute ischemic stroke, treatment concerns include restoration of blood flow and limitation of neuronal damage. Medications, including antithrombotics and thrombolytics, are the most common medical intervention for stroke (National Institutes of Health, 2011). Antithrombotics include antiplatelet drugs (such as aspirin) and anticoagulation drugs (such as heparin) and are used to prevent further clotting or thrombosis. After stroke, physicians mainly prescribe antithrombotics for prevention, because first time stroke survivors are at a high risk for recurrent strokes (National Institutes of Health, 2011). Thrombolytic drugs, such as tissue plasminogen activator (tPA), help reestablish blood flow to the brain by dissolving clots in cerebral vessels. A 5-year trial conducted by the National Institute of Neurological Disorders and Stroke found that appropriately selected subjects treated with tPA within 3 hours of onset of stroke symptoms were at least 33% more likely than patients given a placebo to recover from their stroke with little or no disability (National Stroke Association, 2011). The use of thrombolytics is limited, however, by the associated increased risk of hemorrhage and the fact that they must be administered within a 3-hour window after stroke onset for effectiveness. It is estimated that only 3%–5% of persons suffering a stroke will seek medical attention in time for possible tPA treatment (American Stroke Association, 2011). With hemorrhagic stroke, acute treatment includes control of intracranial pressure, prevention of rebleeding, maintenance of cerebral perfusion, and control of vasospasm. Surgery or endovascular procedures are often recommended to limit damage (National Stroke Association, 2011).

RECOVERY FROM STROKE

The specific abilities lost or affected by stroke and the degree and time course of recovery from stroke vary with

the location, type, and extent of the initial injury, and treatment provided (National Stroke Association, 2011). Early initial improvement or spontaneous recovery occurs because pathologic processes in the brain resolve, and neurotransmission resumes near and remote from an infarct or hemorrhage (Dobkin, 2005). Later, ongoing improvement occurs with structural and functional reorganization within the brain, or neuroplasticity; the term neuroplasticity refers to transiently achieved functional changes in the context of learning and recovery, as well as structural changes on the cellular level. Neuroplasticity includes greater excitability and recruitment of intact neurons in both hemispheres of the brain as a response to stimulation, participation, training, and experience (Albert & Kesselring, 2011). Langton Hewer (1990) described a model of stroke recovery that includes both intrinsic neurological and compensatory adaptive recovery.

Intrinsic recovery refers to the remediation of neurological impairments, such as return of movement to a paralyzed limb. Adaptive recovery entails regaining the ability to perform meaningful activities, tasks, and roles without full restoration of neurological function, such as using the unaffected hand for dressing or walking with a cane or walker. Most patients gain some degree of both intrinsic (neurological) and adaptive (compensatory) recovery. Rehabilitation, including occupational therapy (OT), is designed to facilitate both processes to maximize an individual's function and participation after stroke.

Neurological Impairments and Recovery

Each survivor of a CVA has a unique combination of deficits determined by the location and severity of the lesion. Definition 33-1 lists the most commonly encountered

Definition 33-1

Neurological Impairments Following Stroke

Neurological Deficit	Possible Effect on Occupational Function
Hemiplegia, hemiparesis	Impaired postural adaptation, bilateral integration Impaired mobility Decreased independence in any or all basic activities of daily living (BADL) and instrumental activities of daily living (IADL)
Hemianopsia, other visual deficits	Decreased awareness of environment, decreased ability to adapt to environment Impaired ability to read, write, navigate during mobility, recognize people and places, drive; can affect all BADL and IADL
Aphasia	Impaired speech and comprehension of verbal or written language; inability to communicate, read, or comprehend signs or directions Decreased social, community involvement; isolation
Dysarthria	Slurred speech, difficulty with oral motor functions such as eating, altered facial expressions
Somatosensory deficits	Increased risk of injury to insensitive areas Impairment of coordinated, dexterous movement
Incontinence	Loss of independence in toileting Increased risk of skin breakdown Decreased social, community involvement
Dysphagia	At risk for aspiration Impaired ability to eat or drink by mouth
Apraxia	Decreased independence in any motor activity (ADL, speech, mobility), decreased ability to learn new tasks or skills
Cognitive deficits	Decreased independence in BADL and IADL, decreased ability to learn new techniques, decreased social interactions
Depression	Decreased motivation, participation in activity; decreased social interaction

neurological impairments following stroke and describes the possible effects of each on occupational functioning. The most typical manifestation of CVA is hemiparesis or hemiplegia, ranging from mild weakness to complete paralysis on the side of the body opposite the site of the CVA. About 80% of people who have had a stroke have some degree of hemiparesis (National Stroke Association, 2011), although the rate of physical impairment usually decreases after the first 3–6 months poststroke (Roger et al., 2011).

Certain impairments are associated with lesions in a particular hemisphere. For example, left CVA may cause right hemiparesis, aphasia or other communication deficits, and/or apraxia or motor planning deficits. Right CVA may result in left hemiparesis, visual field deficits (VFDs) or spatial neglect, poor insight and judgment, and/or impulsive behavior (American Stroke Association, 2011).

Many patients do not regain full movement or function of the upper extremity. Studies report that 65% of individuals after stroke are unable to incorporate their hemiparetic upper extremity into daily function (Lum et al., 2009). Historically, motor recovery in the patient with hemiparesis was described as progressing from proximal to distal movement and from mass, patterned, undifferentiated movement to selective, coordinated movement (Brunnstrom, 1970; Fugl-Meyer et al., 1975). Therapists now rarely see such a distinct progression of motor recovery in patients, partly because thrombolytic agents limit brain damage and partly because insurance restrictions limit long-term rehabilitation services.

Functional Recovery

Much attention is given to the functional outcomes of patients surviving stroke. Although residual neurological deficits can lead to permanent impairments, activity limitations, and participation restrictions, impairments alone do not predict levels of disability or occupational functioning (Kelly-Hayes et al., 2003). Important aspects of functional recovery include the amount of assistance required to carryout daily living tasks and whether a stroke survivor can resume function at home. The National Stroke Association (2011) estimates that 10% of persons surviving stroke recover almost complete function, 25% recover with minor impairments, 40% experience moderate to severe impairments requiring special care, 10% require care in a nursing home or other long-term care facility, and 15% die shortly after the stroke. Studies indicate that independence in activities of daily living (ADL) improves with time after an acute stroke, although a large community-based study found that among persons 65 years of age or older who survived an ischemic stroke, 26% were dependent in ADL, and 30% were unable to walk without some assistance 6 months after stroke (Kelly-Hayes et al., 2003).

Few studies have addressed the recovery of instrumental activities of daily living (IADL), such as home management, work, leisure, or community skills. One study analyzing stroke survivors' functional status found that the majority of participants were able to perform basic activities of daily living (BADL) 3 months after acute care but had difficulties in performing more complex IADL, which play a key role in enabling full participation in home and community life (Shih et al., 2009). Most persons surviving stroke report decreased levels of activity, socialization, and overall quality of life, with only an estimated 25% returning to the level of everyday participation of community-matched persons who have not had a stroke (Lai et al., 2002).

Factors Influencing Recovery

Research in stroke outcomes has sought to identify characteristics and indicators that predict survival rate, degree of disability, and functional status. No simple predictors have been identified from numerous prospective studies. Applying the Occupational Therapy Practice Framework (American Occupational Therapy Association [AOTA], 2008) to individuals poststroke illustrates the complexity and wide variability of factors influencing each stroke survivor. Body structures such as the type, size, and site of the brain lesion and body functions such as presence and severity of hemiparesis or aphasia influence the extent and course of recovery. In addition, the context of personal factors such as advanced age and the presence and severity of coexisting disease, such as diabetes, heart disease, and peripheral vascular disease, can impede optimal functional recovery. The effect of age may partly explain more frequent coimpairments, such as arthritis or dementia; many elderly patients with poor outcomes following a stroke had reduced function prior to the stroke (Stein & Brandstater, 2010). Environmental factors, such as access to acute stroke units and rehabilitation services, help from family members, can also enhance or inhibit recovery.

Occupational performance, particularly in BADL, is often used to predict long-term recovery because ADL measures are relatively objective, simple to use, and very relevant to quality of life (Shih et al., 2009). A study of patients with severe strokes, however, found that ADL status at discharge from a stroke center was not accurate for predicting recovery, suggesting that longer periods of time were needed to predict outcome in this group of patients (Kashihara et al., 2011).

Factors associated with poor functional outcomes include severe initial motor deficits, poor sitting balance, dependence in BADL, prior stroke, persistent bowel and urinary incontinence, severe visuospatial deficits, severe cognitive impairments, depression, severe aphasia, altered level of consciousness, and poor social supports (e.g., living alone). Factors that may predict good quality of life after stroke include family support, independence in BADL, and access to continued services (Stein & Brandstater, 2010).

Time Frame for Recovery

Summarizing stroke literature, the largest percentage of motor and functional recovery occurs in the first month after stroke. Improvement after 6 months poststroke can be expected but is limited (Verheyden et al., 2008). Plateaus in recovery may reflect the insensitivity of measurement scales to incremental improvements rather than a patient's reduced potential for learning new tasks or gaining skills (Dobkin, 2005). Lack of rehabilitation continuity or less intensive treatment over time may also explain plateaus (Verheyden et al., 2008). Studies examining recovery status tend to focus on limited factors (motor or BADL improvements) rather than on levels of activity or participation. Multiple studies have shown that patients more than 1 year poststroke can exhibit substantial motor and functional improvement after participation in novel rehabilitation protocols (Page, Gater, & Bach-y-Rita, 2004). Individual stroke survivors who have successfully resumed life roles or taken on new ones report the process of recovery as continuing years after onset of stroke, with gains reported both in component skills and occupational performance (Matola, 2001).

Stages of Recovery

A person's stage of stroke recovery, as well as setting for treatment and extent of impairment, will influence a therapist's selection of assessments and interventions. In this chapter, the description of OT services for stroke patients is divided into three stages: the acute phase immediately following stroke, the rehabilitation phase, and reentry to the community or stage of continuing adjustment (Sabari & Lieberman, 2008). For most patients, progression of recovery and provision of services are not this clear-cut. For a variety of reasons, many patients do not have access to the full spectrum of services with smooth continuity of care. Any evaluation or treatment described, therefore, may apply to any or all other stages for a particular patient and should be viewed as part of a continuum of care adapted to meet changing needs over time. Coordination of services and ongoing communication among patients, families, and care providers at each step of rehabilitation is mandatory for optimum outcomes.

ASSESSMENT

Numerous evaluations exist to identify stroke impairments and disability. Assessment practices vary greatly among therapists caring for individuals poststroke, and no single test is universally accepted (Gresham et al., 1995). To help in the selection and ordering of assessment tools, therapists are guided by models of practice and evidence-based practice guidelines. The OT assessment of a patient poststroke includes both determination of the occupational profile (the roles, tasks, and activities important to that individual) and analysis of the individual's occupational performance (his or her competence in performing these valued roles, tasks, and activities). Therapists consider each individual and the individual's stage of recovery when determining whether to follow a bottom-up or a top-down approach to client evaluation. During the acute stage, assessments of client factors and performance skills are most critical in determining immediate posthospital placement. During the rehabilitation and community-reentry stages, therapists must also consider activity demands, contexts, patterns of performance, and integration of skills in order to help clients reach goals for quality of life and participation in meaningful roles (Sabari & Lieberman, 2008).

Therapists can use available practice guidelines to assist in the selection of assessment tools. Recommended guidelines are the American Occupational Therapy Association's Occupational Therapy Practice Guidelines for Adults with Stroke (Sabari & Lieberman, 2008) and Appendix D of the American Heart Association/American Stroke Association's (AHA/ASA) Management of Adult Stroke Rehabilitation Care: A Clinical Practice Guideline (Duncan et al., 2005). The AOTA guideline lists both standardized assessments and observationally based assessments commonly used by occupational therapists with stroke survivors. The AHA/ASA guideline lists recommended well-validated standardized measures for all disciplines and stages of stroke care. The use of standardized evaluation tools helps ensure reliable documentation, achieve consistency of treatment decisions, facilitate team communication, and monitor progress for each survivor (Duncan et al., 2005). Often, multiple assessment instruments must be used because of the wide variation in individual stroke manifestations and the patient's changing needs over the course of recovery.

Therapists should be familiar with commonly used standardized stroke deficit scales because they are frequently used as an interdisciplinary summary of baseline function and as indicators of recovery or treatment outcomes. The National Institutes of Health Stroke Scale (NIHSS) (Brott et al., 1989) is a brief, well-validated tool that can be administered by physicians, nurses, or therapists. Items scored include consciousness, vision, extraocular movements, facial palsy, limb strength, ataxia, sensation, speech, and language. Although no single measure can fully describe or predict the diverse picture of stroke disability and recovery, the NIHSS is widely used as an initial assessment tool and for planning discharge disposition (Kasner, 2006).

Assessment of Areas of Occupation

The patient's ability to perform the self-care, leisure, vocational, home, and community tasks that he or she hopes to continue is evaluated by observation rather than report because there can be a difference between what a patient can do and actually does. Evaluation to determine a patient's level

of occupational functioning is administered early to predict answers to the following questions (Wade, 1992): (1) Where will the patient live, and what physical adaptations will be necessary? (2) How much and what type of assistance will the patient need? (3) What roles will the patient be able to fulfill, and how will he or she spend his or her time?

A patient's ADL performance in a structured clinical setting may not indicate performance at home. For example, patients who can put on and remove clothing during therapy sessions may not be able to find and retrieve their clothes in a cluttered closet, select clothing appropriate for the weather, or initiate the dressing routine without prompting (Campbell et al., 1991). Conversely, a patient may be unable to master simple meal preparation in the unfamiliar environment of a clinic kitchen but may re-adapt easily to this task upon returning home. A home evaluation can help determine what resources and means a patient has to achieve independence in areas of occupation as well as assessing safety and accessibility (see Chapter 10).

Self-Care

Methods for assessing self-care, or BADL, and examples of evaluation tools are discussed in Chapter 4. Measures of disability in ADL recommended by the AHA/ASA guideline (Duncan et al., 2005) are the Barthel Index (Mahoney & Barthel, 1965) and the Functional Independence Measure (FIM) (Keith et al., 1987). These interdisciplinary measures are well known and widely used in stroke research; the FIM is reported to be the most commonly used functional measure in rehabilitation hospitals. Their use can strengthen the team approach to stroke, with occupational therapists typically completing the self-care portions of these assessments and practitioners of other disciplines completing portions pertaining to bowel and bladder control, mobility, communication, cognition, and social interaction. These functional scales tend to have ceiling effects and are limited in their ability to measure higher levels of function or quality of life (Duncan et al., 2005; Wolf, Baum, & Connor, 2009).

Instrumental Activities of Daily Living

A patient's goals and probable discharge situation may direct a therapist to evaluate more complex areas of occupational performance. The AHA/ASA guideline recommends that "all patients planning to return to independent community living be assessed for IADL before discharge" and recommends that "minimal IADL skills required to stay at home alone include the ability to (1) prepare or retrieve a simple meal, (2) use safety precautions and exhibit good judgement, (3) take medication, and (4) get emergency aid, if needed" (Duncan et al., 2005, p. e120). Measures of IADL recommended by this guideline include the Frenchay Activities Index (Holbrook & Skilbeck, 1983) and the Philadelphia Geriatric Center Instrumental Activities of Daily Living Scale (IADL Scale) (Lawton, 1988). The Frenchay Activities Index

is a self-report tool developed specifically for patients with stroke that compares how frequently a patient engaged in activities, such as washing clothes, going on social outings, and gardening, prior to a stroke with frequency of participation in the same activities afterward. The stated purposes of this evaluation are to record changes in patterns of activity after stroke and to reflect quality of life rather than to measure performance in survival skills. The IADL Scale, on the other hand, is an observed measure that ranks quality of performance of activities such as using a telephone, managing medications, and handling finances. Additional measures recommended by the AOTA Practice Guideline include the Canadian Occupational Performance Measure (Law et al., 2005), the Assessment of Motor and Process Skills (Fisher, 1995) (see Chapter 4), and the Stroke Impact Scale (Duncan et al., 1999). The Stroke Impact Scale was developed to be a more comprehensive measure of outcomes for stroke survivors (Lai et al., 2002). The scale is a self-report interviewer-administered measure with questions pertaining to higher level functions of affected limbs, memory and thinking, mood and emotions, communication skills, home and community mobility, typical daily activities, and participation in meaningful life roles. Items included in this scale were derived from feedback of stroke patients and their caregivers who identified the persistent consequences of stroke that interfered the most with quality of life.

When appropriate, potential for driving and return to work may be evaluated by an occupational therapist or other specialist trained in these areas. A patient's ability to resume driving and/or vocational tasks is discussed later in this chapter (see also Chapters 26 and 28).

Assessment of Performance Skills and Client Factors

Observation of a patient's occupational performance suggests to the therapist specific performance skills and client factors that can enhance or impair the client's desired functional outcome. Assessment of performance skills helps to determine motor and cognitive abilities available to an individual in order to resume valued tasks and roles. Assessment of client factors, including primary and secondary impairments associated with stroke, helps determine potential for improvement in skills and occupational performance (Sabari & Lieberman, 2008). These skills and factors can be measured directly by administration of selected tests. Areas to be evaluated include postural adaptation, specific components of upper extremity function, and motor learning ability.

Postural Adaptation

Postural adaptation, or postural control, refers to the individual's ongoing ability to achieve, maintain, or restore an upright position against gravity (balance) for stability during activities or changes in body position (Pollock et al., 2000). The recognition and treatment of deficits in postural

adaptation constitute an important aspect of therapy for stroke patients because so many daily living tasks (e.g., putting on socks, getting in and out of a bathtub, housework, and participating in sports) depend on this skill. Evaluation and treatment limited to a patient securely supported in bed or in a wheelchair fail to address most usual daily tasks that require dealing with gravity. A person with hemiplegia typically has decreased motor control, poor bilateral and sensory integration, and impaired automatic postural responses (Oliveira et al., 2008). As a result, the patient must devote increased effort to remaining upright, with decreased ability to focus on purposeful tasks. When engaging in a challenging activity, the hemiplegic patient often resorts to compensatory strategies to help maintain stability, such as using upper extremities for support (Oliveira et al., 2008).

Postural adaptation factors and skills can best be observed during the performance of meaningful functional activities, although the Berg Balance Scale (Berg et al., 1989) is listed as a recommended tool in both the AHA/ASA clinical guideline and the AOTA practice guideline. The Functional Reach Test (Duncan et al., 1990) is another measure of balance recommended by the AOTA guideline. Determining status of a patient's trunk control after stroke is an important starting point for assessing motor capacities or skills because poor trunk control can lead to dysfunctional limb control, increased risk of falls, contracture and deformity, diminished sitting and standing endurance, decreased visual feedback and swallowing effectiveness secondary to head and neck malalignment, and impaired ability to interact with the environment (Gillen, 2011a). A patient's posture and balance, both static and dynamic, can be observed and noted while the patient is seated and standing and during self-care tasks such as dressing, transfers, and bathing. Definition 33-2 compares functional seated posture with the dysfunctional positioning typically observed in patients recovering from stroke.

Definition 33-2

Common Impairments in Sitting Posture Seen after Stroke

Body Part	Normal Sitting Posture Ready for Function	Abnormal Sitting Posture Typical of Stroke
Head, neck	Neutral	Forward Flexed to weak side Rotated away from weak side
Shoulders	Symmetrical height Aligned over pelvis	Uneven height Involved shoulder retracted
Spine, trunk	Straight from posterior view Appropriate lateral curves Lateral trunk muscle lengths equal bilaterally	Curved from posterior view Thoracic kyphosis Shortened lateral trunk muscles on one side, elongation on opposite side
Arms	Not used to maintain static upright posture Relaxed	Use of stronger arm to maintain upright posture Increased or decreased muscle tone in involved arm
Pelvis	Symmetrical weight bearing through both ischial tuberosities Neutral to slight anterior pelvic tilt Neutral rotation	Asymmetrical weight bearing Posterior pelvic tilt One hip angled forward
Legs	Hips at 90° flexion Knees aligned with hips; hips in neutral adduction or abduction and internal or external rotation Feet under knees Feet flat on floor, able to bear weight	Hips in more extension Hips adducted so that knees touch or involved hip externally rotated so that knees wide apart Feet in front of knees Feet not flat on floor, unable to bear weight

Upper Extremity Function

Occupational therapists are the clinicians most often involved with the evaluation and treatment of motor deficits in the hemiplegic or hemiparetic upper extremity. Achievement of skilled arm and hand function is a complex, often difficult process following stroke and involves interaction of several body functions and structures. Evaluation of the involved upper extremity should address sensation; the mechanical and physiological deterrents to movement; the presence and degree of active or voluntary movement; the quality of this movement, including strength, endurance, and coordination; and the extent of function resulting from movement.

Somatosensory Assessment. During evaluation of sensory deficits in the person with stroke, it is important to remember that sensation is a component of function that is only a focus for treatment when it relates to the ability to perform usual daily living tasks. When somatosensory disturbances are present, they usually accompany motor impairment in the same anatomic distribution (Stein & Brandstater, 2010).

Most tests of sensation require attention, recognition, and response to multiple stimuli; therefore, sensory testing is difficult in patients with aphasia, confusion, and other cognitive deficits. It is often necessary to determine the patient's level of comprehension and communication, including yes/no reliability. An expressively aphasic patient can nod, gesture, point to written or pictured cues, or select a stimulus object from an array of objects. When testing with standard procedures is not possible, information may still be gained from observing a patient's reactions to the testing. The presence of gross protective sensation (flinching when pricked with a sharp pin) can be documented even if discriminatory perception cannot be determined.

Patients who have had mild CVAs and who have intact primary sensory awareness may need to be tested for more subtle discriminatory problems using two-point discrimination testing or the Moberg Pick-up Test (Dellon, 1981). Such testing is indicated when motor return is good, but hand dexterity remains impaired. Chapter 9 provides details of sensory assessment.

Mechanical and Physiological Components. Factors that can interfere with movement and function of the hemiplegic upper extremity include limitations in PROM, joint malalignment, abnormal muscle tone, and pain. Interview and medical records can help determine whether these conditions resulted from the stroke or were present prior to onset. Passive movement restrictions in the joints and soft tissues of the extremity may result from an individual's anatomy and lifestyle or from premorbid conditions such as arthritis or injury. Limitations may result more directly from the stroke, with sudden and prolonged immobilization of joints caused by weakness or spasticity in muscles. Persistent stereotyped positioning of joints without counteracting movement results in the shortening and eventual contracture of muscles, tendons, and ligaments. Edema secondary to reduced circulation and loss of muscle action can further limit passive joint motion, particularly in the hand. Goniometric measurement of passive range of motion (PROM) is usually not indicated unless treatment is specifically aimed at increasing passive motion, such as when trying to eliminate an elbow flexion contracture. More useful in assessing patients with stroke is a comparison of the involved to the uninvolved arm to determine probable baseline joint motion.

Shoulder subluxation, or malalignment of the glenohumeral joint, occurs in approximately 50% of stroke patients (Yu, 2009). This condition is probably caused by the weight of the arm pulling down the humerus when the supraspinatus and deltoid muscles are weak and by weakness of scapular muscles that allows the glenoid cavity to rotate downward (Stein & Brandstater, 2010). Shoulder subluxation can be identified by palpation: the seated patient's arm hangs freely with trunk stabilized while the examiner palpates the subacromial space for the separation between the acromion and the head of the humerus. The distance separating the two is measured in finger widths, that is, the number of fingers that can be inserted in the space (Yu, 2009). The role of subluxation in the painful shoulder is controversial; in the shoulder, adhesive capsulitis, tendonitis, bursitis, rotator cuff tear, traction/compression neuropathy, and complex regional pain syndrome (CRPS) are common complications of hemiparesis, and all can result in pain and limited range of motion (ROM) (Duncan et al., 2005).

Spasticity, defined as velocity-dependent hyperactivity of tonic stretch reflexes, can result in ROM limitations and pain, often leading to contractures and functional impairments. The Ashworth Scale/Modified Ashworth Scale (Bohannon & Smith, 1987) is included in the AOTA practice guideline as a recommended assessment of spasticity (see Chapter 8; see Chapter 3 for descriptions of pain evaluation).

Voluntary Movement. Determining the amount and quality of voluntary movement a patient can produce is one of the first steps in assessing movement potential (Warren, 1991). The patterns of motion available are different for each stroke patient. Movement can change dramatically or subtly with time; hence, it requires careful reassessment throughout recovery. Factors to consider when evaluating motor control of the involved upper extremity include the following:

- Can the patient perform reflexive but not voluntary movement? Example: Patient demonstrates active elbow extension in the involved arm when balance is disturbed (equilibrium reaction) or flexes the hemiparetic elbow while yawning (associated reaction) but cannot perform these movements on request.

- Do proximal segments (neck, trunk, shoulder, hip) stabilize as needed to provide firm support for movement of the distal parts, or do they substitute for distal movement? Example: A patient can raise his hemiparetic arm only with pronounced lateral bending of the trunk and excessive elevation of the shoulder girdle.
- Can voluntary movement be performed unassisted against gravity, or is it possible only with assistance in the form of positioning, support, or facilitation? Example: A patient can bring her hand to her mouth only by flexing her elbow in a horizontal plane with gravity eliminated.
- Can voluntary movement be performed in an isolated fashion or only in a synergistic pattern? Example: A patient can reach for an object on a table only with a pattern of shoulder abduction, elbow flexion, and trunk flexion rather than with the more efficient pattern of shoulder flexion and elbow extension.
- Can reciprocal movement (the ability to perform agonist/antagonist motion in succession in an individual joint) be performed with practical speed and precision? Examples: A patient cannot produce a smooth pattern of elbow extension-flexion-extension needed to grasp a glass, take a drink, and set it back on the table but can perform each movement separately. A patient cannot perform the rapid alternating movements necessary to brush teeth.

One of the major movement difficulties following stroke is attaining the capacity and ability to isolate and control single muscle actions and combine them in a pattern appropriate for the task at hand. In motor patterns typical in hemiplegia, movement initiated in one joint results in automatic contraction of other muscles linked in synergy with that movement. This results in limited, stereotyped movement patterns rather than adaptive, selective motions. In Brunnstrom's theory of hemiplegic limb synergies (Brunnstrom, 1970), typical stereotyped patterns are described as flexor or extensor synergy patterns according to the motion at the elbow. The flexor synergy presents with scapular retraction and/or elevation, shoulder abduction and external rotation, elbow flexion, and forearm pronation. The extensor synergy presents with scapular protraction, shoulder horizontal adduction and internal rotation, elbow extension, and forearm pronation. Wrist and hand position varies (Brunnstrom, 1970). There is considerable variation in synergistic patterning, and other causes of abnormal stereotyped patterns include compensatory movements, unnecessary movement, muscle tension resulting from exertion or stress, and movement in response to gravity (e.g., pronation). According to Brunnstrom (1970), movement recovery after stroke is determined by an individual's ability to move independently of synergies. More contemporary clinical studies suggest that in addition to pathological limb synergies, loss of strength or centrally mediated impaired interjoint coordination can contribute to

movement disturbances and impaired function (Welmer, Holmqvist, & Sommerfeld, 2006). A study designed to look at the extent abnormal limb synergies influence voluntary movements of hemiparetic patients with first-time stroke found that 3 months after stroke, 13% of all subjects moved within synergies (Welmer, Holmqvist, & Sommerfeld, 2006).

Several methods for evaluating voluntary movement poststroke are described in Chapter 8 and online Chapters A, B, and C. Valid and reliable tools for evaluating voluntary movement poststroke recommended by both the AHA/ASA clinical guideline and the AOTA practice guideline are the Fugl-Meyer Assessment of Motor Function (Fugl-Meyer et al., 1975) and the Motor Assessment Scale (Carr et al., 1985). The Fugl-Meyer Assessment is an adaptation of Brunnstrom's original Hemiplegia Classification and Progress Record (Brunnstrom, 1970) and incorporates Brunnstrom's six stages of motor recovery with an underlying predicted sequence of recovery. The Fugl-Meyer Assessment of the Upper Extremity (FMA-UE) is the most commonly used research assessment to describe upper extremity motor impairment and evaluate the success of new interventions, but its focus on synergy patterns no longer forms the basis for newer function-oriented treatments (Woodbury et al., 2007). After investigating the dimensionality and construct validity of the FMA-UE, researchers suggest that assessment of reflexes in the FMA-UE gives little information about volitional movement. They also challenge the stepwise orderly sequence of motor recovery described by Brunnstrom and Fugl-Meyer and suggest instead that "UE motor behavior during recovery may be a dynamic interaction of neural factors with the task-specific difficulty of a movement" (Woodbury et al., 2007, p. 720).

Strength and Endurance. Muscle weakness ranging from slightly less than normal strength to total inability to activate muscles has been recognized as a limiting factor in the occupation and participation of patients with hemiplegia (Harris & Eng, 2007). The measurement of muscle strength to monitor recovery after stroke has been controversial because traditional neurological rehabilitation frameworks link muscle resistance to increased upper extremity tone and pain (Bobath, 1990). A meta-analysis of randomized controlled trials examining the evidence for strength training of the paretic upper extremity found evidence that strengthening can improve upper limb strength and function without increasing tone or pain in individuals with stroke (Harris & Eng, 2010). Methods used to quantify muscle strength after stroke include assessments of motor performance (e.g., Fugl-Meyer), manual muscle testing, dynamometry to measure grip strength, and measurements of active range of motion (Bohannon, 2007; Wagner et al., 2007). The motor assessment evaluations mentioned in this chapter and techniques described in Chapter 7

are recommended to establish baseline levels of muscle strength. It is important to consider that studies have also demonstrated muscle weakness in nonparetic limbs and trunk muscles of patients after stroke (Bohannon, 2007).

Reduced endurance, seen as a decrease in the ability to sustain movement or activity for practical amounts of time, is an important limiting factor in the motor performance of stroke patients because it affects the patient's ability to participate fully in rehabilitation and occupation (deGroot, Phillips, & Eskes, 2003) (Research Note 33-1). Decreased endurance can be the result of physical and/or mental fatigue caused by the exertion required to move weakened limbs or the result of comorbid cardiac or respiratory conditions (see Chapter 7).

Functional Performance. Assessing functional use of a hemiparetic arm poststroke is problematic, because although occupational performance evaluations identify deficits in ADL and IADL, they do not accurately reflect a patient's ability to use the affected arm for tasks. As observed in a population-based study, recovery of function in more than half of patients with significant upper extremity paresis was achieved only with compensatory use of the unaffected arm (Nakayama et al., 1994). Similarly, evaluations of client factors and motor or process skills may predict a patient's potential for functional use of a hemiparetic arm but are not measures of occupational performance. Studies have suggested that "performance of a functional movement can be normal or near-normal despite the presence of underlying sensorimotor impairments" (Wagner et al., 2007, p. 762). Reimbursement trends in fact encourage focus on a client's ability to perform daily self-care activities after stroke rather than performance skills of the hemiparetic arm (Sabari & Lieberman, 2008). Further, many tests described in the literature as useful for evaluating function of the involved upper extremity can be categorized as task-oriented evaluations, with portions or simulations of familiar activities rather than relevant real-life activities (Okkema & Culler, 1998).

One difficulty in measuring function after stroke results from the normal differences in performance ability between dominant and nondominant arms. Eating with utensils, combing hair, and writing, for example, are

Research Note 33-1

Abstract

The objective was to describe the course of fatigue during the first year poststroke and to determine the relation between fatigue at 1 year poststroke and personal characteristics, stroke characteristics, and poststroke impairments. Participants included 167 patients with a first-ever stroke admitted for inpatient rehabilitation; mean age was 56.4 years, and 73.7% of participants lived with a spouse or partner. The main outcome measure was the Fatigue Severity Scale, a self-report assessment of the impact of fatigue on daily life, measured at admission to rehabilitation, 6 months poststroke, and 1 year poststroke. Results showed that the frequency of self-reported fatigue among patients was greater at 6 months and 1 year poststroke (64.1% and 69.5% of the patients, respectively) than at admission (51.5% of patients). Fatigue impact 1 year poststroke ($p < 0.1$) was greater among subjects with symptoms of depression, higher age, female sex, and those who perceived that their health-related outcomes were controlled more by powerful others (e.g., physicians) than by their own behavior. Of the subjects reporting fatigue 1 year poststroke, 29.3% were also depressed, supporting earlier studies. These four determinants explained 20% of the variance of fatigue impact scores; therefore, the majority of fatigue impact could not be attributed to specific factors. Other factors analyzed and found to not be significant in this study included marital status, type of stroke, extent of physical recovery (patients with both good and poor motor recovery reported fatigue impact), global cognitive impairments, and presence of sleeping disorders. Suggestions for further research on the impact of fatigue would be to analyze factors such as level of physical fitness, medication side effects, use of coping strategies, and higher level cognitive skills.

Implications for Practice

- Fatigue is expected to be a problem soon after stroke but is not always considered a deterrent to functional capacity or occupational therapy treatment several months or years poststroke. The impact of fatigue can become more pronounced as clients try to resume work or social roles. Therapists should recognize the long-term effect of fatigue symptoms when planning therapy in community or home programs.
- Patient education regarding poststroke fatigue should be routinely provided to patients and their families to increase recognition of the problem and decrease distress. Training in energy conservation and work simplification techniques, including pacing and balancing of rest with activity, is appropriate for patients with stroke, as are mind–body wellness interventions to improve perceptions of self-control over health.
- Although depression and fatigue are separate poststroke consequences, depression is an important focus for poststroke fatigue intervention. Therapists should be attuned to patients' symptoms of depression and refer patients and families to appropriate professionals.

normally performed by the dominant arm; testing the ability of a hemiparetic nondominant arm to perform these tasks is not relevant or useful to a patient. The arm has a wide range of functions, and any single test assesses only a portion of the actual possible functions. Therapists must choose tests that seem best suited for the individual patient.

Functional tests listed in AOTA's Practice Guideline for Adults with Stroke include the Functional Test for the Hemiplegic/Paretic Upper Extremity (Wilson, Baker, & Craddock, 1984a, 1984b), the Arm Motor Ability Test

(Kopp et al., 1997), and the Wolf Motor Function Test (Wolf et al., 2001).

The Functional Test for the Hemiplegic/Paretic Upper Extremity is a standardized test developed by occupational therapists specifically to evaluate patients' ability to use the hemiplegic upper extremity for purposeful tasks. This test consists of 17 tasks divided into seven functional levels that range from absence of voluntary movement to selective and coordinated movement (Figs. 33-1 and 33-2). The tasks follow a pattern of increasing difficulty and complexity

and reflect Brunnstrom's hierarchy of motor recovery in hemiplegia. This test was found to be valid because scores strongly correlated to scores on the Fugl-Meyer Assessment of Motor Function (Filiatrault et al., 1991). It is reported to have interrater reliability, but psychometric data are not presented (Wilson, Baker, & Craddock, 1984a). The Functional Test for the Hemiplegic/Paretic Upper Extremity is dominance neutral in that most items are activities normally performed by either arm or bilaterally. Disadvantages of this test are that it does not provide specific information about why a patient has failed a task (Wilson, Baker, & Craddock, 1984a), and it uses pass/fail scoring rather than an ordinal scale, making it difficult to use for documenting partial progress. For descriptions of the Arm Motor Ability Test and the Wolf Motor Function Test, refer to Chapter 8.

Motor Learning Ability

Motor learning refers to an individual's acquisition of strategies for solving movement challenges in changing contexts, enabling one to adapt to his or her environment (Bass-Haugen, Mathiowetz, & Flinn, 2008). Successful motor learning after stroke requires regaining an adequate person-environment-occupation fit for optimal occupational function. In this context, therapists should assess factors that can affect a patient's ability to learn or relearn, including visual function, speech and language disorders, motor planning ability, cognitive disorders, and psychosocial adjustments. Although discussed as separate categories, these factors operate as parts of an integrated system. It is often difficult to discern or separate, for example, cognitive functioning from visual-perceptual or speech-language skills. Does a patient fail to respond to a request to brush his teeth because he cannot locate the toothbrush in his visual field, because he has forgotten how to sequence this task, because he cannot understand the verbal request, or because he is not motivated to perform grooming tasks? These classifications are meant to assist the therapist in recognizing the components of learning impairments that follow stroke.

Visual Function. The visual system is a complex of many parts of the central and peripheral nervous system; therefore, any type or degree of brain damage is expected to have some effect on the function of the visual system (Warren, 1999). Chapter 5 describes assessments of vision and visual perception.

VFD is the most common visual disturbance associated with stroke, and homonymous hemianopsia is the type of VFD occurring most often. Hemianopsia affects half of the visual field. Homonymous means the deficit involves both eyes. A patient with left homonymous hemianopsia has decreased or absent vision in the nasal field of the right eye and the temporal field of the left eye. Deficits in visual attention in stroke patients are hemi-inattention and hemi-neglect or unilateral neglect. Hemiinattention describes a patient's tendency to ignore objects on one side of the visual field and can occur with or without a measureable VFD (Khan, Leung, & Jay, 2008). Similarly, patients can have hemianopsia without hemiinattention or neglect. Neglect, a complex deficit that can affect personal (body) perception as well as near or far extrapersonal space (Albert & Kesselring, 2011), is almost always associated with right parietal lobe damage (Shinsha & Ishigami, 1999) and is highly predictive of poor functional recovery (Khan, Leung, & Jay, 2008). Patients with VFD only will usually learn that there are objects in the area of loss and adapt their head and eye movements in order to complete tasks. For the patient with neglect, however, objects in the area of loss simply do not exist, and adaptation is difficult if not impossible (Khan, Leung, & Jay, 2008).

Because visual deficits are disabling to the degree that they prevent completion of necessary ADL, observation of the patient's occupational performance provides the most valuable information concerning the visual system (Warren, 1999, 2009). A pilot study investigating the impact of VFD on ADL performance by adults with acquired brain injury (Warren, 2009) found that people with VFD were impaired in their ability to use environmental context to inform and assist performance. Evaluation of patients with visual deficits therefore should focus on this capability and assess the space demands of ADL as well as the patient's ability to locate and discern features of objects necessary to complete tasks effectively and safely. The study identified personal hygiene-grooming and feeding as the BADL most difficult for patients with VFD (e.g., behaviors such as not noticing food on the left side of the tray, shaving only the right side of the face). The most challenging IADL were driving, shopping, financial management, and meal preparation, all requiring one or more of the performance skills of mobility, reading, or writing (Warren, 2009).

Speech and Language. Disturbances in the ability to communicate or to comprehend oral or written information can significantly affect the ability to resume or relearn usual activities. The speech and language disorders associated with stroke include aphasia, dysarthria, and apraxia of speech. Aphasia is an acquired multimodality disorder that can result in impaired understanding or input (listening, reading) and/or impaired expression or output (speaking, writing, using gestures) (Cherney & Small, 2009). Stroke is the leading cause of aphasia, with damage to the left cerebral hemisphere the usual origin. Systems for classifiying and diagnosing the various types of aphasia have evolved and remain controversial, but a simplified clinical classification of aphasia recognizes fluent and nonfluent aphasias based on the patient's ability to produce speech (Goodglass, 1993). Other considerations in

classification include auditory comprehension, repetition, and word retrieval (Cherney & Small, 2009). In the fluent aphasias, patients can easily produce spontaneous speech, but auditory comprehension and understanding of language is limited. The most common type of fluent aphasia is Wernicke's aphasia, or "receptive aphasia," characterized by the smooth articulation of speech but marked by incorrect word or sound substitutions and the inability to name objects, repeat phrases, or follow commands. Nonfluent aphasia is speech output that is difficult to produce and is characterized by slow, awkward articulation with limited vocabulary and grammar usage in the presence of relatively well-preserved auditory comprehension. An example is Broca's aphasia, or "expressive aphasia," in which the patient can follow commands but cannot name objects, repeat phrases, or convey ideas. A patient with large or multiple lesions in the left hemisphere may exhibit "global aphasia," with all language modalities severely impaired. Most individuals with aphasia demonstrate reading and writing difficulties (Cherney & Small, 2009). It is important to remember that speech and language disorders are complex, highly individualized, and rarely seen in pure forms of the types just described (Stewart & Riedel, 2011).

Dysarthria is a speech disorder caused by paralysis, weakness, or incoordination of speech musculature resulting in problems in speech production (poor articulation, poor phonation, poor voice quality) as well as drooling or decreased facial expression. Apraxia of speech is a communication problem in which the patient has difficulty initiating and sequencing the movements necessary to produce speech (Cherney & Small, 2009).

The occupational therapist needs to work collaboratively with the speech-language pathologist to learn the results of a patient's communication evaluation, support the patient's language goals, and request suggestions for communication strategies with patients in order to enhance their participation poststroke (Stewart & Riedel, 2011).

Motor Planning. Motor planning deficits, or apraxia, are deficits of skilled, organized, purposeful movement sequences used to achieve a goal. Apraxia cannot be explained by motor or sensory impairments or inability to follow a command (West et al., 2008). These deficits are best identified during performance of daily living tasks. Clinical manifestations of motor planning difficulties include the following (Warren, 1991):

- Failure to orient the head or body correctly to a task, such as a patient attempting a toilet transfer who tries to sit on the toilet before correctly positioning the body in front of it.
- Failure to orient the hand properly to objects and/or poor tool use, such as a patient who has to be reminded of the correct way to hold a pen when writing with the uninvolved hand.

- Difficulty initiating or carrying out a sequence of movements, such as a patient with nearly normal motor performance who cannot put on a shirt without step-by-step verbal and physical cueing.
- Movements characterized by hesitations and perseveration, such as a patient who, after brushing his teeth, is handed a razor and asked to shave. After a delay, the patient brings the razor to his mouth and tries to brush his teeth with it.
- Movements that can be performed only in context or in the presence of a familiar object or situation, such as a patient who does not follow a command to move hand to mouth unless given something to eat or drink.

These deficits are most pronounced during learning sessions, such as when training in wheelchair propulsion or one-handed buttoning, and in activities with multiple steps, such as making a sandwich.

Cognition. Disorders in cognitive functioning, including problems with attention, orientation, memory, and executive functioning, are common after stroke (Duncan et al., 2005). Higher level executive abilities allow individuals to form goals, plan how to achieve them, and complete the plans effectively in order to perform an array of complex ADL necessary for independent living (Baum et al., 2008). Patients impaired in these abilities may have decreased safety awareness and difficulty learning new techniques for performing tasks. Wolf, Baum, and Connor (2009), while analyzing a large population of individuals after stroke, found that increasing percentages of patients who have mild to moderate severity of stroke at a younger age (<65 years old), are discharged directly home, and although they may have received rehabilitation services including OT, are unable to resume IADL requiring complex cognitive behavioral strategies. This suggests a need for greater focus by therapists on the subtle deficits in executive functioning that interfere with family and community participation. Although mental status screening tests such as the Mini-Mental State Examination (Folstein, Folstein, & McHugh, 1975) are often used during the acute phase after stroke, occupational performance-based assessments focusing on the adaptive abilities of planning, initiation, organization, sequencing, judgment, and problem solving are more predictive of real-world ability (Baum et al., 2008). Chapter 6 describes specific cognitive assessment techniques. See also assessments recommended in the AOTA Practice Guidelines for Adults with Stroke (Sabari & Lieberman, 2008). Therapists must be careful to differentiate between cognitive deficits and communication difficulties common to stroke (Gresham et al., 1995).

Psychosocial Aspects. Adjustment to disability is a critical component of rehabilitation, although effective measures

of adjustment have not been described. Most patients have natural emotional reactions to their stroke, including denial, anxiety, anger, and depression (Falk-Kessler, 2011). Poststroke depression is the most frequently reported reaction, affecting 25%–40% of patients within the first year after a stroke (Eriksson et al., 2004). Depression in stroke is both a physiological result of biochemical changes in the brain and a reaction to the personal losses of patients who realize, with time, that they will not fully recover (Eriksson et al., 2004). Although poststroke depression has been found to have a negative effect on recovery and independence for patients with stroke, assessment is difficult: there is no universally accepted assessment tool for poststroke depression, and cognitive and language deficits can make assessment difficult (Duncan et al., 2005).

Other common psychological manifestations poststroke include anxiety and emotionalism. Anxiety disorders have been found to frequently coexist with depression in individuals with stroke and can create feelings of worry or fear as well as physical symptoms that can decrease participation in rehabilitation or family/community roles (Duncan et al., 2005). For individuals poststroke, emotional responses to situations are expected. For many stroke survivors, however, a more extreme form of emotional reaction occurs, referred to as emotional lability. This is an involuntary emotional response, such as uncontrollable laughing or crying, that is disproportionate to the emotional stimulus (Falk-Kessler, 2011). A patient may, for example, cry whenever seeing a family member or when asked about a valued activity.

Emotional reactions, compounded by cognitive, perceptual, and language impairments, may lead to behavioral outcomes including denial, frustration, anger, impatience, irritability, overdependence, apathy, aggression, insensitivity to others, and rigid thinking (Falk-Kessler, 2011). These responses can further result in impaired personal interactions, decreased social participation, and eventual isolation. Evaluation of the patient's and family's adjustments to the stroke, to rehabilitation, and to the prospect of living with the aftermath of the stroke can be done through interview and observation and by sharing information with other members of the rehabilitation team.

TREATMENT

A careful interpretation of evaluation results helps determine a patient's assets and deficits in areas of occupational functioning. General goals of OT intervention with stroke survivors are to prevent secondary impairments, restore performance skills, modify activity demands and contexts as necessary, promote a healthy and satisfying lifestyle, and maintain available performance and health (Sabari & Lieberman, 2008). Intervention is always a collaborative process between therapist

and client/family or caregiver. Possible goals for individuals recovering from stroke include the following:

- The patient will gain competence in valued and necessary BADL and IADL in order to perform at the highest level of independence possible in the desired postdischarge setting.
- The patient will improve postural control in order to perform daily living tasks requiring balance and changes in body position.
- The patient will gain increased somatosensory perception and/or will employ compensatory strategies in order to perform ADL safely.
- The patient and/or caregiver will demonstrate appropriate management techniques for the hemiparetic upper extremity to prevent pain and other secondary mechanical or physiological movement restrictions.
- The patient will gain the necessary strength, endurance, and control of movement of the involved upper extremity in order to use the involved upper extremity spontaneously during the performance of ADL.
- The patient will gain visual function or will employ compensatory strategies in order to safely resume previously performed ADL.
- The patient will improve motor planning ability in order to relearn old methods or learn new methods of performing ADL.
- The patient and/or caregiver will demonstrate appropriate strategies for improving or compensating for cognitive deficits during the performance of ADL.
- The patient and/or caregiver will be able to verbalize the reality and impact of emotional reactions to stroke and identify coping strategies or resources to help adjust to living with a stroke.
- The caregiver will demonstrate appropriate methods and problem-solving strategies for assisting the patient with ADL and with home activities to improve/preserve performance skills.
- The patient will gain competence in tasks and activities necessary to resume valued roles or to assume new meaningful roles in the community.

Intervention will vary with the patient's stage of recovery, intervention setting, living environment, extent of impairment, and personal goals and preferences (Sabari & Lieberman, 2008). Safety of the patient, during and after treatment, is a concern during all phases (Safety Note 33-1).

Acute Phase

Stroke rehabilitation begins "as soon as the diagnosis of stroke is established and life-threatening problems are under control" (Duncan et al., 2005, p. e104). Length of stay in acute hospital beds is typically just long enough for necessary diagnostic tests, for initiation of appropriate

Safety Note 33-1

Precautions with Stroke Patients

- In the acute period after stroke, ascertain the patient's medical status and stability daily before treatment. Know the symptoms of progressing or recurrent stroke.
- In the acute-care setting, know how to read ICU monitors and handle drains and lines as necessary (e.g., vital sign monitors, Foley catheters, IV lines, feeding tubes).
- Determine whether cardiac or respiratory precautions apply for a particular patient and monitor accordingly, watching for signs of cardiac distress and blood pressure changes, including dizziness, breathing difficulties, chest pain, excessive fatigue, and altered heart rate or rhythm.
- Guard against falls by providing appropriate supervision and assistance during transfers and other transitional movements.
- To avoid shoulder injury or pain, never pull or lift a patient by or under the weak arm during transfers or other transitional movements.
- Use appropriate precautions in the presence of skin with diminished sensation, particularly if a patient also has visual field deficits and/or unilateral neglect.
- Ascertain a patient's ability to swallow and follow recommended management techniques during feeding.
- Provide appropriate supervision for patients who demonstrate impulsive behavior and/or poor safety awareness.
- Teach the patient, family members, and other health care workers about safety concerns for an individual patient.

medical treatment, and for making decisions and arrangements for the next phase of rehabilitation. Priorities during this early period are to prevent recurrent stroke and complications, mobilize the patient as soon as possible, encourage performance of self-care activities, and provide emotional support to patient and family (Duncan et al., 2005). Patients who have just had a stroke may need to be seen bedside because of precautions, monitoring, and varying levels of consciousness. During this phase, the patient must adjust to the sudden, unexpected shift from usual life roles to the role of patient.

Early Mobilization and Return to Self-Care

The patient with acute stroke should be mobilized and encouraged to perform self-care as soon after admission as is medically feasible. The early introduction of BADL, such as rolling in bed, sitting on the side of the bed, transferring to a wheelchair or commode, self-feeding, grooming, and dressing, helps the patient reestablish

some control over the environment and begin to improve occupational functioning and component abilities and capacities (Gresham et al., 1995). Even at this early stage, the occupational therapist's assessment of a patient can help determine the most appropriate setting for rehabilitation and discharge. The goals of discharge planning during the acute phase are to determine the need for postacute rehabilitation, arrange the best possible living environment, and ensure continuity of care after discharge (Gresham et al., 1995).

Lowering Risk for Secondary Complications

As part of the stroke care team, the occupational therapist should practice methods to prevent or lessen complications resulting from stroke.

Skin Care. It is estimated that up to 21% of patients with stroke develop pressure sores (Langhorne et al., 2000). Those who are comatose, malnourished, or incontinent or who have diabetes, peripheral vascular disease, abnormal sensation, severe paralysis, or muscle spasticity are at greatest risk (Duncan et al., 2005). The occupational therapist helps patients maintain skin integrity by doing the following:

- Using proper transfer and mobility techniques to avoid undue skin friction
- Recommending appropriate bed and seated positioning and participating in scheduled position changes as needed
- Assisting with wheelchair and seating selection and adaptation
- Teaching patient and caregiver precautions to avoid injury to insensitive skin and involved side of body
- Watching for signs of skin pressure or breakdown on a patient (bruising, redness, blisters, abrasions, ulceration), especially over bony areas, and alerting nursing or medical staff as appropriate

Maintaining Soft-Tissue Length. Contractures, or shortening of skin, tendons, ligaments, muscles, and/or joint capsules, may result from the immobilization following stroke. Risk factors include muscle paralysis, spasticity, and imbalance between agonist and antagonist muscle groups. Contractures restrict movement, may be painful, and may limit functional recovery (Gillen, 2011b). The appropriate management is therefore a preventive program of proper positioning and soft tissue and joint mobilization. Suggested bed positioning for patients with stroke, based on a literature review (Carr & Kenney, 1992), is summarized in Procedures for Practice 33-1. However, bed positioning, like any treatment, must be adapted to meet the individual needs of the patient. Care must be taken to protect the weak upper extremity during

Procedures for Practice 33-1

Recommended Bed Positioning for Patients with Hemiplegia

Supine Positioning

- Head and neck slightly flexed
- Trunk straight and aligned
- Involved upper extremity supported behind scapula and humerus with a small pillow or towel, shoulder protracted and slightly flexed and abducted with external rotation, elbow extended or slightly flexed, forearm neutral or supinated, wrist neutral with hand open
- Involved lower limb with hip forward on pillow, nothing against soles of feet

Lying on the Unaffected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted with arm forward on pillows, elbow extended or slightly flexed, forearm and wrist neutral, and hand open
- Involved lower extremity with hip and knee forward, flexed, and supported on pillows

Lying on the Affected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted forward and externally rotated with elbow extended or slightly flexed, forearm supinated, wrist neutral, and hand open
- Involved lower extremity with knee flexed
- Uninvolved lower extremity with knee flexed and supported on pillows

Information from Carr, E. K., & Kenney, F. D. (1992). Positioning of the stroke patient: A review of the literature. *International Journal of Nursing Studies, 29*, 355–369.

treatment because improper handling, positioning, and transferring techniques can exert great stress on the vulnerable shoulder early after stroke (Walsh, 2001). Specific techniques for supporting the hemiparetic shoulder are discussed later in this chapter. Resting hand splints are often applied to prevent soft tissue shortening, but their use has not been found to significantly prevent or reverse contracture of wrist and finger flexor muscles (Lannin et al., 2007).

Controlled and frequent soft tissue and joint mobilization is the preferred method to prevent contractures (Gillen, 2011b). When a patient cannot use the involved side to engage in meaningful activities, therapists should initiate supervised active or active-assistive movement activities. When active movement is not possible, therapists

should see that immobile body parts go through PROM at least once daily. If performing PROM on the involved arm, ensure mobility of the scapula on the thoracic wall before elevation of the arm and manually assist upward rotation of the scapula if needed. *Safety Message: Do not attempt overhead ranges unless the scapula glides freely in upward rotation.* The humerus should be externally rotated during abduction to prevent impingement of the supraspinatus between the greater tubercle of the humerus and the acromion process (Gillen, 2011b). As soon as possible, patients should learn strategies for safe ROM activities they can perform independently or with assistance of caregivers.

Fall Prevention. For patients hospitalized with stroke, falls are the most common cause of injury (Gresham et al., 1995). Factors that increase the risk of falls include advanced age, confusion, comorbidity, impulsive behavior, mobility deficits, poor balance or coordination, visual impairments or neglect, and communication deficits that interfere with a patient's ability to request assistance in a timely manner. Treatment that helps to prevent falls includes detecting and removing environmental hazards, scheduled routine toileting, optimizing motor control, recommending appropriate adaptive devices, and teaching safety measures to the patient and family.

Patient and Family Education. Early in recovery, support for patients who have had strokes and their families may best be provided in the form of education to promote a realistic understanding of the causes and consequences of stroke and the process, goals, and prognosis of rehabilitation (Duncan et al., 2005). In a systematic review, Forster et al. (2001) found evidence that passive education alone, such as providing written handouts, is not as effective as a combination of passive and interactive education, such as classes or training sessions. All aspects of OT assessment and treatment for survivors of stroke should be considered opportunities for education: to engage cooperation and participation in the identification of meaningful treatment goals, to highlight residual abilities as well as disabilities, and to promote carryover of treatment gains. Because the period after stroke is stressful, emotional, and tiring for both the patient and family, education sessions provided during the acute phase should be brief, simple, and reinforced as needed with repetition or appropriate learning aids (see Chapter 13).

Rehabilitation Phase

Part of discharge planning during the acute phase of stroke is screening for rehabilitation services. The AHA/ASA guideline recommends that "patients who have sustained an acute stroke should receive rehabilitation services if their

poststroke functional status is below their prestroke status, and if there is a potential for improvement" (Duncan et al., 2005, p. e118). Rehabilitation choices depend on a patient's condition, the social support system, and the resources available in a community. To qualify for further treatment in an inpatient rehabilitation facility, a patient must require active and ongoing intervention of multiple therapy disciplines, require an intensive rehabilitation therapy program (generally consisting of at least 3 hours of therapy per day at least 5 days per week), and reasonably be expected to actively participate in and significantly benefit from the rehabilitation program (U.S. Department of Health and Human Services, 2011). Patients who do not qualify for this level of rehabilitation may receive multidisciplinary rehabilitation services at a skilled nursing facility or long-term care facility or treatment by one or more disciplines in home care or in an outpatient clinic.

During this phase of recovery, the patient and family are focused on getting better and are usually more concerned with recovering lost function than on adapting to a life of chronic disability (Sabari, 1998). Successful OT intervention coordinates a patient's striving for restoration of function with the potential for compensation and alternative occupational roles.

Treatment to Improve Performance of Occupational Tasks

The occupational therapist's primary role in stroke rehabilitation is to enhance clients' participation and quality of life through occupation. Interventions to improve performance of BADL is a major component of therapy for people who have had a stroke. Indeed, levels of independence in BADL are used to measure the success of rehabilitation (Stroke Unit Trialists' Collaboration, 2001), serve as outcomes in stroke research trials (Sulter, Steen, & De Keyser, 1999), and, in current U.S. trends, determine reimbursement for services (Sabari & Lieberman, 2008). A systematic review of nine randomized controlled trials (Legg et al., 2007) found that OT focused on improving BADL after stroke can improve performance and reduce the risk of deterioration of these skills.

It is accepted practice to teach patients with significant performance skills deficits compensatory methods for performing important tasks and activities, using the affected limb when possible and, when not, the unaffected limb (Gresham et al., 1995). Many consider that early ADL training focusing on modifying activity demands, contexts, and performance patterns (compensatory techniques) results in faster success and is therefore more cost effective and more satisfying to the patient, who again feels competent (Nakayama et al., 1994). Others contend that, when ADL training focuses on one-handed techniques and use of devices or modifications without working to restore performance skills, the patient fails

to relearn bilateral movements and instead develops unilateral habits (Bobath, 1990; Roberts et al., 2005). Skilled OT intervention considers each individual's needs, goals, and motivations and combines both compensatory and remedial treatment strategies and attempts to improve both areas of occupation and performance skills by engaging the patient in meaningful activities. Putting on a front-buttoning shirt, for example, besides helping a patient gain independence in the task of dressing, addresses the following component abilities, capacities, and conditions:

- Joint and soft-tissue integrity (self-stretching or relaxation techniques for involved arm in preparation for dressing, positioning of arm on a surface to prevent stretching of weak shoulder structures)
- Voluntary movement and function of involved upper extremity (abducting shoulder to put on a sleeve, extending elbow to push the hand through the sleeve, pinching one side of the shirt to stabilize while buttoning)
- Somatosensory perception (the texture of the shirt, the position of the affected arm)
- Postural adaptations (anterior pelvic tilt, trunk rotation, sitting/standing balance, weight shifting)
- Visual-perceptual skills (finding the shirt in the visual field, distinguishing top from bottom, finding the sleeve opening)
- Cognitive skills and emotional reactions (sequencing, attention span, frustration tolerance, motivation)

ADL training with stroke patients begins with simple tasks and gradually increases in difficulty as a patient gains competency (Gresham et al., 1995). Several studies discerned a hierarchy of achievement of self-care skills. Results of one study showed that bathing, dressing, and climbing stairs were the activities for which stroke survivors most often required assistance, with 32% of patients needing help with bathing, 25.5% needing help with dressing, and 32% requiring assistance with stairs 12 months poststroke (Carod-Artal et al., 2002). Aspects of dressing that are particularly difficult for stroke patients are putting a sock and shoe on the affected foot, lacing shoes, and pulling up trousers or pants (Walker & Lincoln, 1990). A study that investigated the relationship between dressing abilities and cognitive, perceptual, and physical deficits found that, in general, lower extremity dressing correlates more with motor performance, and upper extremity dressing correlates more with cognitive or perceptual performance (Walker & Lincoln, 1991). Adaptive devices should be considered if they increase simplicity, independence, and safety for the patient or caregiver.

As the patient progresses, occupational performance tasks other than basic self-care should be addressed, particularly if the patient expects to return to independent community living (Duncan et al., 2005). IADL tasks such as homemaking, home management, and community

mobility involve greater interaction with the physical and social environment and require higher level problem-solving and social skills than BADL tasks (Carod-Artal et al., 2002). Chapter 25 discusses specific techniques for regaining independence in BADL/IADL for those with loss of the use of one side of the body. Avocational interests, including adapted methods of continuing familiar hobbies, are an important area of treatment. Many stroke survivors are faced with increases in leisure time because of the inability to go back to work; however, a reduction in social and leisure participation commonly occurs after stroke (Lai et al., 2002).

Treatment to Improve Performance Skills and Client Factors

Performance-component goals are based on the impairments associated with an individual's stroke and are directly linked to occupational performance goals. The goals and modalities used to address these component deficits must be purposeful and meaningful from the patient's point of view (Trombly, 1995/2011). Therapists use occupation-based interventions, purposeful activity, and preparatory methods to help patients achieve long-term occupational goals (AOTA, 2008). Thus, in addition to direct practice of dressing and grooming activities, a patient may be engaged in a floor game to improve sitting balance needed to don socks, or use therapy putty for resistive grasp activities to strengthen muscles needed to squeeze a tube of toothpaste. Treatments for stroke deficits are described individually in the following sections, but most patients in rehabilitation programs have multiple interacting problems requiring efficient, integrated intervention plans that simultaneously address several deficit areas.

Postural Adaptation. The ability to make automatic postural adjustments, including trunk control and the maintenance of balance, is a prerequisite for successful performance of occupational tasks. A systematic review of recent evidence related to the effect of balance training on balance performance among individuals poststroke supports the use of balance training for individuals with moderately severe stroke (Lubetzky-Vilnai & Kartin, 2010). Part of the occupational therapist's role in training a patient with stroke in ADL independence poststroke is in understanding each patient's particular strengths and weaknesses regarding stability and mobility. For example, some clients may be challenged in maintaining sitting balance on the side of a bed for the duration of eating an entire meal, whereas others may be ready to improve dynamic standing balance in order to cast a fishing line or play golf. Therapists should teach patients the safest, most effective and efficient "ready" position for engaging in activities (see Definition 33-2) as well as strategies for adapting to changes in body position.

Suggested techniques to enhance postural control during task performance include the following:

- Provide feedback to help the patient feel the difference between an aligned and misaligned posture (Gillen, 2011a) (patient views self in mirror or tries to copy therapist's positions/movements).
- Use varying postures and incorporate transitional movements into activities (standing rather than sitting to perform grooming; putting away groceries by reaching for items in bag on floor while sitting, then standing and placing on overhead shelf).
- Grade reaching activities to elicit various trunk movements and weight shifts (place clothing needed for dressing in locations requiring forward flexion or trunk rotation; locate items needed for cooking task in upper and lower shelves).
- Use bilateral upper extremity activities to improve sitting or standing balance without arm support (folding towels; grating cheese at counter using involved hand to stabilize grater).

A particularly challenging and poorly understood impairment of postural control is pusher behavior. Pusher behavior is clinically defined to describe hemiplegic patients who actively push away from their nonparalyzed side with their stronger limbs and resist attempts to make them more upright (Davies, 2000). A pilot study by Perennou et al. (2002) concluded that pusher behavior does not result from disrupted processing of vestibular information but from a higher order disruption in the processing of somesthetic information from the left side of the body, possibly an extinction or neglect phenomenon. Because patients with pusher behavior resist hands-on attempts to correct their alignment, therapists should select treatment that manipulates the environment (reaching for objects to encourage weight shift to the strong side) and provides external cues ("bring your right shoulder toward the wall") (Gillen, 2011a) (see Definition 33-2).

Upper Extremity Function. Bilateral use of the upper extremities is crucial to efficient and effective occupational performance. Patients recovering from stroke usually place a high priority on regaining function in the involved arm. The occupational therapist must determine which deficits most affect a patient's upper extremity performance and plan realistic multilevel, task-oriented treatment to restore function or promote adaptation to the loss of function.

Somatosensory Deficits. It is estimated that 60% of individuals present with some form of sensory deficit poststroke (Winward, Halligan, & Wade, 1999). Decreased sensory awareness in the hemiparetic side can result in safety concerns, impaired grasp and manipulation skills in the affected hand, reduced ability to regain skilled movements necessary for ADL, and impaired spontaneous use

of the affected hand, frequently leading to learned nonuse (Schabrun & Hillier, 2009). In spite of this, there is little evidence to support treatment for sensory impairment poststroke.

Compensatory treatment entails substituting intact senses (e.g., vision) for those lost or dysfunctional and is usually included as safety education during occupational tasks. An example of remedial treatment is the protocol described by Yekutiel and Guttman (1993). Their sensory reeducation program included exploring with each patient the nature and extent of sensory loss, selecting sensory tasks of interest to the patient that promoted learning, and practicing detection, localization, and discrimination. Another proposed method of increasing sensory input to the affected hand is repeated nonspecific exposure to sensory stimuli via passive movements and grasp (Schabrun & Hillier, 2009). The patient is encouraged to use the involved hand in ADL as soon as possible and use different textures (e.g., foam, terry cloth, and Velcro®) on weight-bearing surfaces or on the holding surfaces of commonly used utensils, such as cups, forks, and pens.

Therapists must determine the appropriateness of each type of treatment for individual patients. For example, sensory retraining is unrealistic for patients with minimal voluntary movement, visual field neglect, or poor cognitive skills.

Schabrun and Hillier (2009) examined the volume and quality of evidence available on the retraining of sensory function following stroke and found some support for the effectiveness of passive sensory training (application of electrical stimulation to produce activation of cutaneous nerves in the absence of muscle contraction). Although some individual studies report positive effects on function following sensory discrimination training (Carey, Macdonell, & Matyas, 2011), Schabrun and Hillier (2009) found evidence for active sensory training limited by small sample sizes, subject heterogeneity, and unreliable outcome measures. Treatment to restore tactile awareness and teach compensation for sensory loss is discussed in Chapter 22.

Mechanical and Physiological Components of Movement. Techniques for maintaining soft-tissue length and avoiding pain in the involved upper extremity initiated during the acute phase of stroke recovery should be continued and adapted in response to changes in the patient's movement or muscle tone. As the patient in a rehabilitation program gains in mobility, measures should be taken to protect weak upper extremity structures from stretching or injury caused by the effects of gravity and improper movement. Procedures for Practice 33-2 summarizes handling techniques for an affected upper extremity.

Treatment of problems related to the hemiplegic shoulder centers on prevention and management of symptoms and underlying causes. The use of supportive devices such as slings, orthoses, and wheelchair attachments as a

Procedures for Practice 33-2

Proper Handling of the Hemiparetic Upper Extremity

- Teach the patient as early as possible to be responsible for the positioning of the arm during transfers, bed mobility, and other activities involving change of position.
- Use gait belts or draw sheets, rather than the affected arm, to assist the patient in moving his or her body.
- Avoid shoulder range of motion beyond 90° of flexion and abduction unless there is upward rotation of the scapula and external rotation of the humerus (Gresham et al., 1995).
- Avoid overhead pulley exercises, because they appear to increase the frequency of pain in the shoulder because neither scapular nor humeral rotation occurs, and the force may be excessive (Kumar et al., 1990).

prevention or treatment for subluxation or to decrease pain of the hemiplegic shoulder is not supported by empirical research (Ada, Foongchomcheay, & Canning, 2009). Reasons for using slings are to reduce the subluxation of the glenohumeral joint, provide support for the arm, protect against trauma, and prevent or reduce pain. Zorowitz et al. (1995) studied radiographs of hemiplegic shoulders in four types of slings and reported that the slings did not eliminate the asymmetry of subluxation. Further, these supports have not been found to improve trunk or scapular alignment (Gillen, 2011b). Pain control is a valid reason for use of a positioning device; however, the relation between subluxation and shoulder pain is unclear. A review of literature concerning hemiplegic shoulder pain and the association between shoulder pain and subluxation shows contradictory opinions (Gillen, 2011b), with most studies finding a low correlation between shoulder pain after stroke and subluxation and others finding a high correlation between shoulder pain and limited passive shoulder external rotation (Zorowitz et al., 1996). These studies support a general recommendation that the hemiplegic arm should be appropriately supported but that shoulder supports should not be issued uniformly to all patients with shoulder subluxation. If considering a sling, therapists should address the following questions (Gillen, 2011b; Ridgway & Byrne, 1999). A positive response to the following questions might indicate a sling:

- Does pain or edema increase when the arm hangs down?
- Is the patient's balance and performance during standing, walking, or transfers improved by the use of a sling?
- Is the patient unable to attend to and protect the arm during movement?

- Can the patient or caretaker independently put on and take off a sling correctly?

A positive response to the following questions might contraindicate a sling:

- Would the sling prevent or hinder active movement or function in the arm?
- Would a sufficiently supportive sling impair circulation or cause excessive pressure on the neck?
- Would the sling put the patient at risk for contracture as a result of immobilization?
- Would a sling decrease sensory input and promote unilateral disregard?

Alternative positioning methods and devices for shoulder support include taping of the shoulder and scapula (Ridgway & Byrne, 1999), wheelchair lapboards and armrest troughs, use of a table while seated or standing, putting the hand in a pocket or under a belt, and using an over-the-shoulder bag while standing (Gillen, 2011b) (Fig. 33-3). Functional electrical stimulation (FES) has been used to prevent or improve shoulder subluxation, decrease pain, and improve ROM. Studies evaluating the effectiveness of FES showed benefits during treatment but reduction of gains after treatment was discontinued (Walsh, 2001). Any patient with shoulder pain that persists and consistently interferes with function or progress in therapy should be referred to specialists best qualified to diagnose and treat specific shoulder problems.

Along with protection, patients learning to manage their involved arm should know techniques of active, active-assistive, or passive movement designed to maintain ROM, stretch tight tissues, or relax hypertonicity.

Figure 33-3 Alternative methods for supporting the hemiplegic arm while standing. **A.** Hand in pocket. **B.** Use of shoulder bag.

The combination of positioning for comfort and muscle imbalances brought on by spasticity and weakness can lead to the development of stereotyped nonfunctional positioning of the hemiplegic upper extremity with shoulder retraction, adduction, and internal rotation, elbow flexion, forearm pronation, and wrist and finger flexion. Therapists should emphasize frequent changes of position to prevent contractures and pain and recognize that if a patient is only moving his affected arm during therapy sessions, then therapy alone may not provide sufficient soft-tissue lengthening to maintain full ROM (Ada et al., 2005). In a prospective randomized control trial of 36 subjects with recent strokes, the experimental group received two daily 30-minute sessions of positioning of the affected arm in maximum comfortable shoulder external rotation in addition to shoulder exercise and standard upper limb care, whereas the control group received only exercise and standard care. At the end of 4 weeks, the experimental group had significantly less loss of shoulder external rotation ROM than the control group (Ada et al., 2005).

Even in the absence of motor recovery, passive and assisted active movement of the affected arm can be incorporated into activities, with the patient experiencing and concentrating on movement in a functional context. Methods of teaching self-managed ROM include bilateral activities such as having the patient clasp his or her hands while leaning forward to reach for the floor or pushing both hands forward with arms supported on a towel on a table (Gillen, 2011b). The advantages of these activities are that they can easily be given a functional context, such as picking up objects off the floor or dusting a table, and the patient can monitor his or her own pain threshold and is therefore not apprehensive about movement of the arm. Nelson et al. (1996), in a study of persons with hemiplegia, found that using a simple dice game to achieve bilaterally assisted forearm supination brought better results (more ROM, more repetitions) than use of a rote exercise routine. Self-management of ROM should be closely supervised and may not be appropriate for patients who have decreased awareness of the involved side, who move too quickly, who do not respect pain, or who lack a mobile scapula.

Hand edema is a frequent complication of hemiplegia. Edema control techniques include elevation of the hand, retrograde massage, and use of pressure gloves and sleeves. Patients with minimal voluntary movement should avoid allowing the hand and arm to hang down for long periods. Prolonged hand edema can lead to limited passive movement, pain, and soft-tissue contractures. Edema combined with severe pain, hypersensitivity, and vasomotor disturbances of the hand are signs of shoulder–hand syndrome, often referred to as CRPS and should be addressed vigorously to prevent further loss of functional potential (Gillen, 2011b) (see Chapter 37).

Voluntary Movement and Function. Chapter 21 and Web Chapters A, B, and C describe various treatment approaches to promote motor abilities and capacities in the patient recovering from stroke. Therapists usually employ a variety of techniques in response to the complex multiple factors that interfere with upper extremity use in an individual patient. Studies examining the components of occupational therapy intervention for inpatient stroke rehabilitation found that occupational therapists provide a combination of impairment-focused and function-focused activities tailored to an individual patient's disability (Richards et al., 2005) and that occupational therapists use preparatory methods aimed at improving performance skills and body structures more than occupation-based interventions (Smallfield & Karges, 2009). Gillen (2011b) suggests that "the complex problems that interfere with upper extremity function may require an integrated treatment approach that uses functional tasks as the intervention foundation" (p. 219) and preparatory, remediative methods as adjuncts.

Success in restoring voluntary movement in the hemiplegic upper extremity and incorporating that movement into ADL performance has been limited, perhaps because investigation of factors enhancing or impeding motor skills and processes following stroke is limited (Winstein et al., 2004). Lum et al. (2009) defined recovery of functional voluntary movement as including normalization of movement smoothness, interjoint coordination, active range of motion, and muscle activation patterns. Compensatory movement is defined as the use of alternative degrees of freedom and/or muscles to complete a task (such as using increased trunk movement during a reaching task). Interventions that promote compensation may lead to short-term functional gains but inhibit long-term motor recovery (Lum et al., 2009). Many recent studies have used kinematic and electromyographic (EMG) analysis to identify qualitative features (such as speed, accuracy, and efficiency) of voluntary movement of the hemiparetic upper extremity during components of arm function, such as reach or grasp of an object (Lum et al., 2009; Wagner et al., 2007). These and other studies have supported findings that negative neurological symptoms (decreased strength, impaired coordination) may contribute more to the loss of functional movement than positive neurological symptoms (spasticity and hyperactive reflexes) (Gillen, 2011b).

Although more studies are needed to determine the effectiveness of specific clinical strengthening methods in improving upper limb function and occupational performance of stroke patients, carefully selected resistive activities have been shown to improve performance as measured by motor function tests (Kluding & Billinger, 2005). In their meta-analysis involving 517 patients, Harris and Eng (2010) found significant effect for strength training increasing grip strength and function of the hemiparetic arm but found no treatment effect for strength training on ADL measures. The authors suggest that because ADL

are composed of complex combinations of strength, ROM, and coordination, practice of all components is required for improvement of occupational performance, and it may be difficult to isolate the effect of one component.

Decreased physical and mental endurance resulting from stroke can limit participation and performance in therapy; treatment should therefore be carefully graded to compensate for and improve reduced endurance. Length of treatment sessions, energy requirements, and need for rest periods should be monitored to meet patients' needs.

Coordinated movement is the product of successful control of the strength, range, speed, direction, and timing of movement. Because almost all purposeful activity requires coordination, encouraging use of the affected extremities in BADL or IADL is an appropriate way to improve coordination. Treatment should progress from unilateral activities, in which the patient can concentrate fully on control of the hemiparetic arm, to bilateral simultaneous activities, in which both arms perform the same movement together (such as lifting and carrying a box and catching and throwing a large ball), to bilateral alternating activities, in which the two arms perform different movements at the same time (such as sorting and assembling nuts and bolts). Grading fine motor activities entails progressing from gross to precise manipulation tasks and attempting more difficult patterns of grasp and pinch. Because hand and arm control for patients with hemiplegia becomes more difficult as the arm moves away from the body, the placement of activities should be varied. Writing is a highly coordinated task that is frequently a goal for stroke patients who need at least to be able to sign documents. Training in writing may be necessary if a patient plans to use the hemiparetic hand or the uninvolved nondominant hand.

Task-Specific and Task-Oriented Interventions. In light of the range and complexity of possible motor impairments and the myriad of treatment strategies available, the occupational therapist should design treatment to fit the patient's level and interests. There is growing evidence that intervention strategies providing context-relevant, meaningful engagement in activities are more beneficial for skill acquisition than rote exercise or passive modalities (Winstein et al., 2004). Task-specific training is aimed at improving component skills of selected tasks through goal-directed practice and repetition, such as using hand muscles to practice gripping a fork for feeding. An example of task-oriented training is a patient simulating a useful or familiar activity such as using a spoon to transfer dried beans from one container to another. Occupational engagement, such as a patient using a hemiparetic arm to eat a meal at home, involves the greatest degree of patient self-choice, motivation, and meaning (AOTA, 2008), although therapists must judge adaptations necessary to allow patients to succeed. Trombly and Wu (1999) found that

providing a meaningful object within a functional context during treatment (e.g., reaching for food on a plate) leads to improved performance over exercise or reaching for a neutral target. Similarly, Fasoli et al. (2002) found that, during functional reaching tasks, instructions focused on specific movements (e.g., "straighten your elbow") resulted in slower, less forceful reach than instructions focused on the task (e.g., "think about the size, shape, and weight of the water bottle you are reaching for") in samples of adults with and without CVA.

Therapists should review the wide range of possible functions of the upper extremity to select activities patients can succeed in. Patients who have limited arm movement or no voluntary hand movement can practice nonmanipulatory activities such as actively positioning the weaker arm for safety, bed mobility, or self-care and weight bearing on forearm or hand for support or to stabilize objects. If minimal hand movement is available, patients can hold objects in a static grasp (such as holding a washrag to wash the unaffected arm) and, as able, attempt varying reach-grasp-carry-release activities, graded for different positions of shoulder, elbow, and forearm and for different grasp and pinch patterns. Some patients may be able to work toward isolated finger movements and advanced manipulative skills, such as dialing a touch tone phone or keyboarding.

Constraint-Induced Movement Therapy. It is important to promote functional use of the involved upper extremity early and consistently because patients tend to have difficulty translating limited upper extremity movement into functional use. They often report that their arm is "dead" or "useless" despite sufficient arm movement for simple activities. Movement may return spontaneously, but it appears that function or purposeful use of the arm is enhanced with therapeutic intervention and practice (Blanton & Wolf, 1999). Based on studies involving both animal and human subjects, Taub et al. (1993) described the phenomenon of learned nonuse: the person with hemiparesis notices negative consequences of efforts to use the affected limb that are reinforced by successful compensatory use of the unaffected limb (Blanton & Wolf, 1999). Constraint-induced movement therapy (CIMT), is a well-studied and evidence-based intervention developed to counteract the effects of learned nonuse in stroke survivors who exhibit specific motor criteria (Fig. 33-4). In a comparative clinical study, Taub et al. (1993) restrained the unaffected upper extremity of chronic stroke patients (at least 1 year postonset) in a sling during waking hours for 2 weeks. This group also participated in sessions of intensive practice of functional tasks with the impaired arm. A comparison group was given activities designed to encourage use of the impaired arm but without practice and without restraint of the unimpaired arm. The restraint subjects showed greater improvement on measurements
Figure 33-4 Constraint-induced movement therapy. **A.** Stirring brownie mix. **B.** Playing a board game with involved upper extremity while noninvolved hand is restrained.

of motor function than the control group and showed carryover of this function to life tasks and maintenance of gains during a 2-year follow-up period. Dromerick, Edwards, and Hahn (2000) found that CIMT could be implemented during acute rehabilitation (1–2 weeks after stroke) with resulting improvement in involved arm function at the end of 14 days of treatment. This study suggests that preventing or minimizing learned nonuse with early intervention is preferable to extinguishing learned behaviors. The Extremity Constraint-Induced Therapy Evaluation (EXCITE) trials, a series of multisite, randomized, prospective, single-blind clinical studies including 222 poststroke subjects who met standard CIMT criteria, have strengthened the evidence that this intervention is effective in improving arm and hand function in stroke survivors 3–9 months poststroke (Wolf et al., 2006), that achievements gained from CIMT are maintained 2 years after intervention (Wolf, et al., 2008), and that CIMT is effective for chronic stroke in individuals 15–21 months poststroke (Wolf et al., 2010).

In order to participate in standard CIMT protocols, patients must meet minimal voluntary movement requirements, including the ability to initiate 20° or more of wrist extension and 10° or more of finger extension. As a result, benefits from this treatment are limited to those with less severe motor involvement, or approximately 20%–25% of patients with chronic stroke (Blanton & Wolf, 1999). CIMT is difficult to implement in clinical practice because the standard protocol includes 6-hour sessions of functionally oriented task practice with the paretic arm and hand for 5 days a week for 2 weeks. In addition, the uninvolved arm is physically restrained in a sling or hand mitt during 90% of waking hours. Other problems

limiting the application of CIMT techniques include poor compliance with patient restraint schedules, concerns over safety and limitations on independence caused by the restrictive device, lack of facility resources to provide intensive training sessions, and concerns about reimbursement (Page et al., 2008). In response to these limitations, Page et al. (2004) described a modified constraint-induced movement therapy (mCIMT) for outpatients that combines involving the affected arm in functional tasks during structured 30-minute sessions three times a week with restraint of the unaffected arm every weekday for 5 hours. Subsequent studies have indicated that mCIMT is as effective as CIMT in increasing hemiparetic arm use and function (Page et al., 2008)

Although "the collective body of research about CIMT and its various adaptations provides direct support for the essential OT tenet that opportunities for practice within the natural context of activity engagement are critical and necessary for improving motor skill" (Sabari & Lieberman, 2008, p. 55), more research is needed to identify the most beneficial factors of treatment, dose-response relationships, and kinematic outcomes. Studies of CIMT efficacy have included other commonly used OT interventions, such as massed practice, shaping, functional activities, client-centered approach, home programs, and preparatory modalities without determining the separate effects of each (Hayner, Gibson, & Giles, 2010). Some studies have concluded that treatment intensity rather than constraint of the less involved extremity may account for improved outcomes (Dobkin, 2007; Uswatte et al., 2006). Massie et al. (2009) suggest that CIMT may encourage patients to rely on common compensatory and/or synergy-dominated movement rather than promote more normal movement patterns.

Emerging Techniques and Technologies. The proliferation of novel stroke rehabilitation treatment techniques and technologies in recent years has resulted from growing evidence of neuroplasticity in response to movement therapy, and efforts to improve functional outcomes in the face of increased health care costs and decreased access to rehabilitation services (Fasoli, 2011). Clinicians should explore new approaches and adopt interventions that show evidence of enhancing patients' occupation and participation in more efficient, economical ways. Some of these interventions are used clinically to assist those patients with moderate to severe motor impairments who would not be able to participate in repetitive task-specific or task-oriented therapies, such as CIMT. Others are used to increase the opportunities for repetitive task training in the face of reduced therapy allowances.

- Neuromuscular Electrical Stimulation (NMES)—NMES has been used as an adjunct to poststroke upper extremity rehabilitation to reduce shoulder subluxation and pain, and improve movement and function of the arm. Hsu et al. (2010) found that both higher and lower doses of NMES combined with standard inpatient stroke rehabilitation improved motor recovery for subjects with severe motor deficits of the upper extremity. A systematic review of interventions for upper extremity hemiparesis (Urton et al., 2007) concluded that NMES can be used to improve outcomes of patients with moderate to severe arm deficits and is feasible for home-based use (see Chapter 18).
- Mental Practice/Imagery—Mental practice is a training method increasingly examined as an adjunct for use in stroke rehabilitation that involves the use of motor imagery to rehearse a motor skill without actual physical movement (Nilsen, Gillen, & Gordon, 2010). Page, Levine, and Hill (2007) have suggested that mental practice can be an effective pathway whereby patients with upper extremity hemiparesis can qualify for mCIMT and achieve increased functional gains. A systematic review concluded that mental practice in poststroke rehabilitation appears promising, but more research is required to guide therapists in its use to improve occupational performance (Nilsen, Gillen, & Gordon, 2010).
- Robot-assisted therapy—Many robotic devices for use in neurorehabilitation have been developed in both laboratory and clinical settings. In general, a patient's hemiparetic arm is placed on a handle or support that allows passive, assisted, or graded task-oriented movement. Although currently cost-prohibitive in most clinical settings, robot-assisted therapy allows patients who are unable to independently perform task-specific or task-oriented movements the benefits of intense, repetitive practice greater than possible with one-on-one therapy (Sabari & Lieberman, 2008). A systematic review of the effects of robot-assisted therapy on upper limb recovery after stroke (Kwakkel et al., 2008) found

marked variability in studies between distal and proximal arm robotics, although subsequent sensitivity analysis showed significant improvement in upper arm motor function. Future research is needed to better define the effects of robotics on functional outcomes. For more information, see Fasoli (2011) and Pignolo (2009).

- Virtual reality (VR)—The use of computer technology and "off-the-shelf" gaming consoles (such as Nintendo Wii) to simulate real-world activities and objects is a recent approach to enhance the effects of repetitive task training on stroke upper extremity rehabilitation. VR has the advantage of offering an interactive, highly motivating intervention that can be individualized to offer practice of functional tasks at a greater intensity than traditional therapy. Research is limited, but preliminary studies suggest that VR has promise as an additional tool for improving upper extremity movement and function poststroke (Joo et al., 2010; Saposnik et al., 2010).
- Mirror therapy—In this form of visual feedback, a mirror is placed vertically close to the midline of a patient seated at a table. As the involved arm is placed behind the mirror and the noninvolved arm is positioned in front of the mirror, the patient is instructed to watch the noninvolved arm in the mirror while attempting movements with both arms. The patient thereby receives the visual impression that the affected limb (the limb in the mirror) is functioning normally (Albert & Kesselring, 2011). Although data are limited, two randomized trials have found improved hemiparetic hand function in subjects receiving mirror therapy (Dohle et al., 2009; Yavuzer et al., 2008).
- Orthotic-aided therapy—Two examples of commercial orthotics used for upper extremity neurorehabilitation in OT clinics are a neuroprosthetic device and a dynamic spring-loaded orthosis. The neuroprosthetic device (Bioness H-200: Bioness Inc., Valencia, CA) is a forearm-hand molded orthosis providing functional electrical stimulation for muscle retraining, specifically to elicit active grasp and release in the hemiparetic hand. Although the high cost of this device limits its use, an advantage is that it allows arm support and facilitation without a therapist's physical assistance. Two studies (Alon, Levitt, & McCarthy, 2008; Hill-Hermann et al., 2008) have reported clinically meaningful outcomes in patients participating in this technique. The SaeboFlex (Saebo, Inc., Charlotte, NC) is a mechanical dynamic orthosis that positions the hemiparetic hand so that active finger flexion can be used for grasp and then assists release. A preliminary study on the clinical effectiveness of this device (Farrell et al., 2007) suggests that the SaeboFlex may be an affordable tool for repetitive motor training for individuals with moderate arm movement impairment after stroke who may not be eligible for other treatments such as CIMT (Fasoli, 2011).

Motor Learning Ability. Because occupational therapists mainly teach skills, they must address the learning process to help patients improve occupational performance and participation. Even the most familiar tasks, such as dressing, require adapting to a variety of circumstances or contexts. Therapists can best assist patients with stroke by helping them develop their own problem-solving techniques and strategies to deal with their environment.

Visual Dysfunction. Chapter 23 describes treatment for patients with visual deficits. In general, therapists can employ either of two basic intervention approaches for patients with visual problems following stroke, determined by the extent of visual impairment and a patient's intact capabilities: (1) establish or restore the person's performance skills or (2) modify the context of the activity and/or environment (Warren, 2009). With the first approach, the goal of therapy might be to improve a patient's visual scanning ability using functional activities to increase the speed and accuracy of visual search to the area of the VFD or by training in the compensatory skill of turning the head to the left. Examples of the second approach include simplifying activity demands, such as locating all items needed for grooming in one drawer; simplifying task sequence, such as installing a speed dial feature on a phone; or altering the built environment to eliminate clutter and obstacles (Warren, 2009).

Although research is limited, there is evidence for using visual scanning interventions to improve the efficiency and effectiveness of visual search in clients with VFDs (Pambakian et al., 2004). This study and others suggest that visual-perceptual deficits following stroke must be confronted, and patients must be taught to recognize their deficits for treatment to be effective. Sharing results of objective evaluations with the patient and family, giving feedback on the effects of visual deficits on functional performance, and teaching patients to recognize and correct errors in performance have been suggested as techniques for increasing a patient's awareness of his or her deficits.

Studies of the effects of visual training skills on unilateral neglect (Cherney, Halper, & Papachronis, 2003; Tham et al., 2001) indicate that treatment involving forced awareness of neglected space, task-specific practice, and use of consistent strategies to accomplish functional activities improve cognitive-perceptual abilities after stroke. To ensure transfer of training, Toglia (1991) recommended a multicontext approach of practicing strategies in multiple environments with varied tasks and component demands. Therapists, for example, can provide a stronger learning event by reinforcing a visual searching task (finding all the forks in a dishwasher bin) with touching and moving the targets (picking up the forks and putting them in the correct space in a drawer). Training must be specific to the individual's deficits and goals for occupational

functioning; a patient with hemianopsia and/or unilateral visual neglect with a goal of achieving safe wheelchair propulsion will benefit more from specific environmental scanning activities in a wheelchair (obstacle courses or grocery shopping) than from paper and pencil or computer activities.

Speech and Language Disorders. Occupational therapists should work closely with speech-language pathologists to contribute to a patient's improvement in speech and language functioning. Therapists can promote proper posture to aid respiration and eye contact important to speech. Therapy sessions also provide a social context supportive of communication and opportunities for practice of speech/language skills. Whenever possible, therapists should incorporate speech and language goals into their treatment sessions, such as requiring verbal responses (counting repetitions of an activity or naming objects used) or addressing functional reading and writing tasks (reading signs and recipes or writing checks). Occupational therapists can assist in selecting and adapting a nonverbal form of communication for a patient, such as writing, drawing, use of a communication board, and gestures. Suggestions for working with patients with aphasia and their families include the following (American Heart Association, 1994):

- Avoid unnecessary noise: turn off the television, find a quiet space.
- Do not speak to the patient or request speech when he or she is engaged in a physical activity.
- Allow enough time for the patient to respond; do not rush or force communication; do not switch topics quickly.
- Never assume that the person with aphasia cannot understand what is being said; never allow others to ignore the person with aphasia.
- Speak slowly and clearly using simple, concise language; do not speak loudly unless hearing is impaired; do not talk down as if to a child.
- Use demonstration, visual cues, and gestures as needed to help with comprehension.

Motor Planning Deficits. Motor planning deficits, or apraxia, are serious learning disorders and among the most difficult to rehabilitate. The emphasis of treatment is on teaching compensatory skills during ADL with focus on which stage(s) of motor planning present the most difficulty for a client: initiation of a task, execution of the plan, or control of activity to achieve adequate result (van Heugten et al., 1998). Suggestions for treatment include strategy training for specific ADL, sensory/proprioceptive stimulation, manually guided movement, cueing and prompting, repetitive graded use of objects and contexts to evoke more automatic responses, forward or backward chaining, and

practicing activities as closely as possible to the patient's usual context or routine (West et al., 2008). A Cochrane Collaboration study (West et al., 2008) reviewed the few randomized controlled trials of therapeutic intervention for motor apraxia in stroke and found small short-term clinical effects in two studies.

Cognitive Deficits. Treatment to optimize cognitive abilities is discussed in Chapter 24. As in other areas of dysfunction, treatment for cognitive problems after stroke can include retraining of specific component skills, teaching compensation techniques or substitution of intact abilities, and adaptation of the environment. Examples of treatment techniques include using prompts or cues to shape desired behavior; providing feedback on performance with suggestions and strategies for improvement; providing visual aids, such as memory logs, checklists, maps, or diagrams for deficits of memory, sequencing, or organization; and simplifying the environment and grading tasks for patients with attention deficits. Caregivers must be educated regarding recommended adaptations, safety precautions, and the need for supervision (refer to Safety Note 33-1).

Interventions aimed at the role performance/participation level appear to have a greater impact on an individual's quality of life than approaches stressing only impairment or activity restriction (Gillen & Rubio, 2011). A comprehensive review of evidence-based literature on cognitive remediation for stroke (Cicerone et al., 2000) reveals limited support for remediation of attention and memory deficits and executive function and problem-solving difficulties in stroke patients. Henshaw et al. (2011) have begun preliminary investigation of a cognitive task-specific training program to improve participation after stroke.

Psychosocial Adjustment. Patients and families usually need assistance in making healthy emotional adjustments after stroke. It may be unreasonable to expect full participation in treatment programs when patients and their families are coping poorly with the losses associated with stroke. Patients typically employ hope and determination to cope with hospitalization, the hard work of rehabilitation, and changes in body image, but many cling to the belief that they will be "normal" again (Sabari, 1998). Therapists should reinforce the efforts of the rehabilitation team and encourage patients and families to talk about their reactions to stroke and their comprehension of its progression and prognosis. In light of the shortening time frames for rehabilitation, therapists should make sure patients and families understand that recovery from stroke does not end with discharge from a hospital or rehabilitation program. Therapists should also help patients and families to realize that the ultimate goal of rehabilitation is not complete recovery from physical and intellectual impairments but the ability to resume valued life roles.

Therapists should recognize the signs and symptoms of depression and inform appropriate team members if treatment has not been initiated. For the patient with emotional lability, both patient and family need to be reassured that lability is a symptom of the stroke. Helping patients and families develop coping strategies, including problem-solving strategies, social support, information seeking, and engagement in activities, helps decrease the impact of psychological distress (Falk-Kessler, 2011). Because community support is reported to buffer the effects of disability on stroke survivors and their caregivers (Duncan et al., 2005), therapists should strive to provide opportunities for patients to participate in the community. Group activities, social interactions, and community outings are important methods for allowing a patient to practice roles from before the stroke and to realize that the patient role is a temporary transition to getting on with life despite residual impairments.

Transition to the Community

"Living with disabilities after a stroke is a lifelong challenge during which people continue to seek and find ways to compensate for or adapt to persisting neurological deficits. For many stroke survivors and their families, the real work of recovery begins after formal rehabilitation" (Duncan et al., 2005, p. 135).

Discharge Planning

Discharge planning takes place throughout the rehabilitation phase. Successful planning allows the patient and family to feel comfortable with the decisions made for discharge, feel capable of maintaining gains and continuing progress without the intense level of support provided by rehabilitation specialists, and feel able to monitor for changes requiring adjustments or further intervention. Occupational therapists assist in identifying the most appropriate discharge setting; training the patient, family, and caregiver in essential skills; and arranging for continuity of care with community services. Factors determining discharge setting include patient's and family's preferences, level of patient's disabilities, level of caregiver's support, and safety and accessibility of the home (Gresham et al., 1995). Often, a patient with a fairly high level of physical functioning cannot return home because there is no caregiver or the residence is unsafe or inaccessible, whereas a more disabled patient can return home because a healthy spouse is willing to assume the role of caregiver and the residence is safe and accessible. Therapists perform a major role by participating with patients and families in home visits and safety assessments and recommending necessary home alterations or adaptive equipment.

Patient, Family, and Caregiver Education

Ideally, every treatment session is an opportunity to teach the patient, family, or caregiver techniques and problem-solving strategies for use after rehabilitation. Because learning styles vary and repetition is important for learning, patients and their families are best served by a combination of demonstration, experiential sessions, and written instructions. Caregivers should demonstrate, rather than simply verbalize, their ability to assist the patient safely and independently. At the time of discharge from a rehabilitation program, patients and their families are often overwhelmed with information from several disciplines that they must try to assimilate. After formal therapy sessions have ended, many patients and caregivers report good intentions of following home programs as prescribed but admit that the routine of daily activity leaves little time or energy for carrying out therapeutic recommendations at home. The most effective home programs therefore are those that incorporate treatment for impairments into self-care, IADL, and leisure routines. For example: "Before bathing or dressing, briefly perform the following stretching movements to get the best posture and arm movement for these tasks" is more likely to be continued at home than: "Perform the following exercises, 10 repetitions each, at least twice a day." Home programs should, of course, be individualized and should remind the patient of skills already mastered, of skills the patient can reasonably expect to gain, and of possible problems common to stroke. Patients and families should be well informed of sources for information or assistance as new capabilities or problems evolve. Fall prevention is a necessary component of the home program and should encourage greater independence in mobility while identifying and reducing the risks of falls (Gresham et al., 1995).

Resuming Valued Roles and Tasks

Although most individuals who have had stroke regain functional abilities such as walking and self-care, this does not always mean that an individual will be able to successfully participate in the community (Beckley, 2006). A study of long-term occupational engagement of community-dwelling stroke survivors (White et al., 2008) found that altered occupation and role loss persisted up to 5 years after stroke, regardless of disability levels. These findings support other studies that suggest the need for occupational therapists to expand rehabilitation services into the community and to look beyond an emphasis on basic self-care skills to more complex occupations necessary for resuming or adapting work, family, and community roles (White et al., 2008; Wolf, Baum, & Connor, 2009).

Work. For patients who expect to resume working, prevocational or vocational evaluation and appropriate work-readiness training should be encouraged (see Chapter 28).

Although this area is not emphasized in most stroke rehabilitation programs (Wolf, Baum, & Connor, 2009), return to paid employment is a significant indicator of recovery for many following stroke, especially considering over one-third of stroke survivors are under the age of 65 years, and greater numbers of Americans are working beyond retirement age (Hartke, Trierweiler, & Bode, 2011). A literature review (Treger et al., 2007) examining return to work following stroke found that between 19% and 73% of the patients were able to return to work. The wide variability seen in return to work is explained by the diversity of sample populations and differences in defining work. A smaller percentage of patients were able to resume full-time competitive employment, and a greater percentage returned to part-time or home-based work. Those able to return to work reported significantly higher levels of subjective life satisfaction (Vestling, Tufvesson, & Iwarsson, 2003). The factors generally found to relate positively to return to work included independence in self-care, ability to walk, younger age, high educational and occupational levels, stable marital status, and preserved language and cognitive capacities, whereas the most significant negative predictor is greater severity of stroke (Treger et al., 2007; Vestling, Tufvesson, & Iwarsson, 2003). Treger et al. (2007) noted that the results of this quantitative research have done little to inform us about effective interventions for assisting poststroke clients resume employment. In their qualitative study, Hartke, Trierweiler, and Bode (2011) suggest that interventions to address return to work must focus on the individual (e.g., adjustment to disability), work (physical and psychological demands of a client's job), and community (e.g., access to transportation)—emphasizing the person-environment-occupation fit rather than impairments after stroke.

Leisure and Recreation. Throughout rehabilitation, valued leisure activities should be identified, encouraged, and enabled. Leisure participation has increasingly been included as an important factor in preventing health decline and isolation poststroke (Bhogal et al., 2003). Effective therapy incorporates leisure interests into treatment so that the patient recovering from stroke can begin to analyze the effects of impairments on valued activities and anticipate strategies for return to these activities. A study of 40 individuals discharged from rehabilitation programs poststroke found factors influencing leisure participation include family and social support, transportation or financial barriers, attitudes toward altered leisure performance, amount of free time available and number of leisure interests (Jongbloed & Morgan, 1991). Many patients following stroke report decreased energy, motivation, or time for leisure pursuits because of fatigue, depression, and/or the increased demands of self-care. Many do not accept performance of a valued activity at a lower standard; for example, a patient with hemiparesis

may give up golf rather than play at a reduced level of performance. Many patients, particularly those who were working at the time of their stroke, do not have established leisure roles or do not admit to any leisure interests. A randomized controlled trial by Desrosiers et al. (2007) evaluated the effect of a home-based leisure education program following stroke that included leisure awareness and self-awareness (exploration of new leisure activities suitable for a patient's interests and abilities) and competency development (finding ways to overcome physical barriers in the home or community in order to adapt or adopt a valued activity). The study found positive effects for leisure participation, leisure satisfaction, and reduced depression.

Sexuality. Surveys of patients and their spouses show that typical effects of stroke on sexuality include decreased libido, impaired erectile functioning in men, decreased vaginal lubrication in women, and decreased frequency of sexual activity (National Stroke Association, 2006). Causes may be physiological (decreased motor, sensory, or cognitive functioning; dependency in ADL; decreased endurance; incontinence; coexisting disease; or side effects of medications) or psychosocial (poor self-image, depression, role changes, impaired communication ability, fear of impotence, or fear of recurring stroke) (Farman & Friedman, 2011; National Stroke Association, 2006).

To assist with sexual expression, all therapists can impart the message that patients are permitted to have concerns and seek information about sexual problems after stroke. Therapists should reassure their clients that these problems are common and that sexual activity after stroke is not contraindicated (Duncan et al., 2005). Other possible interventions include providing or referring to resources to increase the patient's knowledge, encouraging open communication between partners, suggesting adaptations such as changes in positioning or timing, and referring to a qualified specialist (Duncan et al., 2005; Farman & Friedman, 2011).

Driving. Nearly all adults in the United States drive (Warren, 1999), so the ability to resume driving is a high priority for most individuals with stroke and is seen as a way to continue community independence and avoid isolation. Improved survival rates and longevity after stroke increase the need for health professionals to make recommendations regarding a patient's ability to drive (Korner-Bitensky et al., 2006). Because of its complexity and danger, driving after stroke is usually not addressed until a patient has returned home and gained a satisfactory level of independence with self-care, IADL, and short-distance mobility. It has been reported that only 30% of those who drove before stroke are able to resume driving, and 87% of those who drove before stroke did not receive any form of driving evaluation (Fisk, Owsley,

& Pulley, 1997). Although it is not known with certainty which factors are associated with return to driving, earlier studies identify younger age, higher functional status, and higher scores on visual attention tasks as predictive of ability to resume driving, whereas a recent multicenter cohort study suggests that clients with ischemic strokes versus hemorrhagic stroke and those with higher levels of strength, motor activity, and cognition at 3 months post-stroke are more likely to be able to resume driving at 1 year poststroke (Perrier, Korner-Bitensky, & Mayo, 2010). Hemiparesis alone does not appear to prevent a return to driving because vehicles or techniques can be adapted to compensate for most motor deficits seen poststroke. A study by Elgin et al. (2010) found that some clients with hemianopsia (without neglect) given a standardized on-road evaluation demonstrated performance ratings similar to those of persons with normal visual fields. There are no standard evaluation procedures for determining the ability of cerebrally injured patients to return to driving, but consistent practices include (1) a predriving evaluation battery to test for visual scanning, visual attention, higher level visual-cognitive skills, distractibility, mental slowness, problem solving, and ability to follow directions; (2) a driving simulator evaluation; and (3) a road test, both on a protected course and in traffic (Korner-Bitensky et al., 2006). Studies have failed to establish evidence of the accuracy of various components of predriving assessment in predicting on-road driving performance.

Few studies have substantiated the effectiveness of rehabilitation to assist patients return to driving, but two approaches used include treatment to remediate underlying impairments through retraining visual and cognitive skills and a functional approach using simulators and on-road driving lessons. Two small randomized controlled trials (Crotty & George, 2009; Devos et al., 2009) found greater improvement in the behind-the-wheel driving performance of poststroke subjects when a more contextual, functional treatment approach was taken. Crotty and George (2009), examined remediation training using the Dynavision, a device designed to address underlying motor and visual deficits such as visual scanning, peripheral visual awareness, visual attention, and visual-motor reaction time. They were unable to find an effect of this training on on-road driving perfomance. Devos et al. (2009) found that subjects who received driver simulator training showed better performance on overall on-road driving when compared with subjects in a cognitive training program. Therapists must remember that the decision to allow a person who has had a stroke to resume driving rests with the state licensing bureau (see Chapter 26).

Community Support and Resources. Methods to reintegrate the patient into the community (e.g., transportation options, dealing with architectural barriers, assistance from family or friends, and access to senior citizen centers)

should be addressed throughout rehabilitation because failure to resume premorbid community activities has been significantly correlated with isolation and depression in stroke patients (Logan, Dyas, & Gladman, 2004). Reintegration into the community, according to individuals who have had strokes, can take years rather than months (White et al., 2008), continuing after a patient has ended regular contact with rehabilitation specialists. The AHA/ASA clinical practice guidelines recommend that acute-care hospitals and rehabilitation facilities maintain current inventories of community resources, provide this information to stroke survivors and their caregivers, and offer assistance in obtaining needed services (Duncan et al., 2005). In general, supports for patients and their families include educational, instrumental, and emotional supports (Duncan et al., 2005). Educational resources are available through organizations (Resources 33-1) that offer direct audiotaped, videotaped, printed, and/or online information specific to stroke. Instrumental supports are physical assistance programs such as personal provider services, Meals on Wheels, and volunteer groups who can build wheelchair ramps. Emotional support can come from family, friends, mental health professionals, and other survivors of stroke.

Support for long-term caregivers is especially important because caregivers appear to be at substantial risk for burnout, depression, isolation, and general health problems (Duncan et al., 2005). Therapists can encourage and suggest sources for respite care, support groups, or counseling. Many communities, unfortunately, are limited in resources for the patient and family. Therapists can be advocates and consultants for the development of community programs; this can range from referring patients and families to others in the community living with stroke, to organizing a stroke club, to identifying opportunities for volunteer jobs for patients.

Postdischarge Continuity of Care. The trends toward decreasing age of people who have had stroke, greater numbers of mild to moderate severity strokes, and earlier discharges from acute centers and rehabilitation programs challenge occupational therapists to expand beyond traditional clinical management of stroke to practices that facilitate community participation. "Stroke is no longer considered an acute episode but rather a chronic condition that requires behavioral and health changes" (Wolf, Baum, & Connor, 2009, p. 625). Sabari and Lieberman (2008) refer to the long-term period after discharge from a rehabilitation program as the "stage of continuing adjustment" when stroke survivors strive to resume activity and role participation in their homes or in a supported environment such as long-term or assisted living facilities. Recommended rehabilitation practices include follow-up visits to monitor a stroke survivor's progress within 1 month of return to the community and

at regular intervals for at least 12 months (Gresham et al., 1995). Sabari and Lieberman suggest that clients and their families may require intermittent OT services at various times after the formal stage of rehabilitation: referrals may be indicated for a home assessment after a change of

living environment, for consultation after placement in a long-term care facility, for assessment/treatment for specific activity or role participation (such as return to work or driving a car), and for evidence of improvements or decreases in motor functioning that might have an impact on occupational performance.

Managed health care programs tend to focus resources on the most acute patients and on the outcomes of independence in BADL and return to home. As life expectancies increase after stroke, occupational therapists should seek improved methods of providing cost-effective community-based services to meet the continuing needs of stroke survivors to remain active and independent in their communities, to reduce the risk of secondary complications, and to enhance quality of life (Sabari & Lieberman, 2008). For example, therapists can investigate with stroke survivors alternative community resources to help promote/maintain health, such as water aerobics (Mehrholz, Kugler, & Pohl, 2011), yoga (Lynton, Kligler, & Shiflett, 2007), and Tai Chi (Taylor-Piliae & Haskell, 2007).

EFFECTIVENESS OF TREATMENT

The Occupational Therapy Practice Guidelines for Adults with Stroke (Sabari & Lieberman, 2008) stresses the importance of using scientific literature to justify the value of interventions provided to patients with stroke. This guideline states that "occupational therapy practice has expanded to unite clinical reasoning with evidence from scientific literature and client characteristics and preferences" (Sabari & Lieberman, 2008, p. 39). The guideline summarizes evidence for the efficacy of OT interventions with stroke survivors to the following broad categories:

- Neural plasticity is possible after brain lesions and is positively influenced by task-based environmental challenges.
- OT interventions are effective in remediating motor and process skills poststroke as seen by functional improvements.
- OT interventions effectively improve activity and role performance, which often leads to perceived improvement in quality of life.

Therapists have a responsibility to use this scientific evidence base when selecting evaluations and interventions rather than relying on dated professional training or clinical resources (Doucet, 2012). For example, see Evidence Table 33-1, as well as the studies cited in this chapter. Basing treatment on scientific evidence often involves giving up traditionally used methods that are not scientifically supported or adopting new evidence-based techniques. Developing evidence-based best practices for the treatment of individuals with stroke is a dynamic, ongoing process: as the body of professional literature grows and more therapists implement evidence-based practice, more data can be collected and assessed so that new practice-based evidence may emerge.

Evidence Table 33-1 | Best Evidence for Occupational Therapy Practice Regarding Stroke

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-specific practice of client-chosen BADL or IADL	Practice of specific tasks in a familiar context	Three hundred twenty-three acute stroke survivors (147 left cerebrovascular accident [LCVA], 156 right cerebrovascular accident [RCVA]); mean age = 72.5 years	Ranged from 1 to 15 visits over a period of 6 weeks to 5 months	Meta-analysis of two studies. Level: I	Yes. The treated groups improved in BADL as measured by Barthel Index, and improved in IADL as measured by Nottingham EADL Scale.	Mean weighted effect size was r = 0.16, equivalent to a 16% success rate over control treatment.	Trombly & Ma (2002)
Use of cueing strategies to improve scanning function in unilateral neglect	Practice of scanning tasks with visual or motor cues	Thirteen acute stroke survivors (0 with LCVA, 13 with RCVA); mean age = 57.5 years	Twenty-one trials/day for 4 consecutive days. Order of condition randomized.	Randomized controlled study. Level: IC1b	Yes. Bias Index of Line Bisection improved in all cued conditions compared with controls (strongest effect with motor cueing).	Mean effect size was r = 0.87, equivalent to a 87% success rate over control treatment.	Lin et al. (1996)
Practice of goal-directed tasks to increase voluntary active range of motion	Experimental group: use of exercise apparatus and game to increase forearm supination. Control: use of same apparatus without game	Thirty acute stroke survivors (11 with LCVA, 15 with RCVA, 4 with other); mean age = 68.4 years	Two sets of 10 trials for each condition; different days	Randomized controlled study. Level: IC2c	Yes. Mean gain of 13.4° more supination (handle rotation) in experimental group.	Effect size was r = 0.42, equivalent to a 42% success rate over control treatment.	Nelson et al. (1996)
Use of goal-directed object-present activity to enhance quality of movement	Practice of reaching movement with object present or to accomplish functional goal versus reaching without object or without functional goal	Twenty-eight chronic stroke survivors (17 with LCVA, 9 with RCVA, 2 with other); mean age = 63.4 years	10 trials/condition within 1 day	Meta-analysis of two studies. Level I	Yes. Better organization of reaching movement for functional goal as described by kinematic variables for speed, smoothness, strategy used, and force.	Combined effect size was r = 0.62, equivalent to a 62% success rate over control treatment.	Ma & Trombly (2002)
Use of modified constraint-induced movement therapy to reduce disability and improve use of paretic arm	Experimental groups: modified CIMT with repetitive task training, ADL tasks; constraint of nonparetic arm. Control groups: traditional rehabilitation treatments included NDT, PNF, ADL compensatory techniques, task training, strengthening	Two hundred seventy-eight poststroke patients with clinical diagnosis of UE hemiparesis; mean age = 57 years; time of onset since stroke ranged from 2 days to 60 months	Ranged from 30 minutes to 3 hours/day for 3–5 days/week for a total of 2 to 10 weeks. For mCIMT group, restraint time of nonparetic arm ranged from 5 to 6 hours/day	Meta-analysis of 13 randomized controlled trials. Level I	Yes. mCIMT groups showed higher scores on Fugl Meyer Assessment, FIM, and Motor Activity Log than patients in traditional rehabilitation group.	For Fugl Meyer Assessment: mean difference (MD) = 7.8; (95% confidence interval [CI], 4.21–11.38; p < 0.001); r_w = 0.40.[1] For FIM: MD 57 (95% CI, 0.75–13.26; p = 0.03); r_w = 0.45.[2] For Motor Activity Log: Amount of use: MD = 1.09, 95% CI, 0.26–1.91; p = 0.01; r_w = 0.64.[3]	Shi et al. (2011)

[1]Average weighted effect size, r, based on two studies (n = 73) that reported effect size; indicates 40% greater improvement rate in motor control of the upper extremity because of CIMT as compared to traditional therapy.
[2]Average weighted effect size, r, based on all three studies (n = 88) using the FIM assessment; indicates a 45% greater improvement rate in basic ADL because of CIMT as compared to traditional therapy.
[3]Average weighted effect size, r, based on four studies (n = 135) that reported effect size; indicates a 64% greater improvement rate in use of affected upper extremity because of CIMT as compared to traditional therapy.
ADL, activities of daily living; BADL, basic activities of daily living; CIMT, constraint-induced movement therapy; FIM, functional independence measure; IADL, instrumental activities of daily living; mCIMT, modified constraint-induced movement therapy; NDT, neurodevelopmental therapy (See online chapter A); PNF, Proprioceptive neuromuscular facilitation (See online chapter C); UE, upper extremity.

case example
Mrs. H.: Right Cerebrovascular Accident

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information	Understand the patient's diagnosis or condition	"The large size of Mrs. H.'s lesion, persistent altered levels of consciousness, initial severe ADL dependence and motor deficits, visuospatial deficits, and incontinence all predict poor functional outcomes and lengthy recovery period. In her favor, Mrs. H. was able to live alone at home and has no significant prior medical history."
Mrs. H. is an 82-year-old widow who lived alone, independent in activities of daily living (ADL) and instrumental activities of daily living (IADL) except for community transportation. She was found unresponsive at home by a neighbor and diagnosed with a large right middle cerebral artery infarction.		
During her acute hospital stay, an occupational therapist evaluated Mrs. H. and reported inconsistent levels of awareness, no spontaneous movement on the left side, and signs of left hemianopsia and spatial neglect. Treatment consisted of involving the patient in simple self-care tasks and initiating a bed positioning and mobility program in conjunction with nursing and physical therapy to prevent secondary complications. Ten days poststroke, Mrs. H. was able to sit in a wheelchair for 1-hour periods, follow one-step commands consistently, and perform simple grooming and bed mobility tasks with minimal assistance. She was transferred to an inpatient rehabilitation unit for more intensive treatment. At the time of discharge from acute care, Mrs. H. was incontinent of bowel and bladder and had a small area of skin breakdown over her coccyx. The social worker reported that Mrs. H. had led a sedentary life and enjoyed going to church, visiting with neighbors and family, reading her Bible, and watching television. Staff reported her verbal skills, comprehension, and memory to be good, although Mrs. H. expressed frustration at her continued hospitalization and stated that she expected a full recovery and return home. Mrs. H.'s family consisted of four adult grandchildren and their families, who were unable to change their work or living situations to care full time for Mrs. H. The family was supportive and hopeful that Mrs. H. could return home with a hired care provider, although they were willing to consider skilled nursing home placement if Mrs. H. did not gain sufficient functioning to return home.	Know the person	"Mrs. H. seems to have limited knowledge and understanding of the nature of her stroke and resulting impairments. She appears to be someone with limited experience living in a dependent role. Because she had not been a physically active person, she may fatigue easily during an intense rehabilitation program. It would not be difficult for her, however, to resume valued roles and activities from a wheelchair level, especially with supportive friends and family. The fact that her thinking skills appear intact will help Mrs. H. achieve her rehabilitation goals, but her visual-perceptual impairments will hinder learning new techniques."
Reason for Referral to Occupational Therapy	Appreciate the context	"I will coordinate my services closely with other disciplines to avoid patient fatigue and develop consistent strategies. I will involve family in therapy early because it seems likely that Mrs. H. will need moderate to maximum skilled care upon discharge."
Mrs. H. was referred to occupational therapy (OT) to increase self-care independence, increase awareness of left visual spatial field, recommend proper management of the left arm, and assist in determination of optimum discharge plans. She will also be seen daily by physical therapy and periodically by speech-language pathology, social work, psychology, and therapeutic recreation.	Develop provisional hypotheses	

Assessment Process and Results

The rehabilitation team completed the Functional Independence Measure (FIM) (Keith et al., 1987) for Mrs. H. as part of the standard care process for the unit. Mrs. H. scored a 28 (out of a possible 91) on the FIM motor score, and 30 (out of a possible 35) on the cognitive score. In areas assessed by OT, Mrs. H. required minimal (25%) assistance with eating, grooming, and upper body dressing; maximum (75%) assistance with bed bathing and toilet transfers; and total (more than 75%) assistance for lower body dressing, toileting, and tub transfers. During interview/observation of leisure skills, Mrs. H. described difficulty reading ("I think I need new glasses") and watching TV ("The picture isn't very good"). Mrs. H. was observed consistently keeping her head turned to the right and having difficulty finding or concentrating on people or objects in her left visual field.

OT assessment of component abilities and capacities revealed impaired sensation in the left arm; inconsistent minimal movement in left pectorals, internal rotators, and biceps only; and mild shoulder pain with movement above shoulder level. In addition, a screen of visual field function found significant loss of left peripheral field perception.

The speech-language pathologist reported swallowing difficulties and recommended a pureed diet with no thin liquids. Physical therapy described Mrs. H. as requiring maximum (75%) assistance to perform a scooting transfer and unable to sit unsupported, stand, or propel a wheelchair.

Occupational Therapy Problem List

- Loss of independence in basic activities of daily living (BADL)
- Loss of independence in IADL and leisure activities
- At risk for injury or complications in left arm because of lack of voluntary movement, decreased sensation, and visual-spatial neglect
- Limited insight into impairments and disabilities resulting from stroke and the predicted course of recovery

Occupational Therapy Goal List

Patient will be able to do the following:

- Perform feeding, grooming, and upper body dressing with supervision and minimal cueing
- Perform lower body dressing, toilet transfers, and bathing on a tub bench with moderate (50%) assistance
- Independently operate television by remote control and tape recorder for books on tape
- Maintain sitting balance on the side of bed for at least 2 minutes while engaged in upper body activity
- Properly position left arm during change of position in bed and while seated in wheelchair
- Independently perform stretching and range-of-motion activities for left hand, wrist, forearm, and elbow; perform stretching and range-of-motion activities for shoulder with moderate assistance
- Demonstrate proper techniques for positioning
- Assist with left arm mobility
- Pay attention to left visual field at least 50% of time

Consider evaluation approach and methods

"From the physical therapy assessment, I learned of Mrs. H.'s postural control deficits. It was important to observe her performance in self-care rather than rely on self-report because she seems to have limited insight into her disabilities. Although observation of ADL gave me information about her visual field and inattention problems, I will consider more in-depth testing of her visual function, perhaps portions of the Brain Injury Vision Assessment Battery for Adults (Warren, 1996) because of her desire to resume reading."

Interpret observations

"I can observe that Mrs. H.'s limited ability in lower extremity dressing, bathing, and transfers are due to her poor sitting balance and lack of mobility. Her difficulties with upper extremity dressing, grooming, and feeding are a result of decreased attention to left visual space and the left side of body. Her left side somatosensory and motor deficits and her lack of awareness of her visual problems add to her left inattention."

Synthesize results

"Mrs. H.'s stroke has severely reduced her ability to live independently in her home, although returning home is her discharge goal. Her degree of hemiparesis, postural instability, and neglect, along with her lack of awareness, increases her risk for secondary complications."

Develop intervention hypotheses

"I do not think Mrs. H. will be able to return to independent living, but improving basic capacities (balance, visual attention) would allow her to succeed in simple meaningful activities. Education will assist with continuity of care in a new setting and allow the patient and family to feel they can contribute to the recovery process."

Select an intervention approach

"Occupational therapy intervention will include restoration, compensation, and prevention approaches."

Consider what will occur in therapy, how often, and for how long

"I predict that Mrs. H. will progress slowly in therapy but will benefit from multidisciplinary treatment. She will need at least 2 weeks of inpatient rehabilitation. She will be seen daily in OT, twice a day for shorter periods (30 minutes) to allow rest between sessions."

Intervention

The treatment program during Mrs. H.'s 2-week inpatient rehabilitation stay consisted of (1) an activity program emphasizing BADL and IADL training to address sitting balance, transitional movements, management of left upper extremity, and attention to and scanning of the left visual field and (2) patient and family education regarding the consequences and course of recovery of stroke, safety awareness and prevention of secondary impairments, and compensatory techniques and adaptations to promote functional independence.

At discharge, Mrs. H. was able to feed herself, perform simple grooming activities, and use her television and tape recorder with setup and supervision. Status in all other ADL remained unchanged. Sitting balance remained poor, and left spatial neglect remained pronounced. Mrs. H. required maximum assistance with protection and mobilization of her left arm.

Mrs. H.'s family attended family training sessions prior to discharge and was provided with written instructions of material covered in training.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

"Mrs. H. had difficulty learning new techniques for familiar activities, so she required repeated practice and reinforcement from nursing and other disciplines. Because Mrs. H. could not recognize or monitor her visual or balance impairments, interventions to improve these capacities had to rely more on external rather than internal adjustments. Mrs. H. was always pleasant and cooperative and continued to feel that soon she would get better and go home. It was disappointing that she did not gain more independence, but I feel the family understands the impact of Mrs. H.'s stroke and the probability of a lengthy recovery period."

Next Steps

Mrs. H. was transferred to a skilled nursing facility, where she will continue occupational and physical therapy. Copies of all therapy documentation were forwarded to the center, and information was shared through phone calls.

During a conference prior to discharge, the family was informed of possible future settings for continuing care for Mrs. H. and provided with a list of home health agencies, outpatient services, and provider services.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether the patient should continue or discontinue therapy and/or return in the future

"I felt it was important to talk directly to the therapists at the skilled nursing facility to discuss Mrs. H.'s unique problems. It has been less than a month since the onset of her stroke, which is too soon to determine the extent of her recovery. I have emphasized to the patient and family that transfer from the rehabilitation unit does not mean her recovery is over, but it is merely moving to a different stage. I have tried to give the patient and family as much information as possible to help them recognize signs of progress or regression so that they can be advocates to ensure that Mrs. H. receives the proper type of therapy at the proper time."

Clinical Reasoning in Occupational Therapy Practice

Preventing Secondary Complications

Mrs. H. has many impairments resulting from her stroke that put her at risk for developing secondary complications. Name these impairments and possible resulting complications. Which impairments increase Mrs. H's risk of falls?

What specific therapy interventions could therapists employ to help prevent these complications? What instructions could therapists give to the patient and family to prevent complications and to prevent falls?

case example

Mr. G. Left Cerebrovascular Accident

Clinical Reasoning Process

Occupational Therapy Process	**Objectives**	**Examples of Internal Dialogue**
Patient Information Mr. G. is a 38-year-old man with a history of hypertension who had abrupt onset of right-sided weakness and loss of speech. He was hospitalized quickly and diagnosed with a left subarachnoid hemorrhage. He spent 9 days in acute care and 2 weeks on an inpatient rehabilitation unit before being discharged home to live with his wife and two children aged 10 and 12 years. During his hospitalization, Mr. G. made rapid progress and regained most of his speech and movement on the right side. Upon discharge, Mr. G. could perform self-care tasks, simple meal preparation, and household walking using a straight cane with supervision for increasing amounts of time. He had mild apraxia resulting in delays initiating and sequencing multistep tasks. He had decreased control of his right arm, particularly when he tried to raise it above shoulder level or attempted fine motor activities. Before his stroke, Mr. G. worked in the parts department of an automobile dealership. His job included inventory, ordering, stocking, and pickup and delivery of parts. His wife was a teacher who was home for the summer but planned to return to work when school started in 2 months.	Understand the patient's diagnosis or condition Know the person	"Mr. G.'s rapid recovery and young age predict good functional recovery. He should continue to gain independence in basic self-care, but persisting problems with higher level right arm and leg function, with higher level cognitive and communication skills, and with skilled motor planning may interfere with his participation in desired life roles." "Mr. G. was quite successful in achieving inpatient rehabilitation goals and will probably expect similar rapid progress after he returns home. He and his wife will be anxious for him to gain higher levels of function within 2 months. The early months after discharge home can be stressful and frustrating as patients encounter difficulty resuming previous roles."
Reason for Referral to Occupational Therapy Mr. G. was referred to outpatient occupational therapy to continue progress in activities of daily living (ADL) and instrumental activities of daily living (IADL) independence and to assist with resuming community roles. He was also referred for outpatient physical therapy to work on improving balance and upgrading gait and for speech therapy to improve word retrieval and higher level reading and math skills.	Appreciate the context Develop provisional hypotheses	"Home is the best place for Mr. G. to practice and refine his ADL/IADL skills. As he gains confidence at home and competence in performance skills, he will look more to resuming community roles, especially his worker/provider role."
Assessment Process and Results Mr. G.'s goals for occupational therapy were to function safely alone at home after his wife returned to work, to regain normal function of his right dominant arm, and to return to work as soon as possible. Initial outpatient assessments included the Stroke Impact Scale (Duncan et al., 1999), which allowed Mr. G. to rate how various impairments and disabilities caused by his stroke affected his quality of life. Responses to this scale and further interview revealed that Mr. G. is concerned about the continuing difficulty in using his right arm; worries about being a burden on his family and returning to work; feels foolish and inadequate because of frequent mistakes in speech, reading, writing, and math; admits that he is very slow with his daily care routine and household tasks and depends on his wife for help more than he would like; tires easily; and feels unable to participate in most previous leisure or social activities. A home assessment was completed to observe Mr. G. perform his morning bathing/dressing/grooming tasks and to assess safety risks. He took almost 2 hours to complete these tasks, needed occasional rest breaks, needed occasional physical assistance for balance, and verbal cueing for sequencing, and had difficulty with fine motor tasks such as buttoning. The Functional Test for the Hemiplegic/Paretic Upper Extremity (Wilson, Baker, & Craddock, 1984a, 1984b) was administered to determine level of functional use of his right arm (see Fig. 33-3).	Consider evaluation approach and methods Interpret observations	"I like using the Stroke Impact Scale and Functional Test for the Hemiplegic/Hemiparetic Upper Extremity because they are specific to stroke and help patients focus on functional results and appreciate that their problems are typical. These assessments are both useful for tracking progress over a long period of time." "Mr. G. is at a stage where he is beginning to experience and realize the effects of his stroke on his unique life roles. He shows good insight into his problems, and that will help him achieve or adapt his goals. His ADL deficits are due to a combination of dynamic balance problems, delays in initiation, fatigue, and decreased coordination of his right arm. He is able to use his right arm effectively as a stabilizing assist and for simple grasp and release, but he has difficulty with activities involving moving the arm above shoulder level or right-hand fine motor prehension or manipulation."

Occupational Therapy Problem List

- Requires supervision and extended time to complete bathing, grooming, and dressing
- Requires supervision and/or increased time to perform home IADL tasks (writing checks, preparing meals)
- Unable to perform tasks required for job, including using computer, lifting heavy boxes, and driving
- Unable to resume leisure activities, including bowling and coaching son's baseball team
- Difficulty using right arm for activities above shoulder level
- Unable to use right hand for fine motor prehension or manipulation tasks
- Depressed, anxious over loss of independence and role functioning and financial uncertainties

Synthesize results

"Mr. G. has shown good functional recovery in a short period of time and is working hard to readapt to his home environment. However, his deficits in higher level areas of occupation and performance skills hinder his role competence."

Occupational Therapy Goal List

- Perform morning self-care independently in 45 minutes or less
- Assume partial meal preparation and laundry tasks
- Use right arm to comb hair and to place and retrieve objects on shelf at eye level
- Use right hand to tie shoelaces, manipulate coins, sign name, and perform simple computer functions
- Participate in gross motor recreational activities with children (swimming, table tennis)
- Perform job simulation activities for 2 hours without rest break
- Complete predriving evaluation
- Be able to use community transportation independently

Develop intervention hypotheses

"I think Mr. G. will gain independence in basic activities of daily living (BADL) and limited IADL. I think he will make substantial progress in resuming valued roles, but this may take a long time, and he may need to accept modified roles."

Select an intervention approach

"Occupational therapy intervention will primarily be restorative and maintaining, with compensation/adaptation intervention used as needed."

Consider what will occur in therapy, how often, and for how long

"Because Mr. G. has a time goal (his wife's return to work), I will see him three times a week for 1 month, and then two times a week for a month."

Intervention

Treatment consisted of the following:

1. Task-specific training in ADL, IADL, and job activities. Activities were adapted, graded, and expanded as Mr. G. gained competency.
2. Repetitive task-oriented program to improve motor planning, postural adaptation, and right arm strength and control. This program was designed to be carried over to home.
3. Education concerning safety issues, home and activity adaptations, social supports, and available community resources.

Mr. G.'s wife and children attended therapy sessions at least once a week and provided valuable suggestions and encouragement for carryover of therapy in the home.

All goals were achieved at the end of 2 months. He scored significant improvements on both the Functional Test for the Hemiplegic/Paretic Upper Extremity and the Stroke Impact Scale. Mr. G. was able to demonstrate independence with written home programs addressing component skills and was able to verbalize appropriate safety precautions.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"Mr. G. was highly motivated for therapy and was relieved to see incremental improvements. He had problems that seemed to respond best to familiar, meaningful, repetitive treatment activities. Treatment was designed to provide structure to substitute for his loss of employment, to allow him to resume alternative roles at home, and to allow him to explore the feasibility of returning to his previous job."

Next Steps

Mr. G. was scheduled for follow-up visits with his neurologist in the outpatient stroke clinic every 3 months for a year poststroke, which allowed OT a chance to contact him and monitor his progress. He was referred for behind-the-wheel driving assessment and training. He initiated application procedures for his state's vocational rehabilitation financial aid and training services. He and his wife were given the names of counseling resources to help them deal with the stresses of his continued recovery.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether the patient should continue or discontinue therapy and/ or return in the future

"I anticipate that Mr. G. will continue to gain competence in component skills and occupational functioning but that his rate of recovery will slow down. I am glad I will have a chance to check with him periodically to alter his home program if necessary and to determine whether he will benefit from additional therapy. Depending on the results of vocational screening, he may decide to pursue different employment that might require specific job training. Both he and his wife seem to understand that depression and fatigue are common complications of stroke."

Clinical Reasoning in Occupational Therapy Practice

Addressing the effects of cognitive impairments on community reintegration

Mr. G. was successful in regaining sufficient physical functioning to allow BADL skills and independence within the home but was less successful in regaining independence in IADL requiring higher level cognitive functions.

What particular cognitive deficits would interfere with Mr. G.'s ability to return to work and to resume his previous community roles? Name interventions that could address these deficits.

Summary Review Questions

1. Name the two main categories of stroke and the subtypes and causes of each.
2. Name six neurological deficits that can result from stroke and describe how each may interfere with the task of dressing.
3. What is the difference between neurological recovery and functional recovery after stroke? How might OT facilitate both types of recovery in a patient?
4. Name five settings where occupational therapists work with patients recovering from stroke, and describe the characteristics of a patient who might be treated in each setting.
5. Define postural adaptation, and name three ways impairments in this area affect occupational performance. Describe treatment methods to improve postural control.
6. What mechanical and physiological components of movement should be evaluated in the hemiplegic upper extremity? What methods can be used to prevent development of a painful shoulder?
7. What variables should be considered during evaluation for voluntary movement in the hemiplegic upper extremity?
8. What factors can affect a stroke patient's ability to learn and organize movement? Describe how deficits in each of these areas affect self-care.
9. Select a treatment activity for a patient recovering from stroke, and describe how this activity can both increase ADL independence (reduce disability) and improve component abilities and capacities (reduce impairment).
10. Describe methods to assist a poststroke patient resume valued home and community roles after discharge from rehabilitation services.

Glossary

Aphasia—Language disorder caused by brain damage that affects production and/or comprehension of written or spoken language.

Apraxia—Impairment of organized, controlled movement or motor planning not explained by motor or sensory impairment.

Hemiparesis—Weakness or partial paralysis on one side of the body caused by brain damage.

Hemiplegia—Paralysis on one side of the body caused by brain damage.

Hemorrhage—Bleeding resulting from the rupture of a blood vessel.

Homonymous hemianopsia—Visual field deficit caused by brain damage in which the patient cannot perceive half of visual field of each eye.

Ischemia—Loss of blood flow through a vessel resulting in an insufficient supply of blood and oxygen to surrounding tissues, as when a blood clot blocks a cerebral artery.

Learned nonuse—Phenomenon observed in patients with hemiparesis in which patient avoids functional use of involved arm after failed attempts to use it and successful attempts to use uninvolved arm.

Postural adaptation—Ability of body to maintain balance automatically and remain upright during alterations in position and challenges to stability.

Shoulder subluxation—Incomplete dislocation of humerus out of glenohumeral joint caused by weakness, stretch, or abnormal tone in the scapulohumeral and/or scapular muscles.

Unilateral neglect—Disturbance in the ability to notice, orient, or respond to stimuli in space on side of body opposite site of brain damage.

Traumatic Brain Injury

Janet M. Powell

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the similarities and differences in the typical course of recovery for persons with severe, moderate, and mild traumatic brain injury.
2. Select appropriate assessment tools and strategies for persons with traumatic brain injury during acute medical management and inpatient and postacute rehabilitation.
3. Apply information from related chapters of this text to the treatment of motor, cognitive, behavioral, and emotional aspects of traumatic brain injury.
4. Analyze how needs of family members change during recovery and adaptation, and determine how to meet their needs in occupational therapy.
5. Anticipate possible roles for occupational therapists in addressing long-term needs of survivors of traumatic brain injury.

People who have had a traumatic brain injury (TBI) with alteration in brain function as a result of some external force often undergo changes in their ability to carry out valued roles, tasks, and activities as a result of impairments in cognitive, behavioral, emotional, and/or physical functioning. In fact, moderate to severe brain injury affects virtually every area of life for the survivor and his or her family (Pagulayan et al., 2006). For the many individuals who are young adults at the time of injury, changes in capacities and abilities may affect their occupational functioning for months, years, or decades. The complex interaction of factors associated with impairment, context, and environment require a multidisciplinary approach to treatment. Therefore, occupational therapists who work with patients with TBI must appreciate the contributions and expertise of other team members as they offer the patient what is unique to occupational therapy.

To enable the reader to appreciate the effect of TBI on society, this chapter begins with a discussion of its incidence and causes. Next, mechanisms of injury are explained. A review of the typical clinical course of recovery from severe TBI emphasizes how occupational therapy contributes to remediation of impairments and adaptation to deficits throughout the continuum of care. The unique needs of persons with mild traumatic brain injury, the least severe type of brain injury, and those with combat-related TBI are also highlighted, but it is hoped that readers can determine appropriate evaluation and treatment approaches for persons with moderate TBI based on descriptions of the two extremes of severity of injury. Because brain injury rehabilitation requires an integration of many aspects of occupational therapy evaluation and treatment, the reader will frequently be referred to other chapters of this text. Evidence Table 34-1 presents evidence for occupational therapy interventions after severe brain injury.

INCIDENCE, PREVALENCE, AND CAUSATION

As noted above, TBI is defined as an alteration in brain function, or other evidence of brain pathology, caused by an external force. Alteration in brain function is determined by (1) any loss of or decrease in the level of consciousness; (2) any loss of memory for events immediately before or after the injury (i.e., post-traumatic amnesia [PTA]); (3) a neurological deficit such as weakness, paralysis, loss of balance, change in vision, sensory loss, or aphasia; (4) any change in mental state at the time of the injury such as confusion, disorientation, or slowed thinking; and/or (5) visual, neuroradiologic, or laboratory evidence of damage to the brain (Menon et al., 2010). External forces causing a TBI can include (1) the head being struck by or striking an object, (2) the brain undergoing an acceleration/deceleration movement without direct external trauma to the head, (3) a foreign body penetrating the brain, and (4) forces generated from events such as a blast or explosion.

Each year, approximately 1.7 million civilians in the United States sustain a TBI (Faul et al., 2010). Of these, 3% (52,000) die, 16% (275,000) are hospitalized, and 80% (1.4 million) are treated in an emergency department and released. In addition, there are an unknown number of individuals with TBI who are not included in these estimates because they are seen in an emergency department but discharged without a diagnosis of TBI (Powell et al., 2008), are seen outside an emergency department or hospital, or do not seek care (Faul et al., 2010). Approximately 80,000–90,000 Americans experience a new onset of disability resulting from TBI each year (Langlois, Rutland-Brown, & Thomas, 2004) with an estimated 3.1 million children and adults in the United States living with a lifelong TBI-related disability. After children ages 0–4 years, older adolescents aged 15–19 years have the highest rates of TBI-related emergency department visits in the United States (2002–2006 data), whereas adults aged 75 years and older have the highest rates of TBI-related hospitalization and death (Faul et al., 2010). Regardless of age, the rates for TBI are higher for males than for females.

Between 2002 and 2006, falls were the leading cause of TBI among all age groups in the United States (35%), followed by motor vehicle-traffic incidents (17%), striking against or being struck by an object (17%), and assault (10%) (Faul et al., 2010). Across all age groups, fall-related TBIs resulted in the greatest number of emergency department visits and hospitalizations, whereas TBIs from motor vehicle-traffic incidents were the leading cause of TBI-related death. Falls accounted for 61% of TBIs among adults age 65 years and older with the rates of fall-related TBIs even higher for adults age 75 years and older. The rates of TBIs from motor vehicle or traffic incidents and assault were highest among adults aged 20–24 years with only 1% of TBIs in adults age 65 years and older resulting from an assault.

Alcohol use is a contributing factor to many events that result in a TBI, with estimates that one-third to one-half of people who sustain a TBI were intoxicated at the time of injury (Corrigan, 1995). Preinjury alcohol use has implications for outcome, treatment, and long-term adjustment to TBI. Patients who were intoxicated when injured reportedly have a longer hospitalization, longer duration of excesses in behavior related to agitation, and lower cognitive status at discharge than those who were not intoxicated (Kelly et al., 1997; Sparadeo & Gill, 1989). Furthermore, a history of TBI increases a person's risk of TBI. After one TBI, the risk of a second may be up to three times greater than for those who have never sustained a TBI, and, after a second TBI, the risk of a third injury may be up to eight times greater (Annegers et al., 1980).

Finally, it is important to appreciate the incidence of TBI based on severity. TBI is typically characterized as mild, moderate, or severe. Severity categorization schemes vary but are most often based on depth of coma as measured by the Glasgow Coma Scale (GCS) (Teasdale & Jennett, 1974)

Evidence Table 34-1	Best Evidence for Interventions Used in Occupational Therapy after Severe Brain Injury						
Intervention	Description of Intervention Tested	Participants	Dose	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Cognitive rehabilitation	Various cognitive rehabilitation approaches	Participants (number not specified) with TBI or stroke from 112 studies	Varied by study	Systematic review Level: I	Recommendations based on review: Practice standard for attention remediation in postacute rehab, metacognitive strategy training; practice guidelines for use of memory compensations in severe TBI	Not calculated	Cicerone et al. (2011)
Errorless learning	Learning tasks such as word lists, word-pair associations	One hundred sixty-eight with severe memory impairment (number with TBI not specified)	Varied by study	Meta-analysis of eight studies Level: I	Yes. Errorless learning was more effective than trial-and-error learning.	Effect size = 0.87 $p = 0.008$	Kessles & de Haan (2003)
Self-care skills training	Subjects received a washing and dressing protocol that involved behavioral methods	Four patients in a residential setting (three with TBI) at least 7 months postinjury, severe physical and cognitive impairments	Daily ADL retraining with fading physical assistance and cueing	Four single-subject studies Level: IV C 2 b	Three of four subjects achieved independence in washing and dressing (in 20, 37, and 11 days, respectively); one of four did not.	No formal statistical tests reported	Giles et al. (1997)

ADL, activities of daily living; TBI, traumatic brain injury.

(Table 34-1), length of loss of consciousness, and/or length of PTA (Institute of Medicine [IOM], 2011). Most people who sustain a TBI have a relatively mild injury (at least 75% of all TBIs in the United States) (Faul et al., 2010).

MECHANISMS OF INJURY AND CLINICAL IMPLICATIONS

A TBI can be classified as either open or closed based on the biomechanics of the injury (IOM, 2009). In an open brain injury, an object, such as a bullet, enters the cranial cavity. Some classification systems categorize all open injuries as penetrating injuries (Mass et al., 2010). Other systems differentiate between penetrating and perforating injuries depending on whether the object remains lodged within the cranial cravity (penetrating) or passes through and exits the cranial cravity (perforating). In an open brain injury, the extent of the damage depends on the shape, mass, direction, and velocity of the object (IOM, 2009).

A TBI that results from a direct or indirect impact, without penetration of the brain tissue, is classified as a closed brain injury. Closed head injuries can result from dynamic or static loading (IOM, 2009). A dynamic loading injury occurs when there is rapid acceleration and deceleration of the brain. A static loading injury, also termed crush injury (Mass et al., 2010), occurs

when a slow mechanical force is applied to the brain, for example, if the head were trapped for an extended time under heavy debris after an earthquake. This type of injury is uncommon. The damage from a closed brain injury is directly related to the type (e.g,. shear, tensile) and amount of forces generated during the traumatic event (Katz, 1992). In the case of crush injuries, there tends to be more damage to the skull than the brain (Mass et al., 2010).

Blast injuries have recently been recognized as a specific type of TBI (Mass et al., 2010). A blast injury results from any type of blast explosion, including improvised explosive devices (IEDs). A blast injury can occur in conjuction with an open or closed brain injury.

Focal versus Diffuse Injuries

Brain injuries can also be categorized into focal or diffuse injuries based on the extent of the pathology. Focal injuries result from brain contusions, lacerations, and masses of blood called hematomas (Duff, 2001). Focal lesions are usually seen at the anterior poles and inferior surfaces of the frontal and temporal lobes. They occur when the brain hits the skull and scrapes over the irregular bony structures at these locations (Katz, 1992). The occipital and parietal lobes, which have smooth surfaces, are less likely to incur damage. Focal lesions to the prefrontal and anterior temporal areas interrupt connections to subcortical limbic structures and affect modulation of memory, emotion, and drive (Katz, 1992). Damage to the orbitofrontal areas generally results in impulsivity that is greater than with diffuse damage, whereas damage to the frontolateral cortex results in hemiparesis, impulsivity, and attentional impairments as well as decreased mental flexibility (Trexler & Zappala, 1988).

Diffuse injuries typically occur in motor-vehicle crashes where there is rapid movement of the head (Smith, Meaney, & Shull, 2003). Traumatic axonal injury (TAI), previously termed diffuse axonal injury (DAI), is a type of diffuse injury that results when the brain accelerates, decelerates, and rotates inside the skull. The brainstem is more stable than the cerebrum, which rotates around the brainstem during impact. The rotation places a stretch or shear force on the long axons that transmit information throughout the brain and brainstem (Leech & Shuman, 1982). Although the mechanisms for TAI are not completely understood, contributing factors include altered permeability of the axonal cell membrane, which impedes axonal transport. This results in focal swelling of the axon and, ultimately, detachment of the axon at the point of the swelling (Povlishock & Katz, 2005). These injuries are likely to result in coma (Duff, 2001).

Coma caused by axonal injuries may quickly reverse if the axonal damage was mild or may continue as a

vegetative state if axons were ruptured. Recovery from coma progresses to a period of confusion with impaired attention and PTA. When confusion clears, any cognitive impairments become more evident. Impairments may include diminished mental processing speed and efficiency and difficulty with divided-attention tasks, which require the patient to respond simultaneously to two sources of information. There is a reduced capacity for higher level cognitive functions, including abstract reasoning, planning, and problem solving. Typical behavioral outcomes range from impulsivity, irritability, and exaggerated premorbid traits to apathy and poor initiative (Katz, 1992). Diffuse injuries often include damage to the brainstem and cerebellar pathways, resulting in ataxia, diplopia, and dysarthria (Trexler & Zappala, 1988). It is common to find both focal and diffuse damage with a TBI, especially in more severe cases. In both types of injuries, secondary pathogenic events at the cellular, biochemical, and molecular levels contribute to widespread damage beyond the effect of the primary insult (IOM,2009).

Cranial Nerve Damage Associated with Traumatic Brain Injury

Cranial nerves can be torn, stretched, or contused. The olfactory nerve (I) is often abraded or torn when the frontal lobes scrape across the orbital surface of the skull (Leech & Shuman, 1982). The optic nerve (II) may be damaged directly, or vision can be compromised by injury to the eye, the optic tracts, or the visual cortex (Brandstater et al., 1991). Cranial nerves III, IV, and VI, which control eye movements, are all vulnerable to injury (Brandstater et al., 1991; Leech & Shuman, 1982). The oculomotor nerve (III) can be stretched when edema or bleeding expands the contents of the skull, causing the uncus of the temporal lobe to herniate into the foramen magnum and compress the brainstem (Leech & Shuman, 1982). The abducens nerve (VI) is very long and consequently vulnerable to injury. The facial and vestibulocochlear nerves (VII and VIII, respectively) may be damaged if the temporal bone is fractured at the base of the skull (Brandstater et al., 1991; Leech & Shuman, 1982). Cranial nerves V and IX–XII are rarely damaged (Leech & Shuman, 1982).

Fractures and Other Cooccuring Medical Conditions Associated with Traumatic Brain Injury

The skull may fracture from the force of the blow in the area of or at a distance from the actual impact site. The patient with a brain injury from a motor vehicle crash or a fall may have other systemic trauma, such as fractures of the extremities, shoulder girdle, pelvis, or face; cervical fractures with possible spinal cord injury; abdominal trauma; and pneumothorax or other chest cavity trauma.

Second Insults and Secondary Effects

Hypoxia, hypotension, hypothermia, and hyperthermia are the most common systemic second insults that occur following TBI (Mass et al., 2010). Medical personnel in the field and the hospital setting strive to avoid or minimize the occurrence of these additional insults because they can exacerbate secondary processes that can cause additional damage to the brain beyond the primary injury (Mass et al., 2010). The secondary effects can occur immediately or develop within hours or days of the injury (Jennett & Teasdale, 1981). Trauma can abolish or disrupt autoregulation of cerebral blood flow, the blood–brain barrier, and vasomotor functions, resulting in disordered cerebral energy metabolism, intracranial hypotension, cerebral vasospasm, and increases in intracranial pressure (ICP) and cerebral edema (Duff, 2001; Jennett & Teasdale, 1981). Other secondary effects of brain trauma include intracranial hemorrhage, uncal herniation resulting in brainstem compression, seizures, electrolyte abnormalities, altered respiratory regulation, intracranial infection, and abnormal autonomic nervous system responses (Lillehei & Hoff, 1985). Usually by the time the patient is stabilized and occupational therapy is ordered, the secondary effects of brain trauma are present, influencing the patient's ability to respond to therapy.

FOUR PHASES OF LIFE FOR THE SURVIVOR OF TRAUMATIC BRAIN INJURY

Based on their review of the literature, authors of the Agency for Health Care Policy and Research Evidence Report on the effectiveness of rehabilitation for persons with TBI described four phases of life for the adult survivor of moderate to severe TBI: preinjury, medical treatment, rehabilitation, and survivorship (Fig. 34-1) (Chestnut et al., 1999). Although management of TBI is typically a multidisciplinary enterprise, the following description of each phase is based on a typical recovery from severe TBI with emphasis on occupational therapy evaluation and treatment. Note how the role of occupational therapy changes with each phase, increasingly focusing on occupational functioning the further the patient progresses in recovery.

Preinjury Phase

In Chris's first 17 years she became used to being called "outstanding." She usually was one of the top students in every honors class. . . . Chris was a fairly good organist and gymnast too. In her first 17 years, outstanding was normal. Outstanding was easy. (Rain, 2000, p. 6)

Occupational therapists always appreciate the person as distinct from his or her condition, impairment, or disability. People who sustain a TBI bring their personal, social,

Pretrauma phase
Duration: variable (prenatal to decades)
   Personality, education, skills, personal history

Preinjury

Postinjury

Acute phase: gurney to intensive care unit (ICU)
Duration: hours
   Diagnosis/triage, treatment(s)

Medical treatment

Intensive phase: ICU to acute hospital discharge
Duration: days/weeks
   Diagnosis/treatment(s)

Rehabilitation

Recovery phase: education and training/conditioning
Duration: months/years
   Assessment of abilities and deficits, training program(s)

Survivorship

Survival phase: establishing and living a new life
Duration: decades/lifetime
   Personal adjustment (abilities, deficits, personality, etc)
   Social adjustment (family, friends, work, peers, etc)
   Quality of life (productive, happy, engaged, etc)

Figure 34-1 Four phases of life of the TBI survivor. (Reprinted with permission from Chestnut, R. M., Carney, N., Maynard, H., Mann, N. C., Patterson, P., & Helfand, M. [1999]. Summary report: Evidence for the effectiveness of rehabilitation for persons with traumatic brain injury. *Journal of Head Trauma Rehabilitation, 14,* 176–188.)

and cultural backgrounds to recovery (see Chapter 3). Chestnut et al. (1999) suggested that, although standard treatments are appropriate for the acute medical treatment phase of TBI, consideration of individual differences becomes increasingly important as patients progress through recovery and adaptation.

Rosenthal and Bond (1990) summarized the importance of understanding premorbid factors that may affect the patient's recovery. They reported that researchers have noted a high frequency of preinjury learning disabilities and behavior disorders in persons with TBI. They suggested finding out about the patient's premorbid cognitive strengths and weaknesses through school records or family interviews and investigating any preexisting neurological conditions. Eames, Haffey, and Cope (1990) further recommended asking family members how the patient previously reacted to frustration so as to recognize and avoid stress-provoking situations.

Medical Treatment of Traumatic Brain Injury

As I gradually regain consciousness in the hospital, I imagine I am having a nightmare. . . . As I open my eyes and stare around the room at the monitors and plugs and dripping IV bottles, I hope this nightmare will end quickly. (Rain, 2000, p. 6)

The primary goals of this phase of recovery center on surviving, achieving medical stability, and preventing or minimizing the impact of second insults and secondary effects on the injured central nervous system (Hartl & Ghajar, 2005).

Emergency Medical Treatment

Emergency Medical Services (EMS) personnel are typically the first medical specialists to respond to the needs of a person with severe TBI. The paramedics' first priority is rapid restoration of physiological homeostasis with stabilization of the airway, breathing, and circulation (Hartl & Ghajar, 2005). Because secondary hypoxia and arterial hypotension are associated with greater mortality and morbidity (Baron & Jallo, 2007), supplemental oxygen or endotracheal intubation may be used to maintain oxygen saturation, and intravenous fluids may be administered to help maintain systolic blood pressure (Brain Trauma Foundation, 2007).

Recommendations for neurological asessment in the field include determination of an initial GCS score (Teasdale & Jennett, 1974) and a pupillary exam. The GCS provides an assessment of brain injury severity using a 15-point system to assess depth of coma through motor, eye-opening, and verbal capabilities (Table 34-1). A GCS score of 13–15 indicates a mild brain injury, a score of 9–12 indicates a brain injury of moderate severity, and a score of 8 or below indicates a severe injury. In some cases, alcohol or other drug intoxication, sedation administered by EMS personnel, and/or intubation prevent assessment of all three areas (Marion, 1996). Whenever possible, patients are transported to the closest facility where computed tomography (CT) scanning, neurosurgical expertise, and ICP monitoring are available. EMS personnel routinely immobilize the injured person's spine using a rigid backboard with the neck in a rigid cervical collar because cervical spinal injury is associated with 4%–8% of TBIs (Baron & Jallo, 2007). Oxygen saturation and blood pressure are monitored en route to the trauma center, and any deterioration is addressed immediately (Brain Trauma Foundation, 2007).

Once in the emergency department, the medical team continues to ensure protection of the airway and adequacy of breathing and blood pressure (Baron & Jallo, 2007). The primary goals at this stage are to avoid further neurological damage and to stabilize critical extracranial injuries to the thorax, abdomen, face, and extremities. The medical team performs a general assessment of other injuries and repeats the GCS and pupillary exam to assess neurological function. Chest and cervical spine x-rays are taken. A CT scan of the head is performed soon after arrival to assess

intracranial injury and identify structural lesions such as hematomas and contusions (Baron & Jallo, 2007).

A hematoma is a mass of blood confined to an organ or space and caused by a broken blood vessel (Scott & Dow, 1995). Acute subdural hematomas are located between the dura and the arachnoid and epidural hematomas between the dura and the skull. With the exception of small lesions in patients with stable neurological signs, hematomas must be surgically evacuated as soon as possible to optimize chances for survival and recovery. Contusions, i.e., bruising of the brain, result in a collection of blood and necrotic tissue. More severe intracerebral contusions may also be treated surgically to reduce ICP (Baron & Jallo, 2007).

Intensive Medical Management

After appropriate evaluation and treatment for life-threatening injuries, the patient with a severe TBI is taken to the intensive care unit (ICU). Medical treatment in the ICU aims to optimize cerebral perfusion and brain tissue oxygenation, minimize brain swelling, and maintain all other physiological variables within the normal range (Marion, 1996). The length of stay in the ICU is primarily determined by the ability to manage the patient's brain swelling, which usually subsides within 4–5 days (Marion, 1996). A physiatrist is typically consulted within the first few days of admisssion to the ICU to make decisions for appropriate rehabilitative care. Other members of the rehabilitation team, including occupational therapists, often see the patient for a rehabilitation consult and contribute their input. The physiatrist orders rehabilitation services, including occupational therapy, for the coma patient that may begin in the ICU. Generally, patients with more severe injuries move from the ICU to acute inpatient rehabilitation facilities. However, rehabilitation may also occur in acute medical or subacute units, skilled nursing facilities, or outpatient clinics. The decisions for care are made based on the degree and rate of recovery, as well as logistical factors such as insurance coverage and proximity of facilities to the patient's support system.

Patients with Severe Disorders in Consciousness

A person with TBI may exhibit any of a number of altered states of consciousness, depending on the severity of the injury. Various terms are used to describe the continuum from complete consciousness to complete absence of consciousness (Definition 34-1). Patients with severe TBI begin

---

Definition 34-1

Definitions of Severe Disorders of Consciousness

Coma

Coma denotes unarousability with the absence of sleep-wake cycles on an electroencephalogram (EEG) and loss of capacity for environmental interaction. Neurobehavioral criteria include (American Congress of Rehabilitation Medicine, 1995):

- Patient's eyes do not open either spontaneously or to external stimulation.
- Patient does not follow commands.
- Patient does not mouth or speak recognizable words.
- The patient does not demonstrate intentional movement (may show reflexive movement such as posturing, withdrawal from pain, or involuntary smiling).
- Patient cannot sustain visual pursuits through a 45° arc in any direction when the eyes are held open manually.
- These criteria cannot be attributed to use of paralytic agents.

Vegetative State

Vegetative state indicates complete unawareness of the self or the environment. Patients in a vegetative state have cyclical patterns of sleeping and waking with periodic opening of the eyes, but no evidence of nonreflexive "sustained, reproducible, purposeful, or voluntary behavioral responses to visual, auditory, tactile, or noxious stimuli" (Multi-Society Task Force on PVS, 1994, p. 1500).

Minimally Conscious State

Patients in a minimally conscious state have some conscious awareness. They demonstate observable behaviors that are not purely reflexive and that show some awareness of the self or the environment (Giacino et al., 2002). Diagnostic criteria consist of reproducible or sustained demonstration of one or more of the following behaviors:

- Following simple commands
- Gestural or verbal yes/no responses (regardless of accuracy)
- Intelligible verbalization
- Purposeful behaviors in response to relevant environmental stimuli such as (1) reaching for objects in a way that demonstrates a clear relationship between object location and direction of reach, (2) shaping the hand to hold an object in response to the object's size and shape, and (3) smiling or crying appropriately in response to emotional topics or stimuli

For a patient to be characterized as having emerged from a minimally conscious state, he or she must demonstrate the ability for functional communicaton and object use (Giacino et al., 2002). Functional communciation is defined for this purpose as accurate yes/no responses to six out of six basic situational orientation questions (e.g., "Are you sitting down?") on two consecutive evaluations. Demonstration of functional object use is based on appropriate use of at least two different objects on two consecutive evaluations (e.g., bringing a comb to the head).

in coma. Some patients gradually or abruptly recover consciousness directly from coma, whereas others shift more gradually over 2–4 weeks into a vegetative state (Duff, 2001). Vegetative patients may still recover consciousness, but they do so gradually, spending long periods in a minimally conscious state in which there is verifiable evidence of conscious processing (Phipps et al., 1997). The ability to sustain visual pursuit eye movement seems to be one of the first signs of the transition out of vegetative state (Giacino & Kalmar, 1997) and is an early indicator of possible readiness for rehabilitation (Ansell, 1993).

Assessment. Diagnosis of specific disorders of consciousness and prognostic decisions must be reserved for physicians and other professionals with experience in neurological assessment of patients with impaired consciousness (American Congress of Rehabilitation Medicine, 1995). The rehabilitation team, however, including occupational therapists, uses a number of objective assessments to monitor changes in function and response to pharmacological, environmental, and behavioral interventions and for early detection of neuromedical complications.

Rancho Los Amigos Levels of Cognitive Functioning Scale. The Rancho Los Amigos Levels of Cognitive Functioning Scale uses behavioral observations to categorize a patient's level of cognitive function (Table 34-2) (Hagen, 1998; Hagen, Malkmus, & Durham, 1979). It helps clinicians to communicate about a patient's level of cognitive function among themselves and with families and to develop appropriate rehabilitation strategies. The first three levels of the Rancho Los Amigos Levels of Cognitive Functioning Scale describe the response to stimulation and the environment of patients emerging from coma.

Behavior-Based Assessment Instruments. In addition to the GCS, the instruments described in Table 34-3 are all brief assessments that occupational therapists and other rehabilitation team members can use at bedside to evaluate patients with severe alterations in consciousness.

Use of Single-Subject Experimental Methodology. DiPasquale and Whyte (1996) proposed that clinicians use single-subject experimental methodology as a means of answering individualized questions about responsiveness. They described how these methods were used to determine whether or not a patient with a brain injury was able to follow a verbal command to squeeze her hand. The protocol began with the therapist performing passive range of motion (PROM) to the patient's right hand, placing the patient's hand in hers, and then waiting 1 minute. There were three conditions: (1) correct command ("Squeeze my hand"), (2) incorrect command ("Tie your shoes"), and (3) observation period (equal duration, but no command given). Six trials were performed in random order with the therapist waiting 5 seconds to observe the patient's response. If the patient did not respond in 5 seconds, the command was given again. If again, there was no response in 5 seconds, the trial was recorded as no response.

Table 34-2   Rancho Los Amigos Levels of Cognitive Functioning

Level	Description
I	No response: unresponsive to stimuli
II	Generalized response: nonspecific, inconsistent, and nonpurposeful reaction to stimuli
III	Localized response: response directly related to type of stimulus but still inconsistent or delayed
IV	Confused—agitated: response heightened, severely confused, may be aggressive
V	Confused—inappropriate: some response to simple commands, but confusion with more complex commands; high level of distractibility
VI	Confused—appropriate: response more goal directed but cues necessary
VII	Automatic—appropriate: response robot-like, judgment and problem solving lacking
VIII	Purposeful—appropriate (*with standby assistance*): response adequate *to familiar tasks, subtle impairments require standby assistance with acknowledging other people's needs and perspectives, modifying plans*
IX	*Purposeful—appropriate (with standby assistance on request): responds effectively to familiar situations but generally needs cues to anticipate problems and adjust performance; low frustration tolerance possible*
X	*Purposeful and appropriate (modified independent): responds adequately to multiple tasks but may need more time or periodic breaks; independently employs cognitive compensatory strategies and adjusts tasks as needed*

Rancho levels I–VIII are widely used in brain injury rehabilitation. The addition of levels IX and X in 1998 (revisions italicized) describe higher level cognitive, behavioral, and emotional barriers to optimal functioning (Hagen, 1998; Hagen, Malkmus, Durnham, 1979).

Table 34-3   **Behavior-Based Assessment Tools for Altered States of Consciousness**

Agitated Behavior Scale[a] (Corrigan, 1989)	Measure of agitation that can be used to measure changes in agitation level over time (Center for Outcome Measurement in Brain Injury [COMBI], 2011). Consists of 14 items. Total score reflects overall agitation, with subscales specific to disinhibition, aggression, and lability.
Disability Rating Scale[a] (Rappaport et al., 1982)	Provides quantitative information on recovery from severe traumatic brain injury (TBI) from coma to community (COMBI, 2011). Consists of eight items in four categories: arousal and awareness; cognitive ability to handle self-care functions; physical dependence on others; and psychosocial adaptability for work, housework, or school.
JFK Coma Recovery Scale-Revised (CRS-R)[a] (Kalmar & Giacino, 2005)	Detects subtle changes in neurobehavioral status to differentiate between vegetative and minimally conscious states and identifies emergence from minimally conscious state (COMBI, 2011). Twenty-three items in six areas: auditory, visual, motor, oromotor-verbal, communication, and arousal. Specific stimuli are administered to elicit specific responses with responses criterion referenced.
Western NeuroSensory Stimulation Profile (Ansell & Keenan, 1989)	Assesses cognitive function in severely impaired adults (Rancho levels II–IV) and monitors change in noncomatose patients who are slow to recover. Battery consists of 32 items related to arousal, attention, response to stimuli, and expressive communication and results in a profile of six subscales that summarize individual patterns of responses.

[a]From Centers for Outcome Measurement in Brain Injury. (2011). COMBI: featured scales. Retrieved from http://www.tbims.org/combi/list.html.

The results of assessment using this approach allowed for objective assessment of volitional responses and helped inform team/family planning. They describe a similar methodology to assessing vision in minimally responsive patients (Whyte & DiPasquale, 1995).

Prognosis and Outcome. Early prediction of outcome presumably helps direct expensive medical treatment or rehabilitation to patients who have the best chance for survival with fewer residual impairments and enables the family to make informed, realistic decisions on immediate and long-term care (Jennett & Teasdale, 1981). Many researchers have attempted to assess the predictive power of age; clinical observations such as the GCS, duration of unconsciousness, and length of PTA; and neuroimaging evidence of structural damage (Healey et al., 2003; Nakase-Richardson et al., 2011). Even with sophisticated clinical and radiological techniques, during the first days after injury, it is not possible to predict outcome with sufficient accuracy to guide early treatment or justify withholding treatment (Marion, 1996). Repeated observations of neurological recovery over weeks or months remain the best means to predict complete or nearly complete recovery (Marion, 1996).

Outcome scales have been developed to allow physicians to correlate "final" recovery levels to early treatment and prognostic indicators. The Glasgow Outcome Scale (Extended) (GOS-E) (Wilson, Pettigrew, & Teasdale, 1998) is one of the most commonly used global outcome measures. The GOS-E uses a structured interview with questions relating to conciousness, independence inside and outside the home, work, social and leisure activities, family and friendships, and return to normal life. For individuals who have survived, outcome is categorized as vegetative state, lower severe disability, upper severe disability, upper moderate disability, lower good recovery, or upper good recovery.

The therapist is not required to predict but should consider predictive factors when deciding on treatment goals or length of rehabilitation efforts. Cognition, personality, and motivation, all of which may substantially affect quality of survival (Jennett et al., 1981), should also be considered in determining treatment goals. However, outcome predictions are based on groups of patients, not on individuals who may recover more completely than anticipated given the severity of the injury.

Intervention for Patients with Severe Disorders of Consciousness. Rehabilitation for patients with severe disorders of consciousness should include both preventative and restorative strategies (Hirschberg & Giacino, 2011). Patients in a vegetative or minimally conscious state are at risk for complications associated with prolonged immobilization, and preventive measures should be taken to minimize or avoid pulmonary and urinary tract infections; skin breakdowns; and muscle, tendon, and soft-tissue contractures (Hirschberg & Giacino, 2011; Mysiw, Fugate, & Clinchot, 1996). Restorative strategies are aimed at fostering alertness and goal-directed behavioral responsiveness and may include pharmacotherapy with centrally activating medications, thalamic deep brain stimulation, and sensory stimulation procedures (Hirschberg & Giacino, 2011). Early intervention is believed to result in shorter rehabilitation stays and higher Rancho levels at discharge (Lippert-Grüner, Wedekind, & Klug, 2003). With contradictory evidence regarding its effectiveness, however, sensory stimulation programs aimed at facilitating coma arousal remain particularly controversial (Giacino et al., 1997; Golisz, 2009). Giacino et al. (1997) recommended that, at a minimum, patients with disorders of consciousness receive intervention that includes range-of-motion exercise, positioning protocols, and tone alteration methods. They suggested that the additional provision of sensory stimulation

trials be considered on a case-by-case basis, appreciating that it is often difficult to distinguish between brain recovery and an intervention effect. Golisz (2009) noted that although existing evidence is not sufficient to determine whether a sensory stimulation program can facilitate return to consciousness, such programs do help the rehabilitation team identify emergence from coma and give therapists a systematic way of reinforcing the patient's purposeful responses to environmental stimuli. Reducing possible agitation (Eames, Haffey, & Cope, 1990) and supporting and educating overwhelmed family members are critical aspects of rehabilitation at this phase (Phipps et al., 1997).

For patients at this phase of recovery, intervention typically addresses impairments in body functions to lay the foundation for later focus on activities, tasks, and roles (Procedures for Practice 34-1). Because of the medical acuity of many of these patients, occupational therapists attend to the safety precautions summarized in Safety Note 34-1.

Positioning. Occupational therapists collaborate with other members of the rehabilitation team to optimize positioning to normalize muscle tone and minimize the development of contractures and atypical postures associated with more severe injuries that can ultimately affect motor performance (Rinehart, 1990). The patient's position must be reevaluated frequently with close monitoring of his or her reactions, including facial expression, changes in muscle tone, and vocalizations. Minor adjustments can make a difference between comfort and discomfort. Assistive positioning supports are removed as the patient's neuromuscular status improves. The nursing staff and the patient's family must be made aware of the desired bed and wheelchair positioning and of the wearing schedule for any splints.

Side-lying or semiprone in bed, if permitted, with good body alignment is preferable to supine if the patient has abnormal posture (Carr & Shepherd, 1980). Lying supine triggers an extensor response. In side-lying, the head, resting on a small pillow, should be in neutral alignment with the trunk; the bottom upper extremity should be in moderate scapular protraction and humeral external rotation; the top upper extremity should be in scapular protraction, slight shoulder flexion, and resting on a pillow to avoid horizontal adduction; the bottom elbow should be flexed; the top elbow should be extended; wrists should be in extension; and cones should be placed in the hands to decrease spasticity and maintain thumb web spaces. Attention should be paid to ensure that the mobility in the thumb comes from the first carpometacarpal (CMC) joint and not compensatory hyperextension in the first metacarpophalengeal joint. A pillow between the knees decreases hip internal rotation and adduction. The lower leg also may need pillow support to align it with the thigh. The foot should not be placed higher than the knee and hip as this can result in torque on the knee and cause the hip to go into internal rotation. The hip and knee are flexed only slightly. If necessary, a firm pillow filling

Procedures for Practice 34-1

Goal Setting for and with Persons with Traumatic Brain Injury

Occupational therapy treatment goals address changing aspects of occupational functioning as patients with severe traumatic brain injury (TBI) progress through recovery and adaptation. Here are some examples based on the phases of recovery and adaptation as described by Chestnut et al. (1999).

Medical Treatment Phase: Treatment Focuses on Body Functions

- In 3 weeks, the patient will make localized responses in less than 15 seconds after the presentation of tactile, olfactory, auditory, or visual stimuli at least 75% of the time to lay the foundation for using a communication board.
- In 3 weeks, the patient will independently reach out to hold a hairbrush in her hand and bring to her hair in four out of five trials.

Rehabilitation Phase: Treatment Primarily Focuses on Abilities and Skills, Activities and Habits, and Task Competency

- In 2 weeks, the patient will follow a checklist to carry out personal hygiene tasks with no more than two specific cues per session.
- In 2 weeks, the patient will independently locate and follow a daily schedule in his planner.
- In 2 weeks, the patient will be able to carry out his upper extremity range of motion exercises without assistance following written and pictorial instructions.

Survivor Phase: Treatment Primarily Focuses on Habits, Competency in Tasks, and Satisfaction with Life Roles

- In 4 weeks, the client will structure 100% of her children's after school activities (scheduling and making transportation arrangements) using compensatory cognitive strategies.
- In 4 weeks, the client will arrive on time to 100% of work meetings using an alarm cueing device.

the space between the thigh and calf can prevent excessive knee flexion. Elongation of the lower side of the trunk between the shoulder and pelvis is desirable. A side-lying trunk position may have to be maintained by a pillow or sandbag behind the back and shoulder. A pillow tucked in front of the trunk can also assist in maintaining the alignment. If a long body pillow is used, it can often be positioned to maintain some abduction in the lower extremities and support the calf and foot of the upper leg. Footboards should be avoided because they elicit extensor thrust. Splints or special shoes that are cut to avoid pressure to the ball of the foot,

⊕ Safety Note 34-1

Safety Precautions for Treating Patients with Disorders of Consciousness

The patient with a severe traumatic brain injury (TBI) may be referred for occupational therapy before he or she is completely medically stable. Precautions may be numerous because of systemic injuries, secondary effects of the brain injury itself, disturbance of basic body regulatory systems, and the life support equipment used to treat the patient; such precautions must be heeded by the therapist. Typical precautions are described here; other precautions may also be necessary and should be ascertained from the nurse, physician, or patient's chart before the evaluation begins.

- A major concern with acute brain trauma is control of intracranial pressure (ICP). Sustained increased ICP can be fatal (Jennett & Teasdale, 1981). The patient with an ICP monitor can be readily checked during treatment sessions. The therapist must closely observe patients who are not on a monitor for pupil changes; decreased neurological responses; abnormal brainstem reflexes; flaccidity; behavioral changes; vomiting; and changes in pulse rate, blood pressure, and respiration rate. Fluids may be restricted, or the patient's head may be positioned in neutral at 30° of elevation in an attempt to regulate ICP. Turning the patient's head to one side may obstruct the internal jugular vein and result in a sudden increase of ICP (Boortz-Marx, 1985). The neck should be neither flexed nor extended but kept in neutral for maximum venous drainage and decreased ICP. The presence of a family member, gentle touching, quiet talking, and stroking the face have been found to decrease ICP in adults (Mitchell, 1986). Side-lying with the head of the bed elevated is the most desirable position. Supported sitting at 90° is used as soon as tolerated to help breathing, to provide symmetrical body alignment, and to increase awareness of surroundings (Palmer & Wyness, 1988).
- Early (i.e., within the first 7 days) post-traumatic seizures occur in 5% of patients with brain injuries, and late post-traumatic seizures occur in 20% of those with prolonged unconsciousness, depressed skull fracture, or intracranial hematoma (Jennett & Teasdale, 1981; Schaffer, Kranzler, & Siqueira, 1985). Current recommendations are to provide pharmacological seizure prophylaxis for the first week after injury. To reduce the chance of a seizure during treatment, begin tactile stimulation and range of motion slowly to assess the patient's physiological response. Monitor the heart rate, blood pressure, and facial color and any autonomic changes, such as sudden perspiration or increased restlessness. As the therapist becomes more familiar with the patient's responses, he or she gradually increases intensity of stimulation. Use seizure precautions: avoid rapid, repetitive stimuli, such as vibration, flickering lights, and an oscillating fan. If a seizure does occur, ensure that the airway is open, position the patient on his or her side to prevent aspiration of stomach contents, and summon medical assistance (Greenberg, Aminoff, & Simon, 1993). The patient's limbs should not be restrained during a seizure.
- If the patient has had a craniotomy for evacuation of a hematoma, the bone flap may be left off, and the brain may be covered only by scalp to allow the brain to expand. Direct pressure to this site must be avoided, and the patient should wear a helmet at all times when out of bed until the bone flap is replaced. This generally occurs within 6 weeks, providing that the edema has resolved and there is no other infection.
- The patient may have a tear in the dura and cerebrospinal fluid leak. In this case, the patient initially is treated with head elevation, antibiotics, and precautions against nose blowing (Jennett & Teasdale, 1981; Schaffer, Kranzler, & Siqueira, 1985).
- If the patient has other systemic trauma, such as fractures or chest cavity trauma, appropriate precautions must be taken when he or she is stimulated or moved. Care must also be taken to avoid disturbing intravenous lines, tracheostomy, nasogastric tube, endotracheal or respirator tubes, and traction for extremity fractures. If the patient has a nasogastric tube, caution must be taken that the patient's head remains above the level of his or her stomach to avoid regurgitation and aspiration.

but still maintain ankle flexion to 90° and reduce foot drop, may be used to avoid stimulating an extensor thrust.

If the patient must be supine, a small pillow under the head is used, with small rolled pillows under that pillow to keep the head in midline if the patient cannot do so. Furthermore, small pillows are placed under the scapulae to protract them slightly, shoulders are positioned in slight abduction and external rotation, elbows are extended, and cones or finger spreaders position the fingers (Charness, 1986). If the pelvis is retracted on one side, a small folded towel is placed behind it, and that leg is positioned in neutral rotation. Some knee flexion should be encouraged by a small towel roll placed under the distal thigh just above the knee, although care should be taken to avoid a knee flexion contracture. A semirecumbent bed position with head-of-bed angle maintained at 45° is recommended for patients on mechanical ventilators to minimize risk of aspiration and pneumonia (Helman et al., 2003).

Early and correct upright positioning in a wheelchair helps to facilitate arousal by stimulating the visual and vestibular systems, inhibiting abnormal tone, providing normal proprioceptive input, and reducing the likelihood and/or extent of contractures and complications from prolonged bed rest. The pelvis must be positioned

correctly before other areas can be addressed. The pelvis should be in a neutral position or have a slight anterior tilt if needed to decrease extensor thrust. The pelvis should be symmetrical, without one side retracted or elevated. Solid seat and back inserts are used along with other inserts, pads, and cushions to gain optimal alignment.

Because the spine and rib cage are the essential connecting parts between the shoulders and the pelvis, it is important to obtain optimal alignment in these structures to facilitate optimal alignment of the shoulders. The trunk should be symmetrical and in midline with shoulders over pelvis in sagittal, frontal, and horizontal planes. Lateral trunk supports can be used to decrease lateral trunk flexion. Experimentation with the positioning is essential because trunk control varies among patients. The therapist must not provide too much trunk support, only enough to facilitate the patient's normal movement and control. With a solid seat and back, the patient may not require additional trunk support, whereas in other instances, a harness, shoulder straps, or a chest strap may be necessary to prevent forward trunk flexion.

Knees and ankles are flexed to 90°, heels are slightly behind the knees in sitting, feet are in neutral pronation-supination and inversion-eversion. The footplate should be large enough to support the whole foot. A foot wedge, heel loops, an insert behind the foot, special shoes, toe guards, or a combination of these may be helpful in decreasing abnormal tone and in achieving weight bearing on the heels.

The ideal upper extremity position is neutral scapular elevation or depression with the scapulae in slight protraction, slight shoulder external rotation, and slight flexion and abduction. Elbows are in comfortable flexion, and the forearm is in partial pronation. The wrists are in neutral flexion-extension and neutral ulnar-radial deviation, the fingers are relaxed, and the thumb is radially abducted with the mobility coming from the first CMC. Reclining the seat unit and/or positioning of shoulder straps, chest straps, and/or lateral trunk supports may help to obtain adequate shoulder position. In addition, a lapboard may be used to allow for upper extremity weight bearing. Note that while positioning recommendations often emphasize scapular protracton, scapular retraction and neutral scapular position are also critical.

Ideally, the head should be in midline with cervical elongation posteriorly and the chin tucked in slightly. It is important that positioning eliminate chin jutting and neck hyperextension. The position of the patient's pelvis, trunk, and shoulders all influence head position. See Chapter 17 for further discussion of wheelchair and seating system selection and positioning.

Passive Range of Motion. PROM programs are used in conjunction with positioning to minimize the development of contractures from abnormal tone and static postures. PROM can be difficult when muscle tone is increased. Inhibitory movements opposite the abnormal tone are performed slowly, holding the stretch until muscles relax. Sudden stretch and inappropriate stimulation and handling should be avoided. Scapular mobility should be addressed before upper extremity PROM to free the scapula and facilitate normal scapular and humeral movement during the rest of PROM (Palmer & Wyness, 1988). PROM within the limits of pain and positioning helps to minimize contractures from heterotopic ossification (Citta-Pietrolungo, Alexander, & Steg, 1992). See Chapter 20 for a complete discussion of exercise to improve range of motion.

Splinting and Casting. The goals of splinting and casting are to decrease abnormal tone and increase the patient's functional movement. Although it appears that serial casting may be more effective in treating range of motion limitations in the lower extremity (Golisz, 2009), plaster or fiberglass serial casting may be indicated when there is severe spasticity in the elbow and/or wrist (Mortenson & Eng, 2003). Dropout casts, which leave a portion of the limb free to relax out of a tightly contracted position; bivalve casts, which are split in two, with moleskin protecting the edges so they can be removed during therapy and nursing procedures; and weight-bearing inhibitory casts, which are fabricated to approximate the ideal weight-bearing posture of the foot or hand, can also be used (Carr & Shepherd, 1980). Casting is contraindicated with uncontrolled hypertension, major open wounds, unhealed fracture, impaired circulation, acute inflammation, a recent episode of autonomic dysreflexia, or if professionals need access to the extremity for lines or monitoring of vital signs (Stoeckmann, 2001).

Sensory Stimulation. The goals of a sensory stimulation program are to promote arousal from coma, appropriate patterns of movement, and interaction with the environment (Rinehart, 1990). Sensory stimulation programs are individualized to the patient's physical and cognitive functioning, but they always include multiple periods of observation and careful data collection (Mysiw, Fugate, & Clinchot, 1996). Clinicians use consistent protocols to standardize the administration of stimuli and data sheets to record observations regarding rate of response and changes in respiration, pulse, blood pressure, head movements, eye opening, eye movements, eye fixations, mimic responses, aimed and nonaimed motor reactions, and articulations (Lippert-Grüner & Terhaag, 2000) in response to tactile, vestibular, olfactory, kinesthetic, proprioceptive, auditory, and visual stimuli. Gustatory stimulation may be used if the patient's oral motor status permits. Pleasant and unpleasant and familiar and unfamiliar stimuli are used. Responses are measured at the beginning and end of every session and as each sense is stimulated. The patient's response to stimulation may be quite slow because central nervous system processing is slowed or prevented by the damage. Stimuli with emotional significance to the patient may be most likely to elicit a response. The therapist should wait for a response to the stimulation and, if necessary, repeat the stimulus.

(Refer back to the earlier discussion of using single-subject experimental methodology [DiPasquale & Whyte, 1996].) Clinicians monitor observation records in the hopes of seeing patterns of increasingly specific responses to stimuli, signifying improved responsiveness. Patients at Rancho level II often demonstrate nonspecific responses, such as motor restlessness in response to auditory stimuli. As the patient moves to level III, the responses become more stimulus specific. For example, with oral motor stimulation, one expects a motor response such as lip closure.

Management of Agitation. Once patients begin localizing stimuli, they may become quite agitated and restless (Scott & Dow, 1995). Post-traumatic agitation is reported to occur in the acute setting in 33%–50% of patients with TBI (Sandel, Bell, & Michaud, 1998) and may last for days or weeks. Agitation is a subtype of delirium in the coma-emerging patient that is associated with frontotemporal injury, disorientation, comorbid medical complications, and/or use of anticonvulsant medication (Kim, 2002). Agitation causes excesses of behavior that include some combination of aggression, akathisia (motor restlessness or a sense of inner restlessness [Ivanhoe & Bontke, 1996]), disinhibition, and emotional lability (Sandel, Bell, & Michaud, 1998). Eames, Haffey, and Cope (1990) suggested that efforts to manage behavior be preceded by a contextual assessment in which clinicians attempt to determine what factors are contributing to the problem. Clinicians examine the following variables:

- Client factors—Extent and location of brain damage; state of bodily dysfunction, including pain; and premorbid factors such as intellect, personality traits, and coping style
- Social context and environment—Persons present during maladaptive behavior; reinforcers
- Physical environment—Properties of the environment in which problematic behavior occurs

During the period of medical instability, patients may exhibit agitation that stems from post-traumatic confusion and inability to process information (Eames, Haffey, & Cope, 1990). Patients may demonstrate apparently non–goal-directed body movements, such as thrashing; goal-directed behaviors, such as trying to remove life-sustaining tubes or get out of bed; screaming, moaning, or bizarre verbalizations; and disinhibited behavior, such as uncontrolled laughter or inappropriate sexual behavior (Eames, Haffey, & Cope, 1990). The primary aim of behavior management at this phase is to avoid inadvertent reinforcement of undesirable behaviors while ensuring the continuation of medically necessary treatment and doing as little as possible to impede the natural course of recovery (Eames, Haffey, & Cope, 1990). Procedures for Practice 34-2

Procedures for Practice 34-2

Managing Agitation: Rancho Level IV

During this stage of recovery, occupational therapists primarily seek to decrease the patient's agitation by attempting to structure tasks and the environment to minimize overstimulation, confusion, and frustration and employing appropriate physical management methods that allow the patient to move and release energy without jeopardizing safety (Eames, Haffey, & Cope, 1990; Golisz, 2009). Remember that the patient is not accountable for the agitation, hostility, or aggressiveness. He or she is responding to internal confusion, not specifically to you as a person or professional. At the same time, you must structure your interactions to protect the patient and yourself.

Strategies to Normalize the Environment

- Ask family members to bring in familiar objects (photographs or belongings) and position them so they are visible to the patient (Eames, Haffey, & Cope, 1990).
- Work in a quiet environment with minimal distracters.
- Provide orientation information and maintain a predictable daily structure and routine.
- Introduce yourself at each session, telling the patient where he or she is and what you are going to do (Eames, Haffey, & Cope, 1990). Minimize asking orientation and other questions when it is unlikely that the patient knows the answer.

Strategies for Physical Management

- Use equipment and devices that maximize freedom of movement along with safety. Mittens without separations for the thumb may keep patients from pulling out tubes. A floor bed (a mattress on the floor that is surrounded by portable walls lined with therapy mats) allows the patient to move freely in bed without risk of falling. Extensions to the wheelchair so that it can neither tip over backward nor fit through doorways also allow for safe mobility (Eames, Haffey, & Cope, 1990).
- Engage the patient in gross motor activities such as face washing, catching a ball, hitting a balloon, and putting on simple clothing, if he or she is able. Physical activity, walking, or even being wheeled in the wheelchair may help decrease agitation.
- Be prepared to change activity or take a break at the first sign that the patient is becoming restless or agitated. Consider moving to another environment or offering a drink or snack if the patient has normal oral motor activity. Avoid responding to obscenities or bizarre verbalizations; simply view them as cues to distract the patient with another activity.
- Exude calm, confidence, and acceptance. The patient needs you to provide consistency and predictability that counters his or her confusion.

has specific suggestions regarding management of agitation during occupational therapy sessions.

Family Support and Education. TBI has almost as many implications for family members as it does for the patient. After an individual sustains a severe TBI, family members are typically relieved that the patient has survived but have little experience to help them understand the situation or what lies ahead (Phipps et al., 1997). Television portrayals of people who abruptly "wake" from coma with no apparent deficits may lead families to expect full recovery, and they may have difficulty processing information that is inconsistent with that hope (Phipps et al., 1997).

Families often see a level of responsiveness that is not verifiable by staff, and early in recovery, they tend to interpret unresponsiveness in ways other than as a reflection of cognitive status, such as deafness, lack of interest, or laziness (Phipps et al., 1997). Because the patient's level of responsiveness often drives decisions about what services are appropriate, how long they will be provided, and whether the patient is making progress, tension between the overwhelmed family and rehabilitation team is fairly common (Phipps et al., 1997). By providing the family with clear and concise information that matches their most immediate concerns, therapists can help families begin to understand what has happened in ways that neither inflame expectations nor squelch hope.

Holland and Shigaki (1998) proposed a three-phase model for educating families and caregivers of persons with TBI. They suggested that families benefit from information that is relevant to the patient's stage of recovery and their own stage of adjustment. They recommended that during the first phase (ICU through acute hospitalization), family education should focus on providing basic orientation to help the family decipher what is unfolding and to clarify terms and procedures associated with trauma care and TBI. Family members also need help to understand the disordered and occasionally bizarre behavior associated with agitation and to appreciate it as a natural part of recovery (Eames, Haffey, & Cope, 1990). Finally, conversations and instructions have to be repeated frequently, because the family is under considerable stress and flux. To provide right-timed education at the appropriate level, clinicians should also try to learn about patient and family background including such matters as family structure, family routines and activities, and experiences with service providers (Sohlberg et al., 2001). (See Resources 34-1 for materials that could be used in family education.)

Rehabilitation

My occupational therapist (OT) has promised to take me to the hospital chapel to play the organ. My mom brought my organ books to the hospital. . . . Now I can show the therapists that I don't need their exercises . . .[and] don't belong here in the hospital. (Rain, 2000, p. 6)

Rehabilitation occurs in inpatient, outpatient, and residential settings. In general, the primary goals of inpatient rehabilitation are medical stability, reduction of physical impairments, and acquisition of basic self-care skills. Postacute rehabilitation emphasizes reducing the obstacles of community integration posed by cognitive and behavioral impairments (Malec et al., 2000). It may take weeks, months, or years until goals are achieved and/or the patient no longer appears to benefit from intervention. Decreases in lengths of stay, however, result in many patients being discharged from inpatient rehabilitation settings without realizing their potential to recover capacities and basic skills. Rehabilitation efforts outside the inpatient setting increasingly address medical needs, fundamental capacities, and basic skill acquisition before or instead of community reentry.

Inpatient Rehabilitation

Although referral patterns vary, patients can generally participate in intensive inpatient rehabilitation when they demonstrate stimulus-specific responses and when post-traumatic confusion and agitation either resolve or do not present a barrier to participation in intensive therapies, such as Rancho levels V and VI. At level V, patients are still disoriented and confused but increasingly goal directed (Heinemann et al., 1990) and capable of teaching–learning interactions (Abreu & Toglia, 1987). They cannot process information at a normal rate or produce an appropriate response to all environmental situations. A patient at this level may require maximum assistance for independent living skills, exhibit significant neuromuscular impairments, need maximum cueing for orientation, display severe memory impairment, possibly show confused verbal and mental processes, and have little carryover of new learning. As patients progress to Rancho level VI, they remain inconsistently oriented but begin to be aware of appropriate responses to staff and family and demonstrate carryover for relearned, familiar tasks (Hagen, 1998).

Assessment: Inpatient Rehabilitation. Patients with TBI who are in rehabilitation can participate in formal assessment. Occupational therapists often begin by screening vision, visual perception, and cognition. Chapters 5 and 6 detail numerous assessment tools and methods appropriate for persons at this phase of recovery from TBI. Clinicians must determine the extent to which patients can scan, attend, follow, and retain instructions to interpret performance on other traditional assessments, including upper extremity strength and function and activities of daily living (ADL). A number of tools developed specifically to assess patients with TBI are used in a variety of rehabilitation disciplines, including occupational therapy (Table 34-4). Assessment tools are also detailed in the Occupational Therapy Practice Guidelines for Adults with Traumatic Brain Injury (Golisz, 2009) and at the Center of

Treatment: Inpatient Rehabilitation. Occupational therapy during inpatient rehabilitation is aimed at optimizing motor, visual-perceptual, and cognitive functions; restoring competence in fundamental self-maintenance tasks; contributing to the patient's continuing behavioral and emotional adaptation; and supporting the patient's family as they prepare for discharge.

Optimizing Motor Function. Therapists initially help patients with more severe cognitive impairments optimize their motor function by engaging them in gross motor activities that they can perform almost automatically, such as playing catch or hitting a punching bag (Fig. 34-2). Such activities minimize the demands on weakened cognitive functions, such as attention, concentration, and memory. Intervention increasingly focuses on refining motor functions as the patient's motor and cognitive recovery progress. Patients perform traditional exercise regimens as well

Table 34-4	**Assessment and Outcomes Tools for Traumatic Brain Injury Patients in Rehabilitation**
Instrument	**Brief Description**
Mayo-Portland Adaptability Inventory[a] (Malec & Thompson, 1994)	Designed for interdisciplinary postacute rehabilitation; covers broad range of observable attributes, such as physical function, cognitive capacity, emotional status, social behavior, self-care, work, and driving (Center for Outcome Measurement in Brain Injury [COMBI], 2011). Patient's status on 30 items is rated on a four-category scale: no impairment, impairment on clinical examination but does not interfere with everyday function, impairment does interfere with everyday function, or complete or nearly complete loss of function.
Moss Attention Rating Scale (MARS)[a] (Whyte et al., 2003)	Twenty-two–item observational scale of attention-related behavior following TBI (COMBI, 2011). Items, which include behaviors indicative of good as well as impaired attention, are rated on a 5-point Likert-type scale.
Neurobehavioral Rating Scale (Levin et al., 1987)	Twenty-seven–item clinical rating scale measures common cognitive, behavioral, and emotional disturbances associated with TBI; used to track neurobehavioral recovery and measure behavioral change in response to intervention.
Patient Competency Rating Scale (PCRS)[a] (Leathem, Murphy, & Flett, 1998)	Thirty-item self-report measure to evaluate self-awareness following TBI (COMBI, 2011). The patient's responses are compared to the ratings of a relative or therapist to identify discrepancies indicating overestimation of abilities. Domains include activities of daily living, behavioral and emotional function, cognitive abilities, and physical function.
Participation Objective, Participation Subjective (POPS)[a] (Brown et al., 2004)	Twenty-six–item measure of participation in five categories: (1) domestic life; (2) major life activities; (3) transportation; (4) interpersonal interactions and relationships; and (5) community, recreational, and civic life (COMBI, 2011). For each item, the person is asked about level of participation (objective), satisfaction with that level of participation (subjective), and how important that particular activity is to satisfaction with life (subjective). Objective and subjective responses contribute to total score.

[a]Available online at http://www.tbims.org/combi. Psychometric data on these instruments, including reliability, are found at the COMBI site.

Figure 34-2 Early efforts to optimize motor function focus on eliciting automatic movement.

as exercise and activity delivered by virtual reality to improve strength and balance (Holden, 2005; Thorton et al., 2005) (Fig. 34-3). Occupational therapists use approaches that best match therapy goals and the patient's abilities, as detailed in Chapters 20 and 21.

Optimizing Visual and Visual-Perceptual Function. TBI frequently results in foundational visual and/or visual-perceptual disturbances that impair occupational function (Bouska & Gallaway, 1991). Transient changes in refractive error, impaired accomodative (i.e., focusing) function, and impaired convergence of the eyes are common

Figure 34-3 Virtual reality allows patients with brain injury to practice skills while participating in interesting and motivating activities that might otherwise be unsafe or unavailable to them.

(Suter, 2004). Visual field loss is often in the superior fields, and the oculomotor system is frequently impaired, with poor fixation, deviation of the eyes resulting in diplopia, and difficulty in visual scanning (Scott & Dow, 1995). Limitations in complex visual processing become evident during perceptual evaluation (Warren, 1993). It is important to identify possible visual impairments as early as possible so that appropriate patients are referred for specialized optometry and/or ophthalmology assessments, and therapists can make an effort to circumvent the influence of visual impairments on performance. Chapter 5 details specific assessments that may be applicable to patients with TBI. As Kaldenberg recommends in Chapter 23, intervention for primary visual deficits emphasizes environmental adaptation, compensatory techniques, assistive devices, and patient and family education. The efficacy of perceptual remediation is controversial. Based on her review of research on remedial perceptual retraining, Neistadt (1994b) was pessimistic about its appropriateness for TBI patients: "Far and very far transfer from remedial to functional tasks will not occur for clients with diffuse brain injuries and severe cognitive deficits, in either early or late stages of recovery, even with a variety of training tasks and up to 6 weeks of training" (p. 232).

Optimizing Cognitive Function. Chapter 24 presents occupational therapy approaches for optimizing cognitive function, all of which may be appropriate for persons with TBI. Inpatients with TBI are typically in a period of relatively rapid improvement, so therapists provide cognitive remediation activities and exercises to challenge and stimulate primary cognitive domains (attention, memory, and executive function) in the hope that natural recovery will be enhanced and accelerated. Card or board games, puzzles, and paper-and-pencil tasks such as word recognition or letter or number cancellation drills, and computer programs may be used. However, sole reliance on repeated exposure to and practice of computer-based tasks devoid of clinician involvement is not recommended (Cicerone et al., 2011). Patients may participate in group treatment, such as an orientation group in which they rehearse and reinforce awareness of time, place, and circumstances.

Vanderploeg et al. (2008) compared two of the primary inpatient rehabilitation approaches to treating TBI-related cognitive impairments in a military and veteran sample with moderate to severe brain injury. The cognitive-didactive approach emphasized trial-and-error learning and building self-awareness with targeted 1:1 remedial training for the various cognitive domains. The functional-experiential approach focused on developing functional abilities or skills using errorless learning techniques, environmental management, and compensatory strategies primarily in group sessions in real-life environments. Patients in both groups used a compensatory memory notebook. In addition to 1.5–2.5 hours

each day of protocol-specific treatment, patients received an additional 2–2.5 hours of occupational and physical therapy daily following the designated approach for each patient. At 1 year postinjury, 56% of the cognitive treatment group and 62% of the functional treament group were living independently, and 39% of the cognitive group and 35% of the functional group had returned to work or school. Although the differences in the primary outcomes between the two intervention groups were not statistically significant, it is not possible to know how people who did not receive either intervention would have fared, as the study did not include a nontreatment group for ethical reasons. Vanderploeg et al. concluded that the relatively high rate of independent living and return to work or school in a sample with 90% severe TBIs was evidence of the potential benefit of both of the two approaches.

The Cognitive Rehabilitatation Task Force of the American Congress of Rehabilitation Medicine Brain Injury Interdisciplinary Special Interest Group conducted three systematic reviews of studies of cognitive rehabilitation, which led to more specific practice recommendations for TBI (Cicerone et al., 2000, 2005, 2011). There was insufficient evidence to determine whether improvements seen in attention during acute rehabilitation are a result of directed attention training, other cognitive interventions, or spontaneous recovery. However, there was substantial evidence to support the use of direct attention training and metacognitive training for the remediation of attention deficits during postacute rehabilitation after TBI. Memory strategy training including internalized strategies such as visual imagery and external memory compensations such as day planners and memory books was recommended for people with mild memory deficits. They recommended the use of external memory compensations directly related to functional activities for people with severe memory impairments. They further recommended metacognitive strategy training to address impairments in executive functioning.

An evidence review by the Institute of Medicine (2011) was more conservative in its recommendations, finding limited to modest support for cognitive rehabilitation therapy (CRT) in TBI with efficacy varying across cognitive domains, injury severity, and time since injury. The committee clarified that the lack of more definite clinical recommendations for CRT was primarily due to limitations in the existing research, which should not preclude the ongoing clinical use of cognitive rehabilitation for individuals with TBI (IOM, 2011).

In conjunction with the approaches described above, occupational therapists often use a dynamic investigative approach (Toglia, 1989) in which cognitive retraining activities become opportunities for assessing performance under a variety of circumstances. Careful activity analysis and logging of observations and environmental variables

informs discharge recommendations to families regarding the circumstances in which their loved one is best able to function. Such information is invaluable to families as they assume day-to-day responsibility for structuring the patient's time and activities.

Occupational therapists also use the physical environment to optimize patients' cognitive capacities and abilities during this phase of recovery. Specialized brain injury units typically incorporate signage and physical landmarks that enhance orientation and technology, such as monitoring systems, that allow the patient to move even though he or she may be confused and disoriented. Occupational therapists also strategically place familiar pictures and objects, calendars, and clocks in the patient's room to optimize orientation.

Restoring Competence in Self-Maintenance Tasks. As previously mentioned, inpatient rehabilitation usually focuses on helping patients reacquire basic self-care skills, such as bathing, dressing, hygiene, and eating. In general, a given self-care task is simplified until the patient is consistently successful in performing it, and then the complexity is gradually increased while the externally provided structure is gradually decreased. Environmental distractions are kept to a minimum. The therapist structures the task, gathers the items to be used, and sequences the task by providing the patient with the appropriate item and instructions, one step at a time. For example, in dressing, the therapist first hands the patient his undershorts and then gives simple verbal instructions and physical assistance as necessary to have the patient put the shorts over his legs and pull them up. The therapist does not present the patient's tee shirt until the shorts are on. Initially, the therapist selects solid colors with minimal fastenings to decrease perceptual confusion. The therapist may also choose to limit the task by having the patient do only one or two steps of the entire task (e.g., put on tee shirt only) if the patient has very low endurance, low frustration tolerance, or limited motor skills. Selection of the position of the patient (i.e., dressing in bed, sitting in the wheelchair, or sitting on the edge of the bed) and the method of dressing is based on the patient's neuromuscular function. Gradually, as the patient becomes more successful in dressing, the therapist decreases verbal and physical cueing, using checklists and/or graded cues (see Chapter 24). Bathing, hygiene training, feeding, and wheelchair transfer training are structured in the same fashion. Occupational therapists can help set the stage for establishing consistent and automatic self-care routines at home by outlining the sequence of steps in which the patient is most successful.

During inpatient rehabilitation, occupational therapists assess the patient's ability to handle more complex ADL, such as meal preparation and cleanup, laundry, and using the telephone (Fig. 34-4). Therapists take into

Figure 34-4 Occupational therapists often simulate real-life activities, such as gathering information over the telephone.

consideration the client's prior familiarity with a task to determine whether the client will be reestablishing familiar habits and routines or learning new, or relatively unfamiliar, skills (Powell et al., 2007). Again, a dynamic investigative approach is employed to determine under what circumstances the patient can safely and competently carry out these activities and the most effective intervention strategies.

Contributing to Behavioral and Emotional Adaptation. Behavioral sequelae may intermittently influence the patient's ability to participate in therapy at this stage. Brain damage itself may cause psychosocial changes, such as irritability, aggressiveness, or apathy (Prigatano, 1992). As the patient becomes more alert, his or her awareness of the situation may increase irritability, uncooperativeness, or mood fluctuations. Patients who lack awareness of deficits may also become frustrated with staff and family who limit their activities. Furthermore, patients who repeatedly fail on a variety of tasks may become depressed or anxious (Prigatano, 1992). It is important for occupational therapists to appreciate the state of internal chaos and vulnerability of many patients with TBI at this phase of recovery (Groswasser & Stern, 1998). Without the anchor of intact memory to make connections between experiences, "life is downgraded to a collection of unrelated, disjointed, and sporadic episodes" (Groswasser & Stern, 1998, p. 73). Rather than force confrontation of deficits early on, therapists avoid placing patients in situations that are fraught with frustration and failure and instead structure experiences that reinforce patients' confidence that they still have the potential to accomplish things (Groswasser & Stern, 1998). Doing so establishes therapeutic trust, the foundation for later phases of recovery, when patients are better able to compare premorbid and current capabilities. See Chapter 14 for guidelines to establish a therapeutic relationship.

When behavioral sequelae associated with brain injury interfere with progress and the potential for community reintegration, the rehabilitation team establishes an interdisciplinary plan to minimize or eliminate socially unacceptable behavior and promote prosocial, adaptive behavior. Eames, Haffey, and Cope (1990) pointed out, "Since the primary aim of rehabilitation is a return to the community, simple containment or toleration of disordered behavior within the rehabilitation setting is inadequate because the community at large will not adopt a lenient attitude toward such behavior" (p. 420). Ylvisaker, Jacobs, and Feeney (2003) recommend focusing on antecedents associated with positive behavior and less on consequences related to problems. The following are examples of strategies that contribute to patients' ability to learn effective behaviors during inpatient rehabilitation and beyond:

- Redesign the environment (Ylvisaker, Jacobs, & Feeney, 2003). For example, if noise and distractions seem to contribute to a patient's irritability and aggressiveness, provide treatment and care in areas that are calm and quiet.
- Capitalize on the superiority of procedural over declarative memory after brain injury by helping patients learn context-sensitive routines rather than broader transfer-dependent strategies (Ylvisaker, Jacobs, & Feeney, 2003).
- Identify positive competing behavior and, as a team, consistently and frequently reward all instances of adaptive behavior (Eames, Haffey, & Cope, 1990).
- Withhold all rewards that maintain maladaptive behavior. Use time-outs in a calm, mechanical manner that does not reward the patient with increased social contact (Eames, Haffey, & Cope, 1990).
- Help the patient to learn new skills and to experience success to reduce frustration-induced maladaptive behavior.

Supporting the Patient's Family. Patients' families continue to require information and support to understand the recovery and rehabilitation process and to inform their decision making and discharge planning. Holland and Shigaki (1998) recommended that the rehabilitation team provide the family with information about (1) the full spectrum of possible TBI outcomes to enhance realistic expectations; (2) the effects of TBI on family systems and possible alterations in family dynamics post discharge; (3) the benefits, challenges, and responsibilities of caretaking and supervision post discharge; and (4) resources available for postacute rehabilitation. Participation in inpatient rehabilitation sessions can help family members learn about the patient's strengths and weaknesses, techniques for helping him or her optimize performance, and help minimize expectations of an abrupt recovery to the "same person" the patient was before the injury (Phipps et al., 1997).

Postacute Rehabilitation

Malec and Basford (1996) described the array of postacute rehabilitation programs in the literature and possibly available to clients with TBI. (The transition to references to the "client" rather than "patient" signifies the increasingly collaborative therapeutic relationship between therapist and TBI survivor during postacute rehabilitation and survivor phases.) Occupational therapists are typically involved in all of these options, including the following:

- Home-based therapy provides a single-discipline or interdisciplinary intervention for clients who are unable to get to clinic-based services or who would benefit from context-specific training within the home environment.
- Residential neurobehavioral programs provide intensive treatment for clients with severe behavioral disturbances.
- Residential community reintegration programs provide integrated cognitive, emotional, behavioral, physical, and vocational rehabilitation to clients who cannot participate in outpatient programs because of severe cognitive and behavioral impairments or lack of availability of outpatient options.
- Comprehensive (holistic) day treatment programs provide integrated, multidisciplinary rehabilitation that emphasizes self-awareness, social skills, and cognitive compensation.
- Outpatient community reentry programs provide specific rehabilitation therapies as well as vocational services.

In their review article comparing outcomes of postacute brain injury rehabilitation with natural recovery after TBI, Malec and Basford (1996) concluded, "Although generally uncontrolled, the studies reviewed document benefits for many individuals with brain injury, including increased independence and a rate of return to independent work or training that exceeds 50% and may reach 60% to 80% for intensive comprehensive (holistic) day treatment programs" (p. 198). Postacute rehabilitation typically is not a continuous sequence of rehabilitation services but, more often, a time-limited, goal-specific series of rehabilitation episodes.

In general, the aim of postacute rehabilitation is to prepare the client to reenter the community, although some programs also offer specialized tracks or pathways that focus on prerequisite physical, behavioral, cognitive, or self-care skills (Abreu et al., 1996). Although the occupational therapist's roles and responsibilities vary with the type and even location of the program, this section of the chapter reviews areas that are typically addressed. This section also discusses mild TBI, because these survivors rarely receive inpatient rehabilitation services.

Occupational Therapy Assessment: Postacute Rehabilitation. Occupational therapists continue to use many of the instruments and methods described earlier in this chapter (see Table 34-4) and text. As clients have more real-world experiences and their self-awareness continues to improve, tools like the Canadian Occupational Performance Measure (COPM) (Law et al., 1994) become appropriate for identifying treatment goals that are important to the client. This instrument, however, is not useful for clients with significant problems with insight and self-awareness, because these individuals are unlikely to view themselves as having problems that can be addressed in therapy. Furthermore, improved accuracy of self-appraisal can result in a self-rated decrease in performance and satisfaction at follow-up despite actual gains.

Treatment: Postacute Rehabilitation. After discharge from acute rehabilitation, many clients require occupational therapy treatment aimed at teaching them to compensate for residual cognitive and visual-perceptual impairments so that they may resume self-maintenance, self-advancement, and self-enhancement roles.

Optimizing Cognitive Function. In postacute rehabilitation, clients (usually in Rancho level VII or VIII) may continue to demonstrate specific impairments in short- and long-term memory, reasoning, conceptualization, comprehension, abstract thinking, information-processing speed, organization of information, simplification of problems, judgment, and problem solving (Dikmen, Reitan, & Temkin, 1983). They may display decreased attention during attempts to store information, inability to determine the salient or relevant details of what they hear or read, decreased ability to structure or associate incoming information appropriately, and decreased cognitive flexibility (Scherzer, 1986). Especially if the client also has decreased self-awareness, these impairments will affect his or her ability to make coherent decisions and plan for the future.

Occupational therapists continue to help clients and their families to change the physical and social contexts and environment to optimize occupational functioning. This may include decreasing distracting stimuli and increasing important visual cues at the home and work site to optimize cognitive function. Home and work site visits allow therapists to identify opportunities for these modifications. Also, because clients in postacute rehabilitation typically have a more stable living situation than they did as inpatients, their occupational therapists can capitalize on consistency of clients' environments and daily activities to help them create routines and habits that minimize the demands of information processing with frequently performed tasks. Occupational therapists also use a variety of activities and exercises, such as computer games, worksheets, crafts and projects, and simulated home and work tasks, to help clients improve their awareness of strengths and weaknesses. As clients appreciate the significance of residual cognitive impairments for resumption of roles, occupational therapists teach them to use compensatory cognitive strategies, such as paper or electronic calendars/organizers, cueing devices, smart phones, and problem-solving schemata, in the context of personally relevant real-world tasks (see Chapter 24).

Optimizing Visual and Visual-Perceptual Function. Similarly, occupational therapists continue to help clients make changes in environment and strategy to circumvent the influence of visual and visual-perceptual impairments. For example, Williams (1995) described occupational therapy intervention for problems with reading and writing of a woman who was more than 12 months post-TBI. A comprehensive vision evaluation performed by an ophthalmologist and occupational therapist revealed adequate central visual acuity, slightly reduced contrast sensitivity, an inferior visual field cut in both eyes, and a dense scotoma bordering the fovea in both eyes. Intervention, which consisted of changes in lighting for reading and writing, oculomotor exercises, and strategy training, ultimately allowed her to resume these valued activities.

Restoring Competence in Self-maintenance Roles. Clients who have not achieved independence in basic self-care and homemaking tasks continue to work toward those goals in postacute rehabilitation. Giles et al. (1997) used behavioral training to help TBI clients in a transitional living center develop independence in dressing and washing skills in a relatively short period (11–37 days) of treatment. Even clients with proficient self-care skills benefit from treatment that links individual skills to automatic routines (see Chapter 24). Based on performance on the Rabideau Kitchen Evaluation–Revised (Neistadt, 1992), Neistadt (1994a) used a meal preparation protocol to help outpatients with TBI learn to prepare a hot beverage and snack. After three 30-minute sessions per week for 6 weeks, participants made gains in independence and decreased their performance times. Interventions in self-care and homemaking always involve input from family and/or caregivers and measures to ensure transfer of newly acquired skills to the client's living environment.

When client and family are satisfied with the client's ability to perform daily living skills and homemaking tasks, such as cleaning, meal preparation, and laundry, occupational therapy addresses community reentry skills. Many clients rely on occupational therapy to help them learn or relearn to manage money, go shopping, use the bank, and use public transportation. To do so, clinicians again adapt the environment, help clients acquire behavioral routines, and teach clients to use compensatory strategies. The therapist must carefully assess the amount of supervision and structuring necessary because of impaired judgment and problem-solving ability, as well as any physical limitations.

Almost as soon as they are discharged from the hospital, many survivors of TBI inquire about their readiness to drive. The client's residual physical, cognitive, perceptual, and visual dysfunction must be thoroughly assessed to determine his or her ability to drive safely. The client's psychosocial status, including self-control, impulse control, and frustration tolerance, must be also carefully considered. A car can be adapted to compensate for some physical problems (see Chapter 26) and measures such as turning off the radio can be taken to reduce distracting stimuli while driving; however, no compensation can be made for slowed reaction to emergencies, lack of judgment or problem-solving ability, spatial or directional confusion on the road, or impairment in depth perception (Jones, Giddens, & Croft, 1983).

Restoring Competence in Leisure and Social Participation. Occupational therapy plays an important role on the postacute rehabilitation team by helping the client resume previous leisure activities or determine new leisure outlets that are more in line with current abilities. Many survivors of TBI have to change not only what they do for fun but also where and with whom they do it. Leisure activities post-TBI tend to be sedentary, home-based, and socially isolated (Wise et al., 2010). Few friendships withstand the cognitive, behavioral, and emotional upheaval that comes with TBI. Changes in the types of activities (e.g., fewer alcohol-related activities), also contribute to less contact with preinjury friends (Wise et al., 2010). Occupational therapy intervention may focus on helping the client initiate new social contacts, participate in support groups, and reestablish the social skills necessary for maintaining and building a social network. Social skills retraining following severe head injury develops skill in social behaviors and facilitates successful social interactions. In general, behavioral learning methods are the most effective for training severely brain-injured individuals to overcome social skill impairments (Giles & Clark-Wilson, 1993). Treatment typically entails instruction and modeling of the social skill, practicing the skill with feedback, and shaping the skill until it is used correctly (Yuen, 1997).

Restoring Competence in Work. After clients reestablish their competence in self-maintenance roles, they are ready to explore return to work. Postacute occupational therapy facilitates that process with prevocational programs that focus on work behaviors and habits, such as punctuality, thoroughness, response to feedback, and ability to take and use notes. Occupational therapists may also link clients with appropriate volunteer jobs where they can employ newly learned compensatory cognitive strategies and build their endurance and work tolerance.

Contributing to Behavioral and Emotional Adaptation. As clients attempt to resume familiar activities, they cannot escape the awareness that they have changed in some manner

(Groswasser & Stern, 1998). Emotional and behavioral difficulties can be attributed to premorbid personality and coping style, cognitive consequences of TBI, and/or grief associated with injury-related losses (Hanks et al., 1999). These emotional and behavioral changes may include social or sexual disinhibition, low tolerance for frustration or stress, reduced insight or judgment, labile affect, irritability, impulsivity, and depression. In the extreme, the patient may experience psychiatric disorders such as paranoia, phobias, confusion, or delusional ideation (Ashman et al., 2004; Benton, 1979). Regardless of the specific goals of therapy, occupational therapists support and guide clients with TBI as the clients confront and address impairments and inefficiencies that interfere with performance. They provide sensitive and timely feedback regarding behaviors that could otherwise result in rejection and social isolation in the community. Because depression negatively influences psychosocial functioning after TBI (Hibbard et al., 2004), occupational therapists also respond to indicators that clients may be in need of psychological or psychiatric intervention and make referrals as needed (see Chapters 3 and 30; see also Research Note 34-1).

Supporting the Client's Family. In most cases, the client's family ultimately provides long-term assistance and support for the survivor. Caregivers of persons with moderate to severe TBI report a mix of positive and negative caregiving experiences with negative experiences associated with more severe injuries, worse neuropsychological functioning, and increased dependence (Machamer, Temkin, & Dikmen, 2002). As time passes and the implications of the injury become clearer, family members may undergo mourning that is intense, disorganized, and prolonged (Muir, Rosenthal, & Diehl, 1990). Occupational therapists continue to support families in this stage by providing education. Holland and Shigaki (1998) recommended emphasis on the following topics in family education at this phase of recovery and adaptation: (1) the protracted nature of TBI recovery, (2) the experience of recovery from the patient's perspective, (3) adjustment to and possible management of behavioral and personality changes, (4) sexuality issues, (5) community resources, and (6) home adaptation.

Survivorship

I have been living with multiple effects of a severe TBI for 23 years. . . . Many of these years were spent in lonely isolation, wondering when the nightmare would end. . . . Now, I am focusing my energy on reaching out as well as within to live this life. (Rain, 2000, p. 6)

The medical treatment and rehabilitation phases of life for the survivor are relatively brief compared to the years during which he or she will continue to live with the consequences of TBI. Most survivors ultimately achieve independence in self-care skills and recover motor function,

Research Note 34-1

Abstract

The purpose of this study was to describe the rates, predictors, outcomes, and treatment of major depressive disorder (MDD) for people with traumatic brain injury (TBI) during the first year postinjury. Researchers contacted 559 consecutively hospitalized adults with complicated mild to severe TBI monthly for the first 6 months postinjury and then at 8, 10, and 12 months. At each follow-up, study personnel administered the Patient Health Questionnaire (PHQ) depression and anxiety modules. Over one-half (53.1%) of participants met the criteria for MDD at least once during the follow-up, substantially more than the expected rate of 6.7% in the general population, with about half of those identified by 3 months. The risk for developing MDD postinjury was higher for those with a history of MDD prior to the time of injury, MDD at the time of injury, and lifelong alcohol dependence. Those with MDD had higher rates of co-occurring anxiety disorders and reported lower quality of life, but only 44% had received antidepressants or counseling.

Implications for Practice

- MDD following TBI is underrecognized and undertreated. Occupational therapists should be aware of the risk factors for MDD and realize that people without full awareness of their limitations can experience a depressive reaction. Occupational therapists should participate with other team members throughout the continuum of care in screening TBI survivors for depressive symptoms and referring for diagnosis and treatment.
- The efficacy of antidepressants in people with TBI may be limited by co-occurring substance abuse and/or anxiety disorders. Individuals with TBI have been found to favor counseling and exercise over other treatment modalities. Occupational therapists can assist TBI survivors in identifying and participating in pleasurable activities and healthy routines, including exercise, using compensatory strategies and devices as needed.

but cognitive, behavioral, and emotional problems are long-term barriers to good quality of life (IOM, 2009). Dikmen et al. (2003) found that personal care and ambulation were least affected at 3–5 years after a moderate to severe TBI, with approximately 65% and 50%, respectively, of survivors having recovered to preinjury levels. However, about 60% experienced cognitive problems in performing their daily activites, 60% were not performing their major role activity at preinjury levels, and approximately 25% were completely dependent on others financially. In comparison with preinjury levels, approximately 60% had more limitations in leisure and recreation, 45% more limitations in social integration, and 40% more limitations in home management.

TBI also affects people's ability to work. Moderate to severe TBI in individuals who were workers preinjury increases the probability of unemployment postinjury and decreases the likelihood of returning to the same position for those who do return to work (IOM, 2009). Individuals with TBI take longer to return to work than people with non-brain trauma with poor employment outcomes associated with injury severity and postinjury neuropsychological impairments (IOM, 2009). Decreased ability to successfully return to work is of particular concern, because employment appears to be linked to quality of life after TBI (O'Neill et al., 1998). O'Neill et al. (1998) found that being employed part or full time contributed to survivors' sense of well-being, social integration, and pursuit of meaningful home activities.

These long-term and often unmet needs underscore the importance of intermittent long-term rehabilitation services and community resources for persons with TBI. Unfortunately, most rehabilitation services remain medically oriented, often focusing heavily on intervention for physical impairments.

The contrast between need and service availability is particularly disturbing to occupational therapists who have the education and skills to make a difference in the lives of survivors of TBI. For example, Nelson and Lenhart (1996) described a case in which weekly outpatient occupational therapy sessions over 5 months helped a woman who was 5 years post-TBI to improve her ability to handle school, household, and social responsibilities. Trombly, Radomski, and Davis (1998) and Trombly et al. (2002) found that adults with TBI, many of whom were more than 2 years postinjury, met self-identified goals in outpatient occupational therapy.

The survivorship phase of life for persons with TBI presents opportunities for clinicians to employ all that is truly unique to occupational therapy, synthesizing the totality of our education, philosophy, and values to enhance occupational functioning in society. Readers are challenged to consider the following ways to poise themselves for action:

- Recommend that a life care plan be prepared for survivors of moderate to severe TBI (Sherer, Madison, & Hannay, 2000). A life care plan delineates the services and items required for the current and long-term care of the survivor as well as the costs of these services. A life care plan can be used clinically to plan appropriate long-term care, including intermittent follow-up,

and for forensic purposes, such as determination of an appropriate settlement that will provide for the lifetime needs of the injured person (Sherer, Madison, & Hannay, 2000). Pursue credentialing to prepare life care plans as part of your role as an occupational therapist.

- Promote to possible referral sources what you are able to do to enhance community integration and quality of life for persons with TBI. Join your local brain injury association, connect with your state's vocational rehabilitation division, familiarize yourself with key personnel supporting disabled students at local colleges and universities.

- Establish the kind of therapeutic relationship with clients and family members that will make them want to return to you for help. Respecting the client's readiness for treatment means sometimes not intervening, but making sure that he or she knows that your door is open in the future.

- Make sure that the discharge from outpatient occupational therapy incorporates plans for follow-up and clear information regarding possible circumstances in the future when further occupational therapy services may be helpful. Provide information to the survivor and his or her family regarding mechanisms to reinstate services. Remember that the nature of TBI interferes with survivors' ability to advocate for themselves (e.g., lack of initiation, impaired memory), and so you must build in opportunities to discern and respond to their needs.

MILD TRAUMATIC BRAIN INJURY

A mild TBI, or concussion, is characterized by a shorter and less severe disruption of brain functioning than with a more severe injury. It is estimated that, each year, more than 1.1 million people in the United States experience a mild TBI (National Center for Injury Prevention and Control, 2003). There is some variation in the specifics of how mild TBI is defined. One of the most commonly used definitions states that mild TBI is an impact to or forceful movement of the head resulting in a brief alteration of mental status, such as confusion or disorentation, loss of memory lasting 24 hours or less, loss of consciousness lasting 30 minutes or less, and/or an acute seizure after injury to the head (National Center for Injury Prevention and Control, 2003). Symptoms of mild TBI may include headache, dizziness, nausea, irritability, fatigue, and cognitive deficits such as impaired concentration, information processing speed, and memory (National Center for Injury Prevention and Control, 2003). Most people with a mild TBI return to normal functioning within 1–3 months, although approximately 10% of patients continue to have problems a year after injury (Ruff, Camenzuli, & Mueller, 1996).

Experts disagree about the persistence and cause of cognitive problems after mild TBI (Dikmen, Machamer, &

Temkin, 2001). Some link cognitive inefficiencies to acute stress disorder (Bryant et al., 2003), whereas others attribute disability to brain damage (DeKruijk, Twijnstra, & Leffers, 2001). Montgomery (1995) described a multifactor explanation for disability after mild TBI. He suggested that personal factors (perfectionism or tendency toward negative thinking) interact with transient sequelae of mild brain injury, such as headache and mental inefficiency, that lead to short-term decrements in performance. Premature resumption of normal activities places an undue load on information-processing capacities that leads to errors and slowness of performance. Over time, the individual begins to make misattributions of causation and starts questioning his or her fundamental competence and even sanity (Montgomery, 1995). These individuals profit from outpatient rehabilitation services that address residual physical symptoms, provide information and support, and teach them to use cognitive compensatory strategies that decrease the demands on working memory. By normalizing and explaining cognitive inefficiencies, helping reestablish routines, and teaching use of memory backups, occupational therapists can play a pivotal role in helping these clients resume premorbid tasks and roles. There is some evidence that it may be possible to minimize the development and subsequent impact of symptoms following mild TBI. Bell et al. (2008) provided a brief program (four or five sessions) of proactive telephone-based counseling to individuals beginning shortly after the onset of mild TBI. The sessions focused on education, symptom management, and encouragement to gradually resume everyday activities. At 6 months after injury, those who received the counseling intervention reported fewer symptoms and less effect of symptoms on everyday function.

Clinicians need to appreciate that persons with mild TBI who find their way to rehabilitation professionals represent a fraction of the cases with mild TBI and that cognitive problems may be observed for a variety of reasons that have nothing to do with brain injury (artifacts from testing, preexisting conditions, litigation, or emotional problems) (Dikmen, Machamer, & Temkin, 2001). Given the disagreement regarding the mechanism underlying cognitive problems after mild TBI, it is not surprising that there is little consensus about the best intervention. At present, there is little in the literature to guide occupational therapists looking for an evidence-based approach to intervention, which is why there is no evidence table to accompany the mild TBI case example in this chapter.

Combat-Related Traumatic Brain Injury

From 2000 to 2012, over 267,000 service members (SMs) sustained a TBI with approximately 20% deployment-related (Defense and Veterans Brain Injury Center, 2013). Combat-related TBI can occur via several mechanisms, the most common being a concussive blast. Powerful blast

waves produced by IEDs or "roadside bombs" can cause damage to the brain in the form of TAI, edema, or hemorrhage (Taber, Warden, & Hurley, 2006). Those injuries resulting from the blast itself are considered primary. A secondary type of blast injury is caused when overpressure from the blast propels debris and shrapnel away from the detonation site causing penetrating injuries to the brain and body. A tertiary form of blast injury occurs when individuals in close proximity to the blast are thrown in the air or against stationary objects causing acceleration/deceleration injuries. Quaternary blast injuries include other related injuries such as burns, respiratory problems from inhaling toxic gases, and blood loss from traumatic amputation (DePalma et al., 2005). TBIs in the military can also result from gunshot wounds to the head or face, training activities, and non–combat-related causes as in the civilian population.

SMs who sustain a moderate or severe TBI in combat are medically evacuated from the war zone and treated at a military medical treatment facility or a Veterans Affairs (VA) Polytrauma Rehabilitation Center. SMs receive treatment in inpatient, outpatient, and community reentry settings. Occupational therapy focuses on resuming independence with ADL, instrumental activities of daily living (IADL), and social and community activities. Through Department of Defense and VA programs, wounded SMs are eligible to receive adaptive equipment for cognition, communication, sensory loss, mobility, and environmental control. Vocational rehabilitation and home modification services are also available.

SMs who sustain a mild TBI in combat experience an alternate course of treatment and recovery. According to civilian estimates, approximately 75%–90% of individuals with a mild TBI experience a full recovery within minutes to weeks of the incident (Levin, Goldstein, & MacKenzie, 1997). SMs exposed to a blast receive evaluation and treatment during the acute stages of injury by military medical professionals. Often, they are able to return to duty after a brief rest period of 3–10 days. In some cases, symptoms persist beyond the anticipated recovery period. Recovery may be mediated by several factors. The presence of concomitant post-traumatic stress disorder (PTSD) and other mental health conditions are associated with persistent mild TBI symptoms and related physical health problems (Bryant & Harvey, 1998; Hoge et al., 2008). Polytrauma injuries, including amputation, burns, and vision and hearing loss may also impact recovery.

Returning to duty is the primary goal for many wounded SMs because of a strong desire to support their battle comrades and use their carefully honed skills. Occupational therapists should be aware that, in some cases, SMs may underreport symptoms in order to be cleared for duty. Careful evaluation and clinical observation is necessary to identify any barriers to function. When injuries render an SM unfit for duty, he or she may reclass into a new military role or transition into the civilian workforce. This can be a challenging process. Occupational therapy interventions such as vocational interest inventories and job-acquisition skills training are valuable tools to assist veterans in making smooth transitions out of the military. Considerations for working with SMs are discussed in Procedures for Practice 34-3.

Procedures for Practice 34-3

Considerations for Working with Service Members

- Observe for symptoms of undiagnosed mild traumatic brain injury (TBI) and make medical referrals as appropriate:
  - Headache
  - Difficulty sleeping
  - Problems with memory and concentration
  - Dizziness and imbalance
  - Light sensitivity
  - Increased irritability
- Become familiar with military terminology and acronyms. Service members (SMs) are often guarded and may be more willing to open up to individuals who they feel understand the military experience and culture.
- When possible, address active duty SMs by their ranks and last names.
- Be mindful of the treatment environment in light of the presence of postcombat stress:
  - Select a private or semiprivate location with limited auditory and visual distractions.

- Allow SMs to sit where they can see the door.
- Reduce the use of bright, fluorescent light.
- Explain the source of unanticipated noises from nearby construction work, lawn care, alarm testing, etc.
- If there is a television in the waiting room, consider positive, uplifting programming versus news of violence or combat.
- Provide patient and family education to explain and normalize symptoms and functional changes.
- Set a positive expectation for recovery.
- Consider group intervention in addition to one-on-one treatment. SMs are trained to operate in small teams or squads and are often motivated and encouraged by working with their comrades.
- Be knowledgeable regarding available community, Veterans Affairs, and Department of Defense resources.
- Make appropriate referrals for comorbid mental health dysfunction.

case example

K.R.: Occupational Therapy during Acute and Rehabilitation Phases of Recovery from Severe Traumatic Brain Injury

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

K.R. is a 20-year-old college student who sustained a traumatic brain injury (TBI) in a motor vehicle accident. Prior to the accident, K.R. was a physics major described by family as dependable and hardworking, with a 3.8 grade point average during his first 2 years of college.

Examination in the emergency department revealed a laceration over his forehead and right pneumothorax. His blood alcohol level was 0.226 (more than twice the legal limit). He had an initial Glasgow Coma Scale score of 3. Intracranial pressure was elevated. He sustained facial fractures. Serial computed tomography demonstrated traumatic axonal injury, edema, and right posterior temporoparietal intraparenchymal hemorrhage. Within the first week after the injury, a tracheostomy and feeding tube were inserted, and shortly thereafter, K.R. underwent open reduction and internal fixation of the right zygomatic maxillary complex fracture.

Occupational and physical therapy were initiated 10 days post-injury, with orders for range of motion, positioning, and assessment of response to sensory stimuli. At the time he was first seen in occupational therapy just before his transfer from intensive care unit (ICU) to the medical unit, his passive range of motion (PROM) was within normal limits for all extremities with mild spasticity in the right elbow and wrist flexors. K.R. did not speak or follow commands consistently. He was frequently observed to thrash around, primarily moving his left side, and at times, his movement appeared purposeful (pulling at tubes, seeming to scratch his right leg with his left foot). He appeared to track objects with his left eye inconsistently. His initial total score on the Western Neuro Sensory Stimulation Profile was 23, and he was believed to be functioning at a Rancho levels II–III (increasingly responsive to specific stimuli).

Objectives column:

Understand the patient's diagnosis or condition

Know the person

Internal Dialogue column:

"K.R.'s recent medical history suggests that he had a severe brain injury and will likely require occupational therapy services and other rehabilitation services throughout the continuum of care (acute medical, inpatient, outpatient, and follow-up)."

"From what his parents tell me, K.R. sounds like a really hardworking guy. Apparently, in addition to his course work, K.R. worked 16 hours a week as a dishwasher in his dormitory. It sounds like K.R. tends to be quiet and soft-spoken but enjoys the company of a small circle of friends. I found out that his leisure interests include golf, cross-country skiing, and playing piano. It was really worth the time it took to talk with K.R.'s parents. I can tell that I will like working with them, and the information they provided me with will help me as I try to make therapy interesting and engaging for K.R."

Reason for Referral to Occupational Therapy

After less than a week on the medical unit, K.R. was transferred to the inpatient brain injury rehabilitation unit and was again referred to occupational therapy and to physical therapy, speech-language pathology, and neuropsychology (he was 3 weeks postinjury). He was referred to occupational therapy to assess responsiveness to stimuli, positioning, and activities of daily living (ADL) training as appropriate. Consistent with his acute hospitalization, a family member (typically his mother) was present at most therapy sessions.

Objectives column:

Appreciate the context

Develop provisional hypotheses

Internal Dialogue column:

"The transfer from the medical unit to the rehabilitation unit represents a significant change in K.R.'s care. There is much more stimulation on the rehabilitation unit, and the overall emphasis of care changes from one of medical survival to recovery and adaptation."

"I anticipate that, by putting in place formal interventions and observational protocols, we will be able to maximize K.R.'s responsiveness to stimuli and ultimately his ability to benefit from rehabilitation. It will be important to involve his family for their sake as much as for his."

Assessment Process and Results

The Western Neuro Sensory Stimulation Profile was readministered, and K.R. obtained scores ranging from 54 to 80, with notable improvements in auditory comprehension, visual tracking, object manipulation, and arousal and attention.

On the Galveston Orientation and Amnesia Test, K.R. was oriented to person, but not to place or time, and was unable to describe events before or after his injury.

During assessment, K.R. sustained eye contact less than 25% of the time and was awake for approximately 20 minutes of each session. He horizontally tracked across midline with both eyes approximately 50% of the time and tracked vertically in one direction somewhat less. He generally followed gross motor commands approximately 25% of the time.

Minimal formal assessment of K.R.'s right upper extremity function was performed, but he was observed to not use or move it. He did not appear to have any limitations in range of motion in either upper extremity.

During assessment, K.R. did not contribute to any aspect of ADL.

| | Consider evaluation approach and methods | "I need to primarily rely on observational methods during assessment and carefully document what I am seeing so that I will be able to detect changes in responsiveness and function." |
| | Interpret observations | "I am finding that my assessment sessions really blur with treatment; it seems I am doing both at all times. I am encouraged that K.R. is demonstrating more specificity in his overall responses. Although his speech is not intelligible, he seems to be making more frequent verbalizations. Since he came to the rehab unit, I am noticing that he can participate for longer periods of time, and that is encouraging as well." |

Occupational Therapy Problem List

- Decreased arousal and attention
- Impaired memory
- Decreased and inconsistent visual tracking
- Inability to follow commands consistently
- Decreased right upper extremity function
- Dependence in ADL

| | Synthesize results | "K.R.'s overall responsiveness appears to be steadily improving based on records of his status on the acute medical unit. I am going to use my interventions related to ADL and upper extremity function as vehicles to improve arousal and attention." |

Initial Occupational Therapy Goal List

Because it was difficult to predict the patient's rate of recovery or response to therapy, the team set goals for 2-week intervals, with the understanding that the patient's length of stay on the rehabilitation unit would be dictated by his apparent ability to profit from intervention. Meanwhile, the patient's family was exploring possible discharge options to home for continued home-based services or to a subacute rehabilitation facility.

K.R. will stay awake for three 30-minute sessions per day, demonstrating sensory-specific responses to visual and auditory stimuli at least 75% of the time.

K.R. will respond to one-step commands during simple grooming activities at least 50% of the time.

K.R. will complete upper body dressing with step-by-step verbal cueing and moderate assistance.

	Develop intervention hypotheses	"My underlying assumption is that, as we provide that 'just-right' amount of stimulation and structure, K.R. will become increasingly aroused and attentive, which is necessary for him to be truly engaged in the rehabilitation process. Daily training in performing familiar basic ADL will facilitate independence in daily activities while providing an opportunity for K.R. to improve his ability to follow simple motor commands."
	Consider the evidence	"The evidence-based review by Cicerone et al., (2011) recommended the use of errorless learning techniques to teach specific skills to patients with severe memory impairments after TBI."
	Select an intervention approach	"At this point, my approach to intervention will involve both remedial and compensatory approaches."
	Consider what will occur in therapy, how often, and for how long	"K.R. is at the beginning of what will likely be a long course of rehabilitation, and it is impossible to come up with firm projections as to how long that process might be. Based on my experience, I expect that it may be a matter of a couple of weeks before K.R. can consistently follow instructions and truly participate in therapy. I will be seeing him at least three times per day throughout his inpatient rehabilitation stay, which could be 3–4 weeks. I am always reluctant to talk about specifics at this point, especially to family members, because it really is hard to project the outcome with any certainty."

Intervention

K.R. was seen three times daily, twice in the therapy clinic, with sessions lasting 20–30 minutes as tolerated. He participated in daily light hygiene and dressing activities in which, for example, he was instructed to turn on the faucet and was handed a wet washcloth and asked to wash his face. As recommended by the therapist, K.R.'s parents brought in pictures of friends and family and posted them in his room. PROM for the right upper extremity was incorporated into his sensory stimulation program, and efforts were made to elicit automatic upper extremity movement by, for example, challenging K.R. to catch or hit a balloon. He made steady gains in all areas, so that within 3 weeks of his admission to rehabilitation, he followed one-step commands approximately 70% of the time and participated in morning hygiene activities for 25-minute intervals with ongoing verbal and tactile cues. He was able to feed himself with the utensil in his right hand once the therapist scooped the food. K.R. started speaking in short phrases approximately 6 weeks after onset and progressed rapidly to whole sentences, indicating, for example, when he had to go to the bathroom. As K.R.'s cognitive recovery progressed, the occupational therapist helped him to become more independent in dressing, grooming, and his upper extremity exercise program and to increase his orientation and attention span. He was able to use a memory log (with entries recorded by others) to answer questions about his daily activities.

At the time of discharge, K.R. needed supervision with grooming and upper extremity dressing and moderate assistance with lower extremity dressing and bathing. K.R.'s mother was taught methods to assist him at home. He was able to walk with a quad cane and moderate assistance; he needed contact guard assistance with standing balance. At discharge, he was oriented to person, place, and time, scoring in the normal range on the Galveston Orientation and Amnesia Test, and demonstrated at least some degree of session-to-session carryover. The therapist recommended 24-hour supervision because of continued impairments in memory, problem solving, and judgment. He was discharged to his parents' home 2 months post-TBI with plans to return for daily therapy in the day hospital program (supervised all-day multidisciplinary therapies with return home each evening).

Assess the patient's comprehension	"At the time of his transfer to the rehabilitation unit and referral to occupational therapy, K.R.'s cognitive status posed the primary barrier to his functioning, specifically his low levels of arousal and attention."
Understand what he is doing	"Motor activities and ADL are means by which I can try to promote arousal, tracking K.R.'s, responsiveness, and ability to follow commands."
Compare actual to expected performance	"K.R. continues to require cueing to perform basic ADL. I can begin to provide more of an active learning-based intervention when K.R. begins to show within-session carryover."
Know the person	"I am beginning to see glimpses of K.R.'s personality and so are his family members. Even though he is disoriented and quite unaware of his circumstances, he can be easily engaged in therapy tasks, especially if he views them as competitive."
Appreciate the context	"K.R. was discharged home before he was fully competent in ADL because his parents were able to provide assistance and supervision and because intensive outpatient services were available."

Next Steps

The occupational therapy intervention plan during K.R.'s 3 weeks in the day hospital focused on use of a memory aid and reestablishing competence in IADLs including light meal preparation, laundry, checkbook management, and bill paying. His living situation contributed to motivation and improved insight more than the insulated experience of the rehabilitation unit. When he no longer required all-day supervision, he was discharged from the day hospital but continued outpatient occupational therapy three times a week.

Anticipate present and future patient concerns	"I feel good about the fact that we can offer K.R. and his family comprehensive and long-term rehabilitation services. They will need us off and on as they face new milestones over the next year such as driving, return to independent living, and return to school and work. His parents have joined a support group and are working closely with our staff to carry over what he is working on in therapy."
Analyze patient's comprehension	"K.R.'s attention and awareness have improved to the level where he could benefit from more active learning-based interventions such as cognitive-didactive treatment and strategy training."
Decide whether he should continue or discontinue therapy and/ or return in the future	K.R. is continuing to make gains and would benefit from continued therapy on an outpatient basis."

⊘ Clinical Reasoning in Occupational Therapy Practice

Occupational Therapy Intervention in the Acute Phase of Recovery

Just prior to K.R.'s transfer to the inpatient rehabilitation unit, his family excitedly reported that he was blinking his eyes when asked almost 100% of the time. Your assessment shows that he is following simple motor commands less than 20% of the time. What are some possible explanations for this discrepancy? How can you help his family better assess his ability to respond?

case example

Dr. N.: Occupational Therapy after Mild Traumatic Brain Injury

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**

Patient Information

Dr. N. is a 29-year-old single woman who sustained a mild traumatic brain injury (TBI) when she fell off her bicycle. She was not wearing a helmet. She reports that she did not lose consciousness, and her Glasgow Coma Scale (GCS) score in the emergency department was 13. Dr. N. returned to work 2 days after her hospital discharge despite moderately severe headaches and balance and memory problems.

Dr. N. has a degree in biochemistry and works as a postdoctoral fellow at a university. Her parents and four siblings reside in another state, and she lives with her significant other of 4 years.

Dr. N. participated in neuropsychological assessment approximately 6 months postinjury because cognitive inefficiencies continued to interfere with her function, especially at work. Findings suggested mild impairment for recent verbal and nonverbal memory and subtle impairment for executive function abilities. These cognitive changes contributed to decreased efficiency at work (slowness in problem solving, needing to reread professional literature, disorganized note-taking, and difficulty keeping track of her schedule and work tasks). Furthermore, Dr. N. was anxious and depressed. She reported difficulty falling asleep despite overwhelming fatigue. She worried about whether or not she had completed intended tasks, checking and double-checking herself throughout the day. She described herself as easily frustrated, lacking confidence, and more dependent than usual on her significant other. She continued to have headaches approximately 4 days a week. The neuropsychologist expected Dr. N. to maintain her job successfully and pursue premorbid career goals with assistance in adjusting self-expectations and information-processing habits.

Objectives

Understand the patient's diagnosis or condition

Know the person

Examples of Therapist's Internal Dialogue

"Given her GCS score and the fact that she did not lose consciousness, I can assume that her TBI was not severe and that she has a good prognosis for a full recovery."

"My guess is that Dr. N. is used to pushing herself, as evidenced by a rather speedy return to work after her hospitalization. Clearly, Dr. N. is a bright woman and has high expectations of herself. The cognitive inefficiencies since her injury must be frightening and confusing for her. I am glad that she appears to have social support."

Reason for Referral to Occupational Therapy Dr. N. was referred to occupational therapy for assistance in developing compensatory cognitive strategies and behavioral routines that would improve her efficiency at home and work. She was also referred to a psychologist for support and biofeedback to help her manage her headaches.	Appreciate the context	"Dr. N. was referred to an outpatient brain injury clinic that has expertise in serving people with mild TBI."
	Develop provisional hypotheses	"The literature suggests that clients with mild TBI are best served if the staff avoids overemphasizing concerns about permanent cognitive impairment and encourages clients to reinterpret symptoms as short term and manageable."
Assessment Process and Results • Interview and self-report questionnaire related to client's problems, inefficiencies, and concerns and how Dr. N. manages information at present • Interview regarding "typical day" • Observations of response and follow-through to orally presented homework.	Consider evaluation approach and methods	"Because I have reviewed Dr. N.'s neuropsychological evaluation results, it is not necessary or appropriate to reassess cognition. In fact, repeated assessment of similar domains might be detrimental, potentially overemphasizing cognitive inefficiencies that will likely be short term. Instead, I will try to find out about performance patterns and daily functioning."
	Interpret observations	"When I asked her to bring photographs to her next session, Dr. N. wrote a note to herself on one of approximately eight 'sticky notes' that were affixed to her wallet. She seems comfortable with note-taking, but I am guessing that her notes do little to supplant her memory as she likely does not find them when she needs them."
Occupational Therapy Problem List • Misattributions and misperceptions regarding personal competence • Inadequate use of external information-processing strategies • Disruption of personal routines, especially surrounding bedtime	Synthesize results	"Dr. N. did not link distracters, such as headache and fatigue, to episodes of memory failure and absent-mindedness or understand the implications of a limited working memory. I noticed that Dr. N. started writing lots of notes to herself but did not store or refer to them in a systematic manner. She worked off a mental plan each day but could not set priorities among multiple tasks. I am concerned about so much sleep in the early evening followed by more active household tasks. It is no wonder she is having difficulty with sleep."
Initial Occupational Therapy Goal List The anticipated length of treatment was four to six sessions. Dr. N. will complete 90% of work tasks on time by independently employing compensatory strategies including maintaining an up-to-date list of pending and completed tasks, using a daily schedule, and working on more difficult tasks in the morning when she is less fatigued. During the work week, Dr. N. will take a 10-minute rest break both midmorning and midafternoon, take a 30-minute break when arriving home from work, complete home management activities by 8 pm, and go to bed by 10 pm.	Develop intervention hypotheses	"There seem to be many contributions to Dr. N.'s problems right now, including the aftereffects of mild TBI, anxiety associated with misattributions related to the problems she is experiencing, and a rather limited repertoire of information-processing strategies. Interventions in occupational therapy will focus on helping her make correct attributions related to performance problems and broadening her repertoire of information-processing and compensatory organizational strategies."
	Consider the evidence	"There has been no empirical study of habit training for patients with mild TBI, but I have used this approach with other patients and seen them benefit."
	Select an intervention approach	"I will use an education-consultative approach, teaching her about information processing and helping her refine her information management strategies."
	Consider what will occur in therapy, how often, and for how long	"I think that she will need a relatively short duration of occupational therapy. I recommend that she come to therapy once per week for a few weeks, which will allow her to try out the strategies that we discuss, and we can work together to refine them accordingly."

Intervention

Dr. N. participated in five treatment sessions over 3 months, attending weekly sessions for 3 weeks and two follow-up sessions over 6 weeks. As cognitive inefficiencies were reframed as partly consequences of a working memory overload related to stress and the distraction of physical symptoms, Dr. N. eagerly explored methods to decrease the demands on internal information processing. She purchased a day planner and, with input from the therapist, established daily and weekly planning routines. Daily and weekly plans helped her set priorities among tasks and allocate time for leisure. She experimented with establishing routines for certain aspects of her "typical" day, scheduling breaks and allocating tasks with low cognitive demands to periods when her energy tended to be low. She changed her afterwork routine to set the timer for a 20–30-minute nap followed by a 30-minute walk. She also established a bedtime wind-down routine that decreased the amount of time she needed to fall asleep.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person
Appreciate the context

"Dr. N. had relatively mild or subtle impairments that changed her cognitive capacity. Similar to many bright individuals, Dr. N. had never thought about her own thinking strategies and did not have a broad repertoire of techniques that she could default to. Furthermore, in her attempts to understand changes resulting from her injury and their implications, Dr. N. failed to appreciate the cumulative effect that subtle impairments, stress, reliance on premorbid cognitive strategies, and distractions associated with pain exerted on her information processing. She was relieved to learn that she was not 'losing it' and quickly engaged in problem solving with me regarding possible changes in strategies and routines that would buoy her everyday performance. Her relatively brief involvement in treatment shows the benefit of holistic occupational therapy services in dramatically improving an individual's occupational functioning and quality of life."

Next Steps

Discharge from occupational therapy.

Anticipate present and future patient concerns

Decide whether the patient should continue or discontinue therapy and/or return in the future

"I do not expect that Dr. N. will need further therapy and anticipate that her overall functioning will continue to improve. She is making correct attributions related to cognitive inefficiencies and knows how and when to use compensatory strategies to lighten her load."

Clinical Reasoning in Occupational Therapy Practice

Taking Multiple Factors into Account in Treatment Planning for Mild Traumatic Brain Injury

Many people with mild traumatic brain injury return to normal functioning within 1–3 months without direct clinical intervention. What factors may have contributed to Dr. N.'s more lengthy recovery and persistence of symptoms? How might those factors affect your provision of occupational therapy services for Dr. N?

Summary Review Questions

1. What are some treatment planning implications related to age of onset of TBI? Describe the relevance of the cause of injury, developmental stage, and possible comorbidities.
2. In what ways do occupational therapists use information regarding mechanisms of injury of each patient in the clinical reasoning process? For example, how is the clinical presentation of a diffuse brain injury different from that of a focal brain injury? How can the therapist obtain information about the mechanisms of injury for a given patient?
3. Describe specific ways a patient's preinjury characteristics and background may affect rehabilitation and outcome.

4. Summarize terms used to describe patients in altered states of consciousness and why distinctions between these states are important to the occupational therapist.
5. What are some of the frequently cited predictors of prognosis and rehabilitation outcome after TBI? What are the occupational therapy implications of these predictors in planning treatment for patients in terms of goals, length of treatment, and needs of the family?
6. Describe the adjustment and adaptation process of the patient with TBI as compared to that of the family.

Detail what support and education patients and family members need from occupational therapy during each phase of recovery and adaptation.
7. How might the treatment approach used to optimize cognitive capacities and abilities for an inpatient be different from the treatment approach used in postacute rehabilitation or if the patient returns for services years later?
8. Compare Montgomery's (1995) multifactor explanation for disability after mild TBI with your own explanation of disability after severe TBI.

Glossary

Agitation—Subtype of delirium that is unique to survivors of TBI in altered states of consciousness in which there are excesses in behavior that include some combination of aggression, disinhibition, restlessness, and confusion.

Hematoma—Masses of blood confined to an organ or space caused by a broken blood vessel (Scott & Dow, 1995).

Mild traumatic brain injury—Brief alteration of mental status, such as confusion or disorientation, loss of memory lasting 24 hours or less, loss of consciousness lasting 30 minutes or less, and/or acute seizure after an impact to or forceful movement of the head (National Center for Injury Prevention and Control, 2003).

Post-traumatic amnesia—Inability to remember day-to-day events after brain injury including those

immediately before the injury (termed retrograde amnesia) and events that occur after the injury. The time elapsed from injury to recovery of continuous memory is one indicator used to describe the severity of brain damage.

Traumatic axonal injury—Axonal damage including shearing of axon clusters with reactive swelling and disconnection of strained and damaged axons as well as occasional tearing of axons. Previously termed diffuse axonal injury (DAI). Results from acceleration or deceleration injuries (Povlishock & Katz, 2005).

Traumatic brain injury—Alteration in brain function, or other evidence of brain pathology, caused by an external force (Menon et al., 2010).

Neurodegenerative Diseases

Susan J. Forwell, Lucinda Hugos, Lois F. Copperman, and Setareh Ghahari

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe four neurodegenerative diseases, including their courses and their symptoms.
2. Select appropriate standardized occupational therapy assessment and evaluation tools for clients with neurodegenerative diseases based on individual clients' characteristics and requirements.
3. Determine appropriate interventions for clients with neurodegenerative disease based on their individual characteristics, requirements, the occupational therapy evaluation, and research evidence to maintain independent function at the highest possible level.

Neurodegenerative diseases are generally chronic, potentially progressive, and frequently require coping with disability and the threat of future loss of function. The underlying pathologies of four neurodegenerative diseases are described in this chapter and are shown to have mechanisms that attack the peripheral nervous system and central nervous system (CNS), resulting in impairments and limitations that affect all aspects of life. Although not curable, research and medical advances, including rehabilitation interventions, have led to treatments that allow people to live longer, more productive lives.

This chapter begins with an overview of occupational therapy for persons with neurodegenerative diseases. Broad considerations related to evaluation, goal setting, and intervention are reviewed, followed by detailed discussions of multiple sclerosis (MS), Parkinson's disease (PD), amyotrophic lateral sclerosis (ALS), and Guillain-Barré syndrome (GBS).

OCCUPATIONAL THERAPY FOR NEURODEGENERATIVE DISEASES

The unique contribution of occupational therapy for persons with neurodegenerative diseases is the consistent focus on participation in occupations and activities that are important and valued in their lives. There is no script, because the nature, type, intensity, and context of these occupations are as individual as each person with a neurodegenerative disease. By listening to each client coupled with professional expertise in occupation, however, occupational therapists provide a repertoire of systematic processes and diverse solutions.

Occupational therapy may frequently begin at diagnosis and continue throughout the continuum of comprehensive care; it may take place in inpatient acute care, inpatient rehabilitation, outpatient, in-home, or long-term care settings. Inpatient acute treatment usually follows a relapse or deterioration in the disease and/or a crisis and is short and limited to stabilizing symptoms with medical interventions. Inpatient rehabilitation may last one to several weeks, with daily therapy sessions to deal with changed symptoms. Outpatient therapy is usually weekly, with 45–60-minute individual sessions to maximize independence in the home, minimize the effects of symptoms on daily activities, and identify and obtain needed equipment. Occupational therapy in long-term care facilities may be similar to inpatient rehabilitation for people adjusting to changing symptoms to ensure maintenance of function or developing palliative care plans for patients. Occupational therapists attend to their own coping and maintain objectivity, especially when treating clients whose disease course portends increasing disability or death.

Occupational Therapy Evaluation

The occupational therapy evaluation begins with an interview to gather information about the client's valued roles and occupations, relevant history of his or her neurodegenerative disease, previous and current strategies used to manage daily life, and the nature of present concerns or problems. This interview must be sensitive to the client's changing function and fear of the unknown and also should attempt to illuminate areas that may not naturally arise such as fatigue, depression, sexual function, and cognitive concerns that impact the person's occupations and social network. With this information, the therapist selects assessments and measurement tools that will provide in-depth information on occupational areas of concern. For persons with neurodegenerative disease, the content of these measures may be limited to a few or cover a broad spectrum of occupational performance areas (such as activities of daily living [ADL], instrumental activities of daily living [IADL], work, recreation, and spiritual occupations) and/or symptoms (such as spasticity, weakness, and memory difficulties).

Occupational Therapy Intervention Process

The unplanned and profound impact of neurodegenerative disease frequently makes realistic goal setting and intervention complex and requires sensitivity, flexibility, and astute negotiation skills on the part of the occupational therapist. The therapist frequently helps the client modify behaviors and assumptions of a lifetime while assisting the person and significant others to move toward realistic new goals. Given the progressive nature of many neurodegenerative diseases, regular reassessment and reordering of goals and priorities may be necessary as intervention proceeds.

Because of the complexity of disability present with neurodegenerative disease, intervening in one area may affect several other symptoms or problems. Fatigue, for instance, may be related to pain and weakness. Interventions must be individually appropriate and may involve significant others, especially as the disease progresses. The following is an overview of ways occupational therapy optimizes performance in key roles for persons with neurodegenerative diseases.

Self-Maintenance Roles

In ADL and IADL, the occupational therapist assists the client to maintain independence in priority activities, use specialized equipment, and participate using energy-conserving methods such as

- assisting in setting priorities
- education in areas such as how the disease process affects motor or cognitive changes
- recommendation of environmental modifications at home to promote safety and independence
- range of motion (ROM) and strength exercises to facilitate occupations like bathing
- behavior modification such as use of energy and time management techniques
- use of smart phone and electronic tablet technology for grocery lists and to provide reminders
- balancing independence with assistance from others

Self-Advancement Roles

The onset of neurodegenerative diseases may affect employment in or outside of the home. Many individuals can and should continue to work rather than pursue disability benefits by seeking advice from an occupational therapist. Continued employment is beneficial for financial independence, access to diverse health care choices, maintaining one's social network, and supporting a productive identity and self-esteem. Therapists critically review job expectations and suggest modifications to the environment, behavioral changes, equipment, resources, and recommendations to the individual or the employer.

Self-Enhancement Roles

Maintaining leisure pursuits as well as involvement in community, neighborhood, and family activities may be a high priority for individuals with neurodegenerative diseases but are often the first roles or occupations to be abandoned.

Modifying activities, creative transportation solutions, and use of web-based interfaces enable the individual to continue to be involved in meaningful occupations.

The tasks associated with self-maintenance, self-advancement, and self-enhancement roles are supported by new and emerging mainstream technology including smart phones, electronic tablets, and environmental controls. For persons with neurodegenerative diseases, many of these advances have erased differences in participation, minimized the need for or altered the way adapted equipment and environmental modifications are implemented, and facilitated access to previously unavailable information and personal connections. (Refer to Chapter 18 for an in-depth discussion on technology.) With technology, however, there are a number of challenges particularly related to the vast amount of information. Occupational therapists assist clients by providing credible websites that can address questions. Examples of trustworthy sites for both occupational therapists and clients are found in Resources 35-1.

Members and Roles of Rehabilitation Team

Depending on the type and severity of functional limitations, involvement of the rehabilitation team may vary but is essential in maintaining the highest level of function and quality of life (Martin & Wieler, 2003). When cognitive problems interfere with everyday occupations, psychologists, speech therapists, and occupational therapists are often consulted (Brown & Kraft, 2005). Depending on the setting, neuropsychologists may conduct in-depth cognitive assessments, and all three professionals may make recommendations and engage in intervention to augment or compensate for deficits in cognitive ability. Speech therapists may be involved when dysarthria or expressive communication is labored. In the presence of dysphagia, an occupational therapist, speech therapist, and/or dietician commonly form the intervention team. Social workers assist when there is a shift in financial or care needs and may help make applications to appropriate programs and counsel individuals and significant others to better cope with role change and demands. Physical changes as a result of weakness, spasticity, sensory problems, pain, and decreased endurance and ROM necessitate the services of physical therapy and occupational therapy to enhance mobility, upper extremity function, and overall conditioning to reduce falls and maintain participation. Occupational therapy services are used when individuals are having difficulty caring for themselves or their environment or engaging in work and/or familiar leisure occupations.

SPECIFIC NEURODEGENERATIVE DISEASES

The following sections focus on four neurodegenerative diseases: MS, PD, ALS, and GBS. The first section on MS provides detailed insights into the clinical reasoning for occupational therapy evaluation and treatment that may be applicable across conditions. For example, a client with ALS who has fatigue may benefit from the energy-conservation techniques described in the MS section. As such, issues occurring across neurodegenerative diseases are not elaborated upon in subsequent sections. Each neurological disorder, however, has its own underlying pathology, peculiarities, and prognosis. Understanding these issues helps the therapist develop appropriate intervention plans.

Multiple Sclerosis

MS is the most commonly diagnosed neurological disease that can cause disability in young adults. An estimated 400,000 people in the United States have MS (National Multiple Sclerosis Society [NMSS], 2012), and worldwide that number is 2.5 million (Multiple Sclerosis Trust, 2012). MS causes severe disability in some people, but many continue to lead active, productive lives and are not severely disabled (Rodriguez et al., 1994).

The precise cause of MS remains unknown. The present theory is that an environmental trigger or an infectious agent initiates the autoimmune response in people with genetic susceptibility (Trapp et al., 1998). The *multiple* in multiple sclerosis refers to both time and location of MS lesions and relapses. The *sclerosis* refers to the hardened or sclerotic plaques that are the scar tissue resulting from autoimmune attacks on the CNS (axons and myelin covering).

Axonal transection is considered as significant as demyelination in MS damage (McGavern et al., 2000). At least temporarily, demyelinated axons may remyelinate and provide conduction of nerve impulses. Transected axons are permanently destroyed and lose all potential for conduction. There is also evidence that disease activity continues even during periods that are clinically quiet or when no change in symptoms is apparent (Trapp et al., 1998). Inflammation occurs with demyelination and axonal damage, which may explain the rapid improvement often seen in treatment of relapses with corticosteroid anti-inflammatory agents.

Diagnosing Multiple Sclerosis

Individuals are typically diagnosed with MS between the ages of 15 and 50 years, although children are increasingly being diagnosed (Krupp & Macallister, 2005). Peak age of onset is at age 20–30 years. Women are two to three times as likely to have MS. Caucasians of northern European descent have the greatest risk of developing MS, whereas groups like the Norwegian Lapps, Inuit, and New Zealand Maoris who live in similar latitudes have no incidence of MS (NMSS, 2012).

The diagnosis of MS has evolved in the last 30 years owing to research and introduction of and advances in magnetic resonance imaging (MRI). The criteria, updated in 2010 and known as the Revised McDonald Criteria, are based on the combination of findings in the medical history, neurological examination, MRI results, and analysis of cerebrospinal fluid (Polman et al., 2011). Additional tests including visual evoked potential and blood tests may be used to corroborate evidence for the MS diagnosis or to rule out other possible diseases. Signs of MS include weakness, hyperreflexia, positive Babinski sign, dysmetria, nystagmus, and impaired vibratory or position sensation. The Expanded Disability Status Scale (Kurtzke, 1983) and the MS Functional Composite (MSFC) (Fischer et al., 2001) are the most commonly used impairment rating instruments in both clinical and research settings.

The Course of Multiple Sclerosis

The course of MS is typically categorized into four types: relapsing-remitting, secondary progressive, primary progressive, and progressive-relapsing. The relapsing-remitting

course, the most common at the time of diagnosis, produces clearly defined relapses of acute worsening of neurological function followed by partial or complete improvement and then stable periods of remission between attacks (Trapp et al., 1998). People with secondary progressive MS start with a relapsing-remitting course of up to 10–15 years. The secondary progressive course is typically diagnosed when there is continued neurological deterioration. People with primary progressive MS have continuously declining neurological function from onset (Lublin & Reingold, 1996). The progressive-relapsing course is much less common and characterized by continued disease progression with superimposed relapses. Clinically isolated syndrome or the first neurological episode that may result in a MS diagnosis is important to identify so that treatments to minimize disease progression can be provided.

Medical Developments Changing Health Care for Multiple Sclerosis

There have been a number of developments in our understanding of MS and the ways to assess and treat problems. The most significant clinical medical advances that have consumed enormous research efforts and impacted clinical practice are the advent of disease modifying therapies (DMTs). There are five self-injectable immune-modulating medications approved for use in the United States (NMSS, 2012): interferon beta-1a (Avonex), interferon beta-1b (Betaseron), interferon beta-1b (Extavia), glatiramer acetate (Copaxone), and interferon beta-1a (Rebif). These drugs have been shown to reduce the number of lesions evidenced on MRI and the frequency and severity of relapses, although a recent study suggests that the beta interferons do not impact long-term disability (Shirani et al., 2012). Natalizumab (Tysabri), a monthly injectable, is administered by qualified practitioners and is approved for relapsing-remitting MS. Mitoxantrone (Novantrone), an immunosuppressant rather than an immunomodulator, is rarely used because of significant side effects. Fingolimod (Gilenya) is the only DMT that is taken orally and is generally used when the response to injectable DMTs has diminished. Another class of medications, neurofunctional modifiers, targets underlying pathophysiology and MS symptoms (Panitch & Applebee, 2012). Of these drugs, dalfampridine has been shown to improve walking ability in people with any type of MS (Goodman et al., 2009).

Clients may want to discuss their medications with therapists, asking their opinion about the efficacy of medications. This is true particularly for DMTs because they are designed not to reverse disability but to slow disease progression. The therapist's responsibility is to understand and explain the importance of taking medications because the benefits may further contribute to maintaining employment and participating in high-priority occupations for a longer period.

The client may also want to discuss the proposed presence of chronic cerebrospinal venous insufficiency (CCSVI), a narrowing of veins in the neck and chest resulting in reduced blood drainage from the brain to the spinal cord (Food and Drug Administration [FDA], 2012), which some suggest is a cause or contributing factor in MS (Zamboni & Carinci, 2011). Despite an international research effort, to date, there remains little to no evidence to support a significant relationship between CCSVI and MS (FDA, 2012; Mayer et al., 2011). The scientific community and health care providers, however, are at odds with the public and persons with MS as social media often portray positive if not miraculous messages about its treatment (Ghahari & Forwell, 2012). The resulting tension has played out in doctors' offices and MS clinics, such that there is an increased distrust, and patients are reluctant to discuss their thoughts or questions about CCSVI.

With conditions such as MS that are not curable and have a progressive course, unproven remedies may emerge periodically. The difference today, compared to past remedies, is the presence of the Internet that enables diverse ideas, including unproven remedies, to capture widespread attention. Occupational therapists must keep abreast of emerging remedies and trends and the research associated with them. Then while communicating the evidence in a balanced way, it is important to listen, to be sensitive to clients' situations, to provide honest, compassionate, accurate responses to their questions, and not to extinguish hope.

Potential Social, Emotional, and Economic Consequences

A disease that strikes young adults has substantial economic, social, and emotional costs that influence all aspects of life. Between the ages of 20 and 40 years, people typically are entering the labor market, establishing themselves in careers, meeting life partners, and forming families. MS, with its common symptoms of fatigue, weakness, difficulties with prolonged standing or walking, cognitive problems, and depression, can impede productivity at work and home and social engagement.

A body of research is developing that may influence family planning. The relapse rate in MS significantly declines during pregnancy, increases in the first 3 months following childbirth, and thereafter returns to prepregnancy levels (Vukusic et al., 2004). It is also known that the incidence of MS is increased between monozygotic twins and from mother to daughter (Sadovnick et al., 1993). Therapists must be aware of this research to assist clients seeking information and refer as appropriate.

Planning for the future is a precarious undertaking given the unknown disease progression in MS. This uncertainty may explain an estimated lifetime prevalence of 50% for depression (Sá, 2007) and 35% for anxiety (Korostil & Feinstein, 2007). Research suggests gaining

control over the everyday management of MS is important for a satisfying life (Thorne, Paterson, & Russell, 2003).

Employment studies conducted prior to the development of DMTs showed that more than 70% of individuals with MS were out of the labor force 10–15 years after initial diagnosis (Kalb, 1996). Employment disability legislation such as the Americans with Disabilities Act, however, has resulted in opportunities for people to maintain productive paid employment for longer periods. It has been shown that persons with MS who leave the labor market are likely to have greater social isolation, psychological distress, and great burden of disease, as well as lower incomes and more limited access to health insurance than if they remain employed (Hakim et al., 2000). Maintaining employment has been shown to have high health-related quality of life (Buchanan, Haung, & Kaufman, 2012).

Symptoms Typically Addressed in Occupational Therapy

Occupational therapy intervention may reduce the impact of MS symptoms including weakness, sensory changes, balance disturbance, visual changes, bowel and bladder disturbance, cognitive changes, dysphagia, dizziness or vertigo, pain, ataxic gait, tremor, sexual dysfunction, depression, spasticity, and fatigue. A few of these are described here to exemplify therapy services.

Fatigue. Fatigue is the most common and pervasive MS symptom and a primary reason for referral to occupational therapy. It affects 60%–80% of people with MS and is a significant contributor to unemployment and overall disability (Julian et al., 2008). Fatigue in MS augments other MS symptoms, varies from slight to severe with worsening typically in the afternoon, and may be related to increased ambient and core body temperature (Leavitt et al., 2012).

Therapists must be aware of both the types of and factors contributing to fatigue in MS (see Definition 35-1) (Forwell et al., 2008; Stewart, Tran, & Bowling, 2007). Numerous screening measures for fatigue in MS include the Fatigue Severity Scale (Krupp et al., 1989), the Modified Fatigue Impact Scale (Fisk et al., 1994), and the Rochester Fatigue Diary (Schwid et al., 2002). The Comprehensive Fatigue Assessment Battery for MS (CFAB-MS) (Dawes, McCloy, & Forwell, 2010) was developed to identify factors contributing to MS fatigue and to guide clinicians' treatment decisions. Interventions are then directed at mitigating these factors as well as managing the primary MS fatigue.

Weakness. Weakness may occur in all parts of the body, resulting in referral to therapy. Weakness that increases after repeated muscle contractions or fatigue of the same muscle(s) is known as "nerve fiber fatigue." The cause is unknown but likely related to the conduction impairment in demyelinated nerves. An example is increased dorsiflexion weakness resulting in foot-drop after walking which may

---

Definition 35-1

Types of Fatigue in Multiple Sclerosis

Primary multiple sclerosis (MS) fatigue—Fatigue caused by MS disease process, the cause of which is poorly understood.

Secondary MS fatigue—Fatigue resulting from untreated MS problem(s) such as walking difficulties.

Physical fatigue—Fatigue experienced in the limbs, torso, head, and neck such that the body is tired.

Cognitive fatigue—Fatigue that affects one's thinking, planning, memory, word-finding, and decision-making processes such that the brain feels exhausted.

Local or focal fatigue—Motor fatigue caused by inefficient nerve conduction to a selected area of the body.

Generalized fatigue—An entire body experience; a complete exhaustion that is physical and cognitive.

Normal fatigue—Fatigue experienced by humans after excessive energy output or several hours of being awake (a normal day) that benefits from rest or sleep.

Factors Shown to Contribute to Fatigue in Multiple Sclerosis

- Other medical issues such as anemia, arthritis, cardiac problems, respiratory inefficiency, infection, and thyroid problems
- Sleep problems, often related to muscle spasms, depression, or urinary problems
- Depression
- Stress
- Anxiety
- Pain
- Deconditioning
- Side effects to medications
- Nutrition or caloric intake
- Ambulation difficulties

---

increase stumbling, especially on uneven surfaces. Coupled with decreased balanced and gait impairment, the risk of falls is increased by 58% (Cattaneo et al., 2002). After resting, conduction and muscle contraction are improved.

Cognition. Up to 65% of people with MS have cognitive problems that vary considerably in severity (Patti, 2009) and that appear related to loss of brain volume, particularly grey matter (Hasan et al., 2011). It is estimated that 5%–10% of those with MS have cognitive problems that interfere with participation in everyday occupations (NMSS, 2012). Cognitive problems are seen at all stages of the disease and are significant in leading to unemployment in MS (Johnson, Bamer, & Fraser, 2009).

Common cognitive problems for people with MS include memory (acquiring and retaining new information);

word finding; attention, concentration, and executive function; and slowed information-processing speed (NMSS, 2012). Perceptual-cognitive problems may also occur such as visual-spatial impairments that might result in a tendency to get lost or a history of motor vehicle accidents. Cognitive issues in MS do not correlate with physical disability but are influenced by depression, stress, anxiety, and fatigue (Bol et al., 2010) and vary during the day, increasing in the afternoon or when sustained mental concentration is required (Krupp & Lekins, 2000). Both individuals and their families may be unaware that cognitive problems such as reduced insight and inflexible thinking are related to the disease and should not be mistaken for personality or psychological issues.

Many areas of cognition remain intact such that screens such as the Mini-Mental State Exam lack sensitivity to detect such problems (Beatty & Goodkin, 1990). Consequently, it is necessary to complete a lengthy neuropsychological evaluation. Fortunately, however, a 90-minute, six-test neuropsychological assessment battery was designed specifically for MS called the Minimal Assessment of Cognitive Function in MS (MACFIMS) (Benedict et al., 2002). In addition, three screening tools, the MS Neuropsychological Screening Questionnaire (Benedict et al., 2004), the Paced Auditory Serial Addition Test, and the Symbol Digit Modalities Test (SDMT) are quick to administer and have been found to be sensitive in MS (Foley et al., 2012). Of these, the oral version of the SDMT is considered a better screen because it has good test–retest reliability and is a predictor of unemployment. By identifying cognitive impairments, individualized compensation strategies can be recommended to reduce their impact on everyday life.

Pain. Pain is estimated to occur in 40%–60% of people with MS, with 48% reporting chronic pain (NMSS, 2012). Pain negatively impacts quality of life and independence (Douglas, Wollin, & Windsor, 2009) and is not related to age, length of time with MS, or degree of disability, although twice as many women report having pain than men. Pain in MS can be localized as in trigeminal neuralgia, Lhermitte's sign (a stabbing, electric shock along the spine when neck forward flexes), or pain as a result of spasticity (Solaro et al., 2004). Pain directly caused by the neurological lesions is considered primary to MS and is treated with medications. Pain secondary to MS is often due to posture, gait, and positioning problems and can be relieved by therapy and proper mobility equipment.

Spasticity. Spasticity in MS is usually greater in the lower extremities and may be source of pain, interrupted sleep, and activity limitations. Up to 30% of patients eliminate or modify activities because of spasticity (Rizzo et al., 2004). Factors that may precipitate or augment spasticity include infections, distended bladder, stress, or disease progression (Schapiro, 2011).

Tremor and Ataxia. Intention tremor is the most common tremor seen in MS and is one of the most difficult problems to manage (NMSS, 2012). As an activity progresses and the extremity approaches the target (a point when the greatest precision is required), the tremor is at its worse. Intention tremor occurs in the upper extremities but may also manifest in the lower extremities, torso, and neck. A comprehensive occupational therapy assessment was developed, the Multidimensional Assessment of Tremor (MAT), which measures both the severity and functional impact of intention tremor (Daudrich, Hurl, & Forwell, 2010).

Ataxia presents in the trunk and lower extremities where postural responses tend to occur before upper extremity movements. The functional challenges of ataxia are further magnified because of the multiple joints involved in the ataxic movement.

Dysphagia. Research on swallowing problems in MS that did not use videofluoroscopy (VF) suggested that 34%–43% of the individuals studied experienced dysphagia, although only half of these patients reported swallowing difficulties (Calcagno et al., 2002; Thomas & Wiles, 1999). When VF was used, however, swallowing abnormalities were identified that were not detected on non-VF swallow assessment (Weiser et al., 2002). These studies suggest that severity of disease and cerebellar or brainstem involvement are risk factors for dysphagia. Occupational therapists should routinely screen for choking, aspiration, and swallowing difficulties, for which additional information can be found in Chapter 43.

Adjusting to Multiple Sclerosis

Although only a small percentage of people with MS are severely disabled, the diagnosis can be devastating. The need to adjust to changing symptoms and impairments and the fear of and uncertainty about the disease process affect self-esteem, relationships, sexuality, physical activities, vocational goals, and recreational interests. From questions about pregnancy to cognitive changes influencing competence or safety, MS affects every role and relationship. The variability of the disease and the hidden nature of many symptoms, such as cognitive changes and fatigue, often make it difficult and uncomfortable to explain to friends, coworkers, and family members.

Each person's reaction to MS events varies and has implications for adjustment. Research has shown that emotion-focused coping techniques were used more often by those experiencing a MS relapse, whereas problem solving and using one's social network were used when in remission (Pakenham, 1999). This is supported by evidence that emotional involvement was a marginal indicator of new MS lesions as shown on MRI (Mohr et al., 2002). It has also been demonstrated that a greater use of problem-solving strategies appears to be an indicator of better psychological adjustment (Warren, Warren, & Cockerill, 1991).

For example, fewer lesions were found in persons who participated in a stress management program as compared to when the program was discontinued (Mohr et al., 2012).

Initially, people may be preoccupied with their diagnosis because it represents a major change that may challenge assumptions about the future. As time passes, particularly if individuals with MS return to full function, they frequently ignore the diagnosis and pay little attention to MS issues. As long as the inattention does not result in adverse decisions, this may be a healthy attitude. The therapist helps clients process the implications of changes and identifies modifications to minimize their effects. Information about new symptoms may be all a person needs to make a successful adjustment.

Occupational Therapy Evaluation

During the evaluation process of a person with MS, there are unique features that must be understood and incorporated from the individual's history with MS and from life experience. Occupational therapy assessment begins with an interview about the person's goals for therapy and a brief history of symptoms and treatment since diagnosis. This gives the therapist an understanding of the disease course and the person's past coping style. Throughout the interview, the therapist listens for hints of cognitive difficulties, being mindful that there may be further significant hidden impairments. Brief questions regarding dizziness, thinking problems, motivation or interest in doing things, numbness and tingling, manual dexterity, prolonged walking and standing, employment, home physical and social environment, leisure interests, bladder problems, ADL, IADL, energy, sleeping pattern, muscle cramping, pain, fine-motor activities, falling and balance problems, and vision can provide clues to the specific assessments that are likely to be relevant. If cognitive problems are present, a family member or significant other should be encouraged to attend the evaluation with the client's consent.

Analysis of Occupational Performance: Tools and Methods. The initial interview gives the therapist an indication of the evaluation tools and methods to use including

- Canadian Occupational Performance Measure (COPM) (Law et al., 2005; Lexell, Iwarrson, & Lexell, 2006)
- Modified Fatigue Impact Scale to screen for fatigue severity (Fisk et al., 1994)
- 6-Minute Walk Test to assess endurance and fatigue (Pankoff et al., 2000)
- Multiple Sclerosis Walking Scale to assess mobility concerns (Hobart et al., 2003)
- Sleep history questionnaire or diary (Paralyzed Veterans of America [PVA], 1998)
- Home assessment
- Beck Depression Inventory-Fast Screen to assess depression (Benedict et al., 2003)
- MS Neuropsychological Screening Questionnaire to screen cognition (Benedict et al., 2004)

- Mobility section of the Functional Independence Measure (FIM™) to assess gait or bed mobility
- ADL, IADL, and dysphagia assessments
- Nine-Hole Peg Test or Purdue Pegboard to assess dexterity (see Chapter 37)
- Semmes-Weinstein Monofilaments to test sensation (see Chapter 9)
- Manual muscle testing (MMT), ROM testing, and grip strength (dynamometry) (see Chapter 7)
- Vestibular evaluation

There are also composite evaluations with a series of assessments that provide a more detailed or diverse estimation of an individual's ability. Examples are the MACFIMS (Benedict et al., 2002) for cognition; the MAT for intention tremor (Daudrich, Hurl, & Forwell, 2010); the MSFC (Fischer et al., 2001) for disability status; the CFAB-MS for fatigue (Dawes, McCloy, & Forwell, 2010); and the Brain Injury Visual Assessment Battery for Adults (biVABA) for vision (Warren, 1999).

Administering such measures requires the therapist to accurately interpret findings in the context of the client's situation and the complex interrelationship between functional challenges and symptoms. For example, therapists must differentiate among various types of fatigue by considering the results of several assessments. A high score on a depression index may indicate that depression is contributing to fatigue, whereas slow times on the 6-Minute Walk Test may also suggest a nerve fiber or motor fatigue component. Information from a sleep questionnaire may indicate that disturbed sleep caused by urinary frequency is a factor in daytime fatigue. It is common for persons with MS to have several sources of fatigue (Forwell et al., 2008), requiring intervention from multiple health care professionals.

Occupational Therapy Intervention Process

Clients' priorities and interests are the cornerstone of goal setting and treatment planning, necessitating a collaborative process to achieve realistic and satisfying outcomes. Frequently, both the person with MS and the referring provider mistakenly believe they have to live with problems as a result of MS that, in fact, are treatable through therapy. The intervention plan must then take into account the unique issues of individuals with MS. For example, Finlayson (2004) suggests that, for older adults with MS, the therapist must ensure they feel a sense of control over their future, work with families affected by the MS, and advocate for enhanced community support options. In addition, treatment that focuses on isolated symptoms is unlikely to be effective, and thus working with and coordinating intervention of the health care team is often indicated. Evidence Table 35-1 presents the best evidence for occupational therapy intervention for MS. Special considerations for activity strategies, equipment and environmental modifications, exercise programs, symptom management, and employment issues are discussed below.

Evidence Table 35-1 | Best Evidence for Occupational Therapy Practice Regarding Intervention Related to Multiple Sclerosis (MS)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Efficacy and effectiveness of an energy-conservation course on fatigue, quality of life (QOL), and self-efficacy for persons with multiple sclerosis (MS)	Community-based energy conservation course including but not limited to importance of rest, effective communication, proper body mechanics, and modification of environments	One hundred sixty-nine persons with MS: 140 women, 29 men; mean age = 48 years	Energy conservation course for 2 hours per week for 6 weeks	Randomized control trial with a crossover design. Level: IA1a	The energy-conservation course significantly reduced the impact of the fatigue, improved vitality, and increased self-efficacy for performing energy conservation strategies.	Results were established at $p < 0.05$. Using Cohen's d for repeated measures, moderate to large effect sizes were shown for the fatigue subscales of cognition (0.52–0.57), physical (0.74–0.90), and social (0.69–0.77) as well as for three of eight subscales on the Short form-36 including role-physical (0.52–0.63), vitality (0.99–1.14), and mental health (0.53–0.60).	Mathiowetz et al. (2005)
Nintendo Wii Fit and its effect on physical activity behavior	Exercise program three times per week that included yoga, balance, strength, and aerobic training using Wii Fit in each session. Participants were telephoned to monitor adverse events and to encourage increase in the duration and frequency of using Wii Fit for the first 7 weeks.	Thirty participants: 23 women, 7 men; with relapsing-remitting MS; living within 40 miles of the University of Illinois, 18–60 years old, and able to walk 25 feet with or without a cane. Excluded if doing 2.5+ hours of activity per week, low vision, lower extremity amputation, pregnant, severe fatigue or depression, or cardiopulmonary disease	Wii Fit exercise program for 14 weeks, 3 days per week	One-group repeated measures design with 5-week baseline control period and 2-week Wii set-up and training followed by 14-week intervention. Level: IIIB3b	Balance and strength were significantly improved at week 7 but at week 14, physical activity levels declined relative to week 7, and the difference was no longer significant compared with the control period.	Results were determined using multi-variate analysis of variance and showed physical activity improved at 14 weeks (p = .001; ES = 0.65) though declined at 21 weeks; self-efficacy progressively improved to 21 weeks (p = 0.025); and no difference in QOL or level of fatigue.	Plow & Finlayson (2011)
Using personal digital assistants (PDAs) as assistive technology for people with MS with cognitive impairment	Training to use a PDA as an organizer (i.e., calendar, alarm, contact list and "to do" list) and transferring data from computer to PDA)	Twenty people with MS: 16 women, 4 men; living in the community; having cognitive limitations; describing cognition as one of their major problems and having vision, hearing, and dexterity sufficient to use a PDA	After an 8-week baseline (no intervention) period, home visits for PDA training were completed over 3 weeks: two for 60 minutes, two for 90 minutes. Then 8 weeks of PDA usage.	One group pre and post treatment repeated measures; testing at weeks 1, 10, 12 and 21. Level: IIIB3b	Functional performance increased significantly with PDA use, which was maintained at 8-week follow-up.	Repeated-measures analysis of variance showed significant results on the COPM ($F = 96.02$, $p < 0.001$, for performance; $F = 104.92$, $p < 0.001$, for satisfaction). There was significant improvement during treatment, with a large effect size ($p < 0.001$, $r = 0.79$). The posttreatment scores remained higher than pretreatment.	Gentry (2008)

Activity Strategies and Energy Conservation. Based on the comprehensive assessment, the fatigue intervention begins with the occupational therapist providing explanations of each relevant underlying type and factor of fatigue impacting the individual (Definition 35-1). The client then completes a detailed activity diary that can be done on well-selected apps and makes a list of goals and priorities (PVA, 1998). The therapist and client use the diary to systematically analyze daily work, home, and leisure activities and understand rest–activity ratios. Identifying activity and environmental modifications, equipment, and technology to address fatigue issues then follows. Energy conservation strategies and exercise routines will also be incorporated to help the individual perform valued occupations and activities through optimal energy management techniques. Refer to the Definition 35-2 for examples of energy management strategies designed to enable persons with MS to use their limited energy on useful, meaningful activities and to exercise choice and control in everyday occupations.

Research has demonstrated the effectiveness of a face-to-face occupational therapy–led group intervention (Packer, Brink, & Sauriol, 1995) in energy conservation strategies for MS (Mathiowetz et al., 2005). A teleconference format (Finlayson & Holberg, 2007) and an online version of this energy conservation program (Ghahari, Packer, & Passmore, 2010) have also been shown to be effective. Further, there is a 6-week group video program called *Fatigue: Take Control!* that has been tested with positive outcomes (Hugos et al., 2010). In addition to these programs, occupational therapists should collaborate with physical therapists who treat fatigue through obtaining gait equipment, recommending appropriate aerobic exercise routines, and educating on the difference between energy expenditure during functional activities and exercise to increase endurance. With any of these interventions, written recommendations and summaries should be provided. Clients then return to occupational therapy for follow-up in 2–3 months, or sooner if changes in symptoms present or there are difficulties implementing strategies.

Equipment, Behavioral, and Environmental Modifications. Equipment, environmental, and behavioral modifications help persons with MS compensate for weakness, spasticity, tremor, fatigue, ataxia, and cognitive problems. Many standard pieces of adaptive equipment are helpful, (for example, scooters, electric wheelchairs, bath benches, shower chairs, and bed poles) in limiting fatigue and mitigating functional limitations related to weakness and spasticity. Because of fatigue, self-propelling manual wheelchairs are not indicated. As noted earlier, mainstream technology such as computers, motion sensors, and smart devices that have audio options reduce the impact of many MS symptoms. When appropriate, the therapist identifies consumer technology and adaptive equipment and facilitates equipment trials.

Behavioral changes, such as moving an exercise program from lunch to after work and incorporating a lunchtime

---

Definition 35-2

Energy Conservation

To save, conserve, or reduce consumption or expenditure of energy. An individual's conservation of energy and optimization of endurance during participation in occupations refers to efficiently using available energy while decreasing unnecessary expenditure. Examples of strategies used to conserve personal energy reservoir include employing a "brains rather than brawn" approach such as:

- Use high, low, and smart technology appropriately.
  - Use smart devices and helpful apps to save steps, such as voice options to replace touch typing.
  - Decrease prolonged standing and walking by modifying tasks to be done sitting.
  - Maintain a cooler body temperature by using, for example, an air conditioner, cooling wraps fitted comfortably at wrist or on neck or a cooling vest when active (Fig. 35-1).
  - Reduce the energy required to walk by using an ankle–foot orthosis, cane, or walker.
  - Obtain seating systems for trunk support in wheelchairs.
  - For work, use a fitted ergonomic chair with armrests, correct height, and back support.
- Plan approaches to occupation and daily schedule.
  - Do important activities in the morning.
  - Break large time-consuming activities into smaller tasks and do one task at a time.
- Problem solve using a step-by-step approach.
  - Use techniques to maintain cooler body temperature, for example layer clothing, have warm versus hot showers, and avoid electric blankets or down comforters when sleeping.
- Delegate necessary highly energy-consuming occupations.
- Manage environmental controls and modifications.
  - Adjust heights of work surfaces to avoid strain.
  - Avoids stairs in daily activities.
- Simplify or eliminate tasks.
  - Avoid multitasking.
  - Have tools required for the task readily available in arm's reach.
- Educate others about your energy limits.
  - Teach others about increased body temperature and effects on reduced function and energy.
  - Work with others to accomplish a task, sharing the energy expenditure.
- Punctuate activities with rest.
  - Alternate activity with intervals of rest, such as walking, sitting, and then walking.

Figure 35-1 Woman in cooling vest vacuuming. Sensitivity to heat when participating in chosen occupation(s) can be mitigated by wearing cooling garments, such as cooling vests (as above) or cooling wraps comfortably worn on the neck or around the wrists.

nap, frequently improve an individual's ability to perform productively. Another example is using the elevator at work (rather than climbing stairs for exercise) to maximize energy for employment and engaging in exercise at another time. Environmental modifications may help in areas as diverse as maintaining independence in ADL to ensuring continued employment and involvement in the community. Home and/or work visits may be necessary to identify environmental modifications. The combination of the right equipment, behavior changes, and environmental modifications depend on the individual's needs, resources, and personal preferences. Scheduled follow-ups are recommended to determine the need for new or further modifications as changes occur.

Exercise Programs. Occupational therapists teach clients to monitor the effects of any MS exercise program on both fatigue and their ability to perform high-priority activities. Two MS symptoms, fatigue and spasticity, often decrease with regular exercise. A structured aerobic program has been shown to reduce fatigue and increase endurance (Kileff, 2005), and spasticity may be managed with a stretching program and rhythmic exercises such as walking or cycling. Therapists can be instrumental in assisting the client to integrate exercise into weekly routines so that exercise does not reduce ability to perform other activities.

An aerobic home program will vary based on several considerations. An employed individual may select a home stationary biking program for 20 minutes three or four times a week instead of a water exercise program at the closest cool water pool. Stretching exercises emphasize fewer repetitions and longer hold. Strengthening programs do not reverse neurological weakness resulting from MS, but they can reduce deconditioning as a result of weakness. A realistic exercise program performed regularly is more desirable than an ideal program that is never followed. Good illustrations and written instructions should accompany every home program.

Spasticity Interventions. The appropriate intervention for spasticity depends on the severity and the extent to which it interferes with function and impacts quality of life (Rizzo et al., 2004). In addition to stretching exercises, adapted dressing techniques may prove helpful, such as using a stool to maintain hip flexion to decrease extensor spasm and/or using dressing sticks to compensate for inability to reach the feet. A standing home program may also be employed, using a standing frame for 30–60 minutes per day. Other interventions include resting splints and posture and positioning techniques, such as bringing the hips into 90° or more of flexion to decrease extensor tone in the lower extremities (PVA, 2003).

Therapists should be familiar with the standard medications for spasticity, such as baclofen and tizanidine, and their side effect of drowsiness that may increase fatigue (PVA, 2003). Botox® (onabotulinumtoxin), a neurotoxin, results in relaxation of the targeted muscle and can last up to 3 months (Hyman et al., 2000). The intrathecal baclofen pump has been shown to reduce pain and improve function and quality of life for people with MS with moderate to severe spasticity (Erwin et al., 2011). Should a baclofen pump be indicated, the therapist may be involved in assessment prior to pump implantation and reevaluation following implantation.

Cognitive Compensation. Occupational therapy intervention for clients with cognitive problems focuses on compensation for deficits and inefficiencies in order to manage everyday life. Treating fatigue often improves self-reported cognitive performance (Diamond et al., 2008). Caution should be exercised in disclosing cognitive issues to employers, with careful consideration given to each circumstance. Education of clients and families about cognition is often beneficial. Awareness that these problems are due to MS and not personality eases stress and optimizes receptivity to modifications.

Interventions that include group therapy, stress management, personal digital assistants, electronic memory aids, and cognitive-behavioral therapy have been shown to

have positive effects on cognitive function in MS (Brown & Kraft, 2005; Gentry, 2008; Johnson et al., 2009). Examples of cognitive techniques, strategies, and modifications include

- scheduling work responsibilities and cognitively demanding tasks to reduce the influence of the cognitive problems; for example, planning to do these in the morning or after breaks
- maintaining a paper, smart phone, or electronic diary as a memory aid and to help identify the timing of cognitive and fatigue problems as well as the environment in which these problems occur
- changing the environment to reduce distractions and interruptions and promote organization
- using problem-solving strategies for decision making rather than emotion-focused strategies
- supporting involvement of social network to assist with problem solving
- using step-by-step written home and/or work directions
- doing one activity at a time and avoiding multitasking
- incorporating assistive technology to improve function in high-order IADL, such as money management and bill payment, family schedules, and transportation options
- increasing time allotted for an activity and reducing the number of activities planned or undertaken
- delegating difficult tasks to others
- using repetition in the learning process
- assessing driving safety and recommending appropriate testing and interventions

Pain Intervention. For pain related to weakness or spasticity, interventions such as posture training, ergonomic seating, stretching, supportive splinting, and focal heat modalities on muscle trigger points may be effective. An ergonomic workstation (such as ergonomic chair with armrests, headsets, and mouse and keyboard trays) tailored to the individual can be beneficial. Exercise and mobility equipment to correct gait problems may also assist to minimize pain.

Tremor and Ataxia Intervention. The hallmarks of occupational therapy intervention for tremor and ataxia are proximal stabilization or support, modified approach to occupations, and adapted equipment and orthoses. Proximal stabilization includes supporting the trunk and larger joints of the upper and lower extremities are. For example, at mealtime, position the client's torso against the table with arms resting on the table (Gillen, 2000). Because the position is sitting, the lower extremities are supported, the trunk is stabilized by leaning against the table, and the shoulders and elbows are supported. A modified approach may be the use of hand-over-hand guidance for writing or dialing a cell phone. If one hand is unaffected by tremor, consider retraining the unaffected hand as tolerated. Orthoses might include a cervical collar to reduce the travel of the head and neck or wrist splints to minimize travel

and number of joints in motion. Weights on the wrist, for example, may also serve to dampen tremor (NMSS, 2012) but may contribute to fatigue. Peripheral cooling of the forearm has been shown to reduce tremor amplitude and frequency and increase functional capacity for up to 30 minutes (Feys et al., 2005). An occupational therapy intervention program, the Step-wise Approach to the Treatment of Intention Tremor (Hawes, Billups, & Forwell, 2010), developed specifically for MS was pilot tested and has shown some promising results.

Employment Modifications. The problems described in the preceding sections may affect the job performance of persons with MS. Modifications to maintain employment, productivity, and satisfaction may include

- changing the times at which tasks are performed
- limiting prolonged walking, standing, and travel by using conference calls, Internet, and apps
- using appropriate gait equipment and powered mobility devices
- changing to an office that is convenient to frequent activities
- modifying work hours
- working completely or partly at home
- arranging a space to rest periodically

Perspective in Intervention

Although referral to occupational therapy services can occur across the MS continuum, often it is those with relatively severe disability that are typically referred for therapy. Unfortunately, by that time, a tremendous window of opportunity has passed for interventions such as improving ambulation skills (and thereby reducing or delaying need for wheeled mobility aids), attending to fatigue and energy management and on-the-job modifications to support continued employment, and advancing self-management skills for living everyday with MS. It is essential that therapists educate physicians and other referral sources about the needs and benefits for early intervention for persons with MS.

It must also be recognized that people with MS, as well as those with other chronic conditions, play an integral role in the self-management of their conditions (Bodenheimer et al., 2002). Individuals with MS understand their needs and unique circumstances and can provide information that is complementary to the health professionals' knowledge. Research shows that those who participate in self-management programs have a higher quality of life and make better use of health professionals' time (Barlow, Turner, & Wright, 2000). There is also evidence that people with MS with poorly developed self-management skills feel less control and more uncertainty, have increased feelings of depression and hopelessness, and experience poor psychological adjustment (Bishop, Frain, & Tschopp, 2008). Self-management decisions for persons with MS involves taking control through

planned strategies and routines and balancing the health care providers' expectations and advice against the practicality in their lives (Thorne, Paterson, & Russell 2003). It is for this reason that self-management is an important part of health care and critical for those living with MS everyday.

Parkinson's Disease

PD is a progressive, variable condition. It is most common in later adult years, with the mean age of onset of 55–60 years. The incidence of PD is 1%, or 1,000 per 100,000 persons in people older than 60 years of age (de Lau & Breteler, 2006). PD is gradual at onset, and symptoms may take years to develop (Baker & Graham, 2004). PD is defined by the three cardinal signs of tremor, rigidity, and bradykinesia. Postural instability is often added to this list (Conley & Kirchner, 1999). Tremor, often the first complaint, is a resting tremor that increases with stress and may present as pill-rolling (Gelb, Oliver, & Gilman, 1999). Rigidity tends to occur at more advanced stages of PD (Gelb, Oliver, & Gilman, 1999). Bradykinesia causes a lack of facial expression, or "mask face," and affects walking, involvement in activities, and eye blink (Conley & Kirchner, 1999). Postural instability begins with reduced arm swing, head and trunk leaning forward, and shorter strides that progress to a shuffling gait. Lack of postural reflexes results in falls and akinesia or episodes of motoric "freezing" that impede spontaneous initiation of walking, turning, and crossing thresholds (Hass et al., 2005; Ward & Robertson, 2004).

Other symptoms of PD, particularly in the middle to later stages, include swallowing changes, soft speech, festinating gait, autonomic deficits, constipation, fatigue, sleep disturbances, psychiatric complications (particularly depression and anxiety), and dementia (Shulman et al., 2002; Verbaan et al., 2007). When festinating gait is coupled with motoric "freezing" of gait, 37% report an increased occurrence of falls (Giladi et al., 2001). Swallowing problems can occur at any point in the course of PD and are not related to disease severity. These include difficulties with delayed swallow reflex, and abnormal tongue control that result in residues of food materials being left in the mouth (Plowman-Prine et al., 2009).

Dementia occurs in 15%–20% of persons with PD and tends to be among those who are older at diagnosis, have a history of PD, and experience depression (Aarsland et al., 1996). The cognitive functions most affected are motor planning, abstract reasoning, concentration, organizing, and sequencing (Ward & Robertson, 2004). It has been shown that persons with PD rely on external cues, feedback, and repetition when learning new tasks (Ward & Robertson, 2004).

The cause of PD is thought to stem from both hereditary and environmental factors. Hereditary factors have been linked to a chromosome 4 mutation in 5%–10% of cases, although the contribution of this mutation to PD is uncertain (Conley & Kirchner, 1999). Environmental factors implicated in PD include exposure to well water and pesticides and living on a farm (Marder et al., 1998).

The pathogenesis is related to loss of dopaminergic neurons of the substantia nigra that provide input to the corpus striatum and, in part, modulate the thalamus and its connections to the motor cortex (Ward & Robertson, 2004). Biochemical anomalies in the basal ganglia are also present (Conley & Kirchner, 1999). Medications to compensate for dopamine loss are effective for a limited period followed by "wearing off," particularly in later stages, and may result in difficult "on/off" fluctuations (Varanese et al., 2010). It is essential that occupational therapy intervention account for these fluctuations.

Diagnosing Parkinson's Disease

In autopsy studies, PD has been shown to be misdiagnosed in 25% of cases (Calne, 1995). In part, the difficulty is a result of the challenges associated with developing and subsequent lack of definitive preclinical biological markers (Wu, Le, & Jankovic, 2011). At present, diagnosis is based on clinical evidence using clinical diagnostic criteria specifically related to the cardinal signs of tremor, rigidity, bradykinesia, and postural stability (Jankovic, 2008).

The Course of Parkinson's Disease

PD has been described as having either five stages (Hoehn & Yahr, 1967) or three stages (Bradley, 1996) (Definition 35-3). These stages are broadly described by the presence of symptoms, functional implications, and response to medications.

Definition 35-3

Stages of Parkinson's Disease

Stages as Defined by Hoehn and Yahr (1967)

Stage 1: Unilateral symptoms, no or minimal functional implications, usually a resting tremor.

Stage 2: Midline or bilateral symptom involvement, no balance difficulty, mild problems with trunk mobility and postural reflexes.

Stage 3: Postural instability, mild to moderate functional disability.

Stage 4: Postural instability increasing, though able to walk; functional disability increases, interfering with activities of daily living (ADL); decreased manipulation and dexterity.

Stage 5: Confined to wheelchair or bed.

Stages as Defined by Bradley (1996)

Early: Not disabling; monosymptomatic; responds well to medication; may remain at this level for years.

Nonfluctuating: Some disability; levodopa added to medication regimen; 80% of function is restored.

Fluctuating: Function limited; side effects to levodopa; difficult-to-control symptoms, postural instability, and gait disturbance become debilitating.

Potential Emotional, Social, and Economic Consequences

In the initial stages of PD, the degree of physical disability is minimal. The emotional burden and social consequences, however, can be marked. Resting tremor, rarely resulting in motor disability, is a frequent source of psychological distress, with many individuals reporting feeling embarrassed or self-conscious (Uitti, 1998). In later stages, tremor and rigidity were highly correlated with distress and reduced quality of life (Peto, Jenkinson, & Fitzpatrick, 1995). Other predictors of poor quality of life are depression, cognitive decline, social isolation, sleep disorders, mobility issues, fatigue, confusion, urinary incontinence, unpredictable on/off fluctuations, pain, and increasing dependence (Rahman et al., 2008). Major depression was found in 45% of those with PD, suggesting that early identification and intervention are crucial (Karlson et al., 1999).

The social consequences of PD are striking. In early stages, for example, handwriting may be shaky and micrographic, reducing legibility (Gillen, 2000). In intermediate and later stages, the voice softens and becomes monotone. Reduced facial expression and minimal hand gesturing contribute to reduced communication and negative messaging (Tickle-Degnen, 2006). The person with PD may have waning interest in social and previously enjoyed leisure activities. PD challenges relationships and roles in families. Both the individual and family members, typically a spouse or adult child, may have feelings of guilt, despair, and anger as caregiving increases (Baker & Graham, 2004).

Economic implications of PD are frequently related to medications, wheeled mobility, accessibility modifications, self-care and safety equipment, and in-home support. If employed, increasing limitations may require employment modifications, early retirement, and application for disability benefits that are usually accompanied by loss of income (Schrag & Banks, 2006). People with PD stop working 5–6 years earlier than the normal population (Dick et al., 2007). The caregiver is likely elderly and may require assistance and respite, which has further financial implications, and if required, long-term care placement is costly.

Occupational Therapy Evaluation

In the early stages of PD, occupational therapy is rarely indicated unless there are functional limitations or psychological issues. At this stage, it is recommended that interests and roles be maintained within and outside of the home, including employment, social activities, and driving (Baker & Graham, 2004). Occupational therapy is most often required in the intermediate and later stages of the disease (Hoehn & Yahr, 1967; stages 3–5). Evaluation should include a brief history and, in the intermediate stages, should identify occupational performance problems related to reduced mobility, safety issues, swallowing, fine-motor incoordination, slowed movements, cogwheel

rigidity, and depressed affect. A standardized quality of life measure, the Parkinson Disease Questionnaire–39, may be a useful screening tool. Its 39 items are clustered into eight domains relevant to occupational therapy: mobility, ADL, emotional well-being, stigma, social support, cognition, communication, and bodily discomfort (Peto, Jenkinson, & Fitzpatrick, 1995). The therapist should also note occupations that have been eliminated (Gillen, 2000). Examples of impairments and limitations in activities that may be included in evaluation are

- fine-motor activities at home, at work, and in the community (writing, eating, shaving, and fastening)
- safe mobility, such as walking, stair climbing, driving, and moving from sit to stand
- fatigue that affects most activities
- work evaluation at early stages of PD to reduce the risk of unemployment or early retirement
- bradykinesia, postural instability, and rigidity that limit participation in self-care, household tasks, and grocery shopping, etc.
- swallowing or other mealtime problems that prolong eating and reduce intake
- cognitive problems that affect activities associated with usual roles
- sexual activity limitations related to bradykinesia, fatigue, depression, and psychosocial issues
- sleep disturbances
- voice changes

Occupational Therapy Intervention Process

When setting goals with the client with PD and significant others, the therapist must balance activity energy demands with motivation and frustration as well as caregiver time in the context of the dependence-interdependence-independence continuum (Gillen, 2000). Participation of others in this process is crucial to the viability of interventions, which vary based on priorities and resources, stage of the disease, and occupational difficulties identified through the evaluation. Many of the interventions described in Procedures for Practice 35-1 may be incorporated at home and in other relevant environments. Numerous studies report an overall effectiveness of both occupational therapy and other rehabilitation interventions for PD (Dixon et al., 2007; Rao, 2010). A meta-analysis showed that 10 of the 15 studies reviewed demonstrated a positive effect for occupational therapy intervention and showed that 63% of those with PD who received therapy improved as compared to 37% who did not receive therapy (Murphy & Tickle-Degnen, 2001). A recent randomized control trial showed the efficacy of a self-management rehabilitation program for persons with PD (Tickle-Degnen et al., 2010). Other studies have tested the Lee Silverman Voice Treatment (LSVT) and Rehab-SelfCue-Speech programs.

Procedures for Practice 35-1

Occupational Therapy for Parkinson's Disease

Interventions Related to Decreasing Isolation and Communication Problems

- Educate about timing activities to synchronize with maximum medication effectiveness.
- Modify leisure activities to encourage participation and decrease isolation.
- Provide information on support and advocacy groups.
- Educate caregivers about modifying communication and activities to support engagement
- Participate in programs such the LSVT and LSVT®BIG.
- Implement writing modifications, including using an enlarged felt-tip pen and writing when rested.
- Use communication aids, including smart devices such as electronic tablets (mobile phone may be too small), large-key telephones, and electronic aids to daily living (EADL)
- Provide home exercise program to maintain facial movement and expression for socializing.

Interventions Related to Safety

- Instruct in sit-to-stand and bed mobility using the Rehab SelfCue-Speech program.
- Instruct to manage motoric "freezing" while walking, includes avoiding crowds, narrow spaces, and room corners; reducing distractions and not carrying items while walking; reducing clutter in pathway; focusing when changing directions; using a rhythmic beat or counting to maintain momentum.
- Recommend equipment to increase independence such as a raised toilet seat and grab bars.
- Prescribe walking aids (walker for festinating gait).

- Recommend, if required, a wheelchair having a proper seating system, cushion, and adjusted foot/leg rests and armrests that is appropriate for transporting within the community.
- Recommend good, uniform lighting, particularly in narrow spaces and at doorways.
- Provide home exercises to maintain mobility, coordination, posture, and tolerance.
- Perform home assessment and recommend modifications that might include alterations to the bathroom (e.g., nonskid surfaces, bath bench/chair) and flooring (e.g., eliminating throw rugs), horizontal strips on the floor where "freezing" episodes occur, and reducing furniture congestion (Gillen, 2000).

Interventions to Maintain Independence and Participation

- Modify eating routine to include small portions, reduced distractions, schedule frequent meals that allow adequate time, and provide adapted equipment such as nonslip surfaces for plates and built-up handles.
- Recommend use of adult absorbent underwear to reduce embarrassment should a bathroom be difficult to access.
- Recommend that sexual activity be engaged in following rest and urination and when medications are most effective.
- Instruct on energy effectiveness strategies in home, leisure, and work activities.
- Reduce or eliminate the need for fine-motor control, such as clothing with minimal or no fasteners.
- Reduce the impact of perceptual problems by using visual cues and rhythmic music in a nondistracting environment; speak slowly using simple instruction.
- Perform a home assessment.

The LSVT is a 4-day-per-week, 4-week program designed to teach and habituate compensatory speech and voice strategies to facilitate a louder, clearer speech that is often run by occupational and/or physical therapists. The LSVT program is beneficial for motivated PD patients to improve vocal loudness, swallowing, speech, gestures used for communication, and facial expression (Sapir et al., 2007). A revision of the Lee Silverman program, known as LSVT®BIG, is used to promote high-amplitude movements in PD patients (Ebersbach et al., 2010). During this program, the participants are encouraged to think BIG. The quick, dramatic, explosive movements are aimed at mitigating the effects of bradykinesia.

The RehabSelfCue-Speech program was designed for people with PD who are in the mild to moderate stages (stage 3 on the Hoehn and Yahr scale) (Maitra, 2009; Maitra & Dasgupta, 2005). It is based on motor control principles and sensory feedback to target bradykinesia and uses self-cueing to initiate movement-related actions. In order to

practice of RehabSelfCue-Speech, the therapist helps the client choose tasks to perform and then selects action words to read aloud during the activity to facilitate the performance. The client practices using these cues during several sessions, with the goal of transferring these techniques to home activities. Here is an example: to get up from a chair, the action words can be SWAY, then RISE. These words are then used each time the client would like to stand up from a chair or from other surfaces. Evidence Table 35-2 presents the best evidence for occupational therapy intervention for PD.

Amyotrophic Lateral Sclerosis

ALS, popularly known as Lou Gehrig's disease, is a late-onset most often fatal neurodegenerative disease of upper motor neurons (UMN) and lower motor neurons (LMN). The incidence of ALS is 2 per 100,000 people, and it occurs more often in men (Amyotrophic Lateral Sclerosis

Evidence Table 35-2 Best Evidence for Occupational Therapy Practice Regarding Intervention Related to Parkinson's Disease

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Interdisciplinary self-management rehabilitation program for persons with Parkinson's disease (PD)	Eighteen hours of group sessions include exercises for flexibility, strength, and speech; activities of daily living (ADL) and gait training and discussion about cognitive strategies, communication, stress management, and fall prevention.	One hundred nineteen persons with PD: 30 women, 90 men; mean age = 66 years	Participants were randomly assigned to one of these three groups: 1. No hours of rehab 2. Eighteen hours of clinic group rehab with 9 hours of social sessions 3. Twenty-seven hours of rehab (18 in group and 9 in-home or community individual sessions for skill transfer)	Randomized control trial. Level of evidence: IB2a	The two groups receiving rehab improved in health-related quality of life (HRQOL) as measured by the Parkinson's Disease Questionnaire-39 (PDQ-39) with relevant gains in communication and mobility. There was no difference between intervention groups for HRQOL.	Using repeated measures analysis of covariance (ANCOVA) the intervention effect post treatment and at follow-up was $F = 3.98, p = .02$, moderate effect size ($\eta = .26$). A significant response ($p = .03$) was shown for the HRQOL domains of communication (2-month follow-up) and mobility (6-month follow-up).	Tickle-Degnen et al. (2010)
LSVT®BIG, which is derived from the Lee Silverman Voice Treatment	The program focuses on intensive exercising of high-amplitude movements.	Fifty-eight people with PD at Hoehn & Yahr stages I–III; 36 women, 22 men	Participants were randomly assigned to one of three groups: 1. One-to-one training in (LSVT®BIG) 2. Group training of Nordic Walking (WALK) 3. Nonsupervised exercises (HOME)	Randomized control trial. Level: IC2b	Improvement to: 1. Unified Parkinson's Disease Rating Scale (UPDRS) motor score 2. Timed up-and-go (TUG) score 3. Timed 10-meter walk No differences for quality of life between groups.	Using analysis of covariance (ANCOVA) between group comparison, the LSVT®BIG program showed significant improvement on UPDRS ($F = 11.9, p = .001$) and TUG ($F = 3.64, p = .033$) while 10-meter walk ($F = 2.97, p = .059$) approached significant benefit.	Ebersbach et al. (2010)
Inpatient rehabilitation program for persons with PD	Rehabilitation included movement strategies and exercise offered by physical therapists and occupational therapists.	Twenty-eight persons with PD; mean age = 68 years hospitalized and at Hoehn & Yahr stage II or III, able to walk 10 meters, three times without assistance	A maximum of 16 sessions of up to 45 minutes per session over a 2-week inpatient period; number of sessions ranged from 5 to 16. Participants were randomized to the strategy group or the exercise group.	Randomized control trial. Level: IC1a	The movement-strategy group showed improvements on the UPDRS, 10-meter walk, 2-minute walk, balance, and quality of life as compared to the exercise group.	Significant improvement in QOL at discharge ($t = 3.65, p = .003$) and 3-month follow-up ($t = 3.65, p = .003$) and for the 2-minute walk at discharge ($t = -5.54, p = .000$) and follow-up ($t = 5.27, p = .000$). UPDRS ($t = 3.16, p = .008$), the 10-meter walk ($t = 3.66, p = .003$) and balance ($t = 3.74, p = .002$) improved at discharge though not retained at 3 months.	Morris, Iansek, & Kirkwood (2009)

Association [ALSA], 2012). There is no test other than a clinical examination, so a selection of diagnostic tests is used in a careful, multistep system of exclusion of other diagnoses (ALSA, 2012). The cause remains unknown, and initial symptoms vary widely.

The average age at onset is 58 years, although adults as young as 20 have been diagnosed. Age at onset and the pattern of symptom development is useful for determining an individual's prognosis, with a younger onset of UMN origin having a somewhat better prognosis. It has also been shown that baseline scores on the Short Form-36 (SF-36) are significant predictors of health status over time (Norquist et al., 2003). Generally, the prognosis for individual patients is best left to neurologists with expertise in ALS.

In ALS, early manifestations indicating UMN or LMN disease vary with the site of the initial disease onset. UMN damage results in general weakness, spasticity, and hyperreflexia. LMN involvement results in weakness or muscle atrophy of the extremities, cervical extensor weakness, fasciculations, muscle cramps, and loss of reflexes. Early bulbar involvement affecting speech, swallowing, and breathing and/or advanced age at time of diagnosis tend to indicate a more progressive course of the disease (Mitsumoto, Chad, & Pioro, 1998). Speech impairment is common as the disease progresses (Ball, Beukelman, & Pattee, 2004), as are UMN and LMN symptoms. Cognition is rarely affected, and vision, bowel and bladder control, and sensation are spared.

No known cure or effective pharmacological treatment is available for ALS, although riluzole (Rilutek), an antiglutamate agent, shown to alter the course of the disease, is the only FDA–approved medication for the treatment of ALS. There are several other medications being investigated, as well as research in the use of stem cell therapy, offer hope to those with ALS (ALSA, 2012). Medications can also assist in the management of symptoms such as spasticity, anxiety, insomnia, and excessive saliva but do not affect the progression of the disease. Assisted ventilation, tracheotomies, and gastrostomies ease problems with eating and breathing (Mitsumoto, Chad, & Pioro, 1998). Because of the disease progression, numerous symptoms, and potential interventions, a multidisciplinary team improves the quality of life for those with ALS (Van den Berg et al., 2005).

The Course of Amyotrophic Lateral Sclerosis

Six stages of ALS are recognized and described according to clinical features (Table 35-1). The median duration of life after diagnosis ranges from 23 to 52 months, although a significant proportion survive 5 years or more (ALSA, 2012; Mitsumoto, Chad, & Pioro, 1998). Weakness of the arm, leg, or involvement of the bulbar area is a common initial symptom (Mitsumoto, Chad, & Pioro, 1998). Atrophy may begin in the hands, with wasting of the thenar and hypothenar eminences, as well as in the shoulder muscles. Finger extension is usually affected earlier than grip strength because of dorsal and palmar interossei wasting. Falling and problems with walking and bed mobility are common due to of lower extremity weakness.

Table 35-1 **Rehabilitation of Patients with Amyotrophic Lateral Sclerosis at Various Stages**

Stage	Clinical Features	Activities to Maintain Motor Function	Equipment
I	Ambulatory, no problems with ADL, mild weakness	Normal activities, moderate exercise in unaffected muscles, active ROM, and strength exercise	None
II	Ambulatory, moderate weakness in certain muscles, increased fatigue	Modification in living; modest exercise; active, assisted ROM exercise	Assistive devices, use of hands-free devices, electronic tablet
III	Ambulatory, severe weakness in certain muscles, increased difficulty with ADL; marked fatigue	Adaptations to continue active life; active, assisted, passive ROM exercise; joint pain management	Smart technology, adaptive devices, home equipment and environmental controls
IV	Wheelchair confined, almost independent, severe weakness in legs	Passive ROM exercise, modest strength exercise in uninvolved muscles	Smart technology, adaptive devices, home equipment, environmental controls, wheelchair
V	Wheelchair confined, dependent, marked leg and arm weakness	Passive ROM exercise, pain management, decubitus ulcer prevention	Smart technology, adaptive devices, home equipment, environmental controls, wheelchair
VI	Bedridden, unable to perform ADL, maximal assistance required	Passive ROM exercise, pain management, prevention of decubitus ulcers and venous thrombosis	Smart technology, adaptive devices and home equipment to assist caregiver(s), environmental controls, wheelchair

ADL, activities of daily living; ROM, range of motion.
From Mitsumoto, H., Chad, D., & Pioro, E. (1998). *Amyotrophic lateral sclerosis. Contemporary neurology series.* Philadelphia: Davis; Sinaki, M. (1980). Rehabilitation. In D. W. Mulder (Ed.), *The diagnosis and treatment of amyotrophic lateral sclerosis* (pp. 169–193). Boston: Houghton Mifflin.

Three forms of ALS have been described including sporadic, familial, and Guamanian (ALSA, 2012). The most common, sporadic, occurs in 90%–95% of those with ALS, whereas familial presents 5%–10% of the time and appears to have a genetic link occurring more than once in a family (ALSA, 2012). When a high ALS incidence appeared in Guam in the 1950s, the third form emerged.

Potential Emotional, Social, and Economic Consequences

ALS is a devastating disease for individuals and their families. Its relatively fast progression, coupled with early loss of upper extremity function and possibly speech and swallowing, means that the disease quickly affects ability to perform ADL and IADL and maintain employment and quality of life. It has been shown that those with ALS, as compared to normal controls, have more depression, external locus of control, and feelings of hopelessness (McDonald et al., 1994) and that this is not related to physical function or sociodemographic factors (Plahuta et al., 2002).

People with ALS and their families have little time to make psychological adjustment to the diagnosis and its implications before having to deal with their loved one's increasing disability. The acceptance of the ALS diagnosis by family members may affect willingness to be involved in planning, incorporating changes necessary to maximize the independence of the person with ALS, and making informed choices for intervention (Ball, Beukelman, & Pattee, 2004).

People frequently withdraw from work soon after diagnosis and may have to confront economic problems and health insurance issues. Because the age group most commonly affected is employed and actively involved in family and community activities, the abrupt change is devastating.

Occupational Therapy Evaluation

Assessments for clients with ALS should be based on clearly defined levels of function (see Table 35-1) and the individual's needs and priorities. Early interventions should target the individual's symptoms as they affect their occupations. As ALS progresses, interventions focus on individual function, as well as physical and social environment. This is supported by Neudert, Wasner, and Borasio (2004), who showed that the quality of life of a person with ALS with a supportive family and social network remains stable over time despite reduced health status.

To assist with the evaluation process, the ALS Functional Rating Scale (Mitsumoto, Chad, & Pioro, 1998) can be used. To determine ongoing functional ability, ADL and IADL assessments should be included in all evaluations. Functional limitations may be due to reduced upper extremity ability, and thus the Purdue Pegboard, 9-hole peg test or other timed upper extremity function tests and standard ROM and MMT are useful. Fatigue is shown to affect physical quality of life (Lou et al., 2003)

and can be assessed with the Multidimensional Fatigue Inventory or other screening measures described earlier in this chapter. As communication and swallowing decline (Higo, Tayama, & Nito, 2004), assessment and intervention is required to ensure that nutritional needs and social participation are maintained. Because of disease progression, reevaluation at each visit is required.

Occupational Therapy Intervention Process

The progressive nature of ALS necessitates that rehabilitation be compensatory, focusing on adapting to disability and preventing secondary complications. Goals center on keeping the person active and independent for as long as possible. Examples of occupational therapy goals in the early stages include

- optimizing strength and ROM using home exercise programs (Drory et al., 2001)
- maintaining function in ADL and IADL through use of assistive or adaptive devices
- decreasing fatigue in the neck and extremities through use of splints and orthotics
- managing pain and energy using joint protection and work simplification techniques

As function declines, mobility and self-care become increasingly difficult. Home evaluations and in-home therapy are important, and intervention focuses on enabling the caregiver to assist the client safely and effectively. The therapist helps the caregiver–client team to

- optimize safety and positioning, perform safe transfers, and maintain skin integrity
- enable communication using augmentative communication equipment (Ball, Beukelman, & Pattee, 2004)
- assess and manage dysphagia (Higo, Tayama, & Nito, 2004)
- optimize social participation
- identify and obtain equipment, such as a hospital bed, to allow continued mobility and comfort
- modify the environmental to enhance participation, safety and comfort

Throughout the stages of the disease, the occupational therapist must be sensitive to the client, family, and caregiver as physical demands, financial concerns, and transformation of the home into a hospital-like setting produce enormous stress and strain (Mitsumoto, Chad, & Pioro, 1998). Open discussions and close collaboration with clients, caregivers, and the ALS team help to address the client's changing needs.

Intervention Implementation. When treating clients with ALS, therapists must be aware of the client's level of gadget tolerance, financial resources, and social and cultural context. The special considerations for exercise, equipment,

assistive technology, and dysphasia management for persons with ALS are reviewed below.

Exercise. Active and passive ROM, strengthening, endurance, stretching, and home breathing programs are appropriate at various stages of the disease and are effective for minimizing secondary complications (Mitsumoto, Chad, & Pioro, 1998). Attention to overexertion, potential secondary problems, muscle spasms, and careful monitoring of fatigue are important to a successful exercise program. A client may initially be able to perform an independent home stretching program, but as the disease progresses and the program becomes too fatiguing or difficult, the caregiver may become involved.

Equipment and Assistive Technology. The therapist will provide information and assist with accessing assistive technology and adaptive equipment that may help the client achieve optimal level of independence at the various stages of ALS (see Table 35-1). Assistive equipment such as a neck collar or universal cuff may be helpful. Because independent walking becomes difficult in a rapidly progressing disease such as ALS, ordering the wheelchair may need to be expedited. Mobility equipment, depending on level of function, may include a foot-drop splint, cane, and/or walker. A study showed that 57% of those with moderate disability used a mobility device in addition to a wheelchair (Trail et al., 2001). Together, a home assessment and client-caregiver consultation inform wheelchair selection. For specific features and details related to wheelchair selection refer to Chapter 17.

Mainstream technology and environmental controls are extremely useful as the disease progresses. This technology, for example, includes lighting and call alert systems, motion sensors, door (un)locking systems, and remote control for TV and radio. Use of smart devices with audio options (something that can be adjusted if the voice is weak) to replace the need for touch typing is helpful to conserve energy and to maintain communication. (see Chapter 18.)

Dysphasia. Swallowing difficulties may be present at any stage of ALS, particularly when bulbar involvement is apparent. Interventions may include, but are not limited to, reducing distractions during mealtime (limit conversation and other activities), altering food consistency (i.e., thicken liquids), teaching manual techniques to swallow, and ensuring adequate time for meals. Early introduction of an alternate route of nutrition may be indicated if nutrition and maintaining weight become issues.

Guillain-Barré Syndrome

GBS or acute inflammatory demyelinating polyneuropathy results in axonal demyelination of peripheral nerves (Meythaler, DeVivo, & Braswell, 1997). Characteristics include a quickly progressing, symmetrical ascending paralysis starting with the feet; pain in the legs; absence of deep tendon reflexes; mild sensory loss in glove-and-stocking distributions; cranial nerve dysfunction with possible facial palsy and swallowing problems; an autonomic nervous system response of postural hypertension and tachycardia; respiratory muscle paralysis; and pain, fatigue, and urinary dysfunction (Gregory, Gregory, & Podd, 2005). Cognition, however, remains intact (Guillian-Barré Syndrome–Chronic Inflammatory Demyelinating Polyneuropathy Foundation International [GBS-CIDP], 2012). Symptoms vary from so mild that medical attention is unlikely to severe disease that may cause death in 1%–10% of cases (Khan, 2004).

The cause of GBS is unclear. Its distribution is worldwide, with an incidence of 1.3–2 per 100,000 (GBS-CIDP, 2012). GBS is 1.5 times more common in men and occurs in adults 20–24 years and 70–74 years (van Doorn, Ruts, & Jacob, 2008). No hereditary susceptibility or vaccinations cause GBS (Hughes & Rees, 1997). Enteritis, however, precedes GBS in 41% of cases, as may respiratory infections and HIV or AIDS (Carroll, McDonnell, & Barnes, 2003; Jiang et al., 1997).

Diagnosing GBS

Diagnosis of GBS entails a history of symptoms and a physical and neurological examination that includes nerve conduction tests and cerebral spinal fluid analysis (GBS-CIDP, 2012). The medical interventions for GBS attempt to lessen the severity but do not cure the disease such that upon initial diagnosis, patients are admitted to hospital to monitor breathing and other functions until the GBS has stabilized (GBS-CIDP, 2012). Treatments include intravenous immunoglobulin, plasma exchange (otherwise known as plasmapheresis), and steroids (van Doorn, Ruts, & Jacob, 2008).

The Course of Guillain-Barré Syndrome

GBS has three phases. In more than 95% of people with GBS, the onset, or acute inflammatory phase, manifests as weakness in at least two limbs that progresses and reaches its maximum in 2–4 weeks accompanied by increasing symptoms (van Doorn, Ruts, & Jacob, 2008). Mechanical ventilation is required for 20%–30% of individuals (Dematteis, 1996). This is followed by the plateau phase of no significant change, which lasts for a few days or weeks, when the greatest disability is present. The third phase is progressive recovery, when remyelination and axonal regeneration occur and may last for up to 2 years, although the average length is 12 weeks (van Doorn, Ruts, & Jacob, 2008). Recovery starts at the head and neck and proceeds distally (Karavatas, 2005) and extent varies; approximately 50% of patients have complete return of function, and another 35% experience some residual weakness that may not resolve. The remaining 15% experience more significant permanent disability (Khan et al., 2010). Fatigue is the most common residual problem for 93% of patients (Parry, 2000). Subtle cognitive deficits in

executive functions, short-term memory, and decision making may occur (Gregory, Gregory, & Podd, 2005).

Potential Emotional, Social, and Economic Consequences

Emotional and psychological reactions are a response to the rapid onset of symptoms and the degree of disability. Shock, despair, fear, and anger may be consuming (Dematteis, 1996). As recovery progresses and improvement is slow, adjustment, impatience, and frustration associated with disability persist (GBS-CIDP, 2012). At follow-up, GBS was reported to impact confidence and ability to live independently, with 18% having depression and 22% having anxiety (Khan et al., 2010).

For young adults, the impact of GBS can have educational, employment, and economic implications. This age group is launching careers and may have only small savings. For those who develop GBS in later years, the economic effect may be less. For those returning to work after GBS, there may be a renewed value for work, a need to cope with losing and recovering a work identity, and dilemmas about work adaptations that require coping strategies. Lack of public awareness of GBS may be a barrier for returning to work (Royal, Reynolds, & Houlden, 2009).

Occupational Therapy Evaluation

Referral to occupational therapy is common when the course of GBS is moderate to severe. Approximately 40% of all GBS patients require rehabilitation services (Meythaler, DeVivo, & Braswell, 1997). Assessment at the onset of the plateau phase typically occurs in the intensive care unit, when the individual is undergoing extensive medical procedures and pain can be significant. Therapists should complete an interview to understand the client's feelings and fears (GBS-CIDP, 2012) and evaluate communication, control of the environment, comfort, and level of anxiety. A sensory assessment is essential because marked sensitivity is typical of acute GBS; the guiding principle is to ask prior to touching the client (GBS-CIDP, 2012). Therapists should also be aware of the 7-point GBS disability scale that primarily assesses ambulation and the need for a ventilator (Hughes et al., 1978).

During the recovery phase, therapists evaluate self-care, communication, leisure, as well as mobility, sensation, strength, ROM and, as appropriate, reintegration into the workplace. Patients with GBS should not be pushed to fatigue, because recovery will be prolonged and fatigue may slow the rehabilitation process (GBS-CIDP, 2012). During this phase, occupational therapy services can be provided in an inpatient rehabilitation facility, through an outpatient program, and/or at home or work (Karavatas, 2005).

Occupational Therapy Intervention Process

Because the natural course of GBS is improvement, patients and caregivers tend to be optimistic about recovery.

The long-term goal is full recovery, so that the individual performs at the same level as prior to the onset of GBS with or without modification. Goals should focus on achieving optimal function at each level of recovery within tolerated pain levels (GBS-CIDP, 2012).

During the acute phase, the patient may be actively involved in directing care rather than physically involved, providing the opportunity for educating the patient and others about maintaining comfort in bed, protecting against bed sores, and future therapy (GBS-CIDP, 2012). Modifications during the acute and plateau phase should be considered temporary and may include

- communication tools, such as sign or picture board or voice-activated devices, if appropriate
- access to the nurse call button, TV, and lights by remote control, as appropriate
- use of hands-free telephone
- modification of lying and sitting positions for optimal function and comfort
- positioning trunk, head, and upper extremities for stability and comfort
- introducing strategies to reduce anxiety

Recovery-phase interventions are initially completed with few repetitions, punctuated with rest. The number and complexity of tasks should be increased gradually (GBS-CIDP, 2012). Examples of interventions include

- providing activities and dynamic splints to maintain ROM, particularly of wrists, fingers, and ankle (hinged drop-foot orthosis)
- instructing both caregiver and client in safe mobility and independent transfers
- providing a sensory stimulation or desensitization program, as appropriate
- training in modified self-care techniques and adapting other daily activities
- using smart devices to facilitate communication and conserve energy
- modifying and encouraging reengagement in routine activities, as appropriate
- adapting equipment for in home, leisure, and work activities
- instructing in energy conservation and fatigue management strategies
- modifying employment roles, tasks, and environment, as indicated
- recommending a fine-motor program to enhance strength, coordination, and sensation
- completing a home assessment and modifications, as appropriate, to facilitate return to home

The GBS-CIDP Foundation International provides guidelines for occupational and physical therapy assessment and treatment of GBS (Resources 35-1) and is an excellent resource about the services available.

case example

Mrs. K: Continuing to Work with Multiple Sclerosis

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information Ms. K., a 37-year-old woman diagnosed with relapsing-remitting multiple sclerosis (MS) 2 years prior to her first visit to occupational therapy (OT), had recently submitted her resignation to her employer of 15 years. Upset by having to quit her administrative job, she reported the following problems: (1) severe fatigue, which had increased in the past year and resulted in her inability to do her household tasks, perform her activities of daily living (ADL), and work without becoming exhausted; (2) increased lower extremity weakness, with decreased ability to perform tasks requiring prolonged walking or standing; (3) a feeling of heaviness and stiffness in upper and lower extremities; (4) decreased manual dexterity; (5) frequent falling; (6) daily headaches; (7) dizziness; (8) bladder problems; (9) vision problems; (10) disturbed sleep; and (11) attention and memory problems. Her adaptive equipment at the time of her initial therapy visit included a manual wheelchair and a quad cane. She had quit driving. Her husband was very supportive and had recently stopped adoption proceedings because of her MS. She was taking bladder medication and a disease-modifying therapy (DMT).	Understand the patient's diagnosis and context of services Know the person	"This is not a new diagnosis for Ms. K., although it is her first interaction with OT because she may not have needed services in the past." "I will want to get to know how long Ms. K. has experienced her current problems and how she has tried to address them before her resignation from work. It appears that she has made some rather significant decisions about her future. In my experience, some patients respond to the relapse of MS symptoms by fearing the worst, not really understanding MS and all the potential treatment options. Getting a sense of 'where she is at' will be my priority."
Reason for Referral to Occupational Therapy Referral was broad, indicating a need to improve overall function due to fatigue. Upon specific discussion with the health care team and Ms. K and her husband, the objective of the occupational therapy referral was to improve function at home and to re-evaluate employment and transportation options.	Appreciate the context Develop provisional hypotheses	"Ms. K. is not working and is having difficulty at home. Because her husband is supportive, he will likely help to make any changes I suggest in therapy. She is probably using inadequate fatigue management strategies."
Assessment Process and Results The OT evaluation revealed the following: decreased strength in the lower extremities and her dominant upper extremity; increased tone in the lower extremities; decreased sensation and manual dexterity in the dominant upper extremity; severe dizziness with head movement; head, neck, and shoulder trigger points; and marked fatigue. Ms. K., determined not to give in to the disease, had made no adaptations to reduce energy expenditure in daily activities. She was scheduled to have a neuropsychological assessment to identify her current cognitive function and problem areas. Her equipment was self-selected and inappropriate for her problems. She was not taking medications to manage spasticity or fatigue. Her seating at home and work was not supportive. Ms. K. purposefully climbs the stairs in the morning and had a desk distant from the bathroom to get exercise, as she had no exercise program.	Consider evaluation approach and methods Interpret observations	"I think I will start with an interview using the COPM to get to know Ms. K., her past coping strategies, and her primary concerns. Depending on that information and what I already know from the client information, I will use some specific assessments such as the Modified Fatigue Impact Scale, Modified Ashworth Scale, and the Functional Independence Measure (FIM™)." "I'm thinking that fatigue underlies most of her occupational performance problems and that weakness and spasticity are adding to this. It also seems that her current equipment and environmental setup are not helping her. I am also very concerned about what (I think) is a premature resignation from her work and withdrawal from driving."
Occupational Therapy Problem List The problems encountered by the patient include 1. use of inappropriate equipment 2. minimal use of fatigue management strategies 3. resigned from work without knowledge of options 4. is not involved in a home exercise program 5. has stopped driving without investigating options	Synthesize results	"Her occupational performance problems are due to inadequate information and modifications related to fatigue, inappropriate equipment, poor ergonomic layout, and lack of exercise routine."

Occupational Therapy Goal List

In collaboration with Ms. K., the goals established were to

- obtain appropriate power mobility equipment
- incorporate at least six energy-saving strategies in her day
- withdraw resignation notice from employer
- make changes in work area by obtaining a headset and ergonomic chair and move her desk closer to the bathroom
- submit a request to her employer for automatic door openers on bathroom
- apply to vocational rehabilitation and work with therapist and vendor to install hand controls for driving
- educate Ms. K. in head, neck, and shoulder exercises

Develop intervention hypotheses	"I will sequence the intervention by focusing on what is most important to Ms. K. I hypothesize that education on energy effectiveness strategies will improve success in performing daily tasks and that assessment and alteration of the work environment and appropriate equipment will facilitate return to work. I will advocate the use of hand controls to return Ms. K. to driving."
Select an intervention approach	"I think the compensatory and educational approach will be most useful."
Consider what will occur in therapy, how often, and for how long	"I recommend one outpatient treatment session per week for 6 weeks. We will work with the physical therapist, who will attend to pain, gait, and exercise interventions."

Intervention

The occupational therapy intervention included (1) instruction in and adoption of energy-conservation techniques at home, at work, and in community (Hugos et al., 2010; Mathiowetz et al., 2005); (2) identifying and obtaining powered mobility equipment; (3) decreasing headaches with head, neck, and shoulder stretching; (4) identifying and obtaining equipment to decrease energy consumption and impact of cognitive issues at home and work (Mathiowetz et al., 2005; PVA, 1998); (5) obtaining ergonomic seating and workstation to decrease pain and energy consumption; (6) facilitating the use of hand controls to drive; (7) continuing full- or part-time employment; and (8) instruction in vestibular and strengthening home exercise program.

Assess the patient's comprehension	"Ms. K. was motivated to participate in therapy because of the potential to return to work. From my experience, I realize the success of therapy depends on her ability (and husband's) to incorporate techniques, access and use equipment, and implement ergonomic changes into her life."
Understand what she is doing	"When discussing fatigue, Ms. K. realized she was fighting the fatigue rather than managing it. At first, it was tough to incorporate suggestions like taking rests, but Ms. K. began to reduce long walks in favor of a short home exercise program."
Know the person	"Although she did not want a lot of equipment, Ms. K. was interested in getting appropriate items if it meant she could continue to do her usual activities."
Appreciate the context	"Because both her husband and employer were supportive, modifications at home and work could be accommodated."

Next Steps

Following the therapy evaluation, Ms. K. withdrew her job resignation and began making modifications in her work. She was also planning to resume driving with the appropriate hand control modifications.

Anticipate present and future concerns	"I will follow-up with Ms. K. when she has returned to work to assist with concerns related to the ergonomic changes and to help problem solve difficult job situations. It is important that she has a positive return-to-work experience without reservations."
Decide whether the patient should continue therapy and/or return in the future	"I will then follow up at the annual visit or earlier if changes in her function occur."

Clinical Reasoning in Occupational Therapy Practice

One-Month Follow-Up: Successes and Continuing Issues

Ms. K. has met her goals for energy conservation and feels more confident that she can manage her fatigue. She was also able to withdraw her job resignation. However, she developed right foot drop, which affected her balance when fatigued. What kinds of work and mobility adaptations might the occupational therapist recommend to optimize her energy and functioning?

Summary Review Questions

1. What are the various courses of MS?
2. What symptoms of MS may require occupational therapy intervention?
3. What are the primary modifications that a therapist might recommend for a woman with severe MS fatigue who is working full time and has two young children?
4. How can an occupational therapist help a person with neurodegenerative disease stay employed?
5. What environmental modifications may be necessary in PD?
6. List the primary modifications you might recommend during a home safety visit for a person with a neurodegenerative disease.
7. Why is it important to include the significant others when developing interventions?
8. Plan an outpatient therapy session to treat a person with PD who has akinesia, bradykinesia, and rigidity and who is falling regularly.

Glossary

Akinesia—Impaired ability to initiate voluntary and spontaneous motor responses, such as the interruption of performance in movement when attention is distracted (e.g., freezing in Parkinson's disease).

Axonal transection—Separation of an axon from its postsynaptic neuron, permanently interrupting action potential propagation.

Bradykinesia—Slowness or poverty of body movement.

Cogwheel rigidity—Series of catches in the resistance during passive motion.

Demyelination—Myelin that covers nerve fibers is lost or damaged, resulting in an absence or impairment of nerve conduction typically manifesting in disability and limitations to function.

Fasciculations—Rapid, flickering twitching movements of a part of a muscle occurring irregularly in time and location.

Festinating gait—Marked by very small rapid steps which occurs in persons with Parkinson's disease when the posture of the head and trunk involuntarily lean forward ahead of the feet, moving the center of gravity (COG) forward. Rather than taking a large step to correct the imbalance, one takes several hurried small steps, increasing gait velocity, which results in running or "chasing" one's COG, which remains in front of the feet.

Intention tremor—A tremor that occurs during visually guided, goal-directed movement that is worse (meaning it has an increased tremor amplitude) as the proximity to the target nears and when increased precision is demanded. The functional repercussions, particularly for fine-motor skills, can be devastating.

Myelin—Lipid-rich insulating material covering nerve fibers that speeds conduction of impulses.

Rigidity—Hypertonicity of agonist and antagonist muscles that offers a consistent, uniform resistance to passive movement.

Orthopaedic Conditions

Colleen Maher

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Identify the role of the occupational therapist in assessing and planning treatment for persons with occupational dysfunction secondary to injuries or diseases affecting the musculoskeletal system.
2. Select appropriate assessments and plan treatment according to the stages of recovery following a musculoskeletal injury or disease of the upper extremity.
3. Describe how to accomplish daily life tasks without causing adverse sequelae following fracture or surgery to the hip.
4. State the principles of body mechanics and describe how to apply them to activities and tasks of daily life.
5. Describe the phases of fracture management of the upper extremity and how to optimize occupational functioning at each stage.

Orthopaedic conditions include injuries, diseases, and deformities of bones, joints, and their related soft tissue structures: muscles, tendons, ligaments, and nerves. These conditions can be caused by traumatic events, such as motor vehicle, recreational, or work-related accidents; by cumulative trauma; by obesity; or by congenital anomaly. Furthermore, musculoskeletal conditions are most common in the elderly population, and it is projected that by the year 2030, the number of adults age 65 years and older will double. This rapidly expanding elderly population is most at risk for developing musculoskeletal injuries and conditions that will result in long-term chronic pain (American Academy of Orthopaedic Surgeons, 2008).

This chapter provides an overview of the occupational therapy assessments and treatment interventions used with adult clients who have orthopaedic or musculoskeletal conditions. Specifically, it reviews upper extremity and hip fractures and their sequelae, hip surgery for trauma and disease, shoulder injuries and their effects on function, and pain with a focus on low back pain.

PURPOSE AND ROLE OF OCCUPATIONAL THERAPY IN ORTHOPAEDICS

The aim of occupational therapy in orthopaedic rehabilitation is to help the client achieve maximal function of body and limb to restore occupational functioning. In the acute stage of recovery, the therapist's role is to help relieve pain, decrease swelling and inflammation, assist in wound care, maintain joint or limb alignment, and restore function at the injury site. The therapist teaches the client to safely perform tasks and activities while protecting the injury site for healing. As healing progresses to clinical union and then to consolidation, the occupational therapist retrains the client in activities of daily living (ADL) and other occupational tasks.

For individuals who have a chronic joint disease, such as osteoarthritis, or cumulative trauma, such as low back pain, the occupational therapist's role depends on the stage of recovery and the directives of the treatment team. The occupational therapist may directly help relieve pain, realign structures, or reduce the stress on soft tissue, or the occupational therapist may work closely with the physical therapist to relate the functional program to treatment offered in physical therapy. As the acute episode of pain decreases, the occupational therapist focuses on an individually tailored education program to help the client physically and psychologically make the required lifestyle changes to reach and sustain optimal occupational functioning.

OCCUPATIONAL THERAPY EVALUATION IN ORTHOPAEDICS

Evaluation is an ongoing process that is carefully coordinated with the stage of recovery. The therapist selects assessments that will provide sufficient information to plan

and to direct treatment but will not threaten the injured or inflamed structure during healing. The therapist chooses assessments that correspond to the level of bone healing, the chosen method of reduction and stabilization, and the plan for movement during healing or the acute inflammatory episode. The therapist assesses participation in life roles including areas of occupations, performance skills and performance patterns, as well as impairments of capacities and abilities.

Participation in Life Roles

Although resumption of life roles may not be possible at the start of the aftercare program, life roles regulate the choices made during treatment planning and serve as the end point for treatment planning. In addition to noting the activities and tasks that can and cannot be accomplished, using the assessment tools described in Chapter 7, the therapist observes whether the client is magnifying the injury or appears to be adopting a sick role.

Impairments of Abilities and Capacities

Physical impairments are directly measured by various assessment instruments. See Chapter 7 for assessment of pain, edema, range of motion (ROM), sensation, strength, and endurance. The surgeon's protocol may stipulate no movement or no force at or near the fracture site, or it may require controlled range of motion beginning immediately or within the first 3–4 weeks after stabilization (Fig. 36-1). If the surgeon's protocol requires complete rest of the injured bone or joint, ROM measurements are deferred until movement is permissible. If the client is on a specific program, such as controlled ROM, the therapist measures the joint, adhering to the precautionary boundaries, and does not allow the client to exceed the limits of the surgeon's prescription. The adjacent joints are measured, and a treatment program is designed for any adjacent joint that demonstrates less than normal function. Detailed strength testing with applied resistance is deferred until there is bony consolidation or the acute inflammation has calmed. Because of the force required, grip and pinch testing are usually deferred for 2–4 weeks following cast removal in forearm fractures. *Safety Message: Assessing strength after a fracture should only be performed when ordered by the orthopaedist.* The occupational therapist not only focuses on direct measurement of the injured and adjacent anatomical regions but also closely observes the client's total body response in terms of postural changes, pain responses, and psychological reactions.

OCCUPATIONAL THERAPY TREATMENT IN ORTHOPAEDICS

The most important treatment goal is the restoration of occupational functioning. To achieve this, the client needs to be directed from the start of recovery to move and to use

Immobilization

Stabilization and Healing

Therapist directs the patient to actively use joints above and below the stabilized part(s)

Mobilization

Therapist assists and supports controlled ROM* of the injured region in a gravity-assisted or eliminated plane:
   Controlled AROM* and may include isometric contraction across the fracture site
         OR
   Controlled AROM* or controlled PROM* and may include isometric contraction across the fracture site and active hold

↓ 3 to 4 weeks (clinical union)

OR

The therapist teaches the patient to move the injured limb against gravity*
   Controlled AROM progresses to full arc
         AND
   Begin PROM
         OR
   Progress controlled PROM to full arc

6 to 12 weeks

Early Consolidation

Mobility: the therapist selects activities/exercises to develop
   (1) AAROM and AROM
   (2) PROM with passive stretching* and joint mobilization*
   (3) Resistive ROM for isotonic strengthening

Stability: the therapist directs the patient to develop muscle contraction

Weight bearing: the therapist directs the patient to bear weight onto the injured limb

Skill: the therapist directs the patient to use the injured limb for skilled tasks and roles

*Follow surgical plan and seek medical approval to proceed.

all joints that are not affected by the injury or the disease. For patients who have an upper limb fracture or a short-term inflammation, the therapist may recommend temporary use of the uninjured hand alone to perform some ADL, assisted by adaptations such as pump bottles for toothpaste and shampoo, a button hook, or a rocker knife. Other ADL may require the temporary assistance of another person so as not to disturb the healing region. When the client is medically ready, the occupational therapist, through careful activity analysis, ascertains how the client can safely resume tasks that correspond with the achieved recovery status to reintegrate the injured or inflamed limb into activity safely. Attention is directed toward redeveloping the function of the injured limb to resume its capacity in mobility, stability, weight bearing, and ultimately skilled activity (see Fig. 36-1). When a condition is chronic, such as status post total hip replacement or low back pain, the therapist recommends alternative methods, adaptive equipment, or environmental modification for safe task completion.

Acute Trauma: Fractures

As long as orthopaedic surgeons have been treating fractures, there has been a controversy between the "movers" and the "resters." The surgeons prescribing rest as a fracture treatment keep their clients immobilized in traction, plaster, or fiberglass for long periods after stabilization. For many surgeons, however, the goal in fracture treatment is to mobilize the injured structures as quickly as is compatible with healing and return the client to work and leisure activities (Salter, 1999).

The goal of fracture treatment is to achieve a precise and effective stabilization for optimal recovery and resolution of function. Closed fractures that are relatively undisplaced and stable may be managed by protection alone, without reduction or immobilization. Fractures that are undisplaced but unstable do not need reduction but do require positioning and immobilization by external fixation methods such as a sling, cast, or a fracture brace. Open reduction internal fixation surgically reduces open fractures and those closed fractures that are unstable, and where the bone fragments cannot be approximated accurately by closed manual reduction alone. The bone fragments are brought into a closer anatomical alignment during surgical reduction and are stabilized by insertion of an internal fixation device, such as a nail, pin, screw, rod, or compression plate or by an external fixator (McKinnis, 2010; Shin, 2011). Surgical repair also can include prosthetic devices that are implanted to restore joint motion.

Fracture healing, when the part is immobilized by a cast, splint, or fracture brace (Fig. 36-2), is accomplished

Figure 36-2 Thermoplastic humeral fracture brace to support the length of the humerus during healing.

through the formation of immature woven bone or external callus. The woven bone then consolidates and remodels so that the fracture is repaired with lamellar bone (Smith et al., 2006). When internal fixation provides complete bone immobilization, external callus does not form, and direct healing occurs. When external callus forms first, more healing time is required. Fracture healing has a general timetable that is confirmed routinely by physical exam and x-rays to reveal the healing status before advancing the rehabilitation program (Definition 36-1). There are three phases of fracture healing: the inflammation phase (which involves up to10% of healing time), the reparative or fibroplastic phase (which accounts for up to 40% of total healing time), and the remodeling phase (which can account for up to 70% of healing time). Restoring bone to its optimal function is evident when consolidation or complete fracture repair has occurred—when there is fibrous union, the fracture site is no longer tender and painful, there is no radiologic evidence of the fracture line repair visible, and there is no movement when the fractured bone is manipulated (McKinnis, 2010).

    Rehabilitation begins as soon as the cast is in place or within a day or two after reduction. The timing, amount, and kind of activity depend on the place and kind of fracture, the

Definition 36-1

Fracture Healing

The estimate of healing time for uncomplicated fractures in adults is as follows:

	Upper Limb	**Lower Limb**
Callus visible	2–3 weeks	2–3 weeks
Union	4–6 weeks	8–12 weeks
Consolidation	6–8 weeks	12–16 weeks

Adapted from Solomon, L., Warwick, D. J., & Nayagam, S. (2005). *Apley's concise system of orthopaedics and fracture* (3rd ed.). London: Hodder Armold.

method of fracture reduction selected by the orthopaedic surgeon, and, in some instances, the age of the client. Clinical experience has shown that early specific use of the injured limb during healing diminishes or eliminates the need for treatment after immobilization (Salter, 1999). Early movement prevents the unwanted side effects of immobilization: stiff joints, disuse atrophy, and muscle weakness.

Evaluation Process in Aftercare for Fractures

The evaluation is carefully designed and adjusted to the stage of recovery and the kind of fracture. This chapter presents the specialized focus for each fracture by the stage of recovery: immobilization and early mobilization or early consolidation.

Immobilization or Early Mobilization (0–6 Weeks). The therapist identifies the tasks and activities for which the client needs to learn an adaptation or obtain assistance during the temporary period of restricted movement so that the fracture site remains undisturbed. Measurements of ROM and circumference for swelling are conducted on adjacent joints. Assessment of ROM of the injured joints depends on the type of protection and stabilization used and the orthopaedic surgeon's protocol for aftercare, as discussed earlier. Clients with secure internal fixation of bone fragments may begin gentle ROM of the involved joints before the consolidation phase. This usually occurs at 1–2 weeks postoperatively under the close supervision of the surgeon.

Early Consolidation (6–8 Weeks). The therapist determines whether, and to what extent, the client can safely reintegrate the injured limb into purposeful and occupation-based tasks. The therapist continually assesses the client's ability to use the injured limb for functional tasks to correspond with clinical progress. The therapist initially measures active

range of motion (AROM) of the involved joints with the exception of shoulder fractures, which are measured for active assisted/passive range of motion (AA/PROM). Edema and sensibility should be assessed. A 10-cm visual analog scale should be used to assess the client's pain level. Grip and pinch measurements are not taken until the surgeon orders strengthening. Observe the patient for signs of infection: redness, heat, swelling, pain, loss of function, or changes in circulation. To do so, look at the limb's skin color: purple, dusky, or white coloration indicates alterations in circulation, as does a skin surface that is too warm or too cold to the touch. Immediately report abnormal findings to the surgeon.

Treatment Process in Aftercare for Fractures

Intervention strategies for addressing orthopaedic injuries are based on the stage of recovery and the orthopaedic treatment protocol. The therapist selects and applies intervention strategies that are consistent with the orthopaedic surgeon's immobilization or mobilization plan, the restrictions or precautions, and goals.

Immobilization or Early Mobilization. Early mobilization treatment programs have specific and focused protocols indicating the timing, type, and quantity of desired movement (see Fig. 36-1). Advancement of the therapeutic program is determined for each client based on the stability of the fracture and radiographic signs of fracture healing (McKinnis, 2010). The cautiously controlled movement usually begins in a gravity-assisted or gravity-eliminated plane. The movement may be AAROM- or AROM-restricted to midrange and gradually upgraded to full ROM. Under careful guidance and manual handling, isometric contraction of the muscles whose bellies extend across the fracture site is encouraged to facilitate circulation and bone healing. Some protocols require controlled PROM, often followed by an active hold pattern. That is, the therapist passively moves the injured part through the prescribed arc, and then the client isometrically holds the achieved position briefly.

The therapist may have to fit the client with a sling, shoulder immobilizer, splint, or fracture brace during healing either to add protective support or to begin early controlled movement. To add to a client's comfort during stabilization in an external fixator, the therapist may recommend and fabricate a supportive static splint. Thermoplastic splinting alone is often used to achieve relative immobilization for fractures of the metacarpals and phalanges (see Chapters 15 and 37). Following the initial treatment of closed reduction of fractures in the shaft of long bones, such as humeral shaft fractures, the surgeon may prescribe a functional fracture brace as popularized by Sarmiento and shown in Figure 36-2 (Colditz, 2011). The lightweight thermoplastic fracture brace allows for motion above and below the fracture site and minimizes

the detrimental effects of prolonged immobilization. The patient is closely monitored for circulation, biomechanical alignment, and desired (controlled) movement. The therapist adjusts the shell to facilitate comfort, to respond to changes such as a reduction of limb volume, and to adjust the amount of movement the splint permits.

Early Consolidation. Therapy usually begins with focused, active use of the limb. Active therapy consists of activities and tasks to remediate the use of the muscles in the injured region. The therapist directs the client in a graduated program to resolve the presenting impairments and to reintegrate the limb into normal and customary use for functional tasks and role performance. If secondary changes are noted in the adjacent body parts or if there is a change in body posture, therapy is also directed to resolving those impairments.

Should edema persist even with elevation and active muscle contraction, additional methods, such as compression gloves or sleeves and gentle lymph massage, are used. To ameliorate stiffness and pain, the therapist may introduce modalities such as paraffin, fluidotherapy, or heat packs before or with exercise or activity (see Chapter 19). If stiffness prevails and the fracture is stable, joint mobilization and passive stretching are performed to facilitate the arthrokinetic accessory movements to increase the passive movement potential. These interventions should be approved by the surgeon before incorporating them into the treatment plan. Dynamic splinting, static progressive splinting, or the use of continuous passive motion (CPM) may also increase passive mobility over time. Adherent or hypertrophic scar formation after open reduction or soft tissue repair can also limit movement, increase pain, and alter sensation. To prevent this, the therapist teaches the patient deep pressure tissue massage and applies continuous pressure to the scar with a scar pad to facilitate scar remodeling (see Chapter 40).

FRACTURES

The care of fractures challenges both the surgeon and the occupational therapist to help the client ultimately reincorporate the injured limb into occupational performance. To initiate the care of a client who sustained a fracture, the therapist must understand the anatomy and biomechanics of the extremity and select intervention strategies that are consistent with the physiological process of fracture repair.

Shoulder Fractures

The shoulder complex is composed of the glenohumeral joint, scapulothoracic joint, sternoclavicular joint, and acromioclavicular joint. The shoulder complex provides a wide range of movements for hand placement but also provides the important functions of stabilization for

hand use, lifting and pushing, reaching, and weight bearing (Greene & Roberts, 2005). The shoulder is considered the most challenging portion of the body to rehabilitate. After traumatic, degenerative, or surgical shoulder lesions, the therapy goals are delicately balanced to relieve pain, to restore movement and muscle strength, and to allow for callus formation and the approximation of the bony fragments in the injured region.

Immobilization of the shoulder results in stiffness and pain; therefore, nonoperative and postoperative therapy programs call for a specific regimen of PROM, AAROM, or AROM within a controlled, guarded range. Shoulder fractures are closely monitored by radiographs as initial controlled PROM and AAROM begin. There is controversy with regard to PROM. Some argue that passive motion is contraindicated, particularly in the elderly (Goldstein, 1999). Others say that passive movement is safe if the provided range corresponds to the surgeon's prescribed limitations. The therapist must also remember that PROM differs from passive stretching. PROM is movement of the limb by an external force to its available end range or prescribed end range. Passive stretching is movement of the limb by an external force to its available end range and then applying overpressure. *Safety Message: Passive stretching is contraindicated in the early stages of fracture healing.* Emphasis is on the patient resuming nonresistive functional activities and using the injured limb as soon as movement is allowed.

Because immobilization quickly results in stiffness, shoulder motion begins as soon as the acute pain diminishes in stable shoulder fractures. Therapy can begin as early as 7–10 days postinjury and includes pendulum exercises and sling immobilization (McKinnis, 2010). Exercises may progress to gentle P/AAROM (beginning with scapular elevation and external rotation. In 2–8 weeks, the client can begin AROM and light self-care activities. At 8 weeks, the sling is usually discarded, and the client can begin strengthening (Hodgson, 2006).

Unstable shoulder fractures usually require surgical intervention for fixation. The protocols are based on the classification of fracture, the type of surgical procedure, and the age and activity level of the client, and they often follow the guidelines as originally described by Neer (1990). Some postoperative protocols start with early mobilization programs, whereas others have a period of immobilization. Agorastides et al. (2007) found no difference in function in a study between those who received early mobilization immediately versus those who started mobilization 3 weeks postsurgical fixation. When approved by the surgeon, the sequence of exercise begins with Codman's pendulum exercises (Fig. 36-3). Codman's exercises are performed with the patient bending over so that the injured upper limb is perpendicular to the floor. In this gravity-assisted plane, the patient does clockwise and counterclockwise circular movements and flexion, extension, abduction, and adduction.

Figure 36-3 Codman's exercise (Pendulum exercise).

Safety Message: Codman's exercises may be contraindicated if the upper extremity is edematous. Also, during the first 6–8 weeks, progressive shoulder exercises for flexion and internal and external rotation are started, as are isometric exercises, a stimulant for fracture healing and callus formation; wall climbing; nonresistive therapeutic activities; and light ADL. PROM only begins when clinical union is evident and when there is no fear of disrupting the fracture.

Humeral head fractures that are unstable and significantly displaced are often surgically treated with humeral head replacement, known as hemiarthroplasty. A total shoulder arthroplasty is considered for clients with severe arthritis in combination with a proximal humerus fracture (Keenan & Mehta, 2006). A new surgical approach is the reverse total shoulder replacement. This approach is used when there is significant damage to the rotator cuff or severe arthritis of the glenohumeral joint. The major limitation of this surgery is impaired shoulder rotation (Gallinet et al., 2009; Garrigues et al., 2012).

Therapy for total shoulder arthroplasty varies with the design of the prosthesis and the surgical procedure. The rehabilitation program begins within the first 1–2 days after surgery. The exercises should not cause any pain. The key to a satisfactory functional result is early achievement of shoulder elevation and external rotation in the plane of the scapula.

Codman's pendulum exercises, passive shoulder elevation done lying supine with the opposite hand assisting the affected limb, and use of an exercise wand to perform

passive external rotation are introduced during the first 2–3 days after surgery (Tan et al., 2011). The client is instructed to perform the exercises 4–6 times daily. Because the subscapularis tendon may be incised during surgery and the integrity of the rotator cuff may be disrupted, some surgeons introduce external rotation slowly in the first 4 weeks; others incorporate passive external rotation on the second postoperative day. The preferred position for passive external rotation exercise is with the humerus adducted. During this phase, the patient is instructed to begin nonresistive everyday activities, such as brushing teeth and self-feeding, while keeping the shoulder adducted to the side.

At 6 weeks postoperative, the client is instructed to add passive internal rotation, extension, and horizontal adduction. The client can progress to isometric strengthening and Thera-band® exercises for internal and external rotation. If the subscapularis was detached during surgery, the surgeon may restrict strengthening of this muscle at this time. At 8–12 weeks, Thera-band® exercises, free weights, and purposeful activities that emphasize shoulder elevation and rotational movements are initiated. At 12 weeks, the client is instructed in sports and work activities. Weight bearing on the injured arm is not allowed for at least 6 months (Neer, 1990; Tan et al., 2011).

Management of humeral shaft or humeral neck fractures is divided into three phases. Phase I includes positioning, Codman's pendulum exercises, and passive assistive exercises that are performed several times a day to prevent stiffness. Fractures of the humeral shaft and humeral neck both respond well to early passive movement and positioning. The occupational therapist may make a fracture brace conforming to the length of the humerus to provide the initial support after a humeral shaft fracture (see Fig. 36-2). *Safety Message: The therapist must be careful to flare and roll the edges of the shell to prevent compromise to circulation and nerve impingement while allowing available movement.* In the case of humeral shaft fracture, there is a risk of radial nerve damage because of the location of the injury relative to the course of the radial nerve. Radial nerve injury is characterized by the inability to extend the elbow, wrist, and digits. Other complications that are not uncommon with humeral shaft fractures are delayed union and nonunion. These complications may occur as a result of an injury to the nutrient artery located at midshaft when the humerus is fractured (McKinnis, 2010). A bone stimulator may be used to facilitate bone healing.

For phase II, the therapist encourages active assisted concentric and eccentric exercises, progressing to AROM and lightly resistive exercises. These patterns often begin with the client supine and progress to seated, in which the weight of the extremity is first supported by the therapist. Phase III addresses both stretching and strengthening. As healing permits, the client can combine shoulder forward flexion with abduction with or without external rotation

(Basti et al., 1994). Use of the injured extremity in occupation-as-end is encouraged.

Elbow Fractures

Elbow motion gives the individual the capacity to position the hand in space close to or far from the body for fine motor activities and to function as a stabilizer for strength activities (Davila, 2011). These movements are accomplished by two degrees of freedom: flexion and extension at the ulnohumeral and radiohumeral joints and pronation and supination at the proximal radioulnar joint. Intercondylar and supracondylar fractures (the extension type) are the most common of the distal humerus fractures that impact elbow function. These fractures are associated with complications that include malunion and peripheral nerve injury and have a risk of Volkmann's ischemia, a compartment syndrome of the forearm (McKinnis, 2010). Ischemia, considered an urgent medical matter, can be caused by edema within a fascia-surrounded compartment or by acute elbow flexion that compresses an artery against bone. Signs of ischemia include pale, bluish skin color; absence of forearm radial pulse; and decreased hand sensation accompanied by severe pain. *Safety Message: Report these signs immediately.* Immediate action is important because the peripheral nerves can withstand only 2–4 hours of ischemia, although they do have some potential to regenerate. The muscle can withstand up to 6 hours of ischemia, but it cannot regenerate (McKinnis, 2010; Salter, 1999). Prolonged occlusion allows for the progression to a contracture as the necrotic muscle becomes dense, shortened, fibrous scar tissue.

The nondisplaced or minimally displaced supracondylar fracture may be treated with closed reduction and immobilization in a removable cast or thermoplastic splint. After 1–2 weeks, the splint is removed daily for gentle AROM in a hinge splint (Beredjiklian, 2011). The splint is discharged after 6 weeks, and clients are encouraged to use their extremity for light ADL.

Complex elbow fractures, which include displaced supracondylar fractures and intercondylar fractures, are most often treated with open reduction and well-secured fixation. Active motion begins 2–3 days after surgery. The elbow fracture is splinted in 90° of flexion rather than extension because flexion has a greater functional importance. The splint is removed by the therapist to begin gentle A/AAROM. ROM of elbow flexion and extension is best performed in a supine position with the shoulder flexed to 90°. Gravity will assist with flexion, and the therapist will assist the client with extension. If the client also injured the collateral ligaments, restrictions on forearm rotation during elbow flexion and extension may be prescribed by the orthopaedic surgeon. Forearm ROM is performed in a seated position with the elbow flexed at 90° (Davila, 2011). Gentle PROM and light isotonic exercises are usually initiated between

6 and 8 weeks. Clients are encouraged to use their extremity for light self-care activities. At 8 weeks, there is an increased emphasis on restoring full ROM and increasing strength. In the elderly, elbow fractures are often treated with a sling alone, and active movement begins early to prevent stiffness and pain. A functional arc of motion for daily activities can be regained, but full ROM is not always achieved.

Radial head fractures can be treated with closed reduction or, depending on the severity, may require radial head excision. Radial head fractures seldom require more than a sling for immobilization. Active pronation and supination exercises are encouraged early. Emphasis should be placed on regaining active supination. Full supination is more difficult and painful than pronation (Davila, 2011). Supination and pronation exercises should be performed seated or standing, with the shoulder adducted to the side and elbow flexed to 90°. Exercises should be performed six times daily, with a minimum of two sets of 10 repetitions. Exercises should be pain free. CPM, dynamic supination splint, and static progressive splinting can be used to further encourage forearm rotation (see Chapter 37 for wrist and hand fractures).

ROTATOR CUFF PATHOLOGIES

The shoulder complex is the foundation of all upper extremity movements. The rotator cuff musculature plays an integral part in the function and control of the shoulder complex. The supraspinatus performs humeral elevation, the infraspinatus and teres minor perform external rotation, and the subscapularis performs internal rotation. Besides the actions they produce, the rotator cuff musculature functions as a force couple to control the head of the humerus on the glenoid fossa. Its anatomical location at the subacromial space, between the coracoacromial arch and the head of the humerus, makes the rotator cuff extremely vulnerable to compression. Charles Neer (1990) described a hooked acromion (type 3) as a possible cause of impingement syndrome that could progress to a tear. The supraspinatus also has an area of hypovascularity known as the critical zone. This zone is where the supraspinatus tendon inserts on the greater tuberosity of the humerus. Because of its anatomical location and area of hypovascularity, the tendon of the supraspinatus is the most commonly impinged rotator cuff tendon. Patients with rotator cuff pathology are often faced with the inability to perform the most personal self-care tasks. Activities such as toileting, hair care, and hooking a bra are all dependent on a normally functioning rotator cuff.

Shoulder Impingement Syndrome

Shoulder impingement syndrome is a compression of the structures found in the subacromial space. Structures found in the subacromial space (superior to inferior) include the subacromial bursa, supraspinatus, joint capsule, and long head of the biceps. Shoulder impingement syndrome is most commonly caused by a hooked acromion and or repetitive or sustained elevation of the shoulder above 90°. If shoulder impingement syndrome goes untreated, it can result in a rotator cuff tear. Neer (1990) developed a classification system to better understand the progression of shoulder impingement syndrome. Stage I is described as edema, inflammation, and hemorrhage. In this stage, the bursa and/or the tendons become irritated and inflamed. The symptoms can be reversed with occupational therapy intervention. The focus should be on activity modification. In stage II, the bursa and tendons become thick and fibrotic. At this stage, a person can be treated conservatively; however, recovery may take longer. In stage III, a person may present with bone spurs and partial- or full-thickness tears. A small tear is less than 1 cm, a medium tear is 1–3 cm, a large tear is 3–5 cm, and a massive tear is greater than 5 cm (Post, Silver, & Singh, 1983).

Rotator Cuff Tendonitis and Bicipital Tendonitis

A person may have rotator cuff tendonitis and or bicipital tendonitis but not shoulder impingement syndrome. The chief complaint of tendonitis is pain during humeral movement above 90°. In most cases, the client is independent with ADL; however, the patient will experience pain while performing these tasks. Common causes are repetitive overhead use, curved or hooked acromion, weakness of shoulder or scapula musculature, and capsular tightness. Tendonitis can be treated conservatively with pain modalities, activity modification, strengthening exercises, and occupation-based activities.

Bursitis

Shoulder bursitis is inflammation of the subacromial bursa. Subacromial bursitis can be differentiated from rotator cuff tendonitis if the patient has pain during passive shoulder elevation and is pain free during AROM and muscle testing of the rotator cuff. It is rarely a major source of pain and usually coexists with shoulder impingement syndrome (McMahon & Kaplan, 2006). See the section on shoulder impingement for causes.

Calcific Tendonitis

Calcific tendonitis results from calcium deposits laid down at the insertion of the tendon on the bone. In the shoulder, calcific tendonitis most commonly occurs in the supraspinatus and infraspinatus tendons. The cause is unknown. This type of tendonitis usually heals on its own by spontaneous reabsorption. Reabsorption of the calcium can take several months. During this time, the

person may experience significant pain. Physical agent modalities, pain-free ROM, and activity modification are used to address the pain.

Rotator Cuff Tear

Tears of the rotator cuff can be of partial or full thickness. See the section on shoulder impingement syndrome for description of size of tear. Causes include trauma, progression of impingement syndrome, and degenerative changes of the tendon and aging. Patients with rotator cuff tears will present with difficulty performing activities above shoulder level and will often compensate by hiking the shoulder using the upper trapezius muscle. Rotational movements, such as reaching the small of the back to tuck a shirt in or remove a wallet from a back pocket, can also be limited. Rotator cuff tears can significantly limit a person's occupational functioning. Rotator cuff tears are diagnosed using magnetic resonance imaging (MRI) and magnetic resonance arthrography (MRA) (Toyoda et al., 2005). Some partial tears can be treated conservatively with activity modification and strengthening of scapula and rotator cuff muscles. Surgical options for those patients who do not benefit from conservative treatment include arthroscopic, mini-open, and open repairs. Postoperative therapy focuses on regaining full ROM, scapula and rotator cuff strengthening, practicing ADL, and other meaningful tasks.

Evaluation of the Nonsurgical Patient

The evaluation should begin with an occupational profile and a thorough history. Discuss the mechanism of injury. Was it a sudden onset or gradual onset? If it was a gradual onset, try to determine what activity or sustained posture led to the rotator cuff problem. Also discuss the client's level of pain (scale of 0–10). Is the pain localized or referred? What activities or occupations cause pain? Can the patient sleep on the involved side? The therapist should also observe the patient's posture and symmetry of the scapula at rest and during upward rotation. The physical assessments can then begin with asking the client to perform various functional movements such as reaching the small of the back, reaching the opposite axilla, and touching the top of the head. See Chapter 7 for assessment of AROM and PROM and manual muscle testing of the shoulder. Active cervical ROM and sensory testing the C4 to T1 dermatomes (see Chapter 9) should be performed to eliminate the possibility of cervical involvement. Palpation of the rotator cuff tendons will assess tenderness and swelling. Special tests should be administered to determine all the involved structures. Special tests for rotator cuff pathology include the Neer impingement sign, Hawkins test, empty can test, drop arm test, and biceps Speed's test (Procedures for Practice 36-1).

Procedures for Practice 36-1

Special Tests for Rotator Cuff Injuries

1. Neer impingement sign: Forced forward flexion with the shoulder internally rotated. If the patient expresses pain, the sign is positive, indicating compression and/or inflammation of the supraspinatus and/or long head of the biceps (Fig. 36-4).
2. Hawkins test: Shoulder and elbow are flexed to 90° followed by forced internal rotation. If the patient expresses pain (Fig. 36-5), the test is positive, indicating compression and/or inflammation of the supraspinatus and long head of the biceps.
3. Empty can test: Shoulder elevation to 45° and internal rotation (thumb facing down). Therapist applies resistance to abduction (downward force) (Fig. 36-6). Positive sign is weakness or pain. This test indicates a tear of the supraspinatus tendon. Repeat the same test at 90°. If pain is only experienced at 90° position, suspect bursitis.
4. Drop arm test: Patient's arm is positioned in 90° of abduction. The patient slowly lowers his or her arm to the side. The test is positive if the patient drops the arm to the side, indicating a supraspinatus tear (Fig. 36-7).
5. Biceps Speed's test: Shoulder flexed to 90°, forearm supinated, and elbow extended. Resistance is applied to flexion (downward force using a long lever arm). Positive sign is pain over bicipital groove (Fig. 36-8).

ADL should be assessed by observing the patient using the involved extremity during activities that are within low range (waist level), mid range (shoulder level), and high range (above shoulder level). The therapist should note any compensating or expressions of pain while performing the activities. There are also numerous standardized

Figure 36-4 Neer impingement sign.

Figure 36-5 Hawkins test.

Figure 36-7 Drop arm test.

functional assessments specific to the shoulder, some of which should be included in the evaluation. Examples of standardized functional assessments that address World Health Organization International Classification of Functioning, Disability and Health (ICF) components: impairments, activity limitation, and participation restriction include the Disabilities of Arm, Shoulder and Hand (DASH), American Shoulder and Elbow Surgeons Self Report, Shoulder Disability Questionnaire, Shoulder Pain and Disability Index, and the Penn Shoulder Score (Dixon et al., 2008; Drummond et al., 2007; Hudak, Amadio, & Bombardier, 1996; McClure & Michener, 2003; Roy, MacDermid, & Woodhouse, 2009).

Evaluation of the Postsurgical Patient

The evaluation for the postsurgical patient will be guided by the surgeon. The decision to begin therapy and how to progress the client is based on many factors that include size and location of the tear, tissue quality, and surgical

approach (Ghodadra et al., 2009). Request for occupational therapy services can begin as early as 24 hours after surgery. Assessments of pain, PROM, and activity adaptation are the usual orders postoperatively. Depending on the type of repair, AROM can be assessed at 4–6 weeks, and strengthening can be tested at 8 weeks.

Treatment of the Nonsurgical Patient

Conservative treatment should begin with educating the patient on activity modification. The patient should be instructed to avoid above shoulder level activities until pain subsides. Sleeping postures should also be addressed. The patient should avoid sleeping with the arm above shoulder level or in an adducted and internally rotated position. Combined adduction and internal rotation for a long period of time can further compromise the blood supply of the supraspinatus tendon. Exercise should focus on pain-free ROM. Begin with PROM. As pain decreases, progress to AROM. Strengthening should include

Figure 36-6 Empty can test.

Figure 36-8 Biceps Speed's test.

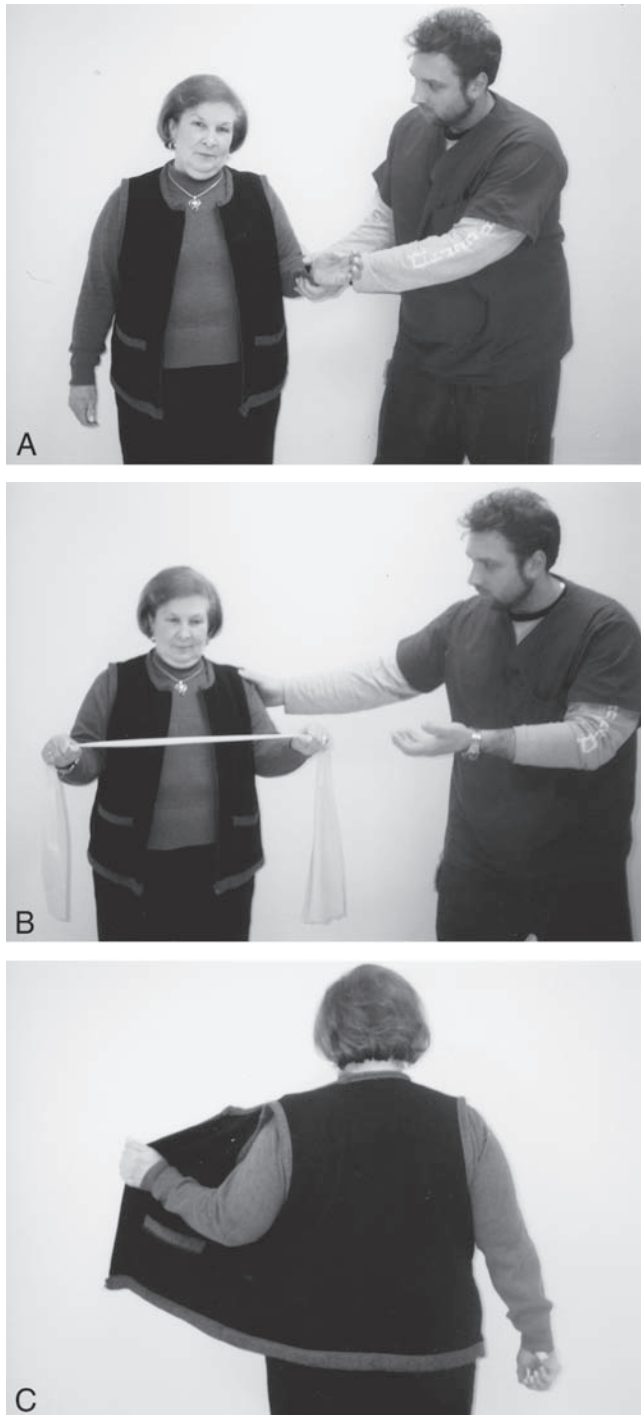
isometric and isotonic exercises for the rotator cuff and scapula musculature. Also improve ROM and strength through functional activities such as dressing (Fig. 36-9, A–C). Investigate what occupations are most important to the patient and have him or her bring in the necessary equipment such as a golf club or tennis racquet. The


Figure 36-9   Progression of strengthening program. **A.** Isometric resistance to external rotation. **B.** Isotonic resistance to external rotation. **C.** Functional activity that incorporates external rotation.

long-term goal is to return the patient to unrestricted, pain-free occupational functioning.

Treatment of the Postsurgical Patient

Initiation of treatment following a rotator cuff repair will be based on the size of the tear, type of surgical repair, and tissue quality. After surgery, the client is placed in an abduction pillow brace. Following repair of a small or medium tear, the patient will begin with PROM/AAROM for the next 4–6 weeks. The movements emphasized should include pain-free Codman's pendulum exercises, passive shoulder elevation, and internal/external rotation in the slightly abducted position in the scapular plane. An ice pack should be used before, during, and after exercise to decrease pain and swelling. The client should be instructed to perform these exercises at home using the uninvolved arm to supply the power. Internal and external rotation is performed with the client supine and the shoulder slightly abducted to 30° (in the scapular plane) and elbow flexed to 90°. A cane or stick is held in both hands, whereas the uninvolved arm supplies the power to move the involved extremity toward the stomach (internal rotation) and away from the stomach (external rotation). Depending on the tension of the repair, the surgeon may set ROM limits. *Safety Message: Overhead pulleys are only used if requested by the surgeon because repetitive shoulder elevation may irritate the repair.* During this time, the patient should be instructed in one-handed techniques to perform ADL. The involved shoulder should not be used for any activity at this time, unless indicated by the surgeon. In between exercise sessions, the shoulder is protected in the abduction pillow brace. At 4–6 weeks, the client progresses to AROM. Begin in gravity-lessened positions and progress to against-gravity movements. Shoulder extension and internal rotation to the small of the back are added at 6–8 weeks. Encourage the patient to achieve functional ROM. Engage the patient in light ADL. Avoid compensatory movements such as hiking the scapula or lateral bending of the trunk. When performing against-gravity ADL, progress from waist level to above shoulder level activities. Strengthening can be initiated at 6 weeks to prepare the patient for functional activities. Initially, the strengthening program begins with isometric exercises for the rotator cuff and scapula stabilization exercises. Eight weeks after surgery, the patient progresses to isotonic exercises using Thera-band® and free weights. All strengthening should be performed below 90° and be pain free. Initially, exercises using free weights should begin supine to lessen gravity and prevent compensating. Then eventually increase to against-gravity strengthening remaining below 90° (Boissonnault et al., 2007; Butler, 2007; Ghodadra et al., 2009). Later, light ADL above shoulder level can be emphasized (if there is no hiking of the scapula), including cooking and folding laundry.

At 12 weeks, the patient can begin resistive occupation-based tasks. Again, the long-term goal is to return the patient to normal pain-free occupational functioning.

Following repairs of large and massive tears of the rotator cuff, the client is immobilized in an abduction brace (O'Brien, Leggin, & Williams, 2011). ROM begins with pendulum exercises only. ROM restrictions vary depending on the surgeon's protocol. Some clients begin PROM within the first week, and others begin 6 weeks following surgery. The preparatory (exercise and ice) and purposeful activities are the same as for a small and medium tear, but the time frame of when they start are delayed. Time frames are determined by the surgeon. The treatment protocols given here are only guidelines; communication with the surgeon should be ongoing throughout the patient's rehabilitation.

HIP FRACTURES

Intertrochanteric hip fractures and femoral neck fractures are the most common fractures in adults older than 50 years of age (Altizer, 2005; Lareau & Sawyer, 2010). These fractures occur in bone that is markedly weakened by osteoporosis (Salter, 1999). Many of these patients have comorbidities, including congestive heart failure, coronary artery disease, hypertension, chronic obstructive pulmonary disease, or diabetes, that affect the duration and potential of the rehabilitation program (Altizer, 2005).

Hip fractures can be treated with closed reduction, which includes bed rest, traction, or early mobilization. The large majority of hip fractures are treated with open reduction with internal fixation using pins, nails, screws and plate, or rods (Keenan & Waters, 2003; Lareau & Sawyer, 2010). Hemiarthroplasty is the treatment for some fractures of the neck and head of the femur. Hemiarthroplasty is a partial joint replacement in which the femoral head

and neck are replaced by a prosthesis composed of ceramic with a titanium stem component. After excision of the femoral head, the stem of the prosthesis is inserted distally into the medullary canal of the femur so that its head articulates with the normal acetabulum (Lareau & Sawyer, 2010). If destructive changes have taken place in both the femur and the acetabulum, a total hip arthroplasty (THA) is necessary (Keenan & Waters, 2003).

Occupational Therapy Following a Hip Fracture and Surgery

The restrictions for weight bearing and hip movement on the operated leg are directly related to the severity and location of the fracture, the surgical approach, the ability of the fixation device or prosthesis to withstand stress, the integrity of the bone, the weight of the patient, and the patient's cognitive status (Goldstein, 1999). The physical therapist teaches the patient to use a walker or crutches, depending on percentage of body weight allowed on the operated limb (Definition 36-2). The occupational therapist teaches the patient to complete ADL safely, corresponding to the medical orders and the physical therapy progression for postoperative weight bearing. For some patients, preexisting factors or the risk of dislodging the new hip joint may necessitate the assistance of another person for lower extremity dressing and for bathing.

The rate of progression of weight bearing and mobility is individually tailored for the patient by the rate of fracture healing and the patient's response (Goldstein, 1999). Close communication among the members of the rehabilitation team is imperative to provide the patient with the best quality of care and consistency in learning how to function after surgery. Essential to the planned discharge following a hospital stay of less than a week, which is common for most, is the therapist's evaluation of the patient's ability to perform basic and instrumental ADL safely and independently and

Definition 36-2

Progression of Weight Bearing after Hip Surgery (Goldstein, 1999)

Weight-Bearing Status	Percentage of Body Weight on Operated Limb	Ambulatory Device
Non–weight bearing	0	Walker (standard or rolling) or crutches
Touchdown weight bearing	10–15	Walker (standard or rolling) or crutches
Partial weight bearing	30	Walker (standard or rolling) or crutches
50% weight bearing	50	Cane
Full weight bearing	75–100	Cane or no device

Procedures for Practice 36-2

Adaptations for Activities of Daily Living after Hip Replacement Surgery

Problem	Adaptation
Bathe feet	Long-handled bath sponge
Get in and out of tub	Nonskid bath mat; grab bar; tub bench
Don, doff shoes	Extended-handled shoehorn (medial side for posterior surgical approach and lateral for the anterior approach); elastic laces
Don, doff socks	Sock aide
Don pants	Reacher or dressing stick
Transfer to and from toilet, tub, and bed	Raised toilet seat, increased height of chair and bed
Sit in and rise from a chair	Wedge cushion with thick end of the wedge at the back of the chair
Open and close cabinets	Relocate frequently used items to eliminate the need to bend; use a reacher

the need for adapted equipment and/or assistance of others (Bargar, Bauer, & Borner, 1998; Sandell, 2008).

It is best to teach the patient who is restricted to non–weight bearing or touchdown weight bearing to sit to perform ADL to conserve energy and increase safety. Once the patient can do partial weight bearing, he or she can safely stand while grooming. For at least 6 weeks, and for some patients longer, movement is restricted. Because these restrictions preclude bending over or bringing the foot closer to the hands, adaptations (Procedures for Practice 36-2) are required to resolve problems in bathing, dressing, functional mobility, and home management. *Safety Message: The patient must be reminded that the operated hip is not to be flexed actively or passively or the leg adducted beyond the midline* (Safety Note 36-1). Long-handled dressing and grooming devices are provided, and the therapist teaches the patient to bathe and dress the operated side using these devices to avoid bending over (flexion) or crossing the operated leg (adduction). For bathing, if permitted, some patients shower standing and require a grab assist bar and nonskid bath mat in the tub area for safety. Others prefer to sit to conserve energy or feel secure, and they require a bath bench. The bath bench must

Safety Note 36-1

Movement Restrictions after Hip Surgery

- No hip flexion beyond 90°, including movement of the trunk over the thighs
- No hip rotation (avoid internal rotation for posterolateral approach and external rotation for anterolateral approach)
- No crossing the operated leg over the unoperated leg
- No adduction of the operated leg

be high enough so the hip does not flex more than 80°–90°. These patients also require a nonskid bath mat and grab assist rail. Procedures for Practice 36-3 describes the procedure to get into and out of a bathtub after hip surgery.

To reduce hip flexion during sitting and rising, the patient is instructed to use a raised toilet seat, bed, and chair. Bed and chair heights are raised by putting wooden blocks under the legs. To increase mattress and chair cushion firmness to prevent passive hip flexion, plywood is inserted between the mattress and box spring or between the chair cushion and its frame. The patient is encouraged to sit in a reclined position enhanced by a wedge cushion or a small rolled pillow or towel at the junction of the chair's seat and back, as originally described by McKee (1975).

Procedures for Practice 36-3

Transferring into and out of a Bathtub after Hip Surgery

To get into the bathtub:

1. Stand with feet parallel to the tub with the operated leg next to the bathtub.
2. Shift body weight to unoperated leg.
3. Hold onto a grab assist rail for support.
4. Position the operated leg into hip extension and knee flexion; then abduct the hip to allow the leg to go over the edge of the bathtub.
5. Extend the knee on the operated side once the leg is over the tub edge.
6. Place the foot on the nonskid bath mat inside the tub.
7. When balance is secure, transfer the body weight to the operated leg.
8. Lift the unoperated leg over the edge of the tub and place the foot on the bath mat.

To get out of the bathtub:

1. Position self so feet are parallel to the side of the tub and the operated leg leads (goes out of the tub first).
2. Use the same procedure as for getting into the tub.

The patient who must sit in a regular-height chair is taught to stand up without overflexing the operated hip. In a chair with armrests, the patient scoots to the front edge of the seat, keeping the operated hip extended, and uses the armrests to push straight up without bending the trunk forward. In a chair without armrests, the patient moves to the side of the chair so that the operated thigh is over the edge with the foot placed at the midline of the chair. This places the operated hip in extension, puts the foot close to the center of gravity, and enables the person to gain momentum to stand without excessive hip flexion. With this technique, the unoperated hip, knee, and ankle are in position for weight bearing.

By 6 weeks, almost all patients walk with a cane, and some walk unassisted; most can return to driving a car, swimming, and work (Goldstein, 1999). Physical restrictions against bending to put on shoes or socks, sleeping on the operated side, and using a regular-height toilet seat are often lifted 8–12 weeks after surgery.

CHRONIC CONDITIONS

Some orthopaedic conditions are chronic. One is progressive hip pain from degenerative disease. When that pain interferes with activities and tasks of daily life despite medication, rest, reduction in lower extremity loading by the use of a cane, walker, or crutches, and physical therapy, hip surgery is indicated (Salter, 1999). After hip replacement surgery, therapists teach the patient to move the operated leg within the ordered weight-bearing and movement restrictions. Another chronic condition seen by therapists who practice in orthopaedics is low back pain. Medical costs for low back pain range between $20 and $50 billion annually (Hu et al., 2006). This section discusses occupational therapy both after hip replacement surgery and to relieve low back pain to enable occupational performance.

Occupational Therapy after Elective Hip Surgery Resulting from Disease

A number of surgical procedures are used for reduction of hip pain. They include osteotomy; arthrodesis, or hip fusion; hip resurfacing; and partial or total hip arthroplasty. To select the procedure, the orthopaedic surgeon considers not only the patient's age and physical status but also his or her occupational requirements and lifestyle.

Osteotomy is a procedure to correct the alignment of the femur to relieve weight bearing on the hip joint. When the osteotomy is done, compression plates stabilize the bone, and the patient can begin early postoperative mobilization with passive movement. Only partial weight bearing on the operated leg using crutches is allowed for 6 months, until the bone is healed. Osteotomies are not the treatment of choice for treating hip pain as a result of arthritis (Namba, Skinner, & Gupta, 2006).

Hip joint arthrodesis fuses the acetabulum with the femoral head at about 25°–30° of flexion and in neutral abduction and rotation. Arthrodesis is considered for patients younger than age 60 years who are in good physical condition and who have only one painful hip. It is not as common as other hip surgeries. A candidate for arthrodesis is a person who is not a candidate for a prosthetic hip implant because of heavy physical demands at work or recreational pursuits that are beyond the tolerances of an implant. This is also considered a salvage procedure for those whose prosthetic hip implant has failed. The patient is mobilized a week after the hip fusion and is allowed gradual weight bearing up to full weight in 2 months. Some patients do use a cane for a long time after surgery. The patient requires long-handled devices to assist with reaching the feet during bathing and dressing because of early postoperative flexion restrictions. In 6 months, when complete healing is established, the patient may be able to put on a sock and shoe when seated by flexing the knee to the side of the chair and reaching behind, using touch without visual guidance. The arthrodesis does leave the patient with a residual disability, but the hip is strong, stable, and pain free, and the patient has adequate endurance for everyday activities including work.

A THA surgically replaces the entire hip joint destroyed by disease or trauma. The main benefit of hip replacement is to resolve arthritic pain. Joint replacement surgery can also restore the length of the limb and its alignment, which has the potential to improve ROM and function (Drake, Ace, & Maale, 2002). This surgery replaces the arthritic acetabular cup with a titanium cup and polyethylene plastic liner. The femoral head is replaced with a femoral head implant made of ceramic and a titanium stem component.

The surgical approach to perform the THA varies among surgeons. The most common is the posterolateral approach (Youm, Maurer, & Stuchin, 2005). With this approach, there is no disruption to the gluteus medius and minimus muscles, and therefore, hip abduction is not compromised. The risk of the posterolateral approach is posterior dislocation. To avoid dislocation, immediately following surgery the patient is placed in an abduction pillow. Some surgeons also opt to place the ipsilateral knee in a knee immobilizer to further decrease the risk of dislocation. The patient is instructed to avoid hip flexion beyond 90°, adduction, and internal rotation. The second most common approach is the anterolateral approach (Youm, Maurer, & Stuchin, 2005). Although this approach decreases the risk for posterior dislocation and does not require an abduction pillow, the surgery requires division of the gluteus medius and minimus muscles and could disrupt the superior gluteal nerve, which leads to hip abductor weakness (Bertin & Rottinger, 2004). This weakness can result in a limp. The patient is instructed to avoid flexion beyond 90°, adduction, and internal and external rotation greater than 45° (Peak et al., 2005).

Another decision the surgeon must make when performing a THA is what type of implant fixation he or she will use. The choices are cemented, cementless, or hybrid prostheses (Namba, Skinner, & Gupta, 2006). The cemented total replacement usually requires 4–6 weeks of weight bearing to tolerance (WBTT) using a standard or rolling walker, and then the patient progresses to a straight cane. The cementless prosthesis, which depends on ingrowth of porous bone for stability, requires 6–12 weeks of partial weight bearing before a cane is used. Some surgeons may initially order non–weight bearing. In the case of the hybrid prosthesis, in which the femoral portion is cemented and the acetabulum is uncemented, 4–6 weeks of partial weight bearing precedes introduction of a cane (Youm, Maurer, & Stuchin, 2005).

Preoperative education should be the first phase of occupational therapy for the patient receiving a THA. Hip precautions, demonstration of long-handled equipment, and medically necessary durable medical equipment should be presented. Preoperative education has been linked to reducing anxiety (Spalding, 2003). The first 2 months after THA is critical for protection and function of the new hip joint. The postsurgical program is designed to allow for healing of the trochanter and soft tissues and for development of a capsule around the joint for future stability. *Safety Message: Until soft tissue is healed, hip flexion beyond 90°, hip adduction, and hip rotation (internal rotation for posterolateral approach and external rotation for anterolateral approach) are avoided.* The extremes of these movements during the first 2 months can dislocate the prosthesis. If dislocation occurs, the hip must be treated with closed reduction or be surgically realigned. The patient may be placed in a hip spica cast or knee immobilizer, delaying rehabilitation (Best, 2005). To protect the prosthesis, the occupational therapist instructs the patient in adaptive procedures and in methods to modify the environment to allow for safe performance of ADL and homemaking (Definition 36-2). The techniques used to help the patient following a THA parallel those described earlier: hip flexion and adduction are discouraged, limit hip rotation, and weight-bearing guidelines are carefully adhered to. Rehabilitation starts as early as 2 days after surgery.

For the client status post posterolateral approach, a foam abduction wedge is used with the patient lying down or sitting to encourage hip abduction. Once the patient achieves 55° of hip flexion in physical therapy, the patient can sit reclined on a raised chair using a rolled pillow or wedge cushion between the seat and the back of the chair and a foam abduction wedge between the legs. The patient learns to transfer from supine to standing without flexing the operated hip beyond 90° by keeping the knees apart (hips abducted) and sliding out of a raised bed to take weight on the unoperated leg. Some patients use an overhead trapeze bar to assist this transfer. The patient also

needs to practice transferring from a variety of surfaces such as high chair (Fig. 36-10, A–C), tub bench, raised toilet seat, and a car seat.

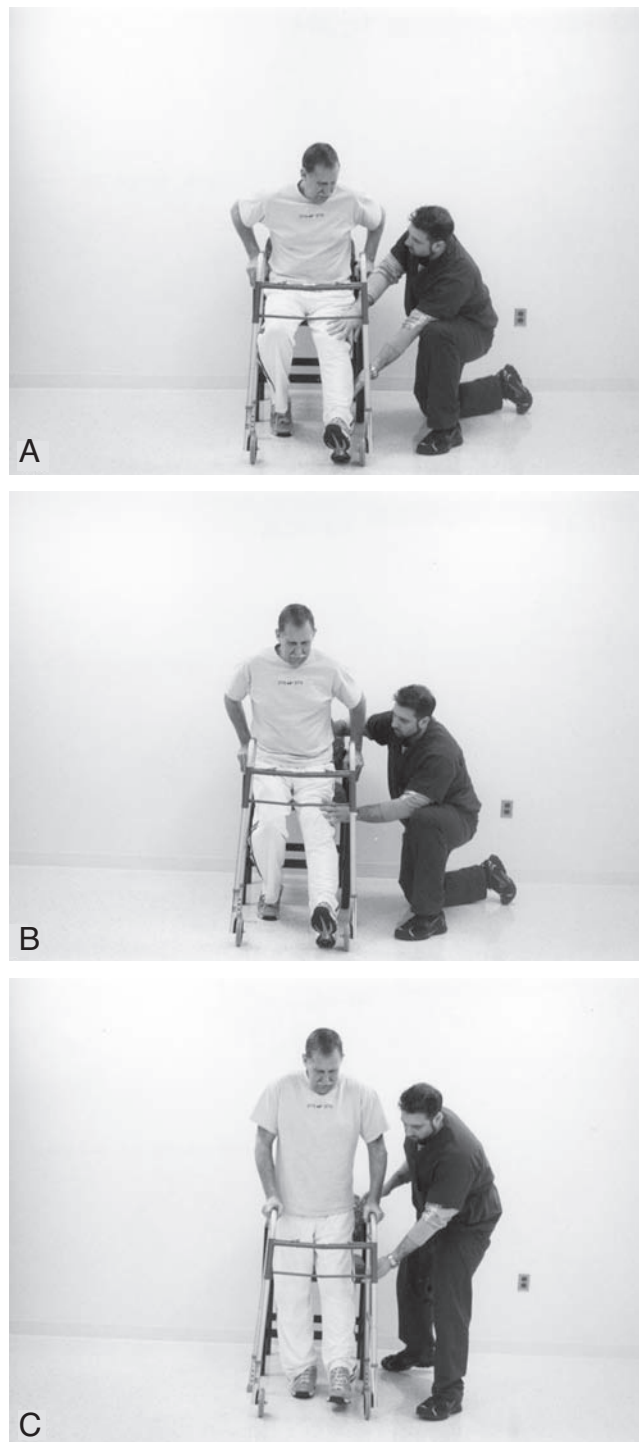
The patient with a cemented or hybrid total hip prosthesis usually begins partial weight bearing with a walker


Figure 36-10 Sit-to-stand transfer for a patient with non–weight-bearing status post total hip arthroplasty (THA). **A.** Extends knee and pushes off arms of chair. **B.** Avoids flexing hip past 90° while pushing off. **C.** Maintains non–weight-bearing status when standing.

Figure 36-11 Removing shoe status post total hip arthroplasty (THA). Approach medial aspect of shoe with long-handled shoe horn to prevent internal rotation if surgery used a posterolateral approach.

or crutches immediately after surgery. In some instances, these patients can withstand full weight bearing within the first 3 days; however, many orthopaedic surgeons wait 3 weeks before ordering full weight bearing (Goldstein, 1999). The ADL program, which can be taught with the patient standing, uses the bathing and lower extremity dressing techniques described for fractures (Procedures for Practice 36-2 and Safety Note 36-1). The patient with a cementless THA is usually touchdown weight bearing for the initial recovery phase and is conservatively progressed to partial weight bearing (Goldstein, 1999). This necessitates learning ADL from the seated position (Fig. 36-11). Once 50% weight bearing is ordered, the ADL program is upgraded to allow for standing with a cane. The cane is used until the Trendelenburg gait disappears.

Usually, after a THA, patients do not receive outpatient therapy following inpatient rehabilitation, although many may receive home care occupational and physical therapy for safety assessment and/or treatment. Evidence Table 36-1 describes an effective postoperative occupational therapy program and two equally effective preoperative exercise programs for persons having joint replacement.

Between the second and third month after surgery, patients usually resume all routine daily activities, with the restrictions listed in Safety Note 36-1 still applicable. For some, this restriction may persist for a long time, even for life. Mayo Clinic has recommended the following low-impact sport activities permissible at >12 weeks after surgery: golf, swimming, cycling, bowling, sailing, and scuba diving (Healy, Iorio, & Lemos, 2001). Tennis, skiing, and jogging are discouraged.

Low Back Pain

Pain is defined as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain, 2012). Acute pain is proportional to the physical findings. It is often an indication that the patient has traumatized or damaged tissue. Physical and psychological responses to acute pain may include muscle guarding, anxiety, and increased pain behaviors (Healy, Iorio, & Lemos, 2001). Chronic pain is described as pain that extends beyond 3 months postinjury (International Association for the Study of Pain, 2012). Patients with chronic pain often become preoccupied with their symptoms, experience sleep deprivation, and have difficulties performing their ADL (Cieza et al., 2004).

Low back pain has been reported at one time or another by approximately 80% of the adult population (Hu et al., 2006; World Health Organization, 2003). Postural stress and disc degeneration are the most common causes of low back pain (Cohen, Argoff, & Carragee, 2008). Examples of postural stressors include poor sleeping and sitting postures, lifting or reaching with a rounded back, and prolonged standing or sitting (McKenzie, 2005). Other causes of back pain include spinal stenosis, vertebral fracture, tumor, infection, spondylolisthesis, and arthritis. Most episodes of low back pain are self-limiting; 90% of patients return to work within 6 weeks. However, 1% of patients have chronic pain and are out of work for more than 6 months (Hu et al., 2006).

The primary goal in medically managed back care is to prevent the patient from developing chronic pain that leads to occupational dysfunction. If pain is not alleviated, the objective findings of assessments done over time may have little or no association to a nociceptive stimulus. Chronic low back pain has become increasingly associated with psychological distress disorders and nonphysiological behaviors such as malingering or symptom magnification (in which one exaggerates the symptoms) and disease conviction or factitious disorder (convince self and others that the disease exists) (Manchikanti et al., 2003). This situation can be very difficult to treat and often requires a multidisciplinary approach.

The primary focus when treating patients with acute or chronic low back pain is to return them to work and to resumption of their daily activities as quickly as possible. All efforts should be made to prevent the development of chronic pain syndrome by adopting practices used in sports medicine treatment to calm the pain and relax the muscles. Bed rest is replaced with early application of physical therapy, a flexibility program, and active involvement in a graduated program of occupation-as-end. Studies have shown that exercise can significantly reduce sick leave in patients with low back pain (Kool et al., 2004). Because physical therapy helps the patient develop dynamic control of the lumbar spine through flexibility training, stretching, and ROM exercises, the occupational therapist directs the patient in performance of activities in a neutral lumbosacral position (the midpoint of available range between anterior and posterior pelvic tilt). The occupational

Evidence Table 36-1 | Best Evidence for Occupational Therapy Practice Regarding Hip Fracture

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Early postoperative individualized occupational therapy	Occupational therapy group: individual daily activities of daily living (ADL) and instrumental activities of daily living (IADL) training, including the use of technical aids plus one home visit. Control group: conventional care	One hundred patients aged ≥65 years having undergone surgery for hip fracture. All lived independently, and none used walking or technical aids prior to hospitalization (randomized to group). Ninety completed the study (10% attrition)	After the third to fourth postoperative day, the occupational therapy group received 45–60 minutes of individualized training (including technical aids) each weekday morning for 3–33 days. The control group received conventional care from the nursing staff for 3–23 days. All patients received instruction in walking with mobility aids.	Randomized controlled trial Level: IB1b	Yes. Occupational therapy sped up the ability of patients to perform ADLs, enhancing probability of discharge home. At discharge, the occupational therapy group had significantly better ability to dress, to toilet, and to bathe independently compared with the control group. No other factors (e.g., age, sex, type of fracture, etc.) explained the outcome. After 2 months, all patients had regained independence.	Klein-Bell ADL Scale subtests: Dressing: $F_{(2,91)} = 79.0$, $p = 0.0001$, $r = 0.79$.[a] Toileting: $F_{(2,90)} = 5.97$, $p = 0.02$, $r = 0.34$. Bathing/hygiene: $F_{(2,91)} = 17$, $p = 0.0001$, $r = 0.52$. Mobility: $F_{(2,91)} = 2.20$, $p = 0.1$, $r = 0.21$. Fifty-two percent of the occupational therapy group (only group evaluated) needed technical aids and adaptation of their homes. Preventative changes (remove loose rugs, etc.) were needed in 90% of the homes.	Hagsten, Svensson, & Gardulf (2004)
Preoperative land-based or pool-based exercise program	Each program included an education session, exercise classes (in pool or on land), a home exercise program, and an occupational therapy home assessment. The pool-based program included the benefits of buoyancy, hydrostatic pressure, and thermotherapy.	Patients (mean age = 70.3 years) waiting for total hip or knee replacement. Eighty-two subjects who (stratified by hip or knee replacement) were randomized to group: land $n = 40$; pool $n = 42$. 51 of the participants were females, and all but 8 were categorized as obese.	Both programs were conducted for 6 weeks and met two times per week. Each session lasted 1 hour.	Randomized controlled trial Level IB2b	Yes. Reduced pain and improved function was noted in both groups although there was no significant postintervention differences between land-based and pool-based programs. Participants in the pool-based program reported significantly ($p = 0.019$) less pain immediately following exercise.	The results indicated no significant difference for the main effect of group for the WOMAC[b] function ($F = 0.112$; $p = 0.739$) or the WOMAC pain ($F = 0.257$; $p = 0.614$) subscales. There were significant main effects for time (baseline to 7 weeks) of both function (land: $p = 0.000$; pool: $p = .016$) and pain (land: $p = 0.000$; pool: $p = 0.011$) measures. Baseline to week 15 assessment showed improvement in both groups for WOMAC function (land: $p = 0.012$; pool: $p = 0.045$), but only the land group for pain (land: $p = 0.015$; pool: $p = 0.431$).	Gill, McBarney, & Schutz (2009)

[a]r value was calculated from data reported, using a formula for F with $df_{numerator} > 1$. Effect size (r) is considered large if ≥0.50, medium if ≥0.30, and small if ≥0.10.
[b]The Western Ontario and McMaster Universities Arthritis Index (WOMAC).

therapist teaches the patient to understand, manage, and protect the low back by using proper body mechanics and alternative techniques to perform activities at home and at work (Sanders, 2004). As endurance training progresses in physical therapy, the occupational therapist upgrades the type and quantity of ADL and work-related task challenges. When return to usual and customary activities is imminent, the treatment addresses safety and prevention of recurrence.

Teaching patients about their back and body mechanics has been part of rehabilitation for many years. The multidisciplinary team usually consists of a physician, a physical therapist, an occupational therapist, and, in some instances, a social worker or psychologist. The philosophy is that education in anatomy, spine function, and proper body mechanics for daily living and leisure activities will help patients with low back pain take responsibility for long-term management of their back. Patients have reported that engagement in daily activities and being able to participate in social interactions is more of an indication of quality of life than the presence or absence of pain (Hush et al., 2009). The multidisciplinary approach to treating patients with low back pain can significantly reduce pain and improve occupational functioning (Guzman et al., 2001) (see Evidence Table 36-2).

Evaluation of the Patient with Low Back Pain

In the initial interview, the therapist asks about the pain history and pain reaction during activity. Patients are asked to describe their pain in relation to location, intensity (using a 0–10 pain scale), quality (the pain is sharp, throbbing, burning, etc.), and duration. Completion of an occupational profile will provide the therapist with information on what occupations are most meaningful to the client and how the client balances those activities throughout the day. In regard to the client's low back pain, additional questions may be needed to determine the person's extent of accommodation and methods for task completion. Observation of actual or simulated performance of tasks may be indicated to reveal the patient's functional limitations and decision-making process.

Treatment of the Patient with Low Back Pain

The occupational therapist facilitates the patient's active participation in tasks and activities by teaching body mechanics and how to perform activities safely. Based on research, effective therapies that may be included in the occupational therapy program include preparatory interventions such as hot packs, transcutaneous electrical nerve stimulation (TENS), stretching exercises, relaxation techniques for stress reduction, biofeedback for muscle control, and group educational sessions (Snodgrass, 2011). Body mechanics are taught relative to static and dynamic postures and transition patterns

(e.g., sit to stand, stand to stoop). The occupational therapist demonstrates body mechanics with commonly performed tasks to show the patient how to apply the principles to everyday tasks. The emphasis is on both cognitive and motor learning to develop the patient's understanding and ability to self-regulate motor activity safely. Therapeutic activity, including games, crafts, ADL, and work tasks, are selected for practice. Through feedback, the therapist guides the patient's performance during the activities and encourages development of self-regulation.

Body Mechanics

Good body mechanics entails practices to reduce the load or stresses on the spine in various positions or when moving objects. Compression and twisting of the spine are avoided, as are attempts to exert force in positions that poorly support the spine (Procedures for Practice 36-4). Suggestions for application of principles of body mechanics in various postures are as follows:

- While standing, for example to cook or wash dishes in the kitchen or to brush teeth at the bathroom sink, the patient places one foot on the shelf under the sink or on a low stool to achieve posterior pelvic tilt. This technique is used whenever prolonged standing is a requirement.
- To sit, the patient lowers the body by flexing the knees and hips without bending the spine. To do so, the patient places the hands on the chair's armrest, both to guide the descent and to provide support through the transition. A raised seat is recommended because it requires less muscle power, which reduces pain and stress on the back. A slightly reclined sitting posture is preferred for prolonged sitting. When seated to work at a table, the patient avoids bending over the work by moving the chair close to the work and raising or inclining the work surface as needed.
- When lying in bed, the ideal posture to decrease pressure on the spine is supine with the knees flexed. A pillow should be placed under the knees to maintain the flexed posture. Log roll to come to a seated position. For patients who sleep on their side, a pillow should be place between their legs with the knees slightly flexed.
- For tasks that ordinarily require excessive reaching and bending of the spine, such as sweeping, vacuuming, or raking, the patient is taught to move the body close to the task, that is, to walk with the broom or rake rather than reaching with it. For lifting objects from the floor, the choice of position depends on the size and weight of the object. To pick up a lightweight object, such as a newspaper, the patient faces the newspaper and lowers both knees in a semisquat (or a ballet position of plié) toward the floor while keeping the back straight and maintaining posterior pelvic tilt. When lifting a large or heavy object or a small child, the patient adds more central support by lowering one knee to the floor

Evidence Table 36-2	Best Evidence for Occupational Therapy Practice Regarding Pain Management					
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Multidisciplinary pain management program	The program included physical, psychological, activity-based, and social interaction–based training and education. The team consisted of occupational therapist, psychologist, physician, physiotherapist, and social worker. Group-oriented program (eight to nine patients per group) but with individually tailored treatment for each patient.	One hundred eighty-eight patients with pain diagnoses (fibromyalgia, low back, whiplash, and myalgia). Males: 42; females: 146. Mean age = 41 years. Mean pain duration was 7.6 years for females and 5.8 years for males.	5–7 hours each session, once a week for 5 weeks	One-group, repeated-measures design Level: IIIA2a	Yes. There was significant improvement in occupational performance and performance satisfaction as measured by the Canadian Occupational Performance Measure (COPM); 30%–37% of patients increased two or more points on the COPM; 44%–56% increased more than one point in performance and satisfaction.	$p < 0.001$; insufficient data to allow calculation of the effect sizes	Persson, Rivano-Fischer, & Eklund (2004)

Procedures for Practice 36-4

Principles of Body Mechanics (Fig. 36-12, A–C)

The patient is taught to do the following:

- Incorporate a pelvic tilt during static sitting or standing to unload the facet joints, aid in pelvic awareness, and decrease muscular tension in the low back.
- Position the body close to and facing the task. This aids in balance by getting the objects as close to the center of gravity as possible. Objects held away from the body require increased force of all muscles to lift or hold them. Getting closer also helps to avoid twisting or bending the spine.
- Avoid twisting. Twisting causes stress on the ligaments and small muscles of the spine. Instead, turn the body by stepping with both legs to face the activity.
- Use the hip flexors and extensors to lower and raise the body. These are large muscles with leverage and power to handle heavy loads. The joints and muscles of the spine are much smaller, with less leverage and power.

- Avoid prolonged repetitive activity or static positions. Take microbreaks and walk briefly or stretch every hour.
- Balance activity with rest to facilitate endurance and safety. Incorporate rest periods into the course of a particular activity or alternate between two work patterns that challenge different muscle groups.
- Use a wide base of support. Stability while lifting is increased when the feet are at least hip distance apart. One foot slightly in front of the other provides additional support.
- Keep the back in proper alignment, ear over shoulder, shoulder over hips, and hips over knees and feet to maintain the natural curves of the back. Practice in front of a mirror.
- Test a load before lifting to decide whether the lift should be modified. Describe how to modify the lift: get help, split the load into more than one lift, or put the object on wheels.
- Stay physically fit. Strong muscles and flexible joints are the best defense against injury or recurrence of an injury.

(half-kneeling) so that the body is close to and facing the object. The goal is to bring and keep the weighted mass as close to the body's center of gravity as possible. A small child is encouraged to climb up into the lap. Once the object or child is grasped securely, the knee on the floor helps push the body up, and then both legs extend to lift the weight. The patient should be

instructed to lift to an intermediate height, such as a chair, if possible, rest briefly, and then lift to carry.
- The patient is taught to carry light, well-balanced loads of laundry, groceries, and parcels close to the body. Infants are best transported in a front or back baby carrier or a stroller. Through practice sessions, the patient learns his or her safe load tolerances over given distances and time.

Figure 36-12 Lift using proper body mechanics. **A.** Move close to object being lifted. **B.** Lift with legs and maintain lumbar curve. **C.** Maintain lumbar curve throughout lifting activity.

It is important that practice employ common items, such as half a gallon of milk, which weighs 4 pounds, or a gallon of bottled water, which weighs 8 pounds.

Complementary and Alternative Medicine for Treating Pain

Complementary and alternative medicines (CAMs) are becoming more accepted as we attempt to move beyond our traditional forms of therapy toward more holistic approaches to addressing pain. Yoga is commonly used to treat arthritis, low back pain, and upper extremity conditions. Yoga combines alignment of posture, stretching, proper breathing, and relaxation. Several studies have shown yoga to be effective in treating pain; however, these studies did not address adverse effects that might occur as a result of using Yoga (Posadzski et al., 2011). Mindfulness meditation combines deep relaxation, meditation, and gentle exercise as an approach to manage pain and stress. Preliminary research on mindfulness meditation has shown promising results in the area of improved pain,

improved sleep, and improved quality of life (Morone et al., 2008). Participating in a 30-minute mindfulness meditation program 4–5 days a week has been shown to improve pain levels of clients diagnosed with chronic low back pain (Morone, Greco, & Weiner, 2008). Tai Chi is another complementary therapy that has been used by occupational therapists. The primary features of Tai Chi are slow sequential movements with a straight spine, proper abdominal breathing and different styles of pushing hands. Research on Tai Chi has found improved pain levels during ADL for clients diagnosed with fibromyalgia, osteoarthritis, and rheumatoid arthritis. Tai Chi is especially effective with improving lower extremity balance, strength and pain (Field, 2011). Therapists using CAMs in occupational therapy should demonstrate competency and be aware of licensure laws in regard to their use (American Occupational Therapy Association, 2011). Occupational therapists who are not specialized should consider referring their clients to other trained professionals to receive therapies such as acupuncture, Ayurveda, energy healing, and massage therapy.

case example

Mrs. B.: Returning to Homemaking and Volunteer Roles after Total Hip Replacement

	Clinical Reasoning Process	
Occupational Therapy Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Mrs. B. is a 72-year-old married female who fell on ice 3 days ago when she walked from her house to her car. She was admitted to the hospital on the same day with a diagnosis of a right intertrochanteric hip fracture. Because of the severity of the hip fracture, Mrs. B. required surgical intervention the same day. She received a cemented total hip replacement. Mrs. B. anticipates returning home to be with her husband and eventually resuming her homemaking and volunteer roles.	Understand the patient's diagnosis or condition Understand postsurgical precautions	"Most patients who are status post cemented total hip replacement (s/p THR) can begin weight bearing as tolerated, and so I am hopeful that Mrs. B. will be given the same weight-bearing orders. The surgeon performed the total hip replacement using a posterior lateral approach, so precautions must be taken to avoid dislocation."
	Know the person	"Mrs. B. has a history of osteoarthritis in both hips; however, she has been able to manage the pain with Advil®."
	Know the environment that she will be discharged to	"Mrs. B. obviously values her home life and being active in the community."

Reason for Referral to Occupational Therapy Mrs. B. was referred to occupational therapy for the duration of her acute-care postoperative hospital stay, approximately 3 days, to learn how to move safely while adhering to hip precautions, to practice transferring, and to begin to resume personal activities of daily living (ADL). She was also referred to physical therapy.	Appreciate the context Develop provisional hypotheses	"Mrs. B. will have to follow the hospital's total hip replacement critical pathway, which allows a 3-day stay. I am glad she was referred to physical therapy, as we will be able to coordinate our services as well as cotreat during some of our sessions. I anticipate at the end of her 3-day stay that Mrs. B. will have improved occupational functioning by understanding hip precautions and practicing with long-handled equipment. The cotreatments with physical therapy will help to improve her confidence and ability to transfer."
Assessment Process and Results • The evaluation began with an occupational profile. Mrs. B. reports that she lives with her husband in a one-story ranch-style home. There are four steps to enter her home. The bathroom has a combined tub and shower. She reports her husband is retired and very supportive. She enjoys cooking for her husband and children. • Bed mobility and transfers were assessed. Mrs. B. required minimal assistance for bed mobility and contact guard (CG) with verbal cues for tub and toilet transfer (using standard walker). • Self-care: Dressing: hip precautions were reviewed, and use of long-handled adaptive equipment was demonstrated prior to the assessment. Mrs. B. was independent with upper body dressing but required moderate assistance for lower body dressing. Mrs. B. required constant verbal cueing on hip precautions during dressing assessment. Bathing: Mrs. B. is independent (I) in sponge bathing (bedside) her upper body but requires moderate assistance bathing her lower body (with aid of long-handled sponge). • Upper extremity ROM: AROM is within functional limits (WFLs) throughout both upper extremities. • Manual Muscle Test (MMT): 4 out of 5 muscle strength throughout both upper extremities. • Pain (scale 0–10): Mrs. B. reported a 7 out of 10 for her right hip. Mrs. B. reports her pain is constant and interferes with her sleep and any movements she has been requested to do by nursing.	Consider evaluation approach and methods Interpret observations	"Because of the orthopaedic nature of Mrs. B.'s injuries, an approach that focused on her impaired performance skills and patterns was used to assess her impaired abilities and capabilities." "Pain was reported throughout the entire evaluation, which I was concerned might interfere with her progress. I contacted the patient's surgeon, and pain medications will be increased and administered to coordinate with occupational and physical therapy treatment sessions. ROM and muscle strength of both upper extremities were assessed to determine their ability to assist with transfers. I spoke with the physical therapist, and we agreed to start her with a standard walker because she has a history of falls. Although many clients use rolling walkers s/p THR, a rolling walker moves quickly and could roll out from underneath Mrs. B.'s weight. Her major limitations are with her ADL and mobility activities."
Occupational Therapy Problem List • Pain that interferes with sleep and movement • Impaired ADL status • Unsafe transfers and mobility because of total hip replacement (THR) • THR restrictions	Synthesize results	"Mrs. B. has the typical problems one faces following a THR."
Occupational Therapy Goal List 1. Mrs. B. will have a pain level of 3 out of 10 during all self-care activities. 2. Mrs. B. will be able to transfer to and from a chair, bed, tub bench, and toilet while adhering to the hip precautions. 3. Mrs. B. will demonstrate how to use long-handled equipment to independently perform functional tasks in the kitchen, bedroom, and bathroom while adhering to hip precautions.	Develop intervention hypotheses Select an intervention approach Consider what will occur in therapy, how often, and for how long	"I feel Mrs. B. will have improved occupational performance by learning total hip replacement precautions. The structured daily therapy will also build her confidence for performing mobility and transfer tasks." "The OT intervention will use a combined compensatory/adaptation approach and restore/remediate approach." "Following the critical pathway, Mrs. B. will have three individualized treatments from OT during her inpatient stay. An additional three cotreatments with physical therapy will be added to address mobility and transfers."

Intervention

Mrs. B. participated in six treatments over a 3-day inpatient stay. Her pain medication was coordinated with OT visits. Both the occupational therapist and physical therapist taught Mrs. B. postures and movements that would be safe for her operated hip during transfers, sitting, standing, lying in bed, and bending and reaching during ADL and instrumental activities of daily living (IADL). Transfers were performed using a standard walker. She practiced with long-handled equipment while adhering to hip precautions. Tasks or components of tasks that she could not complete satisfactorily were identified. Mr. B. attended all of the occupational therapy sessions with his wife, and he agreed to assist his wife with those activities identified as being difficult for Mrs. B. The therapist taught Mrs. B. energy conservation techniques to be used during ADL and IADL. Mrs. B. was given a written and illustrated brochure concerning restrictions related to ADL. The therapist determined that Mrs. B.'s husband, with the assistance of a home health aide, could provide the necessary care for ADL and IADL that she could not manage because of hip precautions. Therefore, the recommendation was to discharge her home rather than to a skilled nursing facility.

Compare actual to expected performance	"Mrs. B. made significant improvement in her occupational performance with intensive therapy that used a team approach and family support."

Next Steps

- Discharge to home with assistance of home health aide.
- Recommend home care occupational therapy.

Anticipate present and future patient concerns	"Mrs. B. is a highly motivated individual who will benefit from home care OT to further maximize her occupational performance. She understands the importance of her home program as well as continuing with structured supervised OT. I feel confident that, in 6 months, Mrs. B. will be successfully participating in those occupational roles that she identified as valuable in her life (wife, homemaker, and volunteer)."
Decide whether the patient should continue or discontinue therapy and/ or return in the future	

Clinical Reasoning in Occupational Therapy Practice

Selecting Treatments for In-Home Therapy

Following Mrs. B.'s discharge to home, she is followed up with home care services. Based on her occupational profile, taken while she was an inpatient, knowledge of Mrs. B.'s surgical history, recovery history, and therapy experience and progress while hospitalized, what interventions might you select to enable pursuit of valued occupations and to assure adherence to hip surgery precautions if you were Mrs. B.'s in-home therapist?

Comprehension of Precautions

During the second occupational therapy session, you discuss her success in using the long-handled equipment issued to her in the hospital. Mrs. B. tells you that she is having her husband help until she is able to "bend over to dress herself without pain." How would you proceed with further treatment?

Summary Review Questions

1. What are the unwanted side effects of immobilization of any fracture?
2. How would you direct your patient to prevent adverse side effects of prolonged immobilization?
3. What is a major treatment goal for any patient with an upper extremity fracture?
4. Why is passive motion not used in the treatment of fractures of the elbow?
5. What are the guiding principles for advancing a patient in the aftercare therapy program following orthopaedic surgery?
6. What is clinical union, and why is it significant in terms of the therapy program?
7. Why are isometric contractions across the fracture site encouraged?
8. What type of activity modifications would you recommend to a client who is diagnosed with rotator cuff tendonitis?
9. Describe the type of preparatory interventions that can be performed at 6, 8, and 12 weeks post–rotator cuff repair surgery.
10. Describe the type of occupation-based activities that can be performed at 6, 8, and 12 weeks post–rotator cuff repair surgery.
11. What is the occupational therapist's role for the patient who underwent hip replacement surgery after a fractured hip?
12. After a hip fracture or total hip joint arthroplasty, the therapist directs the patient to perform occupational performance tasks safely. What specific tasks may threaten the integrity of the surgical procedure? Why?
13. List precautions that must be taught to a patient with a total hip arthroplasty (posterolateral and anterolateral approaches).
14. Describe how lower extremity dressing should be taught to a patient with low back pain, using all applicable body mechanics principles. Do the same for the tasks of sweeping the floor and working at a computer.

Glossary

Abduction pillow brace—A sling or brace that positions the shoulder in 30°–45° of abduction to protect the repaired supraspinatus.

Clinical union—Evidence of bony callus on radiographic examination, although the fracture line is still apparent (Salter, 1999).

Codman's pendulum exercises—Exercises prescribed for most shoulder surgeries in early recovery. The standing or sitting client bends over at the hips so that the trunk is parallel to the floor. The arm assumes a position away from the body and perpendicular to the floor, either with or without a sling. In this gravity-assisted position, the client moves the arm passively or actively, depending on the surgical protocol, forward into humeral flexion and backward into humeral extension; across and away from the body for shoulder abduction and adduction; and then in a circle for circumduction (Salter, 1999).

Controlled range of motion—Active or passive movement within a predetermined safe arc. Often, the allowed movement begins in the middle of the range and is gradually upgraded toward the full arc as healing occurs. A splint can be used to set the boundaries or block unwanted movement.

Deep pressure tissue massage—Firm manual pressure applied to the skin for about 5 seconds to blanch the underlying scar. This massage is initiated once sutures are removed. On a closed wound, lanolin or vitamin E can be used. Massage begins at the perimeter and gradually works toward and then over the surgical scar site.

Factitious disorder—A dysfunctional condition, one in which the person acts out an illness that they do not have.

Scapular plane—Scapular plane refers to the midpoint between shoulder flexion and abduction. The majority of functional activities occur in this plane.

Shoulder immobilizer—Used if strict immobilization is required. Adjustable elastic band that fits around the waist with two straps that position and secure the arm in a slightly abducted and internally rotated position.

Thera-band®—Exercise bands that come in various levels of resistance (denoted by eight different colors ranging from extra thin [tan] to maximum [gold]) used to improve strength. The most commonly used bands are red (2.7 pounds of force at 100% elongation), green (3.1 pounds), and blue (4.5 pounds).

Trendelenburg gait—Gait pattern that results from a weakened gluteus medius muscle. The client lurches toward the injured side to place the center of gravity over the hip. It is characterized by dropping of the pelvis on the unaffected side at heel strike of the affected foot.

Volkmann's ischemia—Increased compartment pressure in one anatomic area of the extremity as a result of a fracture or crush injury. In the upper extremity, it is most common in the forearm. Increased pressure results in closure of the small vessels. The client will experience severe pain, especially with passive stretching. Pressure greater than 30 mm Hg is considered a surgical emergency in which a fasciotomy would be performed (Bednar & Light, 2006).

Wall climbing, finger walking, palm gliding—Exercise to develop shoulder flexion. The client faces the wall, places the injured shoulder's hand on the wall, and either finger walks or glides the palm toward the ceiling and then the floor. For shoulder and scapular abduction, the client turns slightly away from the wall and abducts the shoulder in the plane of the scapula by placing the fingers or palm on the wall for finger walking or palm gliding. Commercially available finger climbers can be mounted on the wall or used on a tabletop with set increments for the finger walk; some climbers can be adjusted to different angles to allow for varying degrees of movement.

Hand Impairments

Cynthia Cooper

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. State principles and general precautions of hand therapy evaluation and intervention.
2. Select splinting (orthotic) positions that minimize, prevent, or correct hand deformity.
3. Describe clinical features of common hand impairments.
4. Recognize and foster favorable tissue responses to hand therapy interventions.
5. Promote pain-free occupational functioning of persons with hand impairment.

Hand problems, which may be cosmetic or functional or both, are hard to hide. Hands function exquisitely to gesture and express, touch and care, dress and feed. Impairment can be devastating. The purposes of this chapter are to introduce readers to the elements of hand therapy, to highlight the breadth of material that hand therapy encompasses, and to identify resources for further study.

The complex arrangement of the hand, with its intimate anatomy and multiarticulate structures, is unforgiving of stiffness, scar, or edema. Injury at one site can lead to stiffness of other parts of the hand. To test this for yourself, passively hold your ring finger in extension and then try to make a fist. This example, called the quadriga effect, demonstrates the interconnectedness of digits, whereby limited movement of one digit may cause restricted motion in uninjured digits (Giambini et al., 2010). For this and other reasons, hand therapists must look at more than the isolated site of injury and must continually reexamine the patient's performance in the areas of occupation.

Hand therapy originated during World War II. Devastating upper extremity injuries of that era and of subsequent wars prompted a team approach to medical care. Today, members of the rehabilitation team in hand therapy can include physicians and physician assistants, nurses, occupational therapists and occupational therapy assistants, physical therapists and physical therapy assistants, and aides or technicians. Workers' compensation representatives or case managers representing payers may also be involved.

Certified hand therapists are occupational therapists or physical therapists with advanced clinical skills who have passed the examination for certification in hand therapy. A minimum of 5 years of clinical experience and other criteria are prerequisites to taking the examination. It is advisable to establish a strong generalist background in occupational therapy before specializing in hand therapy.

Hand therapy differs from other occupational therapy specializations, such as pediatrics or gerontology, because it merges occupational therapy and physical therapy, and it has its own professional organizations. Although most hand therapists are occupational therapists, actual clinical practice may often look more like physical therapy than occupational therapy. Occupational therapy hand therapists should embrace an occupational therapy identity by grounding intervention in core concepts of our profession. To this end, hand therapists should not become so focused on specific anatomical structures that they overlook the person attached to the hand. They should treat the hand and should also address performance skills and performance patterns of the occupational human whose hand it is.

PSYCHOSOCIAL FACTORS AFFECTING THERAPEUTIC OUTCOMES

Why do some people with minor hand injuries wind up with large disabilities and others with devastating injuries have only small disabilities? Adaptive responses to hand impairment are influenced by body image as well as individual functional needs and contextual elements. The personal or symbolic meaning of the hand, self-esteem, family and friend support systems, and coping strategies all influence outcome. Whenever possible, encourage patients to participate in their care. Introduce yourself, maintain eye contact, listen well, use nonmedical terminology and instructional diagrams, and encourage some amiable conversation as appropriate (Vranceanu, Cooper, & Ring, 2009). It can be helpful to touch patients' hands supportively and to make positive remarks (see Chapter 14).

Motivation is the most important variable favorably influencing recovery. Realistic expectations and appropriate communication that emphasizes participatory decision making and education are also important (Moorhead & Cooper, 2007). Psychological symptoms related to hand trauma resolve best when intervention occurs early.

HAND THERAPY CONCEPTS

The following concepts are keys to clinical reasoning for all diagnoses of hand impairment. Intervention should not be determined by diagnosis per se. Rather, hand therapy relies on an understanding of anatomy and physiology, wound healing, biomechanics, tissue tolerances, psychosocial issues, and probable outcomes. Given the infinite variations among people, no two intervention plans should be the same.

Tissue Healing

Tissue heals in phases as follows: inflammation, fibroplasia, and maturation or remodeling. The inflammation phase lasts several days. It includes vasoconstriction followed by vasodilation, with white blood cell migration to promote phagocytic removal of foreign bodies and dead tissue. Depending on the diagnosis, immobilization to provide rest is often advised during the inflammation phase (Fess et al., 2005).

The fibroplasia phase starts at approximately day 4 and continues for 2–6 weeks. In this phase, fibroblasts synthesize scar tissue. The wound's tensile strength increases gradually with the increase in collagen fibers. At this time, active range of motion (AROM) and orthotics may be appropriate to protect healing tissues and promote balance in the hand (Fess et al., 2005).

The maturation, or remodeling, phase may last for years, but tissue is usually more responsive early rather than late in this period. The remodeling phase reflects the changing architecture and improved organization of collagen fibers and the associated increased tensile strength. Gentle resistive activity may be appropriate during maturation, but it may also generate inflammatory responses, which should be avoided. Gentle application of corrective

dynamic or static orthoses may also be appropriate (Fess et al., 2005). Tolerance of tissues to controlled stress requires monitoring throughout all phases of intervention. As tissue continues to heal, the wound contracts, and the scar shrinks. Collagen continues to remodel, as it is constantly doing in uninjured tissue.

Antideformity Positioning

Upper extremity injury and disuse are associated with predictable deforming hand positions. Edema, which typically accompanies injury, creates tension on extrinsic extensor structures. This leads to a zigzag collapse with a resulting deformity position of flexed wrist, hyperextended metaphalangeals (MPs), flexed proximal interphalangeals (PIPs) and distal interphalangeals (DIPs), and adducted thumb (Pettengill, 2011).

Hand joints are anatomically destined to stiffen in predictable positions. Specifically, the MP joint is prone to stiffen in extension. This is because the protruding or cam shape of the metacarpal head causes the collateral ligament to be slack in MP extension and taut in MP flexion. Conversely, the interphalangeal (IP) joints are prone to become stiff in flexion because of shortening of the volar plate and collateral ligaments (Hahn et al., 2010).

When prolonged or constant immobilization is necessary and range of motion (ROM) is at risk, it is usually best to splint the patient's hand in the antideformity position, also called the intrinsic-plus position (Fig. 37-1). This position places the wrist in neutral or extension, the MPs in flexion, the IPs in extension, and the thumb in abduction and opposition. The antideformity position allows the collateral ligaments at the MP joints and the volar plate at the IP joints to maintain their length, which counteracts the forces that promote zigzag collapse. Certain diagnoses, such as flexor or extensor tendon repair,

Figure 37-1 Antideformity or intrinsic-plus position: wrist in neutral or extension, MPs in flexion, IPs in extension, and thumb in abduction and opposition.

are not compatible with antideformity positioning. The physician can assist in this determination.

The Myth of No Pain, No Gain

Regarding tissue tolerances, the myth of "no pain, no gain" must be dispelled in hand therapy. A better mindset would be no pain, more gain. Well-intentioned therapists and overzealous family members of patients have too often caused irreversible damage by applying passive range-of-motion (PROM) forces beyond the tissues' tolerances. Pain induced by therapy can also cause complex regional pain syndrome (CRPS), which is discussed later.

People with upper extremity problems often arrive at therapy prepared for painful intervention. Some patients do not tell the therapist when intervention hurts. It is essential to educate patients about this. In addition, watch the patient's body language and face for signs of pain. Wincing and withdrawing the upper extremity are obvious signals. Proximal guarding is another revealing response. Change the intervention accordingly, and if necessary, try a hands-off approach wherein the therapist coaches and instructs while the patient self-treats.

Passive Range of Motion Can Be Injurious

PROM can be injurious to the delicate tissues of the hand. Specifically, PROM can disturb healing tissues and incite further inflammatory reactions, resulting in increased scar production. PROM can damage articular structures and can even trigger CRPS. A tissue's timeline for remodeling is maximized by noninflaming intervention and is cut short by intervention that is inflaming or provoking. For all of these reasons, if PROM is clinically appropriate, be sure it is done gently and in a pain-free manner. Low-load, long-duration splinting is a safer and more effective method for remodeling tissue and increasing PROM (Fess et al., 2005).

The potential for harm may be compounded if PROM is performed following external application of heat. External application of heat, such as a hot pack, is a popular way to prepare tissues for stretching. Unfortunately, the clinical concerns of externally applied heat have received less attention than they deserve. Heat increases edema, which acts like glue. Heat may degrade collagen and contribute to microscopic tears (Chen et al., 2011). Heat may also incur a rebound effect, with stiffening following its use. *Safety Message: Do not use heat on patients who have edema or sensory loss or whose limb appears inflamed.* Overall, it is safer to use aerobic exercise to warm up the tissues of people with hand impairments. If external application of heat is used, elevate the upper extremity, be gentle with exercise, and promote active movement in conjunction with the heat. Continue to monitor for immediate and subsequent signs of inflammation.

Isolated Exercise, Purposeful Activity, and Therapeutic Occupation

Technically, it is necessary to treat hand impairments with a structure-specific approach to isolate and care for the discrete components that are involved. It may seem easiest to accomplish this type of exacting intervention in the form of isolated exercise. Traditional valuing of the appearance of highly technical clinical environments, medical model indoctrination, busy schedules, and financial or material constraints may contribute to the perpetuation of hand therapy identifying itself within an environment that looks like an exercise gymnasium.

Although some hand therapists do incorporate purposeful activity into intervention, more support is needed for an alternative approach to hand therapy that leads with concepts of therapeutic occupation. One way to achieve this is to integrate patient-directed goals and activities of daily living (ADL) into hand therapy intervention planning and implementation. Whenever possible, encourage upper extremity use in ordinary daily activities as appropriate to the diagnosis. Explore the capabilities in the clinic, and then teach patients to do activities at home. For example, folding socks and underwear can be upgraded to folding heavy towels and jeans, which require greater strength and endurance.

Occupation elicits adaptive responses that do not occur with exercise alone. Compared to isolated exercise, purposeful activity or occupation promotes more coordination and better movement quality (Omar, Hegazy, & Mokashi, 2012). An example of isolated hand therapy exercise to increase grip strength is gross grasp with therapy putty or exercise grippers. An example of purposeful activity to increase strength would be putting away groceries, starting with light items and progressing to heavier objects.

Occupation-as-means instills occupational therapy's heritage in what might otherwise be a less function-oriented context (Trombly, 2011). The examples cited earlier become therapeutic occupation with the use of activity that is meaningful to the particular person to accomplish the therapeutic goal. If the patient enjoys baking, then rolling dough with a rolling pin would be a therapeutic occupation to promote grip function.

EVALUATION

History

History taking as part of the occupational profile offers an excellent opportunity to establish therapeutic rapport. Review medical reports, including radiographs, when possible; learn hand dominance, age, occupation, and avocational interests (Seftchick et al., 2011). Assess deficits in the areas of occupation by asking what the patient cannot do that he or she wants to do, needs to do, or is expected to do. Also discuss the case with the physician.

For trauma, learn the date of injury, dates of any surgery, where and how injury occurred, mechanism of injury, posture of the hand when it was injured, and any previous intervention. For nontraumatic problems, learn the date of onset, whether the symptoms are worsening, sequence of onset of symptoms, functional effects, and what worsens and/or lessens the symptoms (Seftchick et al., 2011).

Pain

Pain may be acute or chronic. Acute pain has a sudden and recent onset, usually has a limited course with an identifiable cause, and can last a few minutes to 6 months. Acute pain serves a physiological purpose, signaling the need to protect tissue from further damage. Chronic pain lasts months or years longer than expected and may not serve a physiological purpose. Myofascial pain, which may be chronic or acute, stems from local irritation in fascia, muscle, tendon, or ligament. It has specific reproducible pain patterns and associated autonomic symptoms. Evaluation of pain may include a graphic representation of pain, in which the patient marks painful areas on a drawing of the human body; analog pain rating scales (see Chapter 5); joint or muscle palpation to identify areas of local pain or qualitative changes in soft tissue; and trigger point sensitivity (Klein, 2007a).

Physical Examination

It is helpful to observe the positioning and use of the patient's upper extremity in the waiting area before the meeting. On examination, look at the entire unclothed upper extremity for posture, guarding and gesturing, atrophy, and edema (Klein, 2007a). Because distal symptoms are often caused by proximal problems, it is important to perform a cervical screening, which is a proximal screening assessment of the neck and shoulder, to identify additional areas requiring intervention (Butler, 2007).

Wounds

Safety Message: Always follow universal precautions (see Chapter 44). Evaluate wound size in terms of length, width, and depth. Wound drainage (exudate) is bloody (sanguinous), serous (clear or yellow), purulent (pus), or deep or dark red (hematoma). Wound odor is absent or foul (Klein, 2007a).

The three-color concept (red, yellow, or black) dictates wound care. Wounds can be one of or a combination of these three colors. A red wound is healing, uninfected, and composed of revascularization and granulation tissue. A yellow wound has an exudate that requires cleansing and debridement. A black wound is necrotic and requires debridement. The goal of wound care is to convert yellow and black wounds to red wounds (von der Heyde & Evans, 2011).

Scar Assessment

Observe scar location, length, width, and height. Hypertrophic scars stay confined to the area of the original wound and usually resolve within a year. Keloids proliferate outside the area of the original wound and do not usually become smaller or less pigmented with time. Note any scar tethering or adherence of skin and tendon causing restricted movement. Any wound or scar crossing a joint may form a contracture, which restricts passive motion. An immature scar has a red or purplish color imparted by its vascularity. It blanches to touch. A mature scar is flatter and softer. It has a neutral color and does not blanch to touch (Klein, 2007a).

Vascular Assessment

Cyanosis, erythema, pallor, gangrene, or grayish color indicates vascular compromise. To test digital capillary refill, apply pressure to the fingernail or distal pad of the involved digit. Color should return within 2 seconds of release of pressure. Compare the refill time to that of uninvolved digits (Klein, 2007a).

Edema

Circumferential measurement is quick to perform and provides a good alternative when it is not possible to use a volumeter (Klein, 2007a). Be consistent with measuring tape placement and tension. Volumetric measurement is contraindicated for open wounds, percutaneous pinning such as Kirschner wires, plaster casts, or vasomotor instability (see Chapter 7 for volumetric and circumferential measurement procedures).

Range of Motion

In hand therapy, both AROM and PROM should be evaluated and compared to the uninjured extremity (see Chapter 7). Facilities usually have their own guidelines for measuring ROM. As expected, consistency of retesting is important.

Total active motion (TAM) or total passive motion (TPM) measures the sum of composite digital flexion and extension. This measurement is used in some studies. Normal TAM and TPM are 270° (Fess, 2002/2011) (see Procedures for Practice 37-1).

Grip and Pinch

When properly calibrated, the Jamar dynamometer is one of the best instruments to assess grip strength because of its reliability, face validity, and accuracy (see Chapter 7). Hand therapy authorities recommend comparing scores with those of the contralateral extremity rather than using

---

Procedures for Practice 37-1

Total Active Motion (TAM) and Total Passive Motion (TPM)

- Add the measurements for flexion of the MP, PIP, and DIP joints.
- Subtract the combined deficits in extension for those joints.

    For example, if the digital AROM is MP: 10–50, PIP: 20–70, DIP: 0–40, the total active motion (TAM) would be 160 (flexion total) minus 30 (extension deficits total) = 130 TAM.

---

norms (Fess, 2002/2011). Goals for grip and pinch strength depend on occupational factors and dominance. There may be approximately 10%–15% difference in strength between dominant and nondominant hands, with dominant hands usually being stronger. It is routine to measure three pinch patterns: lateral, three-jaw chuck, and tip. As with grip, compare pinch scores with those of the contralateral extremity.

No linear relationship exists between improvement in grip and pinch strength and improvement in function. Rice, Leonard, and Carter (1998) noted that even debilitated, deformed hands could be surprisingly functional. These authors found only weak relationships between grip and pinch strength and the forces required to open six containers used commonly in the home. Thus, grip and pinch testing are not substitutes for ADL assessment with contextual relevance (Liepert, 2010). To promote occupational functioning of people with hand impairments, it is far better to have intervention and goals reflect personally meaningful ADL than grip or pinch strength measures.

Manual Muscle Testing

Manual muscle testing is particularly useful for monitoring progress following peripheral nerve lesions (see Chapter 7). Facilities usually have their preferred method of grading, which may be numerical or descriptive.

Sensibility

Inspect the patient's hand for dryness, moistness, and calluses (see Chapter 9). Blisters may be an alert to injurious hand use because of sensory loss. "Wear marks" illustrate where and how the hand is used and which parts of the hand avoid use, indicating sensory impairment (Callahan, 2011).

The Semmes-Weinstein Monofilament Test and the Two-Point Discrimination (2PD) test are most commonly used in hand therapy. The Semmes-Weinstein Monofilament Test assesses pressure threshold, and the 2PD

assesses density of receptors. The Moberg Pickup Test (see Chapter 9) is a functional test appropriate for use on patients with median or median and ulnar nerve lesions. Although the tests described above and elaborated in Chapter 9 are very useful clinically, there is no one tool that evaluates the hand's actual functional sensibility (Moberg, 1991).

Dexterity and Hand Function

No one evaluation covers all features of hand function (Yancosek & Howell, 2009). Standard terminology regarding hand function is lacking, and there is limited evidence that the assessment of hand function indicates the patient's actual performance in ADL. Thus, hand function tests should not substitute for assessments of ADL or other areas of occupation. Hand function tests, however, can be helpful measures of improvement of performance skills.

For dexterity tests to be reliable, therapists must administer them using the standard procedures from the original articles or test manuals, and they must decide whether a specific test is valid for the intended use. The tests described in this section all require further validation.

Box and Block Test

The Box and Block Test measures gross manual dexterity. It was developed to test people with severe problems affecting coordination (Fig. 37-2). The subject transfers 1-inch blocks from one side of the box to the other. The score

Figure 37-2 Box and Block Test of manual dexterity. (Photo used with permission from Patterson Medical, Bolingbrook, IL.)

is the number of blocks transferred in 1 minute for each hand. Procedures for Practice 37-2 presents procedures for administration of the test (Mathiowetz et al., 1985).

Test–retest reliability and interrater reliability of the Box and Block Test is high, with an intraclass correlation coefficient of 0.99 (Yancosek & Howell, 2009) and demonstrated validity (Faria-Fortini et al., 2011; Higgins et al., 2006). One systematic review concluded that this test provided "robust" data and was recommended for clinical use (Connell & Tyson, 2012). Norms for persons aged 20–75 years and older appear in Table 37-1.

Purdue Pegboard Test

The Purdue Pegboard Test of finger dexterity (Tiffin, 1968) assesses picking up, manipulating, and placing little pegs into holes with speed and accuracy. It tests finger or fine motor dexterity (Amirjani et al., 2011). It has a wooden board with two rows of tiny holes plus reservoirs for holding pins, collars, and washers. The four subtests are performed with the subject seated. To begin, there is a brief practice. The subtests for preferred, nonpreferred, and both hands require the patient to place the pins in the holes as quickly as possible, with the score being the number of pins placed in 30 seconds. The subtest for assembly requires the patient to insert a pin and then put a washer, collar, and another washer on the pin, with the score being the number of pieces assembled in 1 minute. The Purdue Pegboard Test manual provides normative data using percentile tables for adults and different categories of jobs and for children 5–15 years of age by age and sex.

One-trial administration of the Purdue Pegboard Test produced good test–retest reliability of 0.60–0.76 in healthy subjects and 0.85–0.9 in patients (de la Llave-Rincon et al., 2011). Three-trial administration produced excellent reliabilities (>0.80) (Buddenberg & Davis, 2000). Among subjects with multiple sclerosis, test–retest reliability coefficients were excellent, with no significant practice effects ($r = 0.85–0.96$) (Gallus & Mathiowetz, 2003).

Nine-Hole Peg Test

The Nine-Hole Peg Test measures finger dexterity among patients of all ages. Test administration is brief, involving the time it takes to place nine pegs in holes in a 5-inch square board and then remove them. The Nine-Hole Peg Test was found to have high test–retest reliability coefficients (0.95 for right hands and 0.92 for left hands) (Wang et al., 2011). High interrater reliability has been reported (Higgins et al., 2006).

The Purdue Pegboard Test is preferred to the Nine-Hole Peg Test in the measurement of finger dexterity. Of the two, the Purdue Pegboard Test has good test–retest reliability; it is time limited; it is for both unilateral and bilateral assessment; and its normative data reflect a broader age range (Gallus & Mathiowetz, 2003).

Procedures for Practice 37-2

Administration Procedures for the Box and Block Test (Mathiowetz et al., 1985)

- Place the test box lengthwise along the edge of a standard-height table (Fig. 37-2).
- The 150 cubes are in the compartment of the test box to the dominant side of the patient.
- Sit facing the patient to monitor the blocks being transported.
- Give these instructions: "*I want to see how quickly you can pick up one block at a time with your right [left] hand [the therapist points to the dominant hand]. Carry the block to the other side of the box and drop it. Make sure your fingertips cross the partition. Watch me while I show you how.*"
- Transport three cubes over the partition in the same direction the patient is to move them. After the demonstration, say, "*If you pick up two blocks at a time, they will count as one. If you drop one on the floor or table after you have carried it across, it will still be counted, so do not waste time picking it up. If you toss the blocks without your fingertips crossing the partition, they will not be counted. Before you start, you will have a chance to practice for 15 seconds. Do you have any questions? Place your hands on the sides of the box. When it is time to start, I will say 'Ready' and then 'Go.'*"

- Start the stopwatch at the word *go*. After 15 seconds, say "*Stop.*"
- If the patient makes mistakes during the practice period, correct them before beginning the actual testing.
- On completion of the practice period, return the transported cubes to the compartment.
- Mix the cubes to ensure random distribution, and then say, "*This will be the actual test. The instructions are the same. Work as quickly as you can. Ready; go. [After 1 minute:] Stop.*"
- Count the blocks transported across the partition. This is the patient's score for the dominant hand.
- If the patient transports two or more blocks at the same time, subtract the number of extra blocks from the total.
- After counting, return the blocks to the original compartment and mix randomly.
- Turn the test around so that the blocks are on the nondominant side.
- Administer the test to the nondominant hand using the same procedures as for the dominant hand, including the 15-second practice.

[a]The values indicate the number of cubes transferred in 1 minute (Mathiowetz et al., 1985).

TEMPA

TEMPA is an acronym from the French for Upper Extremity Performance Test for the Elderly. It consists of nine tasks, five bilateral and four unilateral, reflecting daily activity (Desrosiers et al., 1993). Each task is measured by the three subscores of speed, functional rating, and task analysis. The nine tasks are to pick up and move a jar, open a jar and take a spoonful of coffee, pour water from a pitcher into a glass, unlock a lock, take the top off a pillbox, write on an envelope and affix a postage stamp, put a scarf around one's neck, shuffle and deal cards, use coins, and pick up and move small objects. Instructions are in the manual. The test takes about 15–20 minutes for an unimpaired elderly subject and about 30–40 minutes for an impaired elderly subject. Advantages of the TEMPA are clinical use, especially with hand patients older than 60 years of age; provision of both quantitative and qualitative data; simulation of ADL; test applicability; test availability; and acceptability to patients (Rallon & Chen, 2008). Normative data for young adults has been determined (Nedelec et al., 2011).

TEMPA norms were established on adults 60 years of age or older ($n = 360$) by 10-year age groups and by gender. Interrater reliability of the TEMPA ranged from 0.96 to 1.00. Test–retest reliability was excellent (Rallon & Chen, 2008). Concurrent validity with the Action Research Arm test was 0.90–0.95, and with the Box and Block Test, it was 0.73–0.78 (Desrosiers et al., 1994).

CLINICAL REASONING AND INTERVENTION

Questions to Ask

Close communication with the patient's physician is always advisable. Choosing which questions to ask depends on the diagnosis and structures involved. General categories of questions may include the physician's expectations for functional recovery; tendon status, such as fraying or vascular compromise; whether the patient is medically cleared for AROM only or AROM and/or PROM; and whether the patient is medically cleared for low-load, long-duration dynamic splinting.

Activities of Daily Living and Occupational Role Implications

The functional use of the upper extremity and the patient's ability to perform in the areas of occupation are what really matter. Hand therapists must be careful not to become so focused on the technical aspects of the patient's injury that they overlook the patient's function, personal goals, and life needs. In some circumstances, it may actually be better for patients to accept a stiff finger and get on with life using compensatory techniques than to interrupt the flow of their lives for

therapy (Merritt, 1998). This may be true if gains are exceedingly slow, if function is not dramatically compromised, or if there are other priorities, such as ill family members, for example.

Goal Setting

Express hand therapy goals or projected outcomes in terms that reflect the patient's occupational functioning. Ultimately, the number of degrees achieved in ROM is less important than whether the patient can open a door, get dressed, or return to work. One way to integrate concrete and functional outcomes is to measure the movement needed to accomplish an appropriate patient-specific functional task and incorporate that measurement into the stated goal. For example, if a patient wants to be able to splash water on his or her face but lacks forearm supination to do so, have the patient perform the activity with the opposite upper extremity. Measure the supination needed to perform the task. In this instance, the goal could be stated as "sufficient forearm supination (60°) for ability to wash the face."

Quality of Movement

Poor quality of movement (called dyscoordinate cocontraction) may result from cocontraction of antagonist muscles. The cause may be habit, fear of pain, guarding, or excessive effort. Poor quality of movement looks awkward and unpleasant. It is important to identify dyscoordinate cocontraction early and to work on retraining a smooth, comfortable, effective quality of motion. Pain-free occupation is the best way to promote good quality of motion. Oscillations are rhythmic therapeutic movements that may be helpful, but they must be pain free. Imagery, such as pretending to move the extremity through water or gelatin, may also help (Cooper, 2007). Biofeedback may aid in muscle reeducation as well.

What Structures Are Restricted, and Does Passive Range of Motion Exceed Active Range of Motion?

Hand therapists strive to be structure specific in identifying and treating upper extremity limitations. It is not adequate to identify a general problem, such as decreased ROM. Rather, it is important to understand and treat the specific structures causing the restriction. Limited PROM may be due to pericapsular structures, such as adhered or shortened ligaments, or actual joint limitations, such as mechanical block or adhesions. PROM that exceeds AROM may be due to disruption of the musculotendinous unit, adhesions restricting excursion of the tendon, or weakness. When PROM exceeds AROM, promote active movement and function of the restricted structures with

differential tendon gliding exercises, blocking exercises, place-and-hold exercises, and functional orthoses (discussed later). When PROM equals AROM, discern whether the restriction is joint or musculotendinous or both (see section on Joint versus Musculotendinous Tightness), and promote both passive and active flexibility.

Joint versus Musculotendinous Tightness

With joint tightness, the PROM of the particular joint *does not change* with repositioning of the joints proximal and/or distal to it. With musculotendinous tightness, the PROM of the particular joint *does vary* with repositioning of joints crossed by that multiarticulate structure (Colditz, 2011). Treat joint tightness with dynamic splinting, static progressive splinting, or serial casting, followed by AROM. Treat musculotendinous tightness the same as extrinsic tightness (discussed later).

Lag versus Contracture

A lag is a limitation of active motion in a joint that has passive motion available. A joint contracture is a passive limitation of the joint. A patient with a PIP extensor lag cannot actively extend the PIP joint even though passive extension is available. A patient with a PIP joint flexion contracture lacks passive extension of that joint.

Treat lags by facilitating motion of the restricted structure with scar management, blocking exercises in mechanically advantageous positions, place-and-hold exercises, static splinting to promote normal length of the involved structure, and functional splints. Treat contractures the same as for joint tightness (discussed later).

An advantageous position to test or treat extensor lag at the PIP level is to maintain MP flexion while trying to extend actively at the PIP. An advantageous position to test or treat extensor lag at the DIP level is to maintain MP and PIP flexion while trying to extend actively at the DIP. This is contraindicated if the diagnosis is acute mallet finger (see section on Extensor Tendon Injury).

Intrinsic versus Extrinsic Tightness

Compare the PROM of digital PIP and DIP flexion with the MP joint flexed and again with the MP joint extended. With extrinsic tightness, there is less PIP and DIP passive flexion with the MP joint flexed. With intrinsic tightness, there is less PIP and DIP passive flexion with the MP joint extended (Colditz, 2011).

Treat intrinsic tightness with functional splinting with MPs hyperextended and IPs free. In other words, promote IP flexion with MPs hyperextended. Treat extrinsic extensor tightness with MPs flexed and IPs free, and promote composite digital flexion. Use blocking exercises with an advantageous proximal position (discussed later). Try dynamic or static progressive splinting.

Tightness of Extrinsic Extensors or Extrinsic Flexors

With extrinsic extensor tightness, there is less passive composite digital flexion available with the wrist in flexion than with the wrist in extension. In contrast, with extrinsic flexor tightness, there is less passive composite digital extension available with the wrist in extension than with the wrist in flexion (Colditz, 2011). Treat extrinsic flexor or extensor tightness with place-and-hold exercises, static splinting comfortably at end range (especially useful at night), dynamic or static progressive splinting during the day, and functional splinting.

BASIC INTERVENTIONS

Edema Control

Elevation, active exercise, and compression have been the mainstays of edema control. Treatment of upper extremity edema has also historically included retrograde massage, string wrapping, compression garments, and modalities such as an intermittent pressure pump.

Research has challenged hand therapists to reexamine the anatomical and physiological bases of our treatment of edema. This inquiry has resulted in a new approach to the treatment of upper extremity edema, called manual edema mobilization (Artzberger, 2007), a technique for stimulating the lymphatic system to remove the excess large plasma proteins that cause sustained edema leading to fibrotic tissue and stiffness. This hands-on technique, which must be learned in workshops that last 2 days or longer, can lead to dramatic and effective results (Knygsand-Roenhoej & Maribo, 2011; Priganc & Ito, 2008). The approach used in manual edema mobilization is very different from and, in some ways, opposite to traditional retrograde massage techniques. Furthermore, manual edema mobilization raises questions about whether retrograde massage is sometimes more damaging than helpful. Manual edema mobilization is a wonderful example of the groundbreaking changes in hand therapy, based on scholarly questioning and research, that keep the profession interesting.

Scar Management

Compression (e.g., Isotoner™ gloves, Tubigrip™, or Coban™ wrap) and desensitization are traditionally used to promote scar softening and maturation. Silicone gel applied over the scar helps promote scar maturation, presumably through neutral warmth. Other inserted materials such as padding, otoform, or elastomer can also be used. Application of micropore tape over incision scars is gaining popularity. It has been shown to be very effective and is much more affordable than the other options (von der Heyde & Evans, 2011).

There are three ways of making a fist:

Straight   Hook fist   Straight fist   Full fist
Figure 37-3 Differential flexor tendon gliding exercises. The four positions: straight, hook, straight fist, and full fist. (Adapted with permission from Skirven, T. M., Osterman, A. L., Fedorczyk, J. M., & Amadio, P. C. [Eds.]. [2011]. *Rehabilitation of the hand and upper extremity* [6th ed.]. Philadelphia: Mosby.)

Although friction massage has typically been advocated for scar softening, legitimate questions have been raised as to whether this more aggressive technique may in fact cause inflammation, resulting in deposition of even more scar tissue. Manual edema mobilization may be a more effective alternative. Research is needed in this area.

Differential Digital Tendon Gliding Exercises

Tendon gliding exercises maximize total gliding and differential gliding of digital flexor tendons at the wrist (Fig. 37-3) (Bardak et al., 2009). Because tendon gliding exercises promote digital and joint motions, they are a mainstay of most home exercise programs.

Blocking Exercises

Various blocking tools and orthotics are available commercially or can be made easily with scraps of splinting materials (Fig. 37-4). Digital cylinders blocking the IPs help to isolate and exercise MP flexion and extension. A blocking splint with the MPs extended promotes intrinsic stretch as well as IP flexion. A blocking splint with the MPs flexed promotes extrinsic extensor stretch and recovery of composite fisting [flexion at all finger joints of the hand simultaneously]. A PIP cylindrical block encourages DIP isolated flexion and flexor digitorum profundus
Figure 37-4 Blocking splints. MP splint blocks MP motion, promoting PIP and DIP motion. Digital splint blocks PIP motion, promoting MP, and/or DIP motion.

(FDP) excursion at the DIP. A DIP cap facilitates PIP flexion and flexor tendon excursion at the PIP.

Instruct patients who do blocking exercises to exercise comfortably into the end range to remodel the tissue. Teach them to do the exercises frequently and slowly, holding at the comfortable end range for 3–5 seconds.

Place-and-Hold Exercises

Place-and-hold exercises are effective for achieving increased ROM when PROM exceeds AROM. To perform them, use comfortable PROM to position the hand (e.g., composite fisting). Then release the assisting hand while the patient tries to sustain the position in a pain-free way. Place-and-hold exercises can be effective in combination with blocking exercises.

Mirror Box

Growing interest in neuroplasticity has provided fascinating additions to the traditional repertoire of hand therapists. The use of a mirror box (also called mirror visual feedback or mirror training) is based on research on neural responses to intentional visual confusion, with stimulation of neurons called mirror neurons. Mirror training is used for pain, sensory, and motor problems and can be used in conjunction with laterality and graded imagery interventions. It has been used with clients who have had a cerebral vascular accident (CVA) and is being used more recently with clients with peripheral and orthopedic problems of the upper extremities (Lamont, Chin, & Kogan, 2011; Rosén & Lundborg, 2005, 2011) (see Fig. 37-5).

End Feel and Splinting

If there is a soft end feel (a favorable spongy quality at end range indicative of potential to remodel), it is reasonable to try low-load, long-duration dynamic splinting for a medically cleared patient. Dynamic splint forces must be prolonged and gentle for tissue to remodel. Forceful splinting is contraindicated because it causes pain and injury, hence inflammation and scarring (Fess et al., 2005). Follow dynamic orthotic use with activity that challenges and incorporates the limited motion. For a firmer or hard end feel (an unyielding quality at end range), try increasing the time in the orthosis and decreasing the force. If there is a hard end feel, dynamic splinting may not be effective, and serial casting or static progressive splinting may be more useful.

Splints (Orthotics)

Terminology related to splinting has changed. It is now recommended to use the term "orthotics," especially in regard to occupational therapy documentation and billing. These two terms are used interchangeably in this chapter. Functional splints (or orthotics) can be used in ordinary

A

B

COMMON DIAGNOSES

Hand therapists 15 years ago treated more hand trauma than cumulative trauma, and surgical cases constituted most of the caseload. Nowadays, many hand therapists see a substantially greater number of patients with a soft tissue diagnosis, such as tendinitis or cumulative trauma disorders (see Resources 37-1 for informational products).

Stiff Hand

Any upper extremity injury can result in the serious and sometimes irreversible problem of a stiff hand. Even an injury in the proximal upper extremity can cause serious stiffening of the digits. The stiff hand is what hand therapists try to prevent. Edema is the main culprit in the series of events leading to a stiff hand. Edema is a natural response to trauma, occurring in the inflammatory phase. The challenge for hand therapy is to strike a balance between rest and movement. Too much rest may increase the edema. Too much movement may increase the inflammation. The right amount of rest in an appropriate position reduces inflammation and promotes healing. Proximal motion plus well-tolerated hand and wrist exercise and functional use, particularly while elevated, help to reduce edema and restore motion.

Encourage the patient to achieve gentle full arcs of available motion with functional use or exercise instead of performing quick or incomplete arcs of motion that are less effective. Make exercises relevant to occupational functioning or at least goal oriented whenever possible (e.g., grasping and releasing items). If the patient's hand is painful or more swollen after use or exercise, it is imperative to decrease temporarily the amount of exercise being performed (Colditz, 2011).

Avoid aggressive PROM. It is okay to coax tissues to lengthen within their available comfortable range, but always respect the feeling of tissue resistance, and do not exceed it. Gentle passive motion, if indicated, should be accompanied by joint traction to promote gliding of the joint surfaces. Sustained holding of a position is much

daily activity to promote mobility of restricted structures. For example, if the index finger PIP joint lacks flexion and the MP joint moves normally, try a hand-based index finger MP blocking splint, used off and on throughout the day. When the splint is in use, the patient achieves PIP flexion exercise while performing normal grasping activities.

Buddy straps allow one digit to assist a neighboring digit to achieve greater motion. The offset buddy strap (Fig. 37-6) accommodates different phalangeal lengths of adjacent digits (Jensen & Rayan, 1996). Buddy straps are also useful to retrain keyboard users who habitually maintain the small finger MP in hyperextension or repetitively hyperabduct the small finger when keyboarding.

A dorsal MP flexion blocking orthosis promotes composite flexion incorporating MP flexion and is particularly helpful when there is extrinsic extensor tightness. If the patient has difficulty incorporating MP flexion into composite fisting and instead extends the MPs while flexing the IPs, a dorsal hood maintaining MP flexion promotes recovery of composite fist incorporating MP flexion (see Chapters 15 and 16 for further splinting guidelines.)

more effective than fast jerky stretches, which frequently add to the inflammation.

During the acute inflammatory stage, static splinting is usually most appropriate. After the inflammation has subsided and while the joint displays a soft end feel, dynamic splinting is productive. Inflamed tissue is not as flexible as uninflamed tissue (Glasgow et al., 2011). Watch closely for signs of inflammation and return to static splinting as indicated. Later, if there is a hard end feel, serial static or static progressive splinting will most likely be needed (Glasgow, Tooth, & Fleming, 2010). Many patients with hand impairments complain of morning stiffness. Night splinting, which can be very helpful for this problem, also corrects tissue tightness that limits daytime use of the hand.

Tendinitis/Tendinosis

The pain associated with tendinitis/tendinosis can be severe and can seriously impact performance in all areas of occupation. Symptoms include pain with AROM, with resistance, and with passive stretch of the involved structures. Tendons are made up of connective tissues that are not well vascularized. Tendinitis has been treated historically as if it is an inflammatory phenomenon. More recent histological evidence has shown that the pathology of tendinitis includes alterations in tissue with disorganized and degenerated collagen and atypical vascular granulation tissue. These findings are described as angiofibroblastic hyperplasia or angiofibroblastic tendinosis. It is now believed that the patients who are diagnosed with tendinitis actually have tendinosis. Because the pathology is not primarily inflammatory, treatment approaches now emphasize interventions that restore nourishment to collagen (Ashe, McCauley, & Khan, 2004). The question of use of modalities with this diagnosis remains intriguing. Most authorities report that modalities are effective in reducing pain, normalizing the vascular status of the involved tissue, and quieting inflammation if it exists.

Debate is ongoing over the cause of musculoskeletal problems; whether such problems are work related remains controversial (Seror & Seror, 2012). Tendons are vulnerable because they are relatively avascular. Cell damage may become chronic (Barr, 2006). Biomechanical deficits include muscular weakness, inflexibility, and scar tissue. Early treatment of an acute traumatic case typically has a better prognosis than after the injury has become chronic.

Evaluation

An overaggressive evaluation that provokes pain can set the treatment timetable back significantly and undermine the trust of and rapport with the patient. Start the evaluation with a cervical screening to look for proximal causes of distal symptoms. Compare both extremities. Assess for pain that may be local or diffuse, swelling, sensory changes, and loss of function. Tendinitis typically is accompanied by pain with AROM, with resistance, and with passive stretch of the involved structures. Compare subjective and objective findings, but remember that symptoms are often elusive and may occur dynamically or intermittently. Patients who seem angry or hostile may understandably be depressed over their loss of function.

It is essential to identify the activity causing the pain. Occupational therapists possess unique skills for ergonomic-related analysis of occupational performance and activity modification. It is best to observe the actual activity. If this is not possible, simulate the activity. Ergonomic risk factors for tendinitis include forceful, rapid, repetitive movements. A movement is considered repetitive if it is performed more than once every 30 seconds or for more than half the total work time. Additional risk factors include a history of soft-tissue problems, pressure and shear forces, stress and muscle tension, and hypermobility.

Intervention

Treat the acute phase with ice, compression, elevation of the involved structures, and rest if needed to manage pain. Anti-inflammatory physical agent modalities may be useful at this time (see Chapter 19), but remember that tendinitis/tendinosis is no longer thought to be primarily inflammatory. Splinting is individualized to the patient's and physician's preferences. Orthotic intervention may be most beneficial and least problematic at night. There are also clinical compromises associated with disuse from immobilization. Soft supports may be very helpful. In weighing the advantages and disadvantages of orthotic use, consult closely with the referring physician, try to avoid pain, and monitor the clinical responses. Active pain-free motion is the best way to begin revascularizing the involved tissues.

After the inflammation subsides, upgrade intervention to restore normal function through gradual mobilization balanced with rest. Most importantly, pain must be avoided. Instruct in tendon gliding exercises in a pain-free range

appropriate to the particular structures involved. Progress from isometric exercises with gentle contractions of involved structures to isotonic exercises (Cooper & Martin, 2007). Gradually introduce low-load, high-repetition strengthening in short arcs of motion. Then increase the arc of motion and modify proximal positions to be more challenging if appropriate for work simulation. Instruct in gentle flexibility exercises in a pain-free range. It is often difficult for patients to learn to perform slow and pain-free passive stretch. Aerobic exercises and proximal conditioning are essential.

Prevent reinjury through education (Cooper & Martin, 2007). Simulation and biofeedback (see Chapter 19) can promote biomechanically efficient upper extremity use. Teach the patient to avoid reaching and gripping with an extended elbow or a flexed or deviated wrist. First, solve the easily recognizable issues, such as obviously poor posture or trunk twisting with reaching and lifting. Instruct in pacing to avoid fatigue that leads to reinflammation. Unsupported upper extremity use is taxing, as are nonsymmetrical upper extremity use, nonfrontal trunk or upper extremity alignment, and unilateral upper extremity work. Many people with distal symptoms recover well by focusing intervention on posture, conditioning, and proximal strengthening. Using handheld tools with ergonomic design can be helpful. Even a small ergonomic adjustment, such as learning to lift bilaterally with proper body mechanics or making use of a telephone headset instead of laterally flexing the neck and elevating the shoulder to hold the receiver, can often lead to dramatic improvement.

Lateral Epicondylitis or Tennis Elbow

Lateral epicondylitis involves the extrinsic extensors at their origin. The extensor carpi radialis brevis is most commonly involved. Pain is at the lateral epicondyle and extensor wad (the proximal portion of the extensor muscles). This diagnosis is differentiated clinically from radial tunnel syndrome, in which tenderness occurs more distally over the radial tuberosity. Test for radial tunnel syndrome with the middle finger test (positive if there is pain secondary to resisting the middle finger proximal phalanx while the patient maintains elbow extension, neutral wrist, and MP extension) or by percussing distally to proximally over the superficial radial nerve. This percussion test is positive if it elicits paresthesia (Fedorczyk, 2011).

Exercises should include proximal conditioning and scapular stabilizing. Instruct the client to use built-up handles. If using an orthosis, support the wrist in extension, especially at night. Splinted wrist position recommendations range from neutral to about 30°. Also try a counterforce strap, which is a strap placed over the extensor wad to prevent full muscle contraction and to reduce the load on the tendon during the day with activity. *Safety Message: Avoid applying the counterforce strap too tightly, because this can cause radial tunnel syndrome.*

Medial Epicondylitis, or Golfer's Elbow

Medial epicondylitis involves the extrinsic flexors at their origin. The flexor carpi radialis (FCR) is most commonly involved. Pain is at the medial epicondyle and flexor wad (the proximal portion of the flexor muscles) and worsens with resisted flexion and pronation. Exercise should promote proximal conditioning. Avoid activity that requires force at end ranges. Provide built-up handles. If using an orthosis, maintain the wrist in neutral, and try a counterforce strap over the flexor wad.

De Quervain's Tenosynovitis

De Quervain's tenosynovitis is tendinitis involving the abductor pollicis longus (APL) and extensor pollicis brevis (EPB) tendons at the first dorsal compartment. It is the most common upper extremity tenosynovitis. Finkelstein's test is positive if there is exquisite pain with passive wrist ulnar deviation while flexing the thumb (Fig. 37-7). This diagnosis occurs frequently among golfers, knitters, and racquet sports players. Thumb posture in sustained hyperabduction at the computer space bar may also be provoking. Differential diagnosis is for carpometacarpal (CMC) arthritis, scaphoid fracture, intersection syndrome, and FCR tendinitis (Crop & Bunt, 2011).

Teach patients to avoid wrist deviation, especially in conjunction with pinching. Provide built-up handles. If splinting, use a forearm-based thumb spica, leaving the IP free. Watch for irritation from the radial splint edge along the first dorsal compartment.

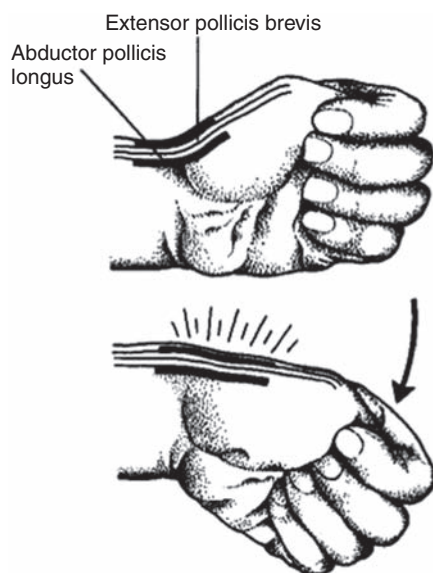
Extensor pollicis brevis
Abductor pollicis longus


Figure 37-7 Finkelstein's test for de Quervain's disease. (Adapted with permission from Rayan, G., & Akelman, E. [2011]. *The hand: Anatomy, examination, and diagnosis.* Philadelphia: Lippincott Williams & Wilkins.)

Intersection Syndrome

Intersection syndrome presents as pain, swelling, and crepitus of the APL and EPB muscle bellies approximately 4 cm proximal to the wrist, where they intersect with the wrist extensor tendons (extensor carpi radialis brevis and extensor carpi radialis longus). This diagnosis is associated with repetitive wrist motion and occurs in weight lifters, rowers, and canoers. Differential diagnosis is for de Quervain's disease, but both diagnoses can occur concomitantly. Teach patients to avoid painful or resisted wrist extension and forceful grip. Orthotic selection is the same as for de Quervain's disease (Mellick & Mellick, 2012).

Extensor Pollicis Longus Tendinopathy

Also called drummer boy palsy, tendinitis of the extensor pollicis longus (EPL) reveals pain and swelling at Lister's tubercle (a dorsal prominence at the distal radius around which the EPL passes). It is less common than other forms of tendinitis, but if left untreated, it can lead to tendon rupture. EPL tendinitis is associated with activities requiring repetitive use of the thumb and wrist, as seen in drummers. Rupture of the EPL may occur in persons with rheumatoid arthritis (RA) or Colles' fracture (Kardashian et al., 2011).

Help patients to identify and eliminate provocative activities. Enlarge the girth of utensils. The orthotic choice is a forearm-based thumb spica that includes the IP.

Extensor Carpi Ulnaris Tendinopathy

Tenosynovitis of the extensor carpi ulnaris (ECU) occurs fairly frequently. It causes pain and swelling distal to the ulnar head and is associated with repetitive ulnar deviation motions. Subluxation of the ECU tendon elicits a painful snap with forearm supination and wrist ulnar deviation. Differential diagnosis includes instability of the distal radioulnar joint and ulnocarpal abutment or tears of the triangular fibrocartilage complex. Teach patients to avoid ulnar deviation with activities. Orthotic intervention consists of a forearm-based ulnar gutter or a wrist cock-up splint.

Flexor Carpi Radialis Tendinopathy

With tendinitis of the FCR, pain is over the FCR tendon just proximal to the wrist flexor creases. Differential diagnosis is for a volar ganglion or arthritis of the scaphotrapeziotrapezoid joint. Orthotic intervention consists of a wrist cock-up in neutral or a position of comfort.

Flexor Carpi Ulnaris Tendinopathy

Flexor carpi ulnaris (FCU) tendinitis is more common than FCR tendinitis. It causes pain along the volar–ulnar side of the wrist. Inflammation occurs where the FCU

inserts at the pisiform. Differential diagnosis is pisiform fracture and pisotriquetral arthritis (Verdon, 1996) or triangular fibrocartilage complex injury. Teach patients to avoid wrist flexion with ulnar deviation. Orthotic intervention consists of a forearm-based ulnar gutter. For comfort, pad the ulnar head if it is prominent, so the splint does not rub or irritate it.

Flexor Tenosynovitis, or Trigger Finger

Trigger finger is also called stenosing tenosynovitis of the digital flexor. The usual cause is stenosis at the A-1 pulley, which is part of the fibro-osseous tunnel that prevents bow-stringing of the digital flexors (Taras, Martyak, & Steelman, 2011). Tenderness is over the A-1 pulley of the digital flexor (Fig. 37-8) along with pain with resisted grip and painful catching or locking of the finger in composite flexion (Lee, Biafora, & Zelouf, 2011).

The origin of this impairment can be inflammatory or not. It has been strongly associated with diabetes and RA. Medical management often consists of a mixture of steroid and local anesthetic injected into the flexor sheath. The injection may be repeated a few times. Therapy consists of splinting the MP in neutral to prevent composite digital flexion (preventing triggering), while promoting tendon gliding, and place-and-hold fisting that avoids triggering. Built-up handles, padded gloves, and pacing strategies are helpful. Instruct the patient to avoid triggering, as this reinflames the tissue (Valdes, 2012). If symptoms persist, the surgeon may surgically release the A-1 pulley.

Nerve Injury

When injury or disease occurs to a neural structure in the upper extremity, there is a high likelihood that multiple areas of neural pathology will develop. This phenomenon is known as the double or multiple crush syndrome (Novak & Mackinnon, 2005). Remembering this concept lessens the possibility of missing relevant clinical findings.

The various mechanisms of nerve injury include acute or chronic compression, stretch ischemia, electrical shock, radiation, injection, and laceration (Smith, 2011). Compression and laceration, impairments that are commonly seen by hand therapists, are described next.

Nerve Compression

Median Nerve Compression at the Wrist, or Carpal Tunnel Syndrome. Carpal tunnel syndrome is the most common upper extremity nerve entrapment. It results from compression of the median nerve at the wrist. The carpal bones form the floor of the carpal tunnel. The transverse carpal ligament, also called the flexor retinaculum, forms the roof of the tunnel and acts as a pulley for the flexor tendons during gripping (Amadio, 2011). Inside the carpal canal are nine flexor tendons (four FDP, four flexor digitorum superficialis [FDS], and the flexor pollicis longus) and the median nerve, which is most superficial (Fig. 37-9).

Swelling or thickening of the tendons can lead to pressure on the nerve, resulting in sensory symptoms in the distribution of the median nerve (van Doesburg et al., 2012).

Typical complaints include hand numbness, particularly at night or when driving a car, along with pain and paresthesia in the distribution of the median nerve (thumb through radial ring finger pads), and clumsiness or weakness (Zhang et al., 2011) (see Research Note 37-1). Associated diagnoses include RA, Colles' fracture, diabetes, deconditioning, obesity, and thyroid disease. Transient carpal tunnel syndrome is fairly common in pregnancy. Carpal tunnel syndrome may be associated with repetitive use or flexor tenosynovitis caused by increased friction between the tendons and nerve. For these people, focus intervention on resolving the tendinitis.

Evaluation. Perform a cervical screening, and evaluate posture, ROM, grip and pinch, and a manual muscle test looking for independent excursion of FDP and FDS. Also do Tinel's, Phalen's, Semmes-Weinstein Monofilament, and two-point discrimination tests. Tapping at the volar wrist elicits Tinel's sign, which is a sensation of tingling or electric shock if the median nerve is compromised. Phalen's test provokes sensory symptoms in the median nerve

distribution if positive, created by maintaining the wrist in flexion for 60 seconds. Phalen's test should be done with extended elbows to avoid confusing these findings with a positive elbow flexion test (see section on cubital tunnel syndrome). Advanced cases of carpal tunnel syndrome reveal thenar atrophy of the abductor pollicis brevis, which can be functionally debilitating (Seftchick et al., 2011).

Intervention. Conservative medical management may include steroid injection (Amadio, 2011). Conservative therapy for carpal tunnel syndrome includes night splinting with the wrist in neutral because this position minimizes pressure in the carpal tunnel, exercises for median nerve gliding at the wrist (Fig. 37-10), differential flexor tendon gliding exercises (Fig. 37-3), aerobic exercise, proximal conditioning, ergonomic modification, and postural training (Schmid et al., 2012). Teach patients to avoid extremes of forearm rotation or of wrist motions and to avoid sustained pinch or forceful grip. Provide padded gloves and built-up handles. Thick padded automobile steering wheel covers are helpful.

Surgical intervention consists of decompression of the carpal tunnel by division of the transverse carpal ligament (Amadio, 2011). Carpal tunnel release is one of the 10 most

Research Note 37-1

Abstract

The delicate tuning of digit forces to object properties can be disrupted by a number of neurological and musculoskeletal diseases. One such condition is carpal tunnel syndrome (CTS), a compression neuropathy of the median nerve that causes sensory and motor deficits in a subset of digits in the hands. Whereas the effects of CTS on median nerve physiology are well understood, the extent to which it affects whole-hand manipulation remains to be addressed. CTS affects only the lateral three and a half digits, which raises the question of how the central nervous system integrates sensory feedback from affected and unaffected digits to plan and execute whole-hand object manipulation. We addressed this question by asking CTS patients and healthy controls to grasp, lift, and hold a grip device (445, 545, or 745 g) for several consecutive trials. We found that CTS patients were able to successfully adapt grip force to object weight. However, multidigit force coordination in patients was characterized by lower discrimination of force modulation to lighter object weights, higher across-trial digit force variability, the consistent use of excessively large digit forces across consecutive trials, and a lower ability to minimize net moments on the object. Importantly, the mechanical requirement of attaining equilibrium of forces and torques caused CTS patients to exert excessive forces at both CTS-affected digits and digits with intact sensorimotor capabilities. These findings suggest that CTS-induced deficits in tactile sensitivity interfere with the formation of accurate sensorimotor memories of previous manipulations. Consequently, CTS patients use compensatory strategies to maximize grasp stability at the expense of exerting consistently larger multidigit forces than controls. These behavioral deficits might be particularly detrimental for tasks that require fine regulation of fingertip forces for manipulating light or fragile objects.

Implications for Practice

- Clients with CTS have sensory loss that affects hand dexterity and use of the whole hand, not just the fingers with sensory impairment.
- Hand therapy for clients with CTS should address occupational tasks that incorporate use of the whole hand, not just those digits with sensory innervation of the median nerve.

frequent surgeries performed in the United States. Postoperative therapy, when necessary, consists of edema control, scar management, desensitization as needed, nerve and tendon gliding exercises (Evans, 2011a), and eventual strengthening. Many therapists postpone strengthening exercises until at least 6 weeks following carpal tunnel release to avoid inflammation. Patients with new and mild symptoms tend to recover best.

Ulnar Nerve Compression at the Elbow, or Cubital Tunnel Syndrome. Cubital tunnel syndrome is the second most common upper extremity nerve entrapment and is the most commonly compressed site of the ulnar nerve, at its location between the medial epicondyle and the olecranon (Oskay et al., 2010). Typical complaints include proximal and medial forearm pain that is aching or sharp; decreased sensation of the dorsal and palmar surfaces of the small finger and the ulnar half of the ring finger; and weakness of interossei, adductor pollicis (AP),

FCU, and FDP of the ring and small fingers. Clawing may be more evident if the FDP is not involved because the long flexors are unopposed. Wartenberg's sign, the inability to adduct the small finger, and Froment's sign, in which effort at lateral pinch elicits thumb IP flexion because of weakness of the AP, may be seen. Grip and pinch strength are decreased, and patients complain of dropping things. Symptoms are worse when the elbow is flexed repeatedly or is kept in flexion because this position dramatically reduces the volume of the cubital tunnel (Porretto-Loehrke & Soika, 2011). Understandably, symptoms may increase at night if the person sleeps with the elbow flexed.

Cubital tunnel syndrome may result from trauma, such as a blow to the elbow or fracture or dislocation of the supracondylar or medial epicondylar area, or it may be due to chronic mild pressure on the elbow. Associated diagnoses include osteoarthritis (OA), RA, diabetes, and Hansen's disease.

Evaluation. Tapping over the cubital tunnel elicits a positive Tinel's sign. However, Tinel's sign may also be positive in 20% of normal people. The elbow flexion test is positive if passively flexing the elbow and holding it flexed for 60 seconds produces sensory symptoms. Keep the wrist neutral while performing the elbow flexion test so as not to confound the findings with Phalen's test. Look for digital clawing and for muscle atrophy in the first web space, hypothenar eminence, and medial forearm. Perform grip and pinch testing and manual muscle testing as appropriate, and test sensation. Goldman et al. (2009) provide an excellent review of ulnar neuropathy assessment.

Intervention. Conservative therapy for cubital tunnel syndrome includes edema control; splinting or padding the elbow; and positioning guidelines to avoid leaning on the elbow, to avoid elbow-flexed postures, and to avoid elbow-intensive activity. An elbow orthosis helps prevent sleeping with the elbow flexed. Types of orthotics include elbow pads or soft splints, pillows, and anterior or posterior thermoplastic orthoses. The splinted elbow position for sleeping is usually about 30° of flexion. Additional therapy includes proximal conditioning, postural and ergonomic training, and ulnar nerve gliding exercises (Porretto-Loehrke & Soika, 2011) (Fig. 37-11).

Radial Nerve Compression, or Posterior Interosseous Nerve Syndrome. Posterior interosseous nerve syndrome is purely motor. It presents two clinical pictures. In one, paralysis affects all muscles innervated by the posterior interosseous nerve, with inability to extend the MP joints of thumb, index, long, ring, or small fingers. Wrist extension occurs only radially because of paralysis of extensor digitorum and ECU. In the other presentation of this syndrome, the person cannot extend the MP joint of one or more digits. Paralysis may spread to other digits if it is not treated on a timely basis (Duff & Estilow, 2011).

A common site of entrapment of the posterior interosseous nerve is at the supinator muscle, where it pierces the two heads of this muscle. Other causes include soft tissue tumors, RA with synovial proliferation, and radial head fractures or dislocations. Therapy focuses on maintaining PROM and orthotic selection to prevent deformity and promote function.

Figure 37-11 Neural mobilization for cubital tunnel syndrome in highly irritable stage. **A.** Ipsilateral scapular elevation and cervical side-bending while the wrist, ring, and small fingers are extended with the forearm remaining supinated and the elbow extended. **B.** Return the scapula and cervical spine to neutral as the patient brings the wrist, ring, and small fingers into slight flexion. Perform this in a slow and in rhythmic manner. (Adapted with permission from Skirven, T. M., Osterman, A. L., Fedorczyk, J. M., & Amadio, P. C. [Eds.]. [2011]. *Rehabilitation of the hand and upper extremity* [6th ed.]. Philadelphia: Mosby.)

Nerve Laceration

Nerve lacerations are categorized as complete or partial. Stretching and contusion injuries can occur along with the laceration. Nerve reconstruction is termed primary if within 48 hours, early secondary if within 6 weeks, and late secondary after 3 months. The advantages associated with primary repair are that nerve stump retraction is limited, and electrical stimulation can be used to identify distal fascicles [nerve bundles] (Smith, 2011).

A neuroma, a disorganized mass of nerve fibers, can follow nerve injury. Significant nerve pain is elicited by tapping over the neuroma, with hypersensitivity limiting functional use of the hand. Desensitization techniques are helpful, along with padding over the painful area to promote functional use.

Following nerve injury, therapy promotes functional performance in the areas of occupation with ADL training and adaptive equipment and assists in prevention of deformity with orthotics and appropriate PROM. Hand therapy provides valuable education to patients about their diagnosis and general recovery sequence and teaches protective guidelines to compensate for sensory loss. Hand therapy monitors changes in sensory and motor function and helps prevent joint contractures and imbalance by reevaluating ROM, sensation, and muscle status. Orthotic modifications are based on clinical changes over time.

Low Median Nerve Lesion. Median nerve laceration at the wrist results in low median nerve palsy, with denervation of the opponens pollicis and abductor pollicis brevis of the thumb and of the lumbricals to the index and long fingers. Clawing of the index and long fingers does not usually occur because the interossei remain ulnarly innervated. Loss of sensation of the radial side of the hand is present. With the absence of thumb abduction and opposition, the thumb rests in adduction, where it may become contracted (Fig. 37-12). Fabricate a hand-based thumb abduction orthosis to maintain balance, to substitute for lost thumb opposition, and to prevent overstretching of denervated muscles (Moscony, 2007a).

Median nerve laceration creates serious functional loss of manipulation and sensibility of the thumb, index, and long fingers. Motor recovery usually occurs before sensory recovery. Be sure to teach compensatory strategies to avoid reinjury while sensibility is impaired. Instruct the patient to perform PROM to maintain joint mobility. Fabricate orthotics to sustain thumb abduction and digital MP flexion with IP extension to promote functional hand use and to counteract the deforming forces of the injury.

High Median Nerve Lesion. Injury near or at the elbow is called a high median nerve injury. Along with the motor loss identified earlier, there is denervation of FDP to index and long fingers, FDS to all digits, pronator teres, and
Figure 37-12 Thenar wasting (atrophy of thumb muscles) caused by median nerve problem.

pronator quadratus. The median nerve is considered the most important sensory nerve, and its loss severely compromises hand function. In therapy, prepare patients for probable tendon transfers by preventing deformity with orthotics and by maintaining PROM of pronation, of digital MPs in flexion, of digital IPs in extension, and of thumb CMC abduction. Visual cues, adaptive devices, and modified handles may help compensate for the functional loss.

Low Ulnar Nerve Lesion. Laceration of the ulnar nerve at the wrist level is called a low ulnar lesion. This injury results in loss of most of the hand intrinsics. Denervation of the abductor digiti minimi, flexor digiti minimi, and opponens digiti minimi results in flattening of the hand with loss of the ulnar transverse metacarpal arch; denervation of thumb AP and deep head of flexor pollicis brevis results in loss of thumb adduction and MP support; denervation of dorsal and volar interossei results in loss of digital abduction or adduction; and denervation of lumbricals to the ring and small fingers results in extrinsic imbalance. The ring and small fingers present a claw deformity, a position of MP hyperextension and PIP flexion associated with muscle imbalance in ulnar-innervated structures (Fig. 37-13). Fine manipulation skills are compromised. Sensory loss involves the ulnar digits.

Orthotic intervention for ulnar nerve palsy aims to prevent overstretching of the denervated ring and small finger intrinsics. An MP blocking orthosis that maintains slight MP flexion and prevents MP extension is recommended (Moscony, 2007a) (see Chapter 15). Teach patients to compensate for sensory loss and to maintain passive range of the MPs in flexion and the IPs in extension. It is very important to prevent PIP flexion contractures. Built-up handles in conjunction with the MP blocking orthosis may be helpful.
Figure 37-13 Clawing of digits seen with ulnar nerve problems. (From Snell, R. S. [2003]. *Clinical anatomy* [7th ed.]. Baltimore: Lippincott Williams & Wilkins.)

Figure 37-14 Wrist drop caused by radial nerve problem. (From Snell, R. S. [2003]. *Clinical anatomy* [7th ed.]. Baltimore: Lippincott Williams & Wilkins.)

High Ulnar Nerve Lesion. A high ulnar nerve lesion is often identified with trauma at or proximal to the elbow. There is involvement of the muscles listed earlier and denervation of FDP of ring and small fingers and of FCU. Ring and small finger clawing is less apparent with the high lesion but becomes noticeable as the FDP are reinnervated and are unopposed by the still-absent intrinsics. Orthotic intervention and treatment are the same as for a low ulnar nerve lesion. If the FDP is absent, teach the patient to maintain full PROM of the IPs of the ring and small fingers to prevent contractures (Colditz, 2011).

Low Radial Nerve Lesion. Low radial nerve injury of the deep motor branch is called posterior interosseous palsy. Presentations vary (see section on Radial Nerve Compression), but brachioradialis and extensor carpi radialis longus function is usually present. Efforts to extend the wrist yield strong radial deviation. MP extension is affected. Sensation on the dorsal radial hand is affected (Wu, Hsu, & Wang, 2010). Therapy is similar to that described for radial nerve compression, with emphasis on maintaining PROM for wrist, thumb, and digital extension and orthotics to promote tenodesis for functional pinch, grip, and release.

High Radial Nerve Lesion. A high radial nerve injury is seen commonly with humeral fractures because this nerve spirals around the humerus. Wrist and digital extensors are absent (Fig. 37-14). Sensory loss occurs on the dorsal–radial hand, which interferes less with function than does sensory loss on the palmar hand. Triceps function remains, but the supinator and all wrist and finger extensors lose function. Tenodesis is lost (Tuncel, Turan, & Kostakoglu, 2011).

Splinting restores tenodesis and may be useful for the many months during the wait for reinnervation, which occurs at approximately 1 inch per month. Various static and dynamic orthoses are available; the dynamic orthotics are most useful functionally. Many patients make good use of both types of orthoses. Compliance tends to be good because of the functional value of these orthoses. It is important to maintain joint suppleness while awaiting reinnervation or reconstructive surgery.

Fractures

Distal Radius Fracture

Distal radius fractures are among the most common upper extremity fractures (Medoff, 2011). Hand therapists frequently treat patients with this diagnosis. Distal radius fractures should not be confused with fractures of the carpal bones. The main complication associated with distal radius fracture is traumatic arthritis caused by poor articular congruency. Decreased wrist ROM, decreased grip strength, alteration of the carpal alignment, and instability may ensue. Other complications include tendon rupture, compression of the median or ulnar nerve, and complex regional pain syndrome (CRPS) (Michlovitz & Festa, 2011).

Therapy during Immobilization. Appropriate early therapy intervention can make a huge difference in the patient's overall functional recovery. If digits are allowed to become swollen and stiff, the long-term functional results can be devastating. These fractures are common among older people with osteoporosis and balance problems. Temporary loss of independence following fracture can trigger an irreversible downward spiral in their occupational functioning.

Typical medical management of Colles' fracture is cast immobilization, usually above elbow with the elbow in 90° of flexion to prevent forearm rotation during the first 3 weeks. When the patient is put in a short arm cast

and the elbow is freed, begin elbow AROM for flexion and extension, but avoid resisted elbow motion so as not to stress the fracture healing. Do not perform elbow PROM without medical clearance, and be very gentle. Biceps tightness commonly follows elbow immobilization.

Certain fractures require some form of fixation. Some physicians delay the referral of patients to therapy, but postponing the initiation of therapy can result in significant problems with edema and decreased ROM. It is a good idea to communicate with referring physicians and encourage routine early therapy referral for this diagnosis.

While the patient has percutaneous pins, provide pin site care as the physician prescribes using sterile technique and universal precautions. Teach the patient digital ROM and tendon gliding exercises, and instruct in precautions related to cast wearing. It is critical to monitor for cast tightness because a tight cast can cause CRPS. Call the physician if the cast is too tight. Discourage the use of slings because they promote unnecessary proximal stiffness, guarded posture, and disuse.

Insidious onset of shoulder restrictions is problematic and best avoided. Physicians most assuredly appreciate therapists' input regarding early signs of this problem. To prevent a frozen shoulder, proximal ROM is a high treatment priority (Michlovitz & Festa, 2011). Instruct in shoulder flexion, abduction, internal rotation, and external rotation. Perform as thorough a physical assessment as tolerated and as cast constraints permit. This may have to be done in phases. Early identification of guarding, excessive pain, or autonomic signs can alert the team to the possibility of CRPS.

Following distal radius fracture, the recovery of function depends on restoration of motion and strength and on maximizing the length-tension relationship of the digital flexors and extensors (Moscony, 2007b). Edema can contribute to decreased ROM at uncasted areas. Patients are often surprised that uninjured and uncasted areas can stiffen.

The goals of early therapy during immobilization are to normalize edema and to achieve as nearly normal AROM of uncasted areas as possible. During this period, intrinsic tightness, extrinsic tightness, and digital joint tightness may occur. The chance of tendon adherence is increased following open reduction and its accompanying incisional scar. Various blocking splints may be used with functional activity and exercise to resolve joint or musculotendinous tightness (Fig. 37-4). Differential tendon gliding exercises are extremely important. Frequent exercise throughout the day is better than a few long sessions. It is generally advised to perform exercises every hour or two, perhaps 5–10 repetitions each, maintaining the end position comfortably for 3–5 seconds. Incorporate exercises into occupation, including ADL, as much as possible (Moscony, 2007b).

If extrinsic musculotendinous tightness persists, it may be appropriate to add night static progressive splinting or low-load, long-duration dynamic splinting in conjunction with exercise to normalize extrinsic length. Consult the physician before making this determination.

Therapy after Immobilization Stage. When fracture immobilization is discontinued, physicians often recommend a custom-fabricated volar wrist orthosis. This is protective and can be corrective to help restore functional wrist motion (usually extension). This temporary support is particularly helpful if the patient maintains habitual wrist flexion because this "doggy paw" posture leads to development of the undesirable deformity position of MP extension, PIP flexion, and thumb adduction and extension discussed earlier.

At this stage of therapy, there is usually measurable limitation in ROM, with patients reporting awkwardness and decreased function (Bruder et al., 2011). Consult the physician for medical clearance and guidelines for forearm and wrist ROM. *Safety Message: Do not initiate PROM of the wrist without medical clearance because this may be injurious.* Teach the patient to wean off the protective orthosis according to the physician's guidelines, which are individualized. Edema control continues to be the highest priority until it is resolved. AROM and ADL can help correct the edema.

At any time, but especially in this early stage, overzealous therapy is harmful. Patients and families who think they should be aggressive in their home programs need education and reinforcement to avoid overdoing it. Use written material and illustrations to teach them how to observe tissue responses and monitor inflammation. Temperature elevation or redness over the joints of digits may indicate that intervention is eliciting an inflammatory reaction and should be adjusted accordingly (Michlovitz & Festa, 2011).

It is extremely important to retrain the wrist extensors to function independently of the extensor digitorum. Have the patient practice wrist extension with available composite digital flexion, being especially sure the MPs are flexed. Then have the patient flex the wrist with digits relaxed but extended to isolate the wrist flexors. Because substitution patterns are hard to overcome, early training of biomechanically efficient movement is best. Progressive grasp-and-release activities reinforce this tenodesis training. It is also important to retrain the extensor digitorum to function independently of the intrinsics. Have the patient extend the MPs with the IPs slightly flexed to isolate the extensor digitorum.

Gradually upgrade therapy with increasingly challenging motions, combined motions, and activities aiming to restore joint suppleness and musculotendinous lengths. Dexterity activities, such as cat's cradle, and games, such as pick-up sticks, promote spontaneous functional movements.

Sorting drawers and folding small items of clothing are good home activities. Initiate graded functional strengthening with medical clearance, usually after good motion has been achieved. Again, it is easy to be too aggressive with these patients. Upgrade carefully, monitor patient and tissue responses, and adjust the intervention accordingly.

Scaphoid Fracture

Some 60% of carpal fractures affect the scaphoid (also called the navicular) bone, making scaphoid fractures the most common of all carpal fractures. The mechanism of injury is usually a fall on the outstretched hand (called FOOSH) with wrist radial deviation. Associated ligamentous injury may also be present. Tenderness in the anatomical snuffbox, a depression at the base of the thumb between the EPL and EPB tendons, where snuff used to be placed, is a classic finding. Scaphoid fracture may be difficult to confirm radiographically initially and may not become apparent until 3 weeks following injury because of resorption at the fracture site. Once fracture is confirmed, the thumb is usually included in the cast, with the IP joint free (Doornberg et al., 2011; Geissler et al., 2012).

Proximal scaphoid fractures may be at risk for developing avascular necrosis because of the pattern of vascular supply. Casting time may be long for this reason. Hand therapy principles are the same as for distal radius fracture (Dell, Dell, & Griggs, 2011).

Nonarticular Hand Fracture

Fracture occurs more often in the hand than any other area, and more than 50% of hand fractures occur at work. Motor vehicle accidents, household injuries, and recreational accidents also account for many of these injuries (Feehan, 2011).

Distal Phalanx Fracture. Distal phalanx digital fractures typically result from a crushing injury and occur most often in the thumb and middle finger. Tuft fractures occur at the distal tip. They are extremely painful, in part because there is often a subungual (i.e., beneath the nail) hematoma (Moscony, 2007b). Following a distal phalanx fracture, hypersensitivity, pain, and decreased ROM of the DIP joint may occur. Monitor closely for signs of DIP extensor lag or the inability to extend the DIP joint actively despite full available passive extension.

Middle Phalanx Fracture. At the middle phalanx, fractures angulate according to their relation to the FDS insertion. Medical management and early positioning guidelines vary among caregivers. Following middle phalanx fractures, decreased PIP and DIP ROM are common problems. Fractures at this site may require long immobilization time for healing, with resulting stiffness. When the patient is medically cleared for therapy, isolated FDS

exercises are very important. Here, too, PIP joint flexion contractures are serious complications that can occur in as little as 2 weeks of immobilization in flexion. Consult with the physician for therapy guidelines based on fracture stability and healing (Moscony, 2007b).

Proximal Phalanx Fracture. At the proximal phalanx, fractures tend to angulate with a palmar apex. This deforming force is due to the action of the intrinsic muscles on the proximal fragment. With proximal phalanx fractures, a hand-based orthosis in intrinsic-plus (antideformity) position is useful at night. A digit-based extension orthosis provides support and protection in the day except during exercise. Again, the physician provides therapy guidelines based on fracture stability and healing. PIP joint flexion contractures are the most likely and most difficult complication. Watch for these, and catch them early. Better yet, avoid them with appropriate orthotics and structure-specific exercise. PIP extensor lag and flexor tendon adherence at the fracture site are other serious problems (Moscony, 2007b).

Metacarpal Fracture. Unless there is associated trauma, metacarpal fractures at the base are frequently stable. Metacarpal fractures at the shaft may be transverse, oblique, or spiral. Metacarpal fractures at the neck are common, occurring most often in the small finger. They may result in muscle imbalance between the intrinsics and extrinsics (Moscony, 2007b).

With metacarpal fractures, dorsal hand edema is a frequent complication that can contribute to MP joint dorsal capsular tightness. If there is associated soft tissue injury, intrinsic contracture or extensor digitorum adherence may occur. Appropriate early therapy and preventive edema control are important (Feehan, 2011).

Unstable fractures require fixation to achieve stability and allow early ROM (Soong, Got, & Katarincic, 2010). Kirschner wires, a common form of fixation used for hand fractures, may be used alone or in conjunction with additional fixation. Other forms of internal fixation include tension band wires, lag screws, plates, and mini external fixators (Belsky & Leibman, 2011). Functional recovery relates to anatomical restoration. To maximize functional outcomes, the ideal situation allows for early motion. Preventing stiffness of uninvolved digits is a high priority that can itself be challenging. Prolonged immobilization is associated with edema and pain. Persistent edema results in joint and tendon scar and adhesions, atrophy, and osteoporosis.

Collateral Ligament Injury

Proximal Interphalangeal Joint Sprain

PIP joint sprains often result from sports involving balls. Their severity, which may be underappreciated, is described as grade I through grade III. In grade I, the ligament

Figure 37-15 Dorsal PIP extension–blocking splint. Protective digit-based splint maintains slight PIP flexion. Used to prevent full extension to protect volar plate injury.

remains intact, but there is diffuse individual fiber disruption. In grade II, there is complete disruption of one of the joint capsule's major retaining ligaments. In grade III, there is complete disruption of one collateral ligament in addition to injury to dorsal and/or volar capsular structures. Pain, decreased ROM, and risk of flexion contracture are the most common problems associated with grades I and II injuries. Joint instability may occur with grade III injuries (Little & Jacoby, 2011).

Therapy focuses on edema control, joint protection, and ROM. Buddy straps are helpful to protect or to promote movement. They may be offset to improve fit (Fig. 37-6). Orthotic intervention is both protective and corrective. A dorsal extension blocking orthosis is often ordered early on for volar plate injuries associated with dorsal PIP joint dislocation (Fig. 37-15). Persistent thickening about the joint commonly occurs, interfering with recovery of ROM.

Skier's Thumb

Disruption of the ulnar collateral ligament of the thumb MP joint occurs with acute radial deviation. This diagnosis, which may entail avulsion of bone fragment at the ligamentous insertion, is often seen among people who fall while skiing (Ritting, Baldwin, & Rodner, 2010). Injury to the radial collateral ligament of the thumb MP occurs only one-tenth as often (Tang, 2011). Following surgical repair, the wrist and thumb are casted. When therapy begins, IP ROM is the priority because full MP flexion may not be achieved, especially among older patients. Avoid resistive exercise until medically cleared. Then begin with lateral pinch but avoid tip pinch until further medical clearance, which may not be for 12 weeks, because tip pinch is strenuous on the injured structures. Use a hand-based spica orthosis for protection. Scar hypersensitivity caused by the underlying radial sensory nerve is common.

Flexor Tendon Injury

Surgical repair of flexor tendon injury is a complex undertaking performed by specialists in the field. Like the surgery, hand therapy for these patients is a complicated and specialized area. Therapy can be time consuming,

and it entails substantial education of the patient, with subtle but significant changes in splinting and exercise at every session to promote function while protecting fragile repaired structures. Multiple structures are often involved, and there are many precautions and contraindications that vary according to the details of the patient's surgery and the surgeon's specifications and preferences. It is essential to maintain close communication with the patient's surgeon. A therapist experienced in the treatment of these patients should closely supervise their care.

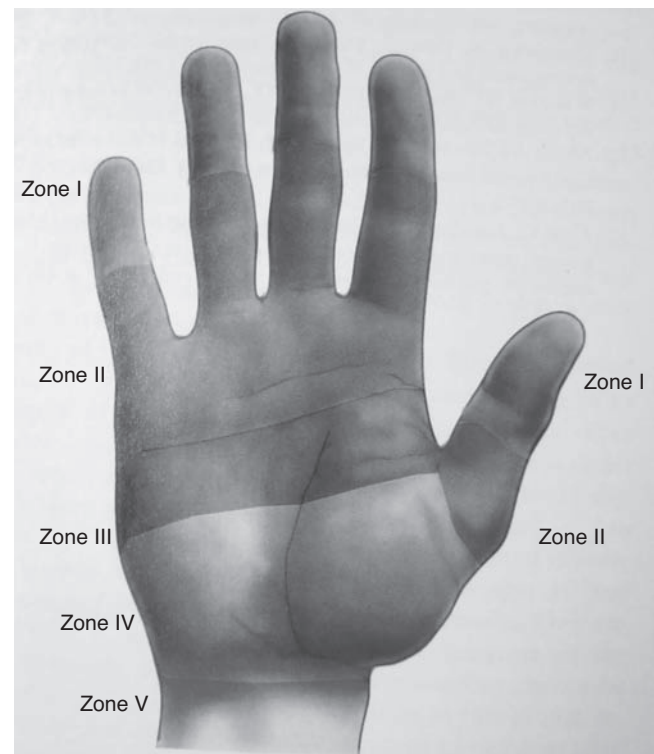
Five anatomical zones describe flexor tendon injury to the index, long, ring, and small digits (Fig. 37-16). Zone I is from the insertion of the FDS to the insertion of the FDP. Zone II is the area where the FDS and FDP both lie within the flexor sheath, from the A-1 pulley to the FDS insertion. This region has memorably been dubbed "no man's land" to reflect the technical challenge and historically poor prognosis for repair in this area (Taras, Martyak, & Steelman, 2011). Zone III describes the area from the distal edge of the carpal tunnel to the A-1 pulley of the flexor sheath, including the lumbrical muscles. Zone IV is where the flexor tendons lie under the transverse


Figure 37-16 The five zones of the hand based on flexor tendon anatomy. Zone I contains flexor digitorum profundus tendon; zone II is the tendon sheath containing flexor digitorum superficialis and flexor digitorum profundus tendons; zone III is the lumbrical muscle zone; zone IV is the carpal tunnel region; and zone V is the forearm area. (From Rayan, G. M., & Akelman, E. [2012]. *The hand: Anatomy, examination, and diagnosis* [Kindle Locations 704–707]. Philadelphia: Lippincott [Wolters Kluwer Health]. Kindle Edition. Used with permission.)

carpal ligament in the carpal tunnel. Injuries in this zone may include the median and ulnar nerves. Zone V is the area from the forearm flexor musculotendinous junction to the border of the transverse carpal ligament (Taras, Martyak, & Steelman, 2011).

Physicians usually indicate specific postoperative positioning guidelines to protect repaired structures following flexor tendon repair. The goals are twofold and contradictory: to minimize adhesion formation and to prevent gap or attenuation of the repaired tendon (Korstanje et al., 2010, 2012). These dual goals highlight the complexity of therapy associated with this diagnosis. Various protocols exist for controlled mobilization, using a dorsal orthosis with the wrist in 10°–30° of flexion, MP joints in 40°–60° of flexion, and IP joints ideally in full extension (unless there has also been a digital nerve repair). The involved IP joints may have to be in some flexion if a digital nerve has been repaired. The Duran protocol entails passive digital flexion and extension within the protective orthosis to achieve 3–5 mm of differential digital tendon excursion (Lalonde & Kozin, 2011). With this protocol, gentle active motion begins with medical clearance about 4 weeks after surgery.

The passive flexion–active extension protocol, also called the Kleinert protocol, uses rubber band attachments to the fingernails to provide passive digital flexion within the protective dorsal orthosis (Fig. 37-17) (Groth, 2005). The patient performs gentle active digital extension, and the rubber band provides passive digital flexion within the confines of the protective orthosis. Exercises are gradually increased to 10 repetitions comfortably every waking hour. At night, the digits may be strapped carefully and comfortably to the dorsal hood of the orthosis to counteract the tendency to develop PIP or DIP flexion contractures.

The Chow protocol uses a combination of the Duran and Kleinert techniques. With advances in suture techniques, flexor tendons protocols are incorporating
Figure 37-17 Modified Kleinert splint. Dorsal splint maintains the wrist in 30° of flexion, MPs in 70° of flexion, and IPs in extension. Rubber band attachments provide passive digital flexion.

early active motion in patients who are good candidates (Chesney et al., 2011; Griffin et al., 2012).

When the physician gives medical clearance to discontinue the dorsal protective orthosis, begin a graded program to promote functional movement. Edema control and scar management remain high clinical priorities. Assess closely and determine tissue-specific limitations that guide the therapy program. Tendon gliding exercises and place-and-hold exercises are typical early techniques. Corrective splinting is useful, along with ADL, graded activity, and upgraded exercise as appropriate.

Staged Flexor Tendon Reconstruction

Staged flexor tendon reconstruction is a complex two-part procedure. It is highly advisable to have an experienced hand therapist supervise the treatment. Staged flexor tendon surgery is chosen when there is significant scarring of the tendon yet potential for eventual function. It may be used in cases of flexor tendon rupture or when primary repair is not possible, such as with a complex injury involving bone and multiple tissues. In the first stage, a tendon implant replaces the scarred tendon, capsular contractures are released, and pulleys are reconstructed. The implant, which may be active or passive, stimulates formation of a new biological sheath. In the second stage, after about 3 months, a tendon graft replaces the implant (Diao & Chee, 2011).

Extensor Tendon Injury

Therapy of extensor tendon injuries is complicated and requires supervision by experienced hand therapists. Various protocols are available for immobilization, controlled passive motion, or active short arc of motion following extensor tendon repair (Klein, 2007b).

Seven zones describe the digital extensors for the index, long, ring, and small fingers, and five zones describe the thumb extensors (Fig. 37-18). Injury in zones I and II leads to a mallet deformity, which follows disruption of the terminal extensor tendon and manifests itself as DIP extensor lag (Fig. 37-19). Depending on the nature of the problem, in nonoperative cases, therapy may include continuous splinting of the DIP in extension for 6–8 weeks as determined by the physician while the tendon heals (Anderson, 2011). It is essential to maintain normal PIP ROM during immobilization at the DIP. When initiating ROM of the DIP after the terminal tendon has healed, watch closely for recurrence of DIP extensor lag and resume splinting as needed to recover DIP extension. Some physicians recommend continuation of night splinting when DIP AROM is begun.

Extensor injuries in zones III and IV lead to a boutonniere deformity, an imbalanced digital position of PIP flexion and DIP hyperextension (Fig. 37-20). The deformity is
Figure 37-18 The seven zones of the hand based on extensor tendon anatomy. The odd zones I, III, V, and VII belong to distal interphalangeal, proximal interphalangeal, metacarpophalangeal, and wrist joints, respectively. The even zones II, IV, and VI belong to phalanx 2, phalanx 1, and metacarpal. (From Rayan, G. M., & Akelman, E. [2012]. *The hand: Anatomy, examination, and diagnosis* [Kindle Locations 742–744]. Philadelphia: Lippincott [Wolters Kluwer Health]. Kindle Edition. Used with permission.)

Figure 37-19 Mallet finger. (From Anderson, M. K., Parr, G. P., & Hall, S. J. [2009]. *Foundations of athletic training: Prevention, assessment and management* [4th ed.]. Philadelphia: Lippincott Williams & Wilkins. Used with permission).

Tenolysis

Tenolysis is a surgical procedure to release tendon adhesions that restrict movement. Physicians do not usually perform this procedure until injured tissues have matured and PROM is maximized, as demonstrated by a plateau in progress during therapy. Therapy following tenolysis may begin as early as a few hours after surgery. The first few days following surgery are considered crucial. The physician's referral should include information on the integrity

due to volar displacement of the lateral bands secondary to involvement of the central slip (Williams & Terrono, 2011). In nonoperative cases, splint the PIP in full extension for 6 weeks, and promote DIP active and passive flexion to prevent stiffness of the oblique retinacular ligament. In operative cases, follow the physician's guidelines, which may vary in timing and technique of mobilization and splinting. When the patient is medically cleared to begin PIP active exercises, watch closely for PIP extensor lag, and modify therapy and splinting accordingly.

Injury in zones V and VI may be treated by immobilization or by controlled early motion (Evans, 2011b) (see Evidence Table 37-1). Specific positioning and motion guidelines vary from surgeon to surgeon and are modified according to each patient's tissue responses. Multiple complex orthotics may be needed to achieve a program that balances rest and motion appropriately.

Injury in zone VII is likely to result in restrictions because of development of adhesions. Communicate closely with the surgeon for specific positioning and motion guidelines.

Figure 37-20 Boutonniere deformity. (From Anderson, M. K., Parr, G. P., & Hall, S. J. [2009]. *Foundations of athletic training: Prevention, assessment and management* [4th ed.]. Philadelphia: Lippincott Williams & Wilkins. Used with permission).

Evidence Table 37-1 | Best Evidence for Occupational Therapy Practice Regarding Treatment of Hand Impairments

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Postoperative treatment protocols for zones V and VI extensor tendon lacerations of the hand	Immobilization (IM): complete immobilization of wrist at 40°–45°, metacarpophalangeal (MCP) and IPs at 0° for 3 weeks in a splint. Early passive motion (EPM): dorsal dynamic splint and controlled passive motion. Early active motion (EAM): palmar blocking splint and active motion	Twenty-seven patients from three sites, within 5 days post surgery for zones V and VI extensor tendon lacerations; randomized to 3 groups (n = 9 per group); mean age = 30.4 years. 33% attrition at 6 weeks: 5 (IM); 4 (EPM); 0 (EAM). Defaulters claimed recovery had occurred and no further treatment was necessary.	IM: Splint was discontinued at 6 weeks, with gradual increase of resistive activity and return to heavy manual labor by the end of 12 weeks. EPM: Passive extension exercises 20 times per hour in the splint and active MP flexion. Passive wrist tenodesis and IP joint motion supervised by therapist. Splint discontinued at 5 weeks, with graded mobilization. Remainder of the protocol same as IM group. EAM: Active motion exercises performed 10 times per hour as allowed by palmar blocking splint extended to the IP joint. At 3 weeks, splint adjusted to allow 70° MCP flexion, and active hook fists were initiated for extensor digitorum glides. At week 5, same as EPM protocol.	Randomized controlled trial (RCT). Level: IC2a	Yes. EAM appears beneficial.	Outcome measured at 3, 6, and 12 weeks. All patients showed steady improvement of total active motion (TAM) during the study period ($F_{2,46}$ = 75.6, $p < 0.001$). There was a significant ($p < 0.004$) difference among the groups in TAM over time, but the pairwise, post-hoc statistics were not reported. EAM group gained more active motion, had less extension lag, more self-reported improvement in function, and greater grip strength; however, none of these differences were significant. A type II error (no difference when one actually existed) could have occurred because of the small sample. Effect sizes for TAM calculated from reported means ± S.D. do indicate moderate strength of relationship between treatment and outcome (EAM versus EPM: r = 0.40; EAM versus IM: r = 0.48)[1]	Hall et al. (2010)

| Intensive lumbrical splint/stretch combination and less intensive lumbrical splint/stretch combinations | Lumbrical splints with wrist in 0° of extension and MCP joints in 0°–10° of flexion Prefabricated cock-up splints with wrist in 0° of extension and MCP joints free Lumbrical stretching and massage General stretches for composite wrist/hand flexion and extension LspLst: lumbrical splint/lumbrical stretch group (intensive lumbrical intervention) LspGst: lumbrical splint/general stretch group GspLst: general splint/lumbrical stretch group GspGst: general splint/general stretch group | One hundred twenty-four volunteers with mild to moderate carpal tunnel syndrome (CTS) randomized to 4 groups: lumbrical splint/lumbrical stretch (LspLst) n = 31; lumbrical splint/general stretch (LspGst) n = 34; general splint/lumbrical stretch (GspLst) n = 34; general splint/ general stretch (GspGst) n = 28. One hundred three subjects remained at 4 weeks (17% attrition rate). Ninety-five subjects remained at 12 weeks; attrition rate 23% from baseline. Eighty-nine subjects remained at 24 weeks; attrition rate 29% from baseline. | Four-week regimen Subjects wore splints at night and performed exercises 10 times per session, six sessions per day, 7-second hold for each stretch. | Randomized clinical trial Level: IA2b | At 4 weeks, all splint/ stretch combinations were equally effective as measured by the DASH (Disabilities of the Arm, Shoulder, and Hand) and Carpal Tunnel Questionnaire. At 12 weeks, LspGst and GspLst groups demonstrated continued significant $p \leq .001$ improvement, and the other two groups did not. At 24 weeks, only the GspLst group improved in function to a clinically important degree. From baseline (chi square analysis significant at $\alpha = .05$) By 24 weeks, 25.5% of subjects chose to undergo surgery; no significant difference between groups. | At 4 weeks, 66% of subjects achieved clinically important improvement in symptoms, but only 34% achieved clinically important improvement in function. At 12 weeks, 68% of subjects achieved clinically important improvement in symptoms, and 37.4% achieved clinically important improvement in function. At 24 weeks, a significantly greater percentage of subjects in the GspLst group achieved a clinically important improvement in function. Conclusion: a cock-up splint combined with stretches targeting the lumbricales is a more effective long term treatment for functional gains than splinting or stretching alone or other tested combinations for people with mild to moderate CTS. | Baker et al. (2012) |

Evidence Table 37-1	Best Evidence for Occupational Therapy Practice Regarding Treatment of Hand Impairments *(continued)*				
Conservative interventions for osteoarthritis (OA) of the hand to relieve pain, prevent joint deformity, and/ or to increase function	Splinting, joint protection instruction with provision of adapted devices, local application of heat (paraffin or hot pack), exercises, and home exercise program	Systematic review of 21 RCT and cohort studies published between 1986 and 2009 that met the following criteria: (1) patients had OA of hands; (2) treatment of OA was conservative. Ten studies were of high quality, 10 were of moderate quality, and 1 was poor quality.	Dosage NA	Systematic review Level: I	Conclusion: (1) High to moderate evidence to support carpometacarpal (CMC) orthotics to lessen pain and increase function; (2) moderate evidence to support hand exercise, low-level heat, and CMC orthotics to increase grip strength; (3) moderate evidence to support hand exercises, joint protection education and provision of adapted equipment, use of CMC orthotics to increase hand function; (4) moderate evidence to support hand exercises to increase range of motion (ROM) (5) moderate evidence to support hand exercises, joint protection education and provision of adapted equipment, low level heat to decrease pain; and (6) weak evidence for paraffin to decrease pain and increase ROM and function

Moderate evidence that low level laser therapy is no better than placebo to increase function or decrease pain or stiffness | No statistics or effect sizes reported | Valdes & Marik (2010) |

[1] Cohen, J. (1992). A power primer. *Psychological Bulletin, 112,* 155–159; Rosenthal, R., & Rosnow, R. L. (1991). *Essentials of behavioral research: Methods and data analysis* (2nd ed.). New York: McGraw-Hill, Inc.

of the tendon and expected ROM goals based on intra-operative findings (Culp, Feldscher, & Rodriguez, 2011). First priorities are edema control and ROM; observe and respect the tolerances of these fragile tissues.

Complex Regional Pain Syndrome

Any upper extremity injury, whether as minor as a paper cut or as major as a complex crush injury, has the potential to result in devastating reflex sympathetic dystrophy (RSD), renamed complex regional pain syndrome (CRPS) by the International Association for the Study of Pain. CRPS type I follows a noxious event. Pain that is not limited to the territory of a single peripheral nerve occurs spontaneously and is disproportionate to the inciting noxious event. Edema is present, with abnormality of skin color or abnormal sudomotor activity in the painful area since the onset. The diagnosis of CRPS is excluded by other existing conditions that may cause the pain and dysfunction (van de Meent et al., 2011).

CRPS type II is the same as type I except that it develops after a nerve injury, whereas type I does not involve a nerve injury. CRPS type III refers to a group not otherwise specified and includes patients who do not fulfill the criteria for types I or II (Veizi, Chelimsky, & Janata, 2012) .

Pain that is disproportionate to the injury is the hallmark of CRPS. Constant attention to the patient's pain level and autonomic responses can lead to early medical management, if not prevention, of this challenging problem. The earlier this problem is diagnosed, the more successfully it may resolve (Walsh, 2011).

The four cardinal symptoms and signs of CRPS are pain, swelling, stiffness, and discoloration. Secondary symptoms and signs include osseous demineralization, sudomotor changes (sweating), temperature changes, trophic changes, vasomotor instability, palmar fasciitis (thickening of palmar fascia), and pilomotor activity (goose pimples or hair standing on end).

Elegant animal studies have shown that self-protection through immobilization, intended to avoid pain, is itself a risk factor for the diagnosis of CRPS. People with CRPS must learn to use the extremity in ways that are pain free and biomechanically efficient. Normalizing sensory input also helps interrupt the vicious cycle of pain and stiffness (Goebel, 2011).

Therapy for Complex Regional Pain Syndrome

The most important therapy guideline is no PROM or painful intervention. The first thing is to control the pain. This includes management through medications, sympathetic blocks such as stellate ganglion blocks, and modalities such as TENS as appropriate. Close communication with medical experts specializing in pain management is ideal (Veizi, Chelimsky, & Janata, 2012).

Provide vasomotor challenge through stress loading (described later), temperature biofeedback, and posture changes during activity. It also helps to reset the sensory thresholds through contrast baths, vibration, and desensitization (see Chapter 22). Water aerobics and functional activities are excellent ways to provide active movement incorporating reciprocal motion. Use stress loading routinely with patients who are at risk for CRPS. Stress loading is proposed to change sympathetic efferent activity. Although the physiological mechanisms of stress loading are not known (Carlson & Watson, 1988), it is popular among hand therapists for treating active CRPS, not the sequelae (Veizi, Chelimsky, & Janata, 2012).

The two components of stress loading are "scrubbing the floor" (performed literally on all fours if possible), in brief sessions, three times per day initially, and carrying a weighted briefcase, done with the extremity in extension. The weight should be light and tolerable. Be sure it is not too heavy. Scrubbing and carrying achieve compressive loading and distraction of the upper extremity. If actual scrubbing cannot be tolerated, substitute comfortable weight-bearing exercises.

The frequency and duration of scrub and carry are upgraded as tolerated. If wrist ROM limitations or injury precautions do not allow the patient to assume the scrub position, positions may be adapted to accomplish comfortable weight bearing (see online Chapter A). Also instruct the patient to perform frequent pain-free proximal AROM bilaterally.

Avoid PROM or other therapy until the pain and swelling begin to subside, and then monitor responses closely. Incorporate traditional hand therapy, including orthotics and other nonaggravating modalities, with edema control, joint ROM, differential tendon gliding, restoration of musculotendinous lengths, strengthening, desensitization, physical agents including transcutaneous electrical nerve stimulation (TENS) and ultrasound as appropriate, and functional activity within tolerance. Manual edema mobilization is effective with this diagnosis.

Perhaps with CRPS more than other diagnoses, patient-directed therapy is essential. It is better to perform gentle, pain-free active exercises frequently for short periods than fewer and longer sessions. Light massage and active exercise help to interrupt the pain cycle. Make the exercise program bilateral and include reciprocal upper extremity motions. Allow the progress to be as slow as necessary to prevent worsening of symptoms. This diagnosis can be overwhelming and discouraging. Provide the patient with appropriate encouragement and reassurances that progress can be made over time.

CRPS typifies the difficult clinical problems that hand therapists are trying to avert or avoid. Intervention programs that are progressing well can be suddenly and unexpectedly derailed by this disorder. For this reason, it is advisable to approach all hand therapy patients

supportively and with a very careful eye, regardless of their diagnosis. Early identification of CRPS is a key to resolving it.

Osteoarthritis

Idiopathic OA is the most common type of OA. In the upper extremity, it often affects the DIP and PIP joints. Osteophytes at the DIP are called Heberden's nodes, and osteophytes at the PIP are called Bouchard's nodes (Beasley, 2012). For painful DIP nodes, small cylindrical splints or a light Coban™ wrap may promote function while decreasing pain (Biese, 2007).

Hand therapy for OA focuses on alleviating symptoms through education in principles of joint protection, protective and supportive splinting, and provision of adaptive devices for ADL (Hochberg et al., 2012) (see Evidence Table 37-1). For OA of the thumb CMC, a hand-based thumb spica orthosis (Fig. 37-21) is often extremely helpful (Beasley, 2011). Some therapists prefer to use a forearm-based spica orthosis, particularly when there is pantrapezial involvement rather than just CMC joint involvement.

Thumb CMC arthroplasty is a common postoperative diagnosis seen by hand therapists. Surgical techniques and timelines for therapy vary among physicians. Patients are often sent to therapy a few weeks after surgery for fabrication of a static forearm-based thumb spica orthosis with the IP free. The physician indicates appropriate guidelines for AROM according to the particular surgical procedures performed. Postoperative therapy goals are to promote pain-free stability and function. ADL modification and joint protection remain a priority.

Rheumatoid Arthritis

Unlike OA, RA is a systemic disease that primarily affects the synovium. Its debilitating and crippling effects can be severely disabling. RA presents as inflammation of synovial membranes of joints and of tendon sheaths, with redness, swelling, pain, and heat in the areas of involvement (Alter, Feldon, & Terrono, 2011).

Digital involvement at the DIP is less common than at the PIP. If DIP involvement does occur, a mallet finger may result. Involvement at the PIP may result in swan-neck or boutonniere deformities (see the section on extensor tendons for clinical management of mallet and boutonniere deformities). A swan-neck deformity presents as MP flexion, PIP hyperextension, and DIP flexion (Fig. 37-22). Fabricate a digital dorsal splint in slight PIP flexion to minimize deforming forces and enhance FDS function. At the level of the MP joints, deformity usually manifests as MP ulnar drift and palmar subluxation. Thumb deformities include boutonniere (primary thumb MP involvement) and swan-neck (primary CMC involvement) deformities. The thumb may also demonstrate stiff, unstable, and painful joints at the levels of the IP, MP, or CMC. RA often affects the wrist (Beasley, 2012). This is significant because the wrist is anatomically critical to proper hand function. Wrist involvement is compounded by concomitant hand deformity. Synovitis at the wrist can lead to flexor or extensor tendon ruptures (Alter, Feldon, & Terrono, 2011).

In evaluating patients with RA, observe deformities and abnormal posture, any atrophy, and skin condition. Identify crepitus of joint or tendon, palpable nodules, tendon integrity, and joint stability. Ask about morning stiffness, fatigue, and pain. The appearance of the deformity (cosmesis) is also relevant (Beasley, 2011).

The goals of upper extremity orthotics for RA include reducing inflammation, supporting weak tissues, and minimizing deforming forces. Orthotic intervention also provides functional assistance. Orthotics are used especially in the acute stage, when inflamed structures are at risk for further damage. Forearm-based resting orthoses may support the wrist and entire hand, the wrist and MPs, or only the wrist.
Figure 37-22 Swan-neck deformity: hyperextension of the PIP joint and dorsal migration of the lateral bands. (From Rayan, G. M., & Akelman, E. [2012]. *The hand: Anatomy, examination, and diagnosis* [Kindle Locations 2124–2127]. Philadelphia: Lippincott [Wolters Kluwer Health]. Kindle Edition. Used with permission.)

Figure 37-21 Hand-based thumb spica splint. Used to provide pain relief and promote functional pinch.

Determine orthotic design according to the pathomechanics of the disease. Involved MP joints are at risk for volar subluxation. Therefore, splint the wrist in neutral or slight extension, the MP joints in available extension, and the PIP joints in slight flexion (Biese, 2007). Radial deviation of the wrist encourages ulnar drift of the digits at the MP joints because of the zigzag deformity. An orthosis to correct MP ulnar drift often improves the biomechanics of hand use. Talk with the patient to identify individual preferences and needs in terms of ADL and joint protection. Adapt the straps and practice with patients to be sure they can open and close

them. For some people who require bilateral orthotics, it may be easier to use one at a time on alternate nights.

CONCLUSION

Wilson (1998) stated, "The hand is not merely a metaphor or an icon for humanness, but often the real-life focal point—the lever or the launching pad—of a successful and genuinely fulfilling life" (p. 14). Occupational therapy can be the launching pad for people with hand impairments to reestablish fulfilling lives.

Client-Focused Activity Analysis Case Example
Client-Focused Activity Analysis: Task of Blow-Drying Hair Independently for Improved Upper Extremity Strength and Function

Patient Information

Mrs. V. is a 59-year-old right dominant female who sustained a left distal humerus fracture and underwent a delayed open reduction internal fixation with plating. Occupational therapy (OT) assessment identified limitations in range of motion (ROM) and strength limiting ability to use the left upper extremity (UE) in self-care including grooming activities. Mrs. V. had worked as a hair stylist in the past and was very concerned about being able to groom herself independently. The therapist decided to incorporate a grooming task into the intervention plan to help Mrs. V. achieve the following goal: *Mrs. V will use her left UE to blow-dry her hair for 10 minutes with pain rating of less than 2 out of 10 and thereby improve her strength and function.*

Task Analysis Process		Intervention Planning	Clinical Transactions: Preparation for and Interactions at the Occupational Therapy Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
S E L E C T I O N	Specify the primary goal that performing this task is intended to advance	Independent grooming	The therapist selected a setup that included a mirror as a venue for grooming activities.	"The therapeutic aim of this task is to improve upper extremity strength and function in unsupported overhead activity. Mrs. V. has told me how important it is for her to become independent in her grooming activities."
	Specify the primary abilities and capacities that the task is intended to challenge: • ROM • Strength • Motor behavior • Praxis • Sensation • Vision-visual perception • Cognition	ROM Strength	The therapist positioned a blow-dryer on the counter in front of the mirror and asked Mrs. V. to use her left UE to lift it into position for blow-drying. She timed the interval that Mrs. V. was able to hold the blow-dryer in position before fatiguing.	"Even reaching for and lifting the blow-dryer is good for ROM and strengthening."

A N A L Y S I S	Evaluate the therapeutic value of activity based on these characteristics: 1. Inherently evoke desired response 2. Be gradable to progress the patient to higher function 3. Be within patient's capabilities 4. Be meaningful 5. Be repetitive	Use of strengthening and flexibility task that relates to Mrs. V.'s personal goal of improved grooming using left UE.	Weight and position of the blow-dryer can be adjusted to increase difficulty reaching and holding it in position.	"Mrs. V. will get practice with this task because she wants to perform grooming activities every morning."
G R A D A T I O N & A D A P T A T I O N	Specify task parameters to calibrate difficulty level of the task: • Method of instruction • Nature and level of cueing • Objects and their properties (materials, equipment) • Environmental demands • Social demands • Sequence and timing • Required actions and performance skills • Required body functions • Required body structures • Context or environment	Lighter versus heavier blow-dryer; smaller versus larger blow-dryer; varying handle sizes of blow-dryer; positioned lower and then higher; activity performed over increasingly longer periods of time before taking a rest.	The therapist monitored Mrs. V.'s responses and tolerance and modified the physical demands of the task accordingly.	"Mrs. V. is so eager to blow-dry her hair independently that she might overlook her fatigue level. I will help provide opportunities to pace this task so she can do it successfully without pain afterward."

case example

Miss L.: Recovery of Upper Extremity Function and Independent Self-Care, Homemaking, and Job Duties Post Distal Radius Fracture

	Clinical Reasoning Process	
Occupational Therapy Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Miss L. is a 49-year-old athletic computer software manager with dominant right hand. She is single and lives alone. Miss L. fell on an outstretched hand while on vacation out of state, sustaining a comminuted displaced right distal radius fracture. She was initially treated with closed reduction and a long-arm cast. Ten days later, after returning home, she underwent open reduction internal fixation of the right distal radius with a volar plate. Family members came to stay with her to assist with self-care and activities of daily living (ADL) needs. At the time of her injury, she was looking forward to a kayaking vacation.	Understand the patient's diagnosis or condition Know the person	"Miss L. sustained a significant injury to her dominant upper extremity (UE) requiring fixation and bone grafting. The immobilization time prior to surgery could potentially lead to significant stiffness of multiple structures." "Miss L. is an independent and active woman who hopes to go on a kayaking trip in a few months. She is not used to depending on others for self-care or other assistance. She likes living alone, driving her sports car, and going on business trips, but right now these aspects of her life are disrupted."
Reason for Referral to Occupational Therapy Miss L. was referred to outpatient hand therapy the day after surgery to maximize her functional abilities while her dominant hand was immobilized and to promote wound and fracture healing, edema control, and mobility of nonimmobilized structures.	Appreciate the context	"Miss L.'s family is with her initially to help her function while she relies on her nondominant UE for use. Although she prefers living alone, it is good that she has some help initially. Her desire to perform her occupational roles will help her recover more quickly."
Assessment Process and Results Miss L. had severe pain (9 out of 10), significant edema, and increased autonomic signs including vasomotor instability and guarded positioning of the right UE. She had extremely limited range of motion (ROM) of the digits of her right hand and was also hesitant to actively move her shoulder or elbow.	Develop provisional hypotheses Consider evaluation approach and methods Interpret observations	"I do not want to impose pain with my evaluation, so I will measure only active range of motion (AROM) in a gentle fashion. I will provide encouragement and explain how autonomic responses can be normalized with pain-free motion, elevation, and edema control." "Miss L. is at risk for complex regional pain syndrome (CRPS) and for significant stiffness of joints and tendons. Managing the edema is a high priority in order to normalize all tissue responses."
Occupational Therapy Problem List • Disruption of independent living and job performance • Interruption of frequent job-related travel • Inability to sleep or to perform self-care or home activities because of pain, edema, and decreased ROM • Risk of developing CRPS with degradation of functional and clinical status as evidenced by increased autonomic signs	Synthesize results	"Miss L. has multiple severe problems that could lead to permanent stiffness and loss of function. Despite this, she is a highly motivated successful professional, and she is eager to recover."

Occupational Therapy Goal List

1. Normalize autonomic signs and ameliorate pain interfering with function and sleep
2. Promote spontaneous pain-free use of the right upper extremity in daily activity
3. Achieve independent self-care and homemaking and resume job-related travel and engagement in athletic activity

Develop intervention hypotheses	"I believe that a gradual and gentle upgrade of exercises to promote healing and recover flexibility will be far more effective than overstressing her delicate healing tissues."
Select an intervention approach	"Occupational therapy will focus on promoting healing and restoring normal joint motions and musculotendinous lengths in order to recover UE function."
Consider what will occur in therapy, how often, and for how long	"Miss L. will need upgrades to her home program weekly. Splints will need to be revised, as well as exercises and instructions/practice in using her right UE for self-care and nonresistive home tasks."

Intervention

Miss L. began a home program of education about the expected clinical course and recovery; edema control; and shoulder, elbow, and digital ROM in pain-free ranges. Emphasis was on shoulder active exercise and upper extremity elevation. A week after surgery, Miss L.'s autonomic signs were resolving. Her digits remained edematous, and AROM was still limited throughout the upper extremity except for her shoulder, which was functional. Gentle wrist AROM was initiated.

At 2 weeks after surgery, digital AROM and passive range of motion (PROM) were slowly improving but still limited. Miss L.'s home program was upgraded to include edema control, functional grip and release activities, blocking exercises with thermoplastic supports, place-and-hold exercises, night composite digital extension static splinting, and day dynamic digital composite extension splinting. She was encouraged to use her injured arm in light self-care and in light household activity as well as desk work in order to reestablish use of the arm in her occupations. Differential digital flexor tendon gliding was restricted by adherence at the volar distal forearm incisional site, which was still healing. She had extrinsic extensor tightness, extrinsic flexor tightness, and intrinsic tightness. Fortunately, Miss L. was not developing PIP flexion contractures. She had been relying on her nondominant left hand for handwriting and all self-care. She returned to work soon after surgery and was once again traveling frequently on business.

At 3 weeks after surgery, when incision sites were healed, manual edema mobilization began, and all functional activities, splints, and exercises were upgraded in a pain-free fashion. Paper tape was applied to incision sites at night for scar management. Miss L. continued to make slow but measurable progress. Her physician reported good radiographic alignment.

At 6 weeks after surgery, Miss L.'s fixator was removed. Her physician reported good reduction and stability of the distal radioulnar joint. She was severely limited in forearm pronation and supination and in wrist AROM and PROM. She was instructed in pain-free forearm and wrist AROM. A thermoplastic volar wrist splint was fabricated for support and to correct limited wrist extension. Miss L. began to resume use of her right upper extremity for handwriting intermittently and for home activities as tolerated. Although she was very compliant with her home program, her progress was slow. She had become quite adept at using her left hand for dexterity tasks.

Assess the patient's comprehension	"I can tell that Miss L. understands her instructions because she demonstrates her activities well. She is exploring what new abilities she has with her right hand and is trying to use it as much as possible in a pain-free way. She demonstrates accurate placement of her splints and describes effective choices in using them. Her follow-through at home is exactly as I hoped it would be. And she understands when to rest her hand so that she does not develop new signs of swelling or pain."
Understand what she is doing	
Compare actual to expected performance	

At 10 weeks after surgery, Miss L. began to demonstrate dramatic gains in suppleness (Fig. 37-23, A & B). She was significantly improved in digital edema and in all ROM. Elbow extension was normal. Forearm supination and pronation were better, with AROM being equal to PROM. Isolated wrist extension was improved. Digital composite fisting and flexor digitorum profundus (FDP) and flexor digitorum superficialis (FDS) differential tendon gliding were nearly normal, and tightness of the extrinsic flexors was almost fully resolved. Miss L. was using her right hand for all handwriting and grooming and for driving her sports car. She was eager to begin simulating kayaking, because she had kept her plans for a kayaking vacation. Miss L. said that her dynamic splints and night static composite extension splints were helpful to her, so these were modified and upgraded. Strengthening exercises were gradually and cautiously upgraded as well.
Figure 37-23   Case example at 10 weeks postsurgery. **A.** active digital extension; **B.** active digital flexion.

Next Steps

Discharge from occupational therapy with home activities and splints.

Anticipate present and future patient concerns

Decide whether the patient should continue or discontinue therapy and/or return in the future

"Miss L. was able to go on her kayaking trip and enjoyed it. She still exercises and knows that it is important not to overdo it. She has learned how to keep her tissues flexible and has gained good strength as well."

Clinical Reasoning in Hand Therapy Practice

Effects of Promoting Occupational Engagement on Upper Extremity Function

Miss L. initially had to rely on her uninjured arm for one-handed self-care and was not able to picture herself resuming enjoyable activities such as kayaking. What recommendations should be made to her regarding her home program to incorporate occupation-based treatment as soon as possible? What clinical activities would be helpful to encourage more functional use of the arm?

Summary Review Questions

1. Why should painful treatment be avoided? What signs are indicative of overaggressive intervention?
2. Name the phases of tissue healing and approximate timelines.
3. Define joint versus musculotendinous tightness, intrinsic versus extrinsic tightness, and tightness of extrinsic extensors versus extrinsic flexors.
4. Describe the antideformity position of the wrist and hand and explain why it is used.
5. What function is lost with a low radial nerve injury? What kind of orthotic intervention (splinting) is appropriate, and why?
6. What distribution of sensation is usually impaired with carpal tunnel syndrome? What musculature might be atrophied in an advanced case? What night orthotic (splint) position is best for carpal tunnel syndrome, and why?
7. Describe CRPS and discuss intervention priorities for this diagnosis.
8. What symptoms are associated with a trigger finger?
9. Name four self-care or home activities that are safe and therapeutic for a person in a short arm cast with a healing distal radius fracture.

Glossary

Antideformity position (intrinsic-plus position)—Position of digital MP flexion and IP extension that maintains the length of the collateral ligaments and volar plate.

Buddy straps—Straps between an injured and an adjacent digit to protect or to promote movement.

Carpal tunnel syndrome—Nerve entrapment involving compression of the median nerve at the wrist causing sensory symptoms typically involving the thumb, index, and long finger and radial half of the ring finger.

Cervical screening—Proximal screening assessment of neck and shoulder to identify causes of or contributors to distal symptoms.

Claw deformity—Position of MP hyperextension and PIP flexion associated with muscle imbalance in ulnar-innervated structures.

Complex regional pain syndrome (CRPS)—Previously called reflex sympathetic dystrophy. CRPS is characterized by pain that is disproportionate to the injury, along with swelling, stiffness, and discoloration. Sudomotor (sweating) changes are often seen.

Contracture—Lack of passive motion caused by tissue shortening.

Counterforce strap—Support or strap used over flexor or extensor muscle wads to support muscles and prevent maximum muscle contraction, decreasing load on the tendon. Often used to reduce symptoms of lateral or medial epicondylitis.

Cubital tunnel syndrome—Nerve entrapment involving compression of the ulnar nerve at the elbow between the medial epicondyle and olecranon. Sensory symptoms affect the small finger and ulnar half of the ring finger.

Motor symptoms affect the FCU, FDP of the ring and small fingers, AP, and interossei.

De Quervain's tenosynovitis—Inflammation of the APL and EPB tendons at the first dorsal compartment.

Extensor lag—Inability to extend a joint actively while passively being able to.

Hard end feel—Unyielding quality of joint motion at end range when moved passively; indicates an established joint restriction.

Kirschner wires—Fixation devices used alone or in conjunction with other forms of fixation to treat unstable fractures of the hand. Kirschner wires are wires or pins that are driven through the skin, into the bone. They may protrude outside the skin, or they may be buried below the skin surface. If they protrude, the physician may request pin site care to prevent infection.

Neuroma—Disorganized mass of nerve fibers that can occur following nerve injury. Significant nerve pain with associated hypersensitivity is elicited by tapping over the neuroma.

Oscillations—Rhythmic movements that may be helpful to reduce guarding and pain.

Place-and-hold exercises—Passive motion used gently to achieve a position, with the patient then actively sustaining or holding that position.

Soft end feel—Spongy quality of joint motion at end range when moved passively; indicates favorable potential for tissue remodeling.

Tenolysis—Surgical procedure to release tendon adhesions that restrict movement.

Spinal Cord Injury

Michal S. Atkins

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define key terms and concepts central to spinal cord injury and its care.
2. Value the physical, psychosocial, and occupational challenges associated with spinal cord injury.
3. Describe the tests and procedures appropriate for occupational therapy assessment.
4. List the roles and priorities of the occupational therapist in each of the treatment phases.
5. Recognize functional expectations of patients with various levels of injury.

A spinal cord injury (SCI) is a devastating event that disrupts every facet of life. Diminished physical capacities, inability to get around and carry out daily routines, and feelings of confusion and despair are coupled with fears about gainful employment and questions about the ability to return home. The occupational therapist may share this burden. With such devastating losses, where does the therapist begin? How do we help patients rebuild a sense of efficacy and self-esteem? How do we set priorities for our treatment interventions?

This chapter provides beginning answers to these questions. First, it introduces epidemiological data, definitions, and classifications of SCI. Next, it discusses the course after injury, followed by information about occupational therapy evaluations, interventions, and a case study. Research data, resources, and suggested readings are listed to assist the therapist in exploring SCI beyond the material outlined in this chapter.

EPIDEMIOLOGY

SCI is relatively rare, afflicting approximately 12,000 people a year in the United States. The number of people with SCI alive today in the United States is estimated to be in the range of 236,000 to 327,000 (National Spinal Cord Injury Statistical Center [NSCISC], 2012). The NSCISC, a federally funded organization established in 1973, collects SCI epidemiological data in the United States. The causes of SCI as tracked by NSCISC since 2005 are as follows. Approximately 39.2% of SCIs are caused by motor vehicle accidents, 28.3% by falls, 14.6% by violence (mostly gunshot wounds), and 8.2% by sports injuries. Other causes, such as nontraumatic SCI, account for the remaining 9.7% (NSCISC, 2012). Nontraumatic SCI is caused by spinal stenosis, tumors, ischemia, infection, and congenital diseases (van den Berg et al., 2010). In large metropolitan areas in the United States, violence, specifically gun violence, accounts for a greater percentage of SCIs (Nobunaga, Go, & Karunas, 1999). In other countries, violence accounts for only a small fraction of injuries. Most SCIs occur in males with a ratio of four injured males per females in the United States (NSCISC, 2012).

The following demographic data paints a picture of those with SCI. Globally, as in the United States, the etiology and age distribution of injury has changed over the past decade with the average age of injury rising (to be further discussed later). SCI occurs mostly in adolescents and young adults (ages 15–29 years of age) and in elderly people aged 65 years and older, and the most common causes of traumatic SCI are vehicular accidents and falls, respectively (van den Berg et al., 2010). In the United States, 66% of those injured are Caucasian, and there is a greater representation of minority groups than in the general population: 26.8% of those injured are African Americans, 8.3% Hispanics, 2% Asian, and 2.9% for all other non-Caucasian ethnic groups (NSCISC, 2010).

Close to half of persons in the National Institute on Disability and Rehabilitation Research SCI Model System of Care have completed high school, and 57.1% were employed at onset (NSCISC, 2010, 2012). Generally, the level of education of injured individuals is somewhat lower and the unemployment rate is somewhat higher than in the general population. At injury, 51.95% of individuals are single, and the likelihood of getting married postinjury is somewhat lower than the general population.

The clinical implications of the SCI epidemiological data have great relevance to the work of occupational therapists. Therapists must appreciate that the patients' ethnic, gender, socioeconomic, and educational backgrounds may differ from their own (see Chapter 3). For example: What language would be best to communicate in? What is the best learning style of the person? What kind of written materials should be given to a patient with little education? Additionally, given that most therapists are females and most patients are males, sexual, bowel, and bladder management issues must be addressed with great sensitivity, and therapists must become comfortable with their role in these matters.

COURSE AFTER SPINAL CORD INJURY

SCI causes a disruption in the motor and sensory pathways at the site of the lesion (Fig. 38-1). Because the nerve roots are segmental, a thorough evaluation of motor and sensory function can identify the level of lesion (Fig. 38-2). For example, if the spinal cord is completely severed at the level of the 6th cervical nerve root, motor and sensory information below that level no longer can travel to and from the brain. This results in paralysis of muscular activity and absence of sensation below the level of injury.

Immediately after the injury, a period of spinal shock occurs, characterized by areflexia at and below the level of injury. Spinal shock may last hours, days, or weeks. As soon as spinal shock subsides, reflexes below the level of injury return and become hyperactive. At the level of injury, areflexia may remain as the reflex arc is interrupted.

Neurological Classification of Spinal Cord Injury

To understand the typical course of recovery from SCI, occupational therapists must be familiar with commonly used terms that describe SCI impairment and know how levels of impairment relate to prognosis.

Evidence Table 38-1 | Comparing Interventions and Their Outcomes

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Intervention to improve voluntary hand function in individuals with incomplete C4–C7 spinal cord injury	Comparison of two treatment groups: conventional occupational therapy and functional electrical stimulation (FES) therapy	Twenty-two individuals with incomplete C4–C7 tetraplegia; single site	Dose defined as 60 min per day, 5 days per week (for 8 weeks). Conventional occupational therapy group: two units of conventional occupational therapy. FES group: one unit of conventional occupational therapy and one unit of FES.	Randomized controlled trial; small groups (10 and 12); no control who did not receive treatment Level: IB	Group that received FES and conventional occupational therapy showed greater improvement than group that had 2 hours of conventional occupational therapy.	FIM™ $p = 0.015$; Spinal Cord Independence Measure upper extremity subscale <0.0001; Hand test Toronto Rehabilitation Institute Hand Function Test: 10 objects = 0.054; Rectangular blocks = 0.124; able to hold wooden bar $p = 0.065$	Kapadia et al. (2011)
Intervention to improve self-efficacy, ability to set/achieve goals, and perceived independent-living status	Occupational therapists and other health care providers conducted health promotional seminars, group discussions, physical and recreational activities.	SCI = 16 MS = 12	Ten full day sessions: twice a month for 5 months	One group, quasiexperimental repeated-measures; nonrandomized Level: IIIC	Yes. Self-efficacy and ability to formulate and achieve goals in the areas of independent-living skills improved for intervention participants.	Statistically significant difference in the change in self-efficacy scores $p = 0.007$; $d = 0.925$ (large effect size)	Block et al. (2010)

Definitions

Tetraplegia results in functional impairment in the arms, trunk, legs, and pelvic organs. The term tetraplegia, which has replaced quadriplegia, is defined as impairment in motor and/or sensory function in the cervical segments of the spinal cord (American Spinal Injury Association [ASIA], 2011). It is caused by damage to neural elements within the vertebral canal, and the term is not used to describe injuries to peripheral nerves. **Paraplegia** refers to motor and sensory impairment at the thoracic, lumbar, or sacral segments of the cord. Likewise,

it refers only to damage to the neural elements inside the vertebral canal. Paraplegia results in sparing of arm function and, depending on the level of the lesion, impairment in the trunk, legs, and pelvic organs. The terms paraparesis and tetraparesis, which were used in the past to describe incomplete injuries, should no longer be used (ASIA, 2011).

The neurological level is diagnosed by the physician according to the motor and sensory level. The motor level is determined by testing 10 key muscles on each side of the body, and the sensory level is determined by testing sensation of 28 key points on each side of the body (Fig. 38-2). The *neurological level of injury* (NLI) is the lowest segment of the spinal cord at which key muscles grade 3 or above out of 5 on manual muscle testing (MMT), and sensation is intact for this level's **dermatome**. Also, the level above must have normal strength and sensation. For example, a person is diagnosed as having C6 tetraplegia when radial wrist extensors test 3 out of 5 and sensation is intact for the C6 dermatome. Furthermore, all motor and sensory status above the C6 level is intact. **Skeletal level** refers to the level of greatest vertebral damage (ASIA, 2011).

Functional level, a term used by occupational and physical therapists, refers to the lowest segment at which strength of important muscles (key and non-key muscles by ASIA terms) is graded 3+ or above out of 5 on MMT and sensation is intact. These muscles significantly change functional outcomes (Zigler et al., 2011). The ASIA muscle list for the physician's motor examination (Fig. 38-2) includes only some of the muscles considered important to determine a functional level.

Two other terms commonly used with people with spinal injuries are complete and incomplete injuries (Definition 38-1). **Complete injury** consists of the absence of sensory and motor function in the lowest sacral segments (S4–S5) (ASIA, 2011). Consider the patient in the Case Example who has a C6 complete injury (also called AIS A). He does not have either sensation or motor have either sensation or motor function in S4-S5 but does have some muscle and sensory function above that level. The term **incomplete injury** should be used only when there is partial preservation of sensory and/or motor function below the neurological level and must include the sacral segments (ASIA, 2011). The physician tests innervation at the lowest sacral segment, including anal sensation and sphincter contraction. The degree of impairment of people with complete and incomplete injuries has been classified to ensure international diagnostic consistency. This impairment scale is called the American Spinal Injury Association Impairment Scale (or AIS) (see Definition 38-1).

The term *zone of partial preservation* is used for patients with complete injuries only who have partial innervation in dermatomes below the neurological level (ASIA, 2011). A patient may have a C5 AIS A neurological level and the radial wrist extensors innervated by C6 are functional. This patient's zone of partial preservation is C6.

Some specific cord lesions cause a common pattern of clinical findings.

- Central cord syndrome, the most common syndrome, is an incomplete injury, often caused by falls; it results in greater weakness in the upper limbs than in the lower limbs. This injury occurs mostly to older people and is often associated with cervical stenosis (ASIA, 2011).
- Brown-Sequard syndrome is an incomplete injury with damage to half of the cord causing ipsilateral proprioceptive and motor loss and contralateral loss of pain and temperature sensation. This syndrome is rarely seen in its pure form (ASIA, 2011).
- Anterior cord syndrome is a rare syndrome associated with absent blood supply to the cord causing the loss of motor control, pain, and temperature sensation below the injury. Proprioception and light touch are preserved (ASIA, 2011).
- Cauda equina syndrome is a lower motor neuron injury to the lumbosacral nerve roots within the spinal canal.

It results in areflexic bladder and bowel and paralysis or weakness of the lower limbs (depending on the level of injury) (ASIA, 2011).
- Conus medullaris syndrome is similar to cauda equina syndrome but in addition to lesions to the lumbar nerve roots, the cord is also damaged, resulting in a mixed physical picture with some preservation of reflex activity. The bladder, bowel, and lower limbs are affected (ASIA, 2011).

Prognosis

Not surprisingly, recovery is very much on the minds of patients, families, and staff. Neural recovery during rehabilitation is common and can result in significant improvement in function. In patients with complete injuries, muscles in the zone of partial preservation strengthen, which may result in significant functional change. This is true especially if a key muscle, such as extensor carpi radialis, strengthens enough to enable the person to

Definition 38-1

ASIA Impairment Scale (AIS)

AIS A = Complete. No sensory or motor function is preserved in the sacral segments S4–S5.

AIS B = Sensory Incomplete. Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4–S5 (light touch, pin prick at S4–S5 or deep anal pressure [DAP]), AND no motor function is preserved more than three levels below the motor level on either side of the body.

AIS C = Motor Incomplete. Motor function is preserved below the neurological level**, and more than half of key muscles below the single neurological level of injury (NLI) have a muscle grade of <3 (Grades 0–2).

AIS D = Incomplete. Motor function is preserved below the neurological level**, and *at least half* (half or more) of key muscles below the NLI have a muscle grade of ≥3.

AIS E = Normal. If sensation and motor function as tested with the International Standards for Neurological Classification of Spinal Cord Injury are graded as normal in all segments, and the patient had prior deficits, then the AIS grade is E. Someone without an initial SCI does not receive an AIS grade.

Note: To receive a grade of C or D, a person must have sensory or motor function in the sacral segments S4–S5. In addition, the individual must have either (1) voluntary anal sphincter contraction or (2) sparing of motor function more than three levels below the motor level.

**For an individual to receive a grade of C or D (i.e., motor incomplete status), they must have either (1) voluntary anal sphincter contraction or (2) sacral sensory sparing with sparing of motor function more than three levels below the motor level for that side of the body. The Standards at this time allows even non-key muscle function more than three levels below the motor level to be used in determining motor incomplete status (AIS B versus C).

Note: When assessing the extent of motor sparing below the level for distinguishing between AIS B and C, the **motor level** on each side is used, whereas to differentiate between AIS C and D (based on proportion of key muscle functions with strength grade 3 or greater) the **single neurological level** is used.

ASIA Impairment Scale reprinted with permission from the American Spinal Injury Association. (2011). *International standards for neurological classification of spinal cord injury*. Atlanta, GA: American Spinal Injury Association.

---

extend the wrist and hold objects. Patients with incomplete injury have a better prognosis, and their spontaneous recovery is less predictable in its pattern and outcome than patients with complete injury (Fawcett et al., 2007).

Immediately after the injury, all reflexes cease to function. When spinal shock resolves, patients have an excellent chance to regain motor and sensory function. As time after injury increases, however, the recovery rate declines. Most motor and sensory spontaneous return in both complete and incomplete injuries occurs in the first 3 months post onset. The rate of recovery declines but persists for up to 18 months or longer (Fawcett et al., 2007). Following encouraging discoveries of adult brain plasticity in the recovery after stroke, some new encouraging brain studies point to similar developments in SCI. These studies point to new formation of neural links associated with prolonged repetitive motion of affected limbs (Hoffman & Field-Fote, 2009). They open a window for future physical improvements over time and are yet to be fully investigated.

Because patients and significant others hope for complete recovery, it is important that the therapist maintain hope while planning a realistic course of treatment. Research data can assist the clinician in predicting recovery and outcomes. The therapist should be sensitive and cautious about sharing this information with patients when they are most vulnerable.

Long-term survival of people with SCI has improved dramatically over the past 50 years and is only slightly less than the general population (Fawcett et al., 2007). The major causes of death are respiratory complications and infections (NSCISC, 2010).

As the search for cure continues, many drug therapies have been introduced to decrease the initial damage to the cord and restore function. Some of the research strategies to heal the spinal cord have included studying nerve protection, nerve regeneration, bridging, and cell replacement (Maddox, 2007).

Some of the most common questions that patients often ask are "Will I walk again?" or "When will I be able to walk?" In many cases, the patient may repeat such questions to different clinicians in an attempt to make sense of their condition, to find a glimpse of hope in their new dire situation and to adjust to their new body. It takes time to learn to answer such questions in a truthful, supportive yet hopeful way. The new therapist may find help in answering such questions through discussion with the rest of the team.

Impairments and Their Therapeutic Implications

Paralysis is the most common result of SCI. This injury is accompanied by a variety of frequent complications.

The therapist must be aware of these impairments to provide a safe therapeutic environment and educate patients in understanding how to live a safe and healthy life.

Respiration

Many patients with SCI have compromised breathing. This is true especially for individuals with cervical injuries. Respiratory complications, specifically pneumonia, have been identified as the leading cause of death in the first year of life after SCI (NSCISC, 2010). In lesions above C4, damage to the phrenic nerve results in partial or complete paralysis of the diaphragm. These patients require mechanical ventilation (Fig. 38-3) (Consortium for Spinal Cord Medicine, 2005b). Lower cervical and thoracic spine injuries can result in paralysis of other breathing muscles, such as the intercostals, abdominals, or latissimus dorsi (Kendall et al., 2005). Thus, patients with such injuries also have impaired respiration.

Use of proper techniques and infection control standards are important for respiratory care. Under the direction of the physician, the physical and respiratory therapists and the health care team work to achieve adequate bronchial hygiene and to facilitate good breathing at rest and during activities. Good communication with the team allows the occupational therapist to support breathing goals.
Figure 38-3 A person with C2 complete tetraplegia, ventilator dependent, using a mouthstick. Notice the plastic hose attached to a tracheostomy tube in the neck. A portable ventilator enables the person to be mobile.

Autonomic Dysreflexia

Autonomic dysreflexia, a sudden dangerous increase in blood pressure, is a possibly life-threatening complication associated with lesions at the T6 level or above (Safety Note 38-1). It is brought on by an unopposed sympathetic response to noxious stimuli. Some of the more common causes of autonomic dysreflexia are distended bladder,

---

Safety Note 38-1

Safety Concerns for Patients with Spinal Cord Injury

Autonomic Dysreflexia

Individuals with injuries at the T6 level or above may develop dangerously high blood pressure in response to a noxious stimulus. This condition is brought about by unopposed hyperactivity of the autonomic nervous system. If not promptly treated, autonomic dysreflexia may result in a stroke or sudden death. An increase of 20 mm Hg or more in systolic blood pressure is a sign that must be attended to. A pounding headache is the most common symptom. Other signs and symptoms include heavy sweating, flushed skin, goose bumps, blurry vision, a stuffy nose, anxiety, difficulty breathing, and chest tightness (Consortium for Spinal Cord Medicine, 1997). Take the following steps:

1. Ask the person to stop any ongoing activity, as it may further increase blood pressure.
2. Check blood pressure. If high:
3. Have the person sit up with head elevated to avoid excessive blood pressure to the brain.
4. Loosen clothing, abdominal binder, and any other constrictive devices.
5. Check the urinary catheter for kinks or folds and straighten any.
6. Continue to monitor blood pressure and seek medical assistance, which may include bladder irrigation, manual fecal evacuation, and medications.

Orthostatic or Postural Hypotension

In contrast to autonomic dysreflexia, in orthostatic hypotension, blood pressure drops to dangerously low levels in response to assuming an upright position. If it is not treated immediately, the person may lose consciousness. Symptoms of orthostatic hypotension include light-headedness, pallor, and visual changes. To resolve the problem:

1. Check blood pressure.
2. If the person is in bed, lower the head of the bed.
3. If the person is in a wheelchair, lift his or her legs and observe for signs of relief. If symptoms persist, recline the wheelchair to place the head at or below the level of the heart.
4. If symptoms persist, put the patient to bed.
5. Continue to monitor blood pressure and seek medical assistance. Do not leave the patient unattended until a nurse or a physician is present.

Principles for treatment of autonomic dysreflexia are derived from Consortium for Spinal Cord Medicine (1997). Principles for treatment of postural hypotension are derived from Alverzo et al. (2009).

urinary tract or other infection, bladder or kidney stones, fecal impaction, pressure ulcers, ingrown toenails, invasive procedures such as urinary catheterization or enema, and pain. The main symptoms are hypertension and a pounding headache (Consortium for Spinal Cord Medicine, 1997).

Orthostatic Hypotension or Postural Hypotension

Orthostatic hypotension is a sudden drop in blood pressure occurring when a person assumes an upright position (Safety Note 38-1). Most common in patients with lesions at the T6 level and above, it is caused by impaired autonomic regulation. A decrease occurs in the returning blood supply to the heart, commonly because of blood pooling in the lower extremities. Orthostatic hypotension is aggravated by a prolonged stay in bed. When the patient attempts to sit up, the blood rushes down to the legs. The patient may complain of light-headedness or dizziness and may faint on moving from reclined to upright. The therapist must use caution when sitting the patient up by having the patient move slowly and in stages and letting the blood pressure adjust to the change. Elevating the head of the bed, using a tilt table, or using a reclining wheelchair can accomplish this. To control this problem further, patients benefit from wearing abdominal binders and elastic stockings (Alverzo et al., 2009).

Pressure Ulcers and the Maintenance of Skin Integrity

Individuals with SCI are in perpetual danger of developing pressure ulcers (Jackson et al., 2010). Most patients do not have the sensory feedback that periodically cues them to shift position in their bed or wheelchair. The constant pressure caused by maintaining a static position without shifting weight can lead to skin breakdown. All individuals with SCI must adhere to a weight-shifting pressure-relief schedule. Generally, in the wheelchair, people that have strong upper limbs perform pressure relief by leaning forward or side to side. Individuals that cannot perform these skills must rely on a powered wheelchair that tilts back (either a tilt-in-space wheelchair or one that reclines).

Although most pressure-relief efforts are aimed at the buttocks, many other parts of the body are vulnerable. All insensate areas must be inspected daily. For high tetraplegic patients, these areas may also include the spine of the scapula and the back of the head.

The pressure-relief program is successful only if individuals with SCI incorporate this practice in their daily routines following hospitalization (Jackson et al., 2010). They must become responsible for carrying out pressure-relief procedures themselves or for asking assistance in doing so. This may sound easy, but data suggest that most people with SCI develop at least one pressure ulcer during their lifetime. This underscores the challenge of living life fully while having to stay vigilant, perform routine thorough skin inspections, shift weight routinely, maintain equipment in good repair, and make minute-by-minute choices about activity levels and durations (Fogelberg et al., 2009). Recent research suggests that intervals of 2 minutes of pressure relief every hour while seated in the wheelchair is required for tissue oxygen perfusion, rather than 1 minute as previously thought (Makhsous et al., 2007). While in bed, people with SCI must change position every 2 hours.

Any client interaction must be viewed as an opportunity for a "teachable moment" (Wolfe, Potter, & Sequeira, 2004). Educational materials, such as the Consortium for Spinal Cord Medicine Clinical Practice Guidelines, *Consumer Guides—Pressure Ulcers: What You Should Know* (2002) and www.PressureUlcerPrevention.com, a user-friendly website for consumers and therapists, are helpful supplements for reinforcing the program. However, education is not enough to prevent ulcers.

Examples of occupational therapy roles in pressure ulcer prevention include

- training in motor skills, such as checking the skin in bed and in the wheelchair
- establishing routines, such as inspecting and wiping any wetness in vulnerable areas
- assessing environmental and contextual factors, such as helping select high-protein, healthy foods when going to the market (Clark et al., 2006; Jackson et al., 2010)
- recommending appropriate equipment such as seating systems, cushions, and padded shower chairs
- assisting in creating a typical day that allows for rest periods and other preventive measures

Bowel and Bladder Function and Management

Bowel and bladder function is controlled in the S2–S5 spinal segments. Therefore, all persons with complete lesions at and above the S2–S5 levels lose their ability to void and defecate voluntarily. With the presence of intact reflex activity but with a lack of cortical voluntary control, patients void and defecate reflexively. Incomplete injuries and disruption at the S2–S5 levels, as seen in conus medullaris and cauda equina, may present with a mixed sensory and/or motor picture. For example, a person may feel the urge but may lack the ability to void and defecate voluntarily. The goal of a sound bowel and bladder program is to allow the person to develop an elimination routine that supports health, reduces potential complications, and allows the freedom to engage in life roles without disruption (Consortium for Spinal Cord Medicine, 1998, 2006).

Following a thorough medical examination that includes studies of the structure and function of the digestive and urinary tracts, a physician establishes a safe elimination program. Most programs involve behavioral and pharmacological interventions (Consortium for Spinal Cord Medicine, 1998, 2006). Surgery is also an option that is typically offered years postinjury to further ease elimination and reduce problems.

Nurses are the primary trainers of bowel and bladder routines, and occupational therapists have a vital role in supporting the acquisition of these new skills and habits. A typical bowel program for a person with paraplegia includes taking oral medications to allow for optimal feces consistency and establishing a daily routine of transferring to the toilet, managing clothing, inserting a suppository, and, after waiting for some time, inserting a finger to the anus (called digital stimulation), which causes reflexive defecation. The occupational therapist may assist in facilitating skill acquisition in a person with poor vision and/or cognitive deficits. A magnifying mirror and a lamp may be placed on the floor to help the person see the process, which helps to further break down the activity to better reinforce each step. Persons with low tetraplegia have added challenges in becoming independent in bowel care. They may achieve independence or assist in managing their bowel care only after much practice. To compensate for poor trunk control, individuals perform the bowel program on a commode; to compensate for finger paralysis, they require a tool called a dill stick to stimulate the anal reflex to defecate (Fig. 38-4); and to compensate

for lack of sensation in the anus and/or parts of the hand, they require a mirror. For safe task performance, occupational therapists may practice commode mobility and dill stick insertion, focusing on effective visual compensation. When patients become skillful at bowel evacuation practices, they decrease the risk of complications. Most individuals, after discharge, opt to carry out their bowel program in the morning every other day and can complete the procedure within 45 minutes (Kirshblum et al., 1998).

As with the bowel program, the goal of the bladder program is to achieve a simple routine with minimal risk of complications. Recurring urinary tract infection is a frequent complication and the most frequent cause of rehospitalization after SCI (Cardenas et al., 2004). To avoid complications, patients must empty their bladder routinely.

An indwelling catheter, which is a catheter that stays in the urethra and is changed only periodically, is commonly inserted soon after the person is admitted to the acute care hospital (Consortium for Spinal Cord Medicine, 2008). Although some patients continue to use an indwelling catheter, an effort is made to find other ways to empty the bladder to reduce the chance of urinary tract infections (Consortium for Spinal Cord Medicine, 2006).

Some common bladder practices include use of either intermittent catheterization (IC) or reflex voiding. IC involves the manual insertion of a catheter into the bladder (Fig. 38-5) at fixed intervals of approximately 4–6 hours. Reflex voiding refers to spontaneous urination when the bladder is full. This voiding method requires that males use a condom catheter and a leg bag and that females use a diaper (Consortium for Spinal Cord Medicine, 2006). As with the bowel program, the bladder programs of persons with tetraplegia need more intervention, and the occupational therapist must become thoroughly familiar with individual techniques. Interventions may include finding

Figure 38-4 A simulation of a bowel program for a person with low-level tetraplegia (AIS A). The person is hooking his left arm under the handle for stability. He is using a dill stick to stimulate reflexic evacuation and a mirror to compensate for his lack of sensation in the anal area.

Figure 38-5 Catheterization: Inserting a catheter into the bladder and waiting for urine to flow.

a way to keep down the pants when performing IC in the wheelchair and training with a tool that helps insert the catheter into the urethra. Urinary management is more challenging to females than to males. Women have a shorter urethra and the opening is between the folds of the labia, so it is much harder for women to insert a catheter. In addition, women often need to wear diapers because their shorter urethra is more prone to leakage, and there are currently no acceptable female external collection devices that can keep the skin dry.

To best meet the person's environmental and contextual demands, the occupational therapist must think and practice beyond the hospital or clinic when helping patients rehearse and refine bowel and bladder routines. As patients rebuild new routines and habits, the therapist helps identify and embed these new functional skills in real-life scenarios such as emptying a full leg bag at a party, changing clothes when an accident happens in a mall, and performing IC while attending school.

Sexual Function

The need for emotional and physical intimacy does not diminish after SCI, and questions about intimacy, sexuality, fertility, and reproduction must be answered by a team of sensitive and knowledgeable professionals. SCI affects both sexual intercourse and reproduction, both of which are determined by the level of injury and its completeness. Most male patients with complete injuries are unable to have psychogenic (voluntary) erections and ejaculations. They can, however, have reflex erections that may be controlled by stimulation, such as pulling the pubic hairs or using a vibrator. Although most cannot feel orgasms, many describe developing new erogenous zones, such as around the neck and face (Consortium for Spinal Cord Medicine, 2010). Patients with complete injuries at S2–S5 lose bowel, bladder, and genital reflexes and have a complete loss of erection. As with physical performance, male fertility is decreased after SCI. Advances in technology, however, provide ways for male patients to sustain an erection and improve the chances of fathering children (Consortium for Spinal Cord Medicine, 2010).

Although sexual and reproductive functioning is less affected in women, sex, fertility, and menopause are still issues of concern. Some consequences related to these issues are dysreflexia and bladder incontinence during intercourse and complications of pregnancy and delivery (Consortium for Spinal Cord Medicine, 2010).

For both men and women, other psychological, social, and physical issues add to the difficulty in resuming satisfying sexual roles. Problems with mobility, dependency, and societal role expectations are some of the issues the person with SCI must face. Individual counseling, often by a psychologist, takes place after a thorough evaluation by a physician. Some areas addressed are sexual satisfaction, sexual function, fertility, and desirability. Patients learn that, despite their injury, they can continue to be desirable and have an active sex life (Consortium for Spinal Cord Medicine, 2010).

Optimally, experienced clinicians who are a part of an interdisciplinary team specializing in sexual functioning facilitate candid discussion about the topic. In this context, the role of the occupational therapist is to address varied individual needs. The therapist may become involved in helping people groom themselves to improve their appearance and to feel more attractive, help create a cozy environment that allows for intimacy, or find equipment to either compensate for lack of hand function or to help position the person for optimal, safe physical contact. In discussing sexual issues, the therapist must be particularly sensitive to the needs of the individual. To learn more about sexuality and reproductive health, *Sexuality and Reproductive Health in Adults with Spinal Cord Injury: A Clinical Practice Guideline for Health-Care Professionals* is an excellent comprehensive resource (see Resources 38-1) (Consortium for Spinal Cord Medicine, 2010).

Temperature Regulation

Many people with SCI cannot regulate body temperature, which can lead to hypothermia or heat stroke (Alverzo et al., 2009). Because of decreased sensation, patients may become severely sunburned or frostbitten. Education in the importance of neutral temperatures and the prevention of skin exposure to sun and severe temperatures is an important part of the occupational therapy program (Hill, 1986).

Pain

Acute and chronic pain (duration of more than half a year) are common after SCI. Studies vary greatly in estimating the prevalence of chronic pain, with the reported range of pain being 26%–96% regardless of completeness and level of injury (Dijkers, Bryce, & Zanca, 2009). Considering the violent nature of most injuries and the courses of illnesses that affect the spinal cord, it is not surprising that most patients have pain at onset and that pain persists for a long time. The Bryce-Ragnarsson Pain Taxonomy and the International Association for the Study of Pain task force on SCI pain created taxonomies and algorithms to help diagnose and treat the patient with pain (Bryce & Ragnarsson, 2000; Siddall, Yezierski, & Loeser, 2000). These algorithms simplify somewhat the complex nature of pain and SCI. These algorithms share some concepts in classifying pain according to location either being above, below, or at the level of injury and sharing two other major pain taxonomies: nociceptive and neuropathic. Nociceptive pain is caused by a normal reaction to a noxious stimulus like inflammation, or tissue tear. Examples of

nociceptive pains are local soft tissue pains above the level of injury associated with the injury or pain common in the shoulder of the person with tetraplegia because of muscle imbalance and overuse of weak muscles. Neuropathic pain originates in the nervous system and may be caused by different mechanisms such as misdirected neural sprouting after the injury. Neuropathic pain is hard to treat. Individuals with gunshot wounds often have severe shooting and burning neuropathic pains below the level of their injury.

Because most people with SCI experience pain, often in more than one location and throughout their life, the occupational therapist has many tools that help reduce pain levels and manage and cope with pain, including the following:

- Listen to the person, watch for signs of pain (such as facial expressions), and communicate clearly about the pain. The experience of pain is subjective and must be honored for what it is.
- Modify plans to help relieve the pain prior to activities. For example, instruct the patient to take pain medication half an hour prior to your session.
- Consider the contributing factors to pain such as feeling sad, being tired, or sitting too long and adjust your interventions accordingly.
- Be aware that people with complete injury (AIS A) with no sacral sensory and motor sparing may experience pain below their injury level, and this pain has to be taken seriously because it may signal medical problems such as bowel obstruction or skin breakdown.
- Facilitate positive and meaningful experiences that teach the power of diversion and meaningful occupations in reducing, managing, and coping with pain. For example, the patient may resist going shopping because of pain but after doing so report having enjoyed the outing and feeling less pain.
- Educate and practice routines to prevent long-term complications such as chronic shoulder pain caused by pushing a manual wheelchair. Guidelines for such programs are available from the PVA Clinical Practice Guideline: *Preservation of upper limb function following spinal cord injury* (Consortium for Spinal Cord Medicine, 2005a) and from a strengthening program derived from a 2011 study: *Strengthening and optimal movements for shoulders* (STOMPS) (Mulroy et al., 2011).

Fatigue

Physiological, psychological, and environmental factors all contribute to patients' fatigue. Persistent pain, antispasmodic medications, and prolonged bed rest are physical factors that can make the patient feel tired or sleepy. These factors are often compounded by restless nights interrupted by hospital routines, such as repositioning patients in bed and waking them for checking vital signs and administering medications. Occupational therapists

must be aware of these constraints and observe and listen to the patient. They must find the optimal waking hours for activities and report nighttime sleep disturbances, any changes of behavior that medication may cause, and other factors.

Spasticity and Spasms

An injury to the spinal cord often results in an increase in transmission within the synaptic stretch reflex. This results in spasticity. Spasticity develops into clonic or tonic spasms triggered by sensory stimuli such as sudden touch, infection, or other irritation. Management of spasticity is important in maximizing a patient's functional independence. Severe spasticity may hinder function. For example, the hypertonicity of the hip and knee adductors can make donning pants difficult. The most common way to decrease spasticity is to use a muscle relaxant, such as baclofen or diazepam. An intrathecal pump, motor point, or nerve blocks may be used in severe cases (Botte, Peace, & Pacelli, 2011). Spasticity can lead to contractures and so routine positioning in bed (Fig. 38-6) and in the wheelchair and range-of-motion exercise are essential; patient and family must participate in these measures for continuity of care (see Chapter 20).

Deep Vein Thrombosis

Deep vein thrombosis is the formation of a blood clot, most often in a lower extremity or the abdomen or pelvic area. A clot may develop further and dislodge from the venous wall, forming an embolus. This condition poses a threat to the patient because the embolus may travel and occlude pulmonary circulation (Consortium for Spinal Cord Medicine, 1999). The therapist helps prevent this condition by observing any asymmetry in the lower extremities in color, size, and/or temperature. When deep vein thrombosis is identified, the patient must have complete bed rest and anticoagulants to prevent embolus (Consortium for Spinal Cord Medicine, 1999). This is a good time to inform the patient and family about the symptoms, prevention, and care of deep vein thrombosis.

Heterotopic Ossification

Heterotopic ossification, which is pathological bone formation in joints, has been recorded in 15%–53% of SCI patients (van Kuijk, Geurts, & van Kuppevelt, 2002). It is a condition in which connective tissue calcifies around the joint. Heterotopic ossification usually appears 1–4 months after injury.
Figure 38-6 Positioning in bed. **A.** Alternate the arm in shoulder abduction and external rotation. **B.** Side view of A, showing placement of foam wedge. **C.** During side-lying, keep the upper back flat on the bed to protect the weighted shoulder. (Printed with permission from Rancho Los Amigos National Rehabilitation Center, Downey, CA.)

The symptoms are a warm, swollen extremity; fever; and/or range-of-motion limitations. Most often seen in the hip and shoulder joints, heterotopic ossification can result in joint contractures. Positioning in bed and in the wheelchair (see Fig. 38-6) and daily range of motion prevent or control heterotopic ossification. Because the first indication of heterotopic ossification most typically is range-of-motion limitation, the occupational therapist must use each range-of-motion session to monitor joint ranges, especially in patients with spastic muscles (Garland, 1991).

Psychosocial Adaptation

SCI, independent of its severity, is an emotionally traumatic event. During the first days after injury and often during acute rehabilitation, paralysis, multiple medical problems, and the need to rely on others for basic functions is overwhelming. Patients may experience a myriad of feelings such as confusion, anxiety, loss, hope, grief, depression, and helplessness. Family and significant others may also experience similar emotions (Consortium for Spinal Cord Medicine, 2008). Despite the paucity of evidence-based data specific to SCI, stage-based models have been prevalent in past decades. Fortunately, they have been replaced with a more open and fluid understanding of an individualized coping process (Magasi, Heinemann, & Wilson, 2009).

On average, people with SCI experience more distress and depression than the general population (Post & van Leeuwen, 2012). However, individual differences are great, and generally emotions improve over time (NSCISC, 2010). With time, most people with SCI report living satisfying lives and feeling well. Research Note 38-1 explains the importance of staff attitudes in making rehabilitation from SCI as positive an experience as possible. Social support, financial stability, meaningful occupations and full participation all play a vital role in improving the quality of life of individuals with SCI.

The occupational therapist must facilitate the enlistment of positive coping skills throughout the continuum of care. Here are some examples of how to do this during the acute phase.

- Foster autonomy in making decisions ("What clothes do you want to wear today?" "How long would you like to rest between sessions?").
- Facilitate solving problems ("What do you think is the best way for you to hold your pen?" "What do you think will make you sleep better at night?")
- Engage the person in activities that are personally relevant and meaningful.

Later in the continuum of care, therapists can facilitate positive coping by helping the patient identify optimal transportation, reduce environmental barriers, and facilitate the return to gainful employment.

Research Note 38-1

Hammell, K. W. (2007). Experience of rehabilitation following spinal cord injury: A meta-synthesis of qualitative findings. *Spinal Cord, 45,* 260–274.

Abstract

In this comprehensive literature synthesis, the author reviewed qualitative articles that describe the subjective experience of rehabilitation following SCI. The author conducted a thematic comparison and found seven concepts that were identified as key factors in shaping the rehabilitation experience. These are: "(1) the importance of specific staff qualities; (2) the need for a vision of future life possibilities; (3) the importance of peers; (4) the relevance of program content; (5) the institutional context of rehabilitation; (6) the importance of reconnecting the past to the future; (7) the importance of meeting the needs of the real world" (Hammell, 2007, p. 260). In conclusion, the author states: "If rehabilitation services are to be evidence-based, relevant, and effective in meeting the needs of people with SCI, they must be informed by the perspectives of people with SCI. The findings of this review suggest that the most important dimension of rehabilitation for people with SCI is the caliber and vision of the rehabilitation staff" (Hammell, 2007, p. 260).

Implications for Practice

This literature synthesis suggests that staff member competence, attitudes, and interactions have powerful influences on patients' experience in rehabilitation. Participants felt positive about optimistic, genuinely caring staff members who treated them as individuals, who listened to them, who showed flexibility in addressing their needs, and who seemed to be willing to bend rules to meet their needs. They felt unsupported by staff members who treated them as "numbers," who were pessimistic in their view of the future, and who were not knowledgeable. These findings are consistent with central tenets of occupational therapy including the emphasis on empathic, goal-directed, client-centered approach and understanding patients as occupational beings who derive meaning from engaging in meaningful activities and in unique contexts.

To understand the complexity of the psychosocial adjustment to SCI, we must also examine the reactions of the patient's relevant others. Family members and friends may also experience distress, sadness, anger, or a myriad of other emotions. Concurrently, they may have to reassess their future commitment to the injured person. A mother, for example, may grieve and be sad while having to decide whether to take her fully dependent son home after a turbulent adolescence.

We must also examine our own emotional reactions and the influence of these emotions on the patient and therapeutic process. For example, sometimes upon interviewing a newly injured person, I become especially sad as I strongly identify with something in the patient's life narrative (e.g., the struggles of a mother with two young children). I am reminded of my projection, as the patient may be more accepting and positive. As occupational therapists, we contribute to psychosocial adaptation after SCI by incorporating the following considerations into evaluation and treatment:

- Set aside all preconceived biases about who the patient is and how he or she should feel or behave. Instead, concentrate on learning to know patients' factors, their unique life contexts, and their individual reactions to their trauma or illness.
- Provide psychological support. At times when the patient is overwhelmed with sadness, it is okay just to be present and available to the person. It is okay to stop an activity, find a quiet environment, possibly outside, and listen, affirm, and educate.
- Select activities with a just-right challenge. After weeks of being dependent, patients find hope by being able to feed themselves or use their cell phone independently.
- When providing information, do not overwhelm the person with too much detail. Find the opportunity for a "teachable moment" for a particular "chunk" of information, and be sensitive of patients' signs to help you determine how to proceed and when to stop (Potter et al., 2004; Wolfe, Potter, & Sequeira, 2004).
- Accept patients' emotional states without judging them (Hammell, 1995). Lack of evidence of depression or anger does not necessarily mean that individuals are coping poorly with their injury. They may be using ways of coping that are not the textbook ones. Remember that there is no requirement to mourn to learn to accept and live with the injury (Magasi, Heinemann, & Wilson, 2009). Consult with the team physician and mental health providers if the person expresses suicidal ideations (Magasi, Heinemann, & Wilson, 2009).
- Create opportunities for peer education and support. Peers with SCI are often very effective in reaching patients and helping them feel less isolated and more optimistic. Individuals with similar levels of injury can truly understand the pain that comes with SCI and may help the therapeutic process.

ASSESSMENT: GETTING TO KNOW THE PATIENT

Prior to the assessment, the occupational therapist checks the medical chart for medical clearance to begin the evaluation. The patient often has other trauma, such as lacerations of internal organs, closed head injury, and fractures. Special care is taken to review records and communicate with the physician to ensure the safety of the patient. The initial evaluation is often difficult, because the newly injured patient may be sedated, in pain, and/or confused. Furthermore, this assessment may be interrupted by numerous medical procedures and may be restricted by medical and spinal precautions. Therefore, the occupational therapist must be flexible in choosing an appropriate evaluation time, in gathering bits of information in interrupted sessions, and in choosing the right tool for the moment when the patient is available. In essence, the evaluation process should not be limited to set scheduled intervals, and the therapist must view each encounter with the patient as part of an ongoing evaluation. Information should be also collected from relevant others and other team members. Thus, at the end of the assessment period, the therapist assembles all fragments of information into a full, initial evaluation (American Occupational Therapy Association, 2008). Treatment begins while the evaluation is in progress. This prevents further complications, such as range-of-motion limitations and edema. The therapist may also address patients' immediate needs, for example making them more comfortable in bed, which further establishes rapport and trust.

A positive trend toward an initial interdisciplinary team evaluation in which a few members of the team (physician, nurse, social worker, case manager, occupational therapist, and physical therapist) evaluate the patient together allows for organized information gathering with no redundancy. Next, the occupational therapist completes more detailed assessments with the patient alone.

Occupational Profile

The goals of the initial evaluation include beginning to establish rapport and trust, teaching patients about their potential, and learning about who they are and what is important to them. From the first encounter, the therapist also begins to educate the patient and to plan discharge. This is true especially today, when hospital stays have been cut to a bare minimum. In the acute phase and shortly after the injury, patients may be quite limited in their knowledge of the nature of their injury, prognosis for recovery, and potential for function. It is important not to overwhelm the patient with more than can be absorbed at that moment. The therapist must always leave room for hope without deceiving the patient.

To gather deeper understanding of patients' roles, activities, and the meaning behind the activities, use open-ended questions. Charting a typical day's schedule prior to injury allows for creative questioning and enables the therapist to sketch a person's habits, routines, and other activities.

The Canadian Occupational Performance Measure (COPM) is an excellent tool for working with the SCI population. It focuses on finding out patients' occupational goals and their priorities (Donnelly et al., 2004) (see Chapters 3 and 4). If patients are not psychologically ready to formulate goals that are important to discharge, first goals may be directed toward attaining more control over their immediate environment.

Evaluation of Performance Skills

Spinal stability must be established prior to any physical contact with the patient. The occupational therapist must clarify with the primary physician how much movement and load are allowed without jeopardizing spinal integrity.

The physical evaluation includes upper extremity range of motion, strength, muscle tone, and sensation (see Chapters 7 and 9). The therapist also observes the patient's endurance, trunk balance, fatigability, and pain. The Manual Muscle Test is most widely used to measure strength. This test is useful in determining the functional level of the person. The appearance of the upper extremities can reveal signs of Complex Regional Pain Syndrome, which is a chronic limb disease marked by severe pain, swelling, and skin changes. Such findings are vital for prevention of further deformity by immediately initiating an aggressive treatment regimen.

Hand and Wrist of the Patient with Tetraplegia

Evaluation of the hands and wrists is both physical and functional. Following the administration of the Manual Muscle Test and range-of-motion and tone assessments, most therapists observe hand use while the person is performing activities such as eating and picking up coins or pieces of a game (see Fig. 38-9 A–C). Standardized hand function tests, specific or nonspecific for people with tetraplegia, are typically not performed during acute rehabilitation. Some such tests are the Sollerman Hand Function Test (Sollerman & Ejeskar, 1995) and the Jebsen Test of Hand Function (Jebsen et al., 1969). Most tetraplegia hand tests have been specifically developed to assess hand function before and after hand reconstruction and hand neuroprosthesis surgeries (e.g., the Motor Capacities Scale [Fattal, 2004] and the Grasp and Release Test [Wuolle et al., 1994]) (van Tuijl, Janssen-Potten, & Seelen, 2002). Hand muscle function and pinch and grip strength are measured by dynamometers (van Tuijl, Janssen-Potten, & Seelen, 2002). To measure weak pinch and grip, more sensitive instruments than the standard dynamometer and pinch meter are used. Finally, by asking the person to list functions they want and need to perform with their hands and then examining their performance in these areas, the thera-

pist can concentrate on those functional components most relevant to the person.

Evaluation of Performance in Areas of Occupation

Selection of appropriate functional evaluations is determined by level of injury and stage of recovery. Occupational therapists rely on observations and standardized and nonstandardized assessments to evaluate activities of daily living (ADL) and instrumental activities of daily living (IADL), leisure, school, vocational interests, and aptitudes (see Chapter 4).

Activities of Daily Living and Instrumental Activities of Daily Living

Often, full ADL evaluation is postponed because of medical and spinal restrictions, and predictions regarding length of stay and functional outcomes are rendered without complete data. The Spinal Cord Independence Measure III (Catz et al., 2007) is a new SCI-specific instrument that is widely accepted in the United States (Anderson et al., 2011). It measures ADL, respiration, sphincter management, and mobility. Using a simple one-sheet scoring sheet, clinical staff scores performance while the patient engages in routine activities. The Quadriplegia Index of Function (Gersham et al., 1986) is a tetraplegia-specific instrument that is less widely used. A non–SCI-specific measure that is widely used in the United States is the Functional Independence Measure (FIM™) (see Chapter 4).

Leisure and Sports

Finding relevant and meaningful leisure activities is of great importance for improving quality of life (see Chapter 29). Leisure assessments may include the COPM and interest inventories. Because SCI typically occurs to young men, it is not surprising that sports are meaningful to many patients and become a big part of their lives. Assessing the potential for engaging in sports following the injury may include activities such as an outing to a game and/or being introduced to a wheelchair sports program. Most able-bodied sports are available to people with paraplegia and low tetraplegia. To enhance performance and safety, specialized equipment is available, such as a racing wheelchair or a specialized handle to compensate for a weak hand grip (Rice et al., 2009). With less physical capacities, finding meaningful recreational activities for people with high cervical injuries is challenging. Evolving high-tech solutions such as voice-activated computers allow people with high tetraplegia to find and access community resources and to engage in activities such as social networking and gaming.

School and Vocation

A full vocational evaluation is rarely performed during acute rehabilitation because patients are focused on more immediate challenges. Many have lost the physical ability to engage in prior occupations. Vocational exploration begins with defining patients' abilities and interests. Observation of factors such as hand function and work habits contribute information for the prevocational team and department of vocational rehabilitation.

Home and Community

The home visit is an invaluable assessment tool for the person with SCI, and the earlier it is performed, the better. This visit allows the therapist to assess home accessibility and safety and to evaluate the capacity of patients and their families to problem solve (Atkins, 1989).

Assessing transportation issues is important, because persons with SCI must often find new ways to get around. This evaluation may involve taking a bus for the first time or referring the patient to special driving services for the disabled (see Chapters 10, 26, and 31).

SETTING GOALS: ORDERING PRIORITIES FOR MEANINGFUL AND RELEVANT ACTIVITIES

Setting treatment goals in the acute phase may seem overwhelmingly difficult for both patient and therapist. Complications hinder progress, and patients are often confused, fearful, and uncertain about their impairments and abilities. Answers to the following questions help patient and therapist set priorities, establish short-term goals, and start treatment while evaluation is still in progress:

- What must be done to prevent further deformities and complications?
- What activity is important for the patient to engage in right now?
- What skills must patients and caregivers have for a safe return home?

The development of short-term goals stems from the therapist's ability to perform an activity analysis. Short-term goals may address functional performance areas and tasks, underlying problems, or activity demands. For example, a person with C4 tetraplegia who wants to use a mouthstick for word processing on a computer must first tolerate sitting upright in the wheelchair for significant periods. Increasing tolerance for sitting upright is an appropriate short-term goal for achieving the independence of mouthstick computer use.

Functional Expectations

Data collected from disability outcome measures inform the clinician of performance capacities of individuals with a similar clinical picture. This knowledge assists in formulating realistic goals and in selecting optimal activities that the person can perform successfully. These data also help the therapist predict how much help a person may need following discharge from rehabilitation.

Expected functional outcome charts (see Appendix 38-1) predict the degree of functional independence for a particular level of injury. One such chart was published in a 1999 document, *Outcomes Following Traumatic Spinal Cord Injury: Clinical Practice Guidelines for Health Care Professionals* (Consortium for Spinal Cord Medicine, 1999).

When studying this chart, consider the following (see Appendix 38-1):

- Expected functional outcome charts represent functional performance outcomes of individuals with complete (AIS A) injuries. As stated previously, when patients have complete injuries (AIS A), the muscle paralysis is more symmetrical, and the prognosis is somewhat more predictable, making it easier to set goals.
- The data were collected 1 year after injury and thus represent the functional level after people completed their inpatient rehabilitation stays.
- Patients with incomplete injuries (not represented in this chart; mostly individuals with AIS C and D) present greater challenges in goal formulation. With AIS C and D, muscle return is unpredictable and not symmetrical, making recovery and outcomes more individual and harder to predict.
- Expected functional outcome charts do not address many of the tasks, activities, and occupations that individuals would like to engage in. For example, they do not inform us about functions such as writing or driving a car.

Age-Specific Considerations

Although every patient has unique considerations in treatment planning, this chapter highlights the unique needs of adolescents and older adults with SCI.

Adolescence and Young Adulthood

The adolescent with SCI must deal with complex normal developmental factors coupled with new impairments and disabilities (Smith et al., 1996). Psychological adaptation to the injury may be especially difficult for adolescents, because the injury comes in the midst of development of adult self-image, identity, and independence. The therapist is challenged to

maintain a delicate balance between the sometimes competing needs to support patients and families and to encourage the young person to be self-reliant. Warning the family about avoiding overindulgence can lead to more engaged and assertive participation by the patient (Smith et al., 1996). At times, when the adolescent exhibits brooding or defiant behaviors that are harmful to progress, a strict behavioral program becomes necessary to draw the adolescent into positive participation (Massagli & Jaffe, 1990). Along with establishing independence, primary goals for the adolescent must include the following.

- Reentering the student role—Goals may include meeting with school personnel and visiting the school with the patient (Massagli & Jaffe, 1990; Wilkins, 2011).
- Sexual roles—Adolescents must be assured that individuals with SCI can remain sexually active (Massagli & Jaffe, 1990).
- Driver role—Initial evaluation and referral may be carried out in the acute rehabilitation phase and may be continued in the transition and adaptation phases. Driving, if possible, may provide the adolescent with a valuable sense of empowerment, independence, and increased motivation.
- At times, it is hard to remember that adolescents are minors and that all fundamental decisions must be made with parental participation and consent. The parents must be supported and must be part of the team, helping the patient make appropriate choices. Parents must also participate in educational sessions to ensure consistency in treatment, for example, with pressure relief.

The Older Adult

With rising longevity and greater participation of older adults, the number of people age 60 years and older with SCI is rising worldwide. The etiology of SCI of older adults is mostly falls and nontraumatic SCI such as tumors, vertebral degeneration, and vascular problems. In this population, etiology is often less clear because several medical conditions can cause spinal trauma (van den Berg et al., 2010). Falls, the number one cause of injury for this population, result in lesions at the cervical level, often causing central cord syndrome.

Having SCI and being elderly may be considered a dual diagnosis. The physiological process of aging can make rehabilitation from SCI particularly difficult, and older patients tend to have more medical complications (Scivoletto et al., 2003). The geriatric patient may require downgrading of expected functional outcomes, given physical and/or cognitive limitations. Some important factors are decreases in muscle strength, endurance, energy, and physical fitness; joint degeneration; bone decalcification; skin integrity; cognition; vision; and emotional changes. Older patients may require more assistance in ADL, and

hence, the focus of rehabilitation may be helping them identify resources in the community, teaching them to effectively direct their care, and involving family members in therapy (Scivoletto et al., 2003).

INTERVENTION

The occupational therapist treats individuals with SCI at various settings and at various times. Throughout this treatment continuum of acute care, acute rehabilitation, transition, and adaptation, most treatment principles remain the same. The focus of care changes, however, as the patient's internal processes (such as the psychological adjustment to the injury) and external environments change.

Acute Recovery: Focus on Support and Prevention

Immediately after injury, most patients are admitted to an intensive care unit, where the focus is on preservation of life and stabilizing fluids, electrolytes, cardiopulmonary and other vital functions. The patient is immobilized in traction and waiting to hear whether surgery is required to stabilize the spine. For prevention of pressure ulcers, the patient is put in a rotating bed (Consortium for Spinal Cord Medicine, 2008). In the intensive care unit, medical and surgical procedures take precedence over therapy. The therapist must be flexible, often seeing the patient for brief periods throughout the day. One or two 15-minute sessions per day are often helpful to the patient, who may be in pain, fatigue easily, and become confused or overwhelmed by this fast-paced environment of electronic devices and medical procedures. The occupational therapist's initial contact should be within the first few days after admission and when medically cleared by a physician. Treatment begins as the initial evaluation is in progress, allowing the therapist to begin to gain a full picture of the patient (Hammell, 1995). In addition to ongoing patient and family support and education, the focus of therapy in the acute recovery phase includes the following:

1. Providing some environmental controls to help the patient get some control of their immediate environment such as nurse call button or bed controls.
2. With individuals with tetraplegia, maintaining normal upper limb joint range of motion and preventing edema and deformities (Consortium for Spinal Cord Medicine, 2008).

To prevent range-of-motion limitations, therapists use positioning techniques and assist with range-of-motion exercises. In bed, most persons with tetraplegia tend to lie with their arms adducted close to their body, internally rotated, and with elbows flexed (Consortium

for Spinal Cord Medicine, 2005a). Therefore, movement in joints particularly susceptible to contractures must be monitored daily. Important movements include scapular rotation, shoulder scaption (the functional motion between abduction and flexion), shoulder external rotation, elbow extension, and forearm pronation. Hands are fitted with resting hand splints. Upper limbs are placed in either some abduction or external rotation (see Fig. 38-6, A & B). Alternating arms between these positions puts all vulnerable joints in stretch. It is important to note, however, that although the goal is to preserve range of motion, one must consider the comfort of patients to allow them a good night's sleep.

Range of motion to the hand of the patient with tetraplegia is performed in a special way to facilitate tenodesis grasp: passive opening of the fingers when the wrist is flexed and closing of the fingers when the wrist is extended (Fig. 38-7, A & B) (Wilson et al., 1984). The patient, family, and others are taught how to perform range-of-motion exercises to the arm and to facilitate tenodesis. Again, range-of-motion exercises must be augmented with proper positioning in bed and in the wheelchair.

During the acute phase and when medically cleared, the occupational therapist may also evaluate the person's ability to swallow, sit upright, and begin evaluating and training in appropriate ADL (Consortium for Spinal Cord Medicine, 2008).

Acute Rehabilitation: Focus on Support, Education, Acquiring Performance Skills and Meaningful Activities

In the United States in the 1970s, the mean length of stay in acute SCI rehabilitation was 144.8 days. By the late 1990s, mean length of stay had decreased to 97 days and is now less than 37 days (NSCISC, 2010). To a lesser extent, this trend of shortening rehabilitation length of stays has been also occurring worldwide. With such short stays, individuals are discharged way before their physical condition plateaus. Because rehabilitation institutions are the major venues for delivering intensive therapy, this trend has been difficult for patients and clinicians alike, who must make tough decisions about what is most important to accomplish during inpatient stay. The growing availability of ambulatory services have helped ease the sense of urgency somewhat, allowing patients and therapists to focus their attention on the present and near future while in rehabilitation.

During acute rehabilitation, occupational therapy continues to focus on providing education and support to patients and helping them begin to explore meaningful activities that restore a sense of efficacy and self-esteem. Treatments must always be structured with these overriding goals in mind. This chapter offers basic information. For specific detailed interventions, consult the reference and suggested reading lists.

Educating Patients and Family

Each encounter with patients and families must be viewed as an educational opportunity. The style, quantity, and direction of each session must be carefully considered (Hammell, 1995; Wolfe et al., 2004). While patients are learning to put on a shoe, for example, the therapist may ask if they have checked skin integrity and, by so doing, draw attention to the importance of skin inspection. This discussion may also inform the patient about preferable shoe styles and sizes, pedal edema, and deep vein thrombosis. These "teachable moments" arise often and help embed details of newly learned skills and routines (Wolfe et al., 2004). Nurses, the only team members who see the patient throughout the day, are pivotal in enforcing a daily routine. The therapist must communicate with them daily to ensure a coherent and consistent program.

Education is often enhanced by learning and problem solving with a peer or in a group (Hammell, 1995; Wolfe, 2004). Group learning is widely used in SCI centers, to inform and invite group dialogue on topics such as home modifications, accessibility rights, attendant management, assertiveness, travel, and driving. Experiential group activities, such as going to a restaurant, are recommended for building emotional and social alliances with peers while learning from each other's successes and failures. Educational materials and videos are available through groups such as the Paralyzed Veterans of America and the Spinal Cord Injury Association (Resources 38-1). Participation in self-initiated learning, such as surfing the Internet, empowers the patient. On the Internet, many SCI consumer websites offer tips, personal stories, and chat rooms, which can provide a lively forum for communication, self-expression, and information. Family education must result in competence in range of motion, positioning, pressure relief, assistance in ADL, and use of equipment. Home and weekend passes provide an excellent opportunity to develop and refine skills.

Self-Efficacy and Self-Management Skills

Patients' medical and psychological status, as well as being in a hospital environment, invite passivity and submission to hospital routines and to professional staff recommendations of care. The therapist and the rest of the health care team must encourage patients in taking an active role in managing their care, in evaluating behaviors, and in self-reflection about failures and successes (Lorig, 2003; Radomski, 2000). In addition, our challenge as therapists is to recruit, educate, and empower our patients to be problem solvers. By so doing, we encourage active participation, generalization of information, and the transfer of learning to the post-discharge environment (Radomski, 1998; Wolfe et al., 2004). When planning an outing, for example, ask the group to prepare a list of items to be checked to ensure a safe, successful outing.

Figure 38-8 A person with paraplegia using a reacher to retrieve hard-to-reach items on a shopping outing.

Upon return to the hospital, encourage discussion of the outing to reflect on ways future outings can be improved (Fig. 38-8). Practical issues such as restaurant accessibility to wheelchairs and self-catheterization in public bathrooms may arise. This discussion is also a good time to reflect on performance accomplishments during the outing and to share failures and success experiences in a supportive environment.

Balancing Self-Maintenance Skills and Meaningful Activities

In acute rehabilitation, most patients are relearning skills that they mastered in childhood, such as eating and dressing independently. This training is an important part of our job. For many patients, however, this training is frustrating, time consuming, tiring, and a constant reminder of their impairments and disabilities. The therapist has the difficult task of helping the patient see when relearning skills is valuable and when the skill should be accomplished by a caregiver, either for now or permanently. The ultimate goal of rehabilitation is no longer viewed as the attainment of maximal functional independence. Rather, it is the attainment of optimal desired functional independence. Functional expectations charts (see Appendix 38-1 at the end of this chapter) help us understand the range of expectations for a given level of injury considering only the motor and sensory status of the patient. These charts do not answer such ques-

tions as these: Why should the patient dress for half an hour when his wife can dress him in 5 minutes? Will it still take that long after adequate training? What will the patient do when his wife is away? Such discussions encourage patients and families to explore the range and consequences of their choices. The novice therapist will find books such as *Spinal Cord Injury: A Guide to Functional Outcomes in Occupational Therapy* (Hill, 1986) and *Physical Management for the Quadriplegic Patient* (Ford & Duckworth, 1987) especially valuable because they contain photographs that demonstrate various skills, their sequencing, and the use of assistive devices (both books are out of print but can be found in libraries and as used books for purchase on the Internet).

Choosing Equipment

Initially, when pain, spinal precautions, and orthoses, such as a body jacket, may stand in the way of accomplishing goals, assistive devices may be handy facilitators. When obstacles diminish, some equipment, such as a dressing stick, can be eliminated. Only essential equipment should be sent home with the patient, because much of it is costly, and it may further complicate the person's life. Also, a universal device should be favored over multiple assistive devices.

Most persons with SCI require lifetime use of wheelchairs for their mobility. Choosing the optimal wheelchair requires great expertise and has important implications for ease of mobility, accessibility, and participation (see Chapter 17). The therapist and the patient must consider many factors in weighing the advantages and disadvantages of specific chairs (Consortium for Spinal Cord Medicine, 2005a). For example, if a young adult with a functional level of C6 is returning to college following a rehabilitation stay and would like to use an attractive manual wheelchair to look and feel less disabled, questions about the layout of campus, the terrain, and distances between classes must first be answered prior to recommending the optimal wheelchair. The person's endurance, posture, and transportation are factors that must all be weighed in selecting either a manual wheelchair or a power wheelchair.

Patients and families should be involved also in the purchase of any other major equipment, such as commode, other bathroom equipment, or a bed.

The Patient with High Tetraplegia: C1 to C4

Patients with complete C1–C3 require an external breathing device because their diaphragm is either paralyzed or only partially innervated (C3). Most persons with C4 tetraplegia require assistance with ventilation during acute care, but as the diaphragm strengthens, they are able to breathe independently. The most common device for assisted breathing is the ventilator, a pneumatic electric machine that forces room air into the lungs. Expiration is passive. This device is attached via plastic tubes directly to a hole in the trachea (see Fig. 38-3).

People with complete high tetraplegia are paralyzed from the neck down. These patients require a highly specialized team to stabilize them medically and to prevent further complications, such as respiratory infections and pressure sores. The occupational therapist who works with this population must be comfortable with nursing procedures. These tasks include suctioning (removing secretions from the trachea), manually ventilating the patient with a manual resuscitator (Ambu-bag), and proficiently managing a ventilator (Consortium for Spinal Cord Medicine, 2005b). The rehabilitation team must also be well coordinated, providing the patient and family with care while preparing them for discharge. Patients with high lesions have a myriad of issues to deal with in many domains of their life. It may be surprising to realize that, despite seemingly insurmountable obstacles to success, many patients with such lesions live healthy and meaningful lives (Whiteneck et al., 1989).

Some additional roles the therapist may have in treating persons with high cervical injury include teaching them to direct their own care; helping them select specialized and sophisticated equipment (see Chapter 18) for life support, mobility, and ADL; and training them in the use of mouthsticks, which are rigid long rods held in the mouth that allow the patient to perform activities such as turning pages, drawing, typing, painting, and playing board games (see Fig. 38-3) (Atkins, Clark, & Waters, 2010; Hammell, 1995).

The Patient with Lower Cervical Injuries: C5 to C8

As in the acute recovery phase, physical intervention includes positioning in bed and in the wheelchair (see Fig. 38-6), splinting the upper extremities, daily upper extremity range of motion, and strengthening. Strengthening, an important goal in this phase, can be performed by using weights, pulley systems, tabletop skateboards, suspension slings, mobile arm supports (discussed later), and modalities such as biofeedback neuromuscular electrical stimulation and robotics (Hill, 1986; Hoffman & Field-Fote, 2009) (see Chapters 19, 20, and 22).

New evidence of neuroplasticity once thought unattainable in the adult brain shows some promise for upper extremity recovery. Emerging research demonstrates that mass repetitive upper extremity task practice with sensory stimulation can bring about greater brain excitability in the corresponding brain sites and some improvement in function (Hoffman & Field-Fote, 2009). A growing number of rehabilitation centers offer intense repetitive upper extremity training with the aid of robotic arms and/or video games to enhance repetitive motion with the hope of increasing function.

To enhance function and engage in a variety of activities, the therapist works closely with the patient, exploring wrist and hand compensatory techniques and finding devices to compensate for hand paralysis (Curtin, 1999) (see Fig. 38-9, A–E).

Figure 38-9 Hand compensatory techniques. **A.** Pressing one hand against the other to lift a bottle. **B.** Pressing one hand against the other to write. **C.** Dragging the coin to the edge of the table in order to pick it up. **D.** Using devices to compensate for lack of ability to point and isolate finger movements. **E.** Using a track ball instead of a mouse.

Patients with C5 Tetraplegia. Initially, the deltoids and biceps, key muscles for this level of injury, are weak, so upper limbs require support to function. The mobile arm support, also called a ball-bearing feeder, is a mechanical device attached to the wheelchair. (See Chapter 15 for further discussion of this device.) This shoulder and elbow support carries the weight of the arm (Wilson et al., 1984). The mobile arm support can assist the patient in driving the wheelchair, feeding, hygiene and grooming, and carrying out tabletop activities, such as writing and cooking (Atkins et al., 2008). If and when the strength of the deltoids and biceps is 3+/5 or greater and endurance is good, patients can engage in activities without mobile arm supports (Zigler et al., 2011).

Patients with C5 complete tetraplegia need a way to grasp and hold objects, because their wrists and hands are paralyzed. First, the wrist must be stabilized with a splint or orthosis. Next, a device is attached to the hand to enable the person to perform activities. The universal cuff is a simple, inexpensive utensil holder is worn around the palm (Fig. 38-10). Other U- or C-shaped clamps can be attached to objects such as telephone receiver or a shaver. Some splints, devices, and orthoses accommodate the wrist and the hand as a unit. To maximize functional gain with any device, the patient must have adequate time and repeated training sessions.

Most patients with C5 tetraplegia can master tabletop activities. They lack trunk control and muscles below the shoulder, however, so they are mostly dependent in dressing and bathing (see Appendix 38-1) (Consortium for Spinal Cord Medicine, 1999). With adequate emotional and financial resources, persons with C5 tetraplegia engage in meaningful, productive activities. Case in point: Mr. L. is a financial consultant who lives on his own and has part-time caregivers. He lives a busy life full of business trips and leisure activities with friends. He attributes his success to much planning and good organizational skills.

Patients with C6 and C7 Tetraplegia. Patients with C6 and C7 tetraplegia may attain significantly higher levels of independence than those with C5 injury. The addition of radial wrist extensors allows patients to close their fingers with a tenodesis grasp. This is a critical functional enhancement because, with it, light objects may be picked up, held, and manipulated. The wrist-driven wrist–hand orthosis (also called the flexor hinge splint or tenodesis splint) is a metal device that transfers power from the extended wrist to the radial fingers, allowing a stronger pinch (Fig. 38-11) (Atkins et al., 2010; Consortium for Spinal Cord Medicine, 1999).

More fully innervated proximal scapular and shoulder muscles, such as the rotator cuff, deltoids, and biceps, allow for an increase in upper limb strength and endurance. Patients can also roll in bed, and their arms can cross the midline more forcefully, with the addition of the clavicular pectoralis muscle. The ability to use the triceps, the

Figure 38-10 A person with C5 tetraplegia using a universal cuff.

Figure 38-11 A woman with C6 complete tetraplegia using the wrist-driven wrist–hand orthosis to apply makeup. This device enables the person to hold on to objects tightly despite finger paralysis.

key muscle for C7 tetraplegia, allows the patient to reach for objects above head level, such as items on a store shelf; transfer with greater ease; and push a manual wheelchair.

Patients with C8 Tetraplegia. Hand function is significantly improved with the addition of extrinsic finger muscles and thumb flexors. Hand dexterity and strength are limited by the absence of intrinsic finger and thumb muscles. A person with complete C8 tetraplegia grasps objects with the metacarpophalangeal joints in extension and the proximal interphalangeal and distal interphalangeal joints in flexion. This is called a claw hand or intrinsic minus hand (Zigler et al., 2011).

Surgical Options for the Upper Extremities. Restoring hand function is the top priority of many individuals with tetraplegia (Moberg, 1978; Snoek et al., 2004). To improve hand function, persons with C5, C6, C7, or C8 injuries may have surgical options. These options do not provide for a normal hand but aim to restore pinch, grasp, and reach. Tendon transfer surgeries are recommended only after full spontaneous motor and sensory recovery has occurred and no earlier than a year after injury because most of these procedures permanently alter the musculoskeletal structures (Waters et al., 1996).

Upper limb reconstructive surgeries, although not frequently performed, are available for increasing motion and function of the upper extremities. These surgeries may shorten or change the direction of pull of tendons of passive (paralyzed) muscles to provide a mechanical advantage to the thumb or fingers. Other common procedures may entail tendon transfers of functioning muscles. Typically, a proximal functional muscle with strength of 4 out of 5 or above is attached to a tendon of a distal paralyzed muscle. Following the surgery, the patient learns to contract a proximal muscle to move a distal joint (Waters et al., 1996). An example of a hand tendon transfer surgery is the brachioradialis to flexor pollicis longus. This surgery restores lateral pinch by attaching the tendon of a strong (4 out of 5 muscle or above) brachioradialis to a paralyzed flexor pollicis longus. To pinch an object, the patient flexes the elbow while the forearm is in pronation. To improve the stability of the thumb, the interphalangeal joint is fused.

The preoperative and postoperative evaluation, education, wound care, and muscle reeducation must be carried out by an experienced therapist. Additionally, consistent communication with the operating physician is vital for favorable outcomes. Overall, patients who have gone through reconstructive surgeries perceive their surgeries positively and as improving their function and appearance (Jaspers Focks-Feenstra et al., 2011).

A select number of centers worldwide offer complex procedures for achieving hand function. One such system is the second generation neuroprosthesis, a permanently implanted electrical stimulation device, which allows the person with C5–C6 injury to open and close the hand by moving the opposite shoulder. This electrical device is composed of 12 electrodes implanted into various muscles, electrode leads, transmitter, and a shoulder sensor. An external controller box attached to the wheelchair controls the device remotely with no connecting wires. Often, the neuroprosthesis surgery is either combined with or follows other hand surgeries that allow for optimal use of the device (Kilgore, 2008).

The Patient with Paraplegia

Most people with complete or incomplete paraplegia become independent in self-maintenance, self-enhancement, and self-advancement roles, although they require assistance with heavy housekeeping and physically demanding vocational pursuits (Consortium for Spinal Cord Medicine, 1999). Paraplegics with injuries at T10 and below may attain skills more easily and rapidly than patients with higher injuries (Fig. 38-12). Good trunk control enables a person with low paraplegia to bend down and from side to side without fear of falling forward. Skills performed while upright (e.g., bowel management, lower body dressing, undressing, and bathing) require the patient with a higher injury to secure the trunk by supporting the body with one arm while performing the activity with the other to prevent falls (Zigler et al., 2011).

Typically, patients with paraplegia have fewer medical complications than those with tetraplegia, and self-maintenance skills are learned quickly. Patients with paraplegia are discharged quickly from acute rehabilitation settings and may benefit greatly from more interventions and support as they reenter the community. These interventions often include reassessing routines

Figure 38-12 A person requiring assistance in transferring from his wheelchair to a mat.

such as re-examining self-care skills, facilitating return to school, and exploring work and leisure interests, skills, and opportunities.

The Ambulatory Patient: Incomplete Paraplegia and Tetraplegia

Typically, when we think of spinal cord injuries, we picture a person using a wheelchair, yet many individuals with incomplete SCI are able to walk (Fig. 38-13). Walking potential is mostly determined by the level and completeness of the injury (Consortium for Spinal Cord Medicine, 1999). Other factors may include body weight, age, upper extremity involvement, and pain. Ambulation, a primary goal for most patients, carries with it some unique challenges to the patient and occupational therapist.

For expedient and relevant treatment planning, the occupational therapist must clearly understand ambulation goals soon after admission. Early discussion with the physical therapist helps clarify goals and enables the occupational therapist to outline a treatment course that takes walking into consideration. Answers to the following questions guide treatment planning:

1. Will upper extremity aids be needed to assist in walking (e.g., a forearm trough walker)? If so, how will the patient carry objects if both hands are occupied?
2. What lower extremity braces are needed? Will the patient require assistance in donning and doffing the braces?
3. Is the goal to walk short distances only? Will the patient need a wheelchair for mobility in the community?
4. What can be done for fall prevention: Better lighting, the removal of area rugs and extension cords?

Figure 38-13 A person with incomplete (AIS D) tetraplegia cooking while using an arm trough walker. The 8- to 10-pound Halo vest interferes with balance and limits vision.

Not surprisingly, ambulatory patients with tetraplegia pose the greatest challenge with their often weak upper extremities. In the wheelchair, equipment such as lapboards, armrests, and mobile arm supports support weak arms and allow for function. When upper limb proximal muscles are weak, hand function becomes difficult or impossible, because the patient lacks a mechanism for bringing the hand to the mouth or face. Various devices are available that enable the person to both lift and support the arm. A solution for supporting the arm depends on the pattern of upper extremity muscle strength (e.g., a table versus a chair-mounted mobile arm support). Frequently, however, these devices are less than optimal.

Concomitant Brain Injury and Cognitive Deficits

Much attention is given to the visible paralysis of the injured patient, whereas less visible traumatic brain injury may be overlooked and unattended to. If we think about the velocity of the body at the time of impact in injuries caused by motor vehicle accidents and falls, it becomes apparent that head injuries are common. The percentage of patients who suffer concomitant injuries to the brain and spinal cord may be as high as 40%–50% (Davidoff, Roth, & Richards, 1992). These injuries may be diffuse or focal and mild or severe. Because Chapter 34 is solely devoted to traumatic brain injury, the discussion here is limited to elements that are unique to the dual diagnosis.

The occupational therapist must be vigilant for clues of brain injury in the first encounters with the patient. A period of unconsciousness and post-traumatic amnesia raises a red flag (Consortium for Spinal Cord Medicine, 2008). Therapists should ask patients directly whether they have trouble remembering events or sense any changes in their thinking. Patients may lack insight, however. Often, the family is an excellent source of information because they usually know the premorbid cognitive status of the patient. The evaluation of the patient is made more challenging with factors such as fatigue, medication side effects, pain, depression, sleep deprivation, and sensory deprivation (Davidoff, Roth, & Richards, 1992). A formal screening can determine whether a detailed neuropsychological assessment is indicated. It is common in many hospitals to request such consultations automatically if the patient had a period of unconsciousness or post-traumatic amnesia.

Cognitive deficits in the SCI population may not be limited to those incurred as a result of the injury. Factors such as previous head injuries, learning disabilities, and a history of alcohol and drug abuse are often present, and they affect the patient's cognitive functioning (Davidoff, Roth, & Richards, 1992). Although the effects of a mild brain injury associated with SCI may diminish over time, the prognosis for recovering from a preexisting cognitive deficit is poor (Davidoff, Roth, & Richards, 1992).

Transitions: Restoring Roles at Home and in the Community

With the short length of acute rehabilitation hospitalization stays, the health care team and occupational therapists are challenged to transition quickly from a protective role to a "launching" role, exposing the person to the real world and promoting autonomy and self-efficacy. This may include offering patients an increased number of activity choices, having them assess their own competence in performing a skill, requiring them to prepare for the activity on their own (call in preparation for an outing or search the internet, for example). After completing activities, having feedback sessions to celebrate successes and reflect on failures further helps to facilitate self-efficacy and a feeling of autonomy.

If therapists conclude that the rehabilitation program is too short for achieving optimal outcomes, they must be prepared to articulate and document the need for longer hospitalization. This is especially true if the short stay may jeopardize the safety of the patient. The therapist may also be called upon to find resources that allow the patient to continue to receive care and engage in occupations following discharge.

If geographically possible, many patients benefit from outpatient occupational therapy services. In a prospective U.S. study on the amount of therapy given after discharge from acute rehabilitation care within a year postinjury, Whiteneck et al. (2011) found that 52% of the total therapy time (inpatient and outpatient) was delivered in an outpatient setting. There was, however, a great variability between centers, and 8% of patients received no outpatient care because of such factors as location, and lack of reimbursement (Whiteneck et al., 2011). Not surprising, this study also found that the highest number of hours of occupational therapy, both inpatient and outpatient, was spent with patients with tetraplegia.

Most patients continue to gain strength during the first year after their injury, allowing them to become more independent. In outpatient clinics, the occupational therapist continues to facilitate performance skills and performance patterns and explore meaningful occupations in greater depth. Outpatient programs teach clients to use newly acquired voluntary movements and offer them additional ADL training. As clients gain strength and endurance and improve their balance, they reassess and reprioritize their goals. For example, a person with tetraplegia who once could not carry out a bowel program but who now exhibits normal strength in manual muscle testing of the triceps and latissimus dorsi and exhibits improved body handling skills can begin bowel training.

To ensure good fit and function, training in the use of orthoses and devices often begins during the last days of hospitalization and continues during outpatient visits. Outpatient evaluation and training in the use of other equipment is beneficial because the patient and family can use the equipment at home and provide ongoing feedback about its fit and use.

The outpatient occupational therapist should begin and/or continue working on goals and skills that move the patient toward greater community integration (e.g., driving and vocational evaluation and training). The outpatient education of family members and attendants must continue to assure continuity and progress.

With the help of the social worker, liaison nurse, or case manager, the therapist can minimize barriers to receiving therapy after discharge. A frequent barrier is a lack of transportation. If patients cannot leave home, an agency such as the Visiting Nurses Association may provide occupational therapy services at home for a limited time.

Other transitional services, such as support groups and transitional living centers, must be identified. Independent living centers are federally funded programs designed to promote reintegration. They are located in most large cities in the United States and provide resources and access to financial, vocational, rehabilitative, and community-based programs (Forchheimer & Tate, 2004).

To further ease clients' transition from hospital to home, models are continuing to emerge and evolve and reflect third-party payers' growing awareness of the benefits of less costly alternatives to hospitalization, preventing complications, enhancing health and quality of life, and supporting the goal of full participation. Examples of such models include the following:

- Clients living for days to months in a transitional residence with family members and/or attendants. Clients and their families are encouraged to seek health care providers' help only when they cannot solve problems independently. Such residential programs are often located in close proximity to acute rehabilitation centers.
- Following discharge, clients sometimes receive the assistance of a federal or state transitional services team, which may include a case manager, an occupational therapist, a physical therapist, a vocational counselor, and others. They may assist in finding accessible housing, implementing home modifications, and finding financial benefits.

Adaptation: Focus on Facilitation toward Full Participation, Improved Quality of Life, and Wellness

The path from being a dependent patient to becoming a person with a sense of efficacy and self-esteem is long and individual. Occupational therapists are increasingly involved in helping individuals with SCIs to be aware of their special health risks, how to prevent secondary conditions, engage in productive, meaningful activities, and

sustain a good quality of life. Some newly emerging programs were created to meet these challenges:

- Lifestyle Redesign® is a program that encourages participants to select health promoting personalized goals and to work toward their achievement and maintenance (Mandel et al., 1999). The therapist helps the individual identify risks and health-promoting behaviors and build routines to sustain healthy behaviors. For example, if a young adult loves to play wheelchair basketball for hours at a time and forgets his pressure reliefs, both the therapist and the person work together to identify the problem, find alternative solutions, test them, and incorporate them into the game and other daily activities.

- Telehealth, an all-encompassing term for electronic technologies that promote and maintain health, is becoming more prevalent and opens new avenues for interventions (Carson, 2012). It offers an ongoing communication with consumers through technologies such as two-way computer monitors, texting, and phone calls, thereby assisting individuals in developing skills, forming new routines and habits, and problem solving together with occupational therapists. This is especially important in rural communities and in areas with harsh winters that make it difficult for clients to get to a hospital (Carson, 2012). During telehealth sessions, the client may ask the therapist to look at a wheelchair or cushion that suddenly does not feel the same.

- Wellness programs are offered by an increasing number of rehabilitation hospitals, independent living centers, nonprofit organizations, and other agencies. They typically offer wellness classes, supervised adapted exercise programs, community recreation programs such as sailing and skiing, adaptive driving programs, computer access programs, and counseling services.

- Patient self-management programs, which provide group support and patient education for prevention of secondary conditions and facilitation of healthy living habits, with peers and clinicians acting as facilitators. These models of health care are offered to address the challenge of providing care throughout the life span in an environment of minimal resources (Dames et al., 2009).

Living Fully and Growing Older

Long-term survival rates of patients with SCI have improved dramatically in recent decades. Along with the decline of normal aging, some unique problems arise in this population. Multiple secondary health conditions and rehospitalizations are common with people with SCI. Clinicians must address these conditions throughout the individual's life span (Krause & Saunders, 2011). Conditions most linked to decreased life expectancy are pressure ulcers, amputations, infections, and clinical depression. Not surprisingly, rehospitalizations, multiple health problems, and pain have also been linked to reduced reported subjective well-being. Other common body changes include decreased bone density with susceptibility to fractures, and renal and bowel problems. Other concerns and risk factors include impaired cardiovascular fitness, because of the inability to walk and limitations in engaging in aerobic exercises, as well as the early development of diabetes. As a result of a more sedentary life, many also become overweight, which makes engaging in self-care and other activities more challenging. To address obesity, occupational therapists and other clinicians are involved in creating and testing programs that facilitate adherence to a healthy lifestyle, focusing on routine exercise and nutrition, by offering supportive environments with education classes, exercise regimens, and mechanisms to encourage the maintenance of healthy routines (Radomski et al., 2011).

Often, to achieve better health, the occupational therapist must ask the person to make difficult choices. Having to make functional adjustments, modify routines and habits, and reduce intensity and occupational engagement is difficult for most people but especially for individuals with SCI who have over many years learned to live with their disability. Therefore, the need to modify daily occupations to meet declining physical capacities or to add exercise to the daily routine must be addressed with great respect and sensitivity. The occupational therapist and client must work together to optimize daily occupations with dialogue, practice, and problem solving. Often, this involves performing detailed activity analyses to better understand and modify routines and habits. An aging client once independent in all self-maintenance skills may need help in the morning to conserve energy for work. A grandmother who wants to interact with her toddler grandson may have to teach him to climb onto her lap rather than picking him up.

For many people with SCI, pain contributes to limited activity, lack of participation, and depression. Available treatments include prescription and nonprescription medications, physical agent modalities, medical procedures such as nerve blocks, and psychotherapy (Widerstrom-Noga, 2009). The occupational therapist's contribution to pain management includes a thorough evaluation and a myriad of possible interventions. Although treatment goals are often directed toward reducing impairments, our main contribution is in changing habits and roles and in facilitating engagement in meaningful activities with full participation. This approach is especially valuable because most persons continue to live with some pain throughout their lives and new pains arise with aging.

The World Health Organization's development of the International Classification of Functioning, Disability and Health (ICF) (World Health Organization, 2001) reflects a growing global recognition of the importance of people with disabilities living healthy, productive lives; engaging

in social, vocational, and avocational pursuits; and feeling well. This model parallels occupational therapy values and beliefs. Occupational therapists around the world are at the forefront of creating innovative programs and challenging old models in order to create greater opportunities for people with SCI. Although some laws (e.g., the Americans with Disabilities Act) aim to encourage individuals with SCI to participate fully in all societal roles, many barriers continue to hinder full participation. The unemployment rate of individuals with SCI is significantly higher than in the general population, and income is lower (Lidal et al., 2009).

As all of health care moves toward preventative care and healthy living, occupational therapy has a great opportunity to continue developing, shaping, and implementing new programs to better serve people with SCI. To fill this role, we must continue to seek work in group homes and governmental agencies and to engage in shaping public policy (Baum, 2000; Hammell, 2004).

As occupational therapists, we have the opportunity and obligation to educate consumers, the public, and policy makers with the goal of enabling people with SCI to live full, meaningful lives by facilitating full participation in their desired life roles.

case example

Able: Optimizing Occupational Performance after Spinal Cord Injury

	Clinical Reasoning Process	
Occupational Therapy Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Able is a 19-year-old man with C6 AIS A (complete) tetraplegia resulting from an ocean diving accident 3 months ago. Able is a sophomore at a community college. He came to the United States from Samoa to attend college on a football scholarship. Able is single and lives with fellow students in a rented house near campus. He has a large and supportive family in Samoa. After his injury, Able's mother, aunt, and two of his sisters came to be with him for a month. Able is fluent in English. He was hoping to stay in California and resume his studies. He did not have a discharge destination. Following his injury, Able was sent to a trauma center, where he underwent posterior fusion surgery to stabilize C4–C7 vertebrae and was placed in a Philadelphia collar, a rigid collar that limits neck motion. Following surgery, Able was prescribed spine restrictions in order to protect the surgical site. Precautions allowed Able to perform shoulder bilateral/symmetrical activities with minimal resistance (no greater than 3+/5) and unilateral, active-only activities with no resistance.	Understand the patient's diagnosis or condition	"If Able has a functional level of C6, he may be able to achieve independence in many areas. Unfortunately, because he has an AIS A (complete) injury, his muscle and sensory return will most likely be only in the zone of partial preservation (ZPP)."
During the postoperative hospital stay, Able was on a rotating bed to prevent pressure sores. The occupational therapist performed daily upper limb range-of-motion exercises. She established a shoulder-positioning program and fitted Able with prefabricated resting hand splints. In conversations with the patient and his family, the therapist began to explain the process of rehabilitation. The occupational therapist documented that the family was engaged and supportive and that the patient appeared passive and quiet. Able was transferred to a rehabilitation center 3 weeks post injury.	Know the person	"Able is passive and quiet and seems quite depressed. Knowing that the best predictor of future behaviors and disposition is premorbid personality and behaviors, I am very hopeful that he soon will feel better, as he sees his renewed abilities. It is excellent that he has such a supportive, loving family; however, later in the course of rehabilitation, we will request that they limit their visits somewhat, in order to enable Able to see that he can manage without them, to allow him to become more active in his rehabilitation, and to encourage him to begin directing his own care. Prompt identification of discharge destination and potential caregivers is crucial for goal setting. Therefore, the social worker must address these important issues as soon as possible."

Reason for Referral to Occupational Therapy

Able was referred to occupational therapy to address limitation in performance skills and patterns.

| Appreciate the context | "Able's past accomplishments and tough school/sports schedule required him to be disciplined and structure his time efficiently. I think this will help him in the acute rehabilitation setting, a place that requires hard work. More importantly, his past level of engagement is an indicator that he will be able to continue a life full of participation in meaningful occupations." |

Assessment Process and Results

Occupational profile: Interviews included establishing rapport; in-depth interviews about Able's typical day, interests, routines, habits and roles; and administering of the Canadian Occupational Performance Measure. Initially, because of Able's withdrawn mood, the therapist secured Able's permission and interviewed his family about his life and about family goals.

| Consider evaluation approach and methods | "Two casual contacts were made, establishing rapport with Able and his family and meeting Able's immediate needs. These included making Able more comfortable in bed and assessing his ability to press key pads (nurse call light, phone use, and bed and TV controls). The installation of key pads allowed Able to stay alone in his room for short periods of time and increased his autonomy." |

Findings: Able was clear about wanting to stay in California and resume his studies. His family was going to go back to Samoa in a few weeks. He and his family described his busy schedule. Football occupied most of his nonstudy time. For fun, he "hung out" with his roommates, some of whom were also from Samoa. Information from the social worker indicated no clear discharge destination and no knowledge of who will assist Able with his care.

Physical evaluation: Physical evaluation included measuring bilateral upper extremities (BUE) passive range of motion, tone, sensation (pain, light touch, proprioception, and object identification), and Manual Muscle Test (MMT). Observations of reach and hand use included activities such as picking up a coin or a tissue and pushing a button.

Results of MMT:
Scapulae and shoulder muscles: 3+ or above/5 throughout.
Elbows: 4/5 flexion; 0/5 extension.
Forearms: 4/5 supination; 2/5 pronation.
Wrist: Radial wrist extensors: Right 3+/5; left 3/5; bilateral ulnar wrist extension and flexion 0/5
Fingers and thumbs: 0/5
Sensory level: C2–C6 dermatomes intact; impaired C7 and absent below (see Fig. 38-2).
Tone throughout both upper limbs: Within normal limits.
Hand use: Drags objects to edge of table; picks up objects with the two hands

Summary of upper limb findings: Right hand dominant. Symmetry in strength with right arm slightly stronger than left. Shoulder strength 3+/5 and above. Deficits in reaching away from body and in pronation. Fair tenodesis action bilaterally; beginning effective hand compensatory techniques for picking up and manipulating objects.

Activities of daily living (ADL): Able was given a universal cuff in the acute hospital, and he is able to feed himself with a spoon and a fork and to brush his teeth. He needs assistance with setup for these activities (Functional Independent Measure-5). He is dependent with all other self-maintenance skills.

| Interpret observations | "I hope that Able's roommates and friends will help and support him when his family is no longer here. When he indicates that he wants his friends around, we will encourage them to visit and be involved in his therapy."

"Able had a large repertoire of occupations prior to his injury, and his self-efficacy is strong. He has excellent potential for resuming his studies. I need to further explore his engagement with football and, as he gains skills and feels more self-confident and competent, explore with him the range of options for engaging in sports. For example, either being a spectator and/or acquainting him to wheelchair sports."

"Initial spinal precautions limit full resistive exercises to neck, scapulae, and shoulders and allow only for minimal-resistance, symmetrical exercises. This will be achieved with routine activities such as washing the face. A full strengthening program can be carried out to elbows and wrists. The left wrist will also benefit from neuromuscular electrical stimulation (NMES) to radial wrist extensors."

"Able is beginning to compensate for his finger paralysis. He has learned to drag objects to the edge of a table and to hold objects with two hands to compensate for weak grip. Further education and experiential training will help him with other compensatory techniques such as weaving objects through his fingers." |

Occupational Therapy Problem List • Decreased performance skills: moderate depression, lack of engagement with the rehabilitation team, excessive dependency on family. • Decreased performance skills: upper limbs weakness, sensory deficit, decreased endurance and control. • Limitations in all performance patterns including ADL, instrumental activities of daily living (IADL), education, work, leisure, and social participation. • Decreased knowledge of spinal cord injury (SCI) management, resources, and of directing own care.	Synthesize results	"The problem list is overwhelming because Able's disability is devastating, affecting physical capacities and all his occupational roles. I have to remind myself that tackling this long list will sort itself out daily, as we reassess Able's engagement in the program, his progress, and his evolving list of priorities."
Occupational Therapy Goal List (In the Acute Rehabilitation Facility) Initially, Able had difficulty coming up with goals, as he appeared overwhelmed with his paralysis and was not able to determine what he would be able to physically do. With the help of his therapist, the team, and his family, his short-term goals included strengthening his arms, feeding, brushing his teeth, shaving, upper body dressing, writing, and using the phone and the computer. **Other goals included:** • Learn routine SCI precautions for skin care, pressure relief, bowel and bladder care, and autonomic nervous system functioning. • Learn to direct own care. • Learn SCI resources in the community. • Select and trial a cushion and wheelchair.		"Able views his primary role as an athlete. It is not surprising that exercising the arms is his first goal. This activity has the potential of transforming Able's attitude toward therapy, becoming more engaged in the process. Strengthening his weak muscles will improve his sense of control and feelings of renewed hope. Feeding, brushing teeth, writing, and using the computer are skills that will be easy for Able to develop. Able will have a harder time dressing, especially his lower body. The reality of the amount of energy and time it takes to complete this task right now may help Able sort out his priorities as to what a caregiver will do for him and what he will do himself."
	Select an intervention approach	"The occupational therapy intervention approach will focus on compensatory techniques."
	Consider what will occur in therapy, how often, and for how long	"I must remember that the interventions in acute care are only the beginning of a long process of rehabilitation toward participation. His acute rehabilitation stay provides intense therapy for only a few weeks: 3–5 hours of combined OT and PT per day, 6 days a week for 4–5 weeks."
Intervention in the acute rehabilitation facility **First 3 weeks:** • Upper limbs passive and active exercises (nonresistive shoulder exercises because of spinal precautions). • Wrist strengthening program through exercises, activities, and NMES. • ADL training including feeding, brushing teeth, and grooming using a universal cuff. • Exploration and training in writing, computer skills, and telephone use with adaptive equipment. • Hand use in routine activities, such as compensatory techniques in swiping a card, handling money, and opening pill bottles. • Individual, short educational sessions focused on specific interventions, such as how to use the hand and how to best maximize hand function. • Trialing different power wheelchairs.	Compare actual to expected performance Know the person	"Able's premorbid self-discipline and high level of occupational engagement were, indeed, reliable predictors of his ability to engage in therapy despite his depression. In the first few weeks, he talked little, and although not fully engaged, he went along with the program as if 'going through the motions' of therapy. As he gained some independence, he became more animated. He enjoyed working with the computer because he realized that going back to school would be possible. It was wonderful to get to know Able as his warm and engaging personality began to emerge when his depression lifted. He began initiating ideas, solved problems easily, and seemed interested in newly introduced equipment. He also became more outgoing and started socializing with other patients. Able's family needed to return to Samoa close to his discharge from acute rehabilitation. The shift from family to friends' support happened naturally as all his acquaintances understood his need for support."

Weeks 4 and 5:
- Spinal precautions were lifted, allowing Able to move his neck and shoulders freely and engage in a full strengthening program. Evaluation for the use of right wrist-driven wrist–hand orthosis with clinic trial equipment. Ordering, checking fit, and beginning training in use of orthotics. Training in upper body dressing and beginning of lower body dressing.
- Expanded on student role activities such as using a computer and an iPad and handling books and papers.
- Education: Individual and group. Group experiential training in topics such as taking public transportation, assertiveness training, and directing care. Individual: Daily self range-of-motion exercises.
- Training in hand use with and without the orthosis through activities with peers (for example, board games).
- Ordering of a wrist-driven wrist–hand orthosis.
- Ordering of cushion and permanent wheelchair.

Predischarge goals:
- Prepare Able to live in a transitional living center (TLC).
- Train a caregiver in assisting Able with his care.
- Engage Able in directing his care.

Predischarge interventions:
Visiting a transitional living center and meeting the staff.

Postscript:

Able was accepted to a TLC. This facility offered continued rehabilitation services at reduced intensity and cost. The strong support of his friends helped his transition. He resided in the facility for 8 months, sharing a room with a roommate. He received assistance from a caregiver twice a day. With the help of the TLC team and his occupational therapist, he established a daily routine that enabled him to continue learning new skills, managing his care, and exploring his return to school. His caregiver came in the morning for 3 hours assisting Able in getting out of bed, bathing, dressing, and setting up his breakfast. In the evening, the caregiver came again for 3 hours to help Able manage his dinner, bowel program, undressing, and getting into bed.

During the day, Able received TLC services. His occupational therapy program included individual and group therapy sessions, engaging in activities such as learning to use his new wrist-driven wrist–hand orthosis and learning to empty his bladder independently by carrying out self-intermittent catheterization. Other activities included attending Able's college football team's game, touring his college to assure full wheelchair accessibility, and meeting with the disabled students counselor.

Throughout his TLC stay, Able established new habits. As previously predicted, he worked hard, became more independent, and directed his caregiver effectively. Before leaving the TLC, Able explored community resources to support a healthy lifestyle. He found accessible transportation and a venue for routine exercise. After leaving the TLC, Able rented an apartment with a roommate he met at the TLC and resumed college.

Appreciate the context

Assess outcomes

"Because Able decided to stay in California with no family around, team meetings involved finding alternatives for further care because all felt that Able would not be ready to live alone postdischarge. Able liked the idea of an interim discharge to a transitional living facility (TLC). This would enable him to acquire more skills and to attain greater self-efficacy prior to returning to school and to independent living."

Prepare for discharge from acute rehabilitation

"Being admitted to the TLC requires hiring a caregiver because Able requires assistance in ADLs. He must learn to direct his own care effectively, to supervise the activities of a caregiver, and to be vigilant about new daily routines such as daily skin inspection and bowel and bladder care."

? Clinical Reasoning in Occupational Therapy

Helping the Client Hire a Caregiver

Able is hiring his first caregiver. A. What activities will the caregiver need to perform? B. What important precautions does the caregiver need to exercise? C. As Able's therapist how would you facilitate the caregiver's learning?

Summary Review Questions

1. List three key epidemiological factors of the SCI population and describe how these factors influence evaluation and treatment.
2. List three precautions the therapist must consider in planning for an outing with a patient with C5 injury.
3. What is a tenodesis grasp? Why is it important, and how can the occupational therapist facilitate it?
4. List five parts of the initial occupational therapy evaluation of a patient with SCI.
5. Describe a typical feeding setup for a person with C5 tetraplegia.
6. What are the functional expectations for the patient with a C7 injury?
7. You read in the medical chart that a patient lost consciousness at the time of injury. How do you modify your evaluation? Describe how concomitant brain injury may alter your treatment goals and interventions.
8. What are the roles of the occupational therapist in the transition phase?

Glossary

Dermatome—"The area of skin innervated by the sensory axons within each segmental nerve (root)" (ASIA, 2011, p. 7).

Complete injury—"Absence of sensory and motor function in the lowest sacral segments (S4–S5) (i.e., no 'sacral sparing')" (ASIA, 2011 p. 10).

Functional level—Lowest segment at which strength of important muscles is graded 3+ or above out of 5 on MMT and sensation is intact.

Incomplete injury—"Preservation of any sensory and/or motor function below the neurological level that includes the lowest sacral segments S4–S5 (i.e., presence of 'sacral sparing')" (ASIA, 2011, p. 9).

Paraplegia—Loss or impairment in motor and/or sensory function in the thoracic, lumbar, or sacral segments of the cord resulting in impairment in the trunk, legs, and pelvic organs and sparing of the arms (ASIA, 2011).

Skeletal level—Level of greatest vertebral damage.

Tenodesis grasp—Passive opening of the fingers when the wrist is flexed and closing of the fingers when the wrist is extended (Wilson et al., 1984).

Tetraplegia (in the past called quadriplegia)—Loss or impairment in motor and/or sensory function in the cervical segments of the spinal cord resulting in functional impairment in the arms, trunk, legs, and pelvic organs (ASIA, 2011).

Appendix 38-1
Expected Functional Outcomes*

EXPECTED FUNCTIONAL OUTCOMES TABLES

Outcome-based practice guidelines can provide estimates of the effect of rehabilitation on functional status or activity restrictions. In the expected functional outcomes charts that follow, the Consortium for Spinal Cord Medicine has put forth its best description, based on outcome studies and expert consensus, of outcomes of people with motor complete spinal cord injury (SCI) 1 year after injury. These outcome guidelines are presented with the full recognition that outcomes are not fully under the influence or control of health care providers. Differences in patient characteristics; the course of medical events; psychological, social, and environmental supports; and cognitive abilities have strong influences on outcomes.

These outcome-based guidelines can be used to establish goals, provide information for quality improvement, and compare performance across facilities with similar populations. When used appropriately, outcome-based practice guidelines provide a benchmark for comparing programs and services while improving both the processes and outcomes of care that have an enduring impact on long-term functioning in the community. Disability outcome measures are generally focused on the degree to which a person can independently complete an important function or activities of daily living (ADL). This definition of disability is consistent with the World Health Organization model of disablement in which disability is measured at the level of the person interacting with the environment during daily routines. In the completion of daily tasks, adaptive equipment becomes a crucial adjunct to the independence of the person with SCI.

The following charts present expectations of functional performance of SCI at 1 year postinjury for each of eight levels of injury (C1–C3, C4, C5, C6, C7–C8, T1–T9, T10–L1, and L2–S5). The outcomes reflect a level of independence that can be expected of a person with motor complete SCI, given optimal circumstances.

The categories presented reflect expected functional outcomes in the areas of mobility, ADL, instrumental ADL, and communication skills. The guidelines are based on consensus of clinical experts, available literature on functional outcomes, and data compiled from the Uniform Data System and the National Spinal Cord Injury Statistical Center (NSCISC). Within the

functional outcomes for people with SCI listed in the tables that follow, the panel has identified a series of essential daily functions and activities, expected levels of functioning, and the equipment and attendant care likely to be needed to support the predicted level of independence at 1 year postinjury. These outcome areas include the following:

- **Respiratory, bowel, and bladder function.** The neurological effects of spinal injury may result in deficits in the ability of the individual to perform basic bodily functions. Respiratory function includes the ability to breathe with or without mechanical assistance and to adequately clear secretions. Bowel and bladder function includes the ability to manage elimination, maintain perineal hygiene, and adjust clothing before and after elimination. Adapted or facilitated methods of managing these bodily functions may be required to attain expected functional outcomes.
- **Bed mobility, bed/wheelchair transfers, wheelchair propulsion, and positioning/pressure relief.** The neurological effects of SCI may result in deficits in the ability of the individual to perform the activities required for mobility, locomotion, and safety. Adapted or facilitated methods of managing these activities may be required to attain expected functional outcomes.
- **Standing and ambulation.** SCI may result in deficits in the ability to stand for exercise or psychological benefit or to ambulate for functional activities. Adapted or facilitated methods of management may be required to attain expected functional outcomes in standing and ambulation.
- **Eating, grooming, dressing, and bathing.** The neurological effects of SCI may result in deficits in the ability of the individual to perform these ADL. Adapted or facilitated methods of managing these ADL may be required to attain expected functional outcomes.
- **Communication (keyboard use, handwriting, and telephone use).** The neurological effects of SCI may result in deficits in the ability of the individual to communicate. Adapted or facilitated methods of communication may be required to attain expected functional outcomes.
- **Transportation (driving, attendant-operated vehicle, and public transportation).** Transportation activities are critical for individuals with SCI to become maximally independent in the community. Adaptations may be required to facilitate the individual in meeting the expected functional outcomes.

- **Homemaking (meal planning and preparation and home management).** Adapted or facilitated methods of managing homemaking skills may be required to attain expected functional outcomes. Individuals with complete SCI at any level will require some level of assistance with homemaking activities. The hours of assistance with homemaking activities are presented in the tables.
- **Assistance required.** The Expected Functional Outcomes charts include the number of hours that may be required from a caregiver to assist with personal care and homemaking activities in the house. Personal care includes hands-on delivery of all aspects of self-care and mobility, as well as safety interventions. Homemaking assistance is also included in the recommendation for hours of assistance and includes activities previously presented. The number of hours presented in both the panel recommendations and the self-reported Craig Handicap Assessment and Reporting Technique (CHART) (Whiteneck et al., 1992) data is representative of skilled and unskilled and paid and unpaid hours of assistance. The 24-hour-a-day requirement noted for the C1–C3 and C4 levels includes the expected need for unpaid attendant care to provide safety monitoring.

   Adequate assistance is required to ensure that the individual with SCI can achieve the outcomes set forth in the expected functional outcomes charts. The hours of assistance recommended by the panel do not reflect changes in assistance required over time as reported by long-term survivors of SCI (Gerhart et al., 1993), and they also do not take into account the wide range of individual variables mentioned throughout this document that may affect the number of hours assistance required. The Functional Independence Measure (FIM™) estimates are widely variable in several categories. One does not know whether the representative individuals with SCI in the individual categories attained the expected functional outcomes for their specific level of injury or whether there were mitigating circumstances such as age, obesity, or concomitant injuries that would account for variability in assistance reported. An individualized assessment of needs is required in all cases.

- **Equipment requirements.** Minimum recommendations for durable medical equipment and adaptive devices are identified in each of the functional categories. The most commonly used equipment is listed, with the understanding that variations exist among SCI rehabilitation programs and that use of such equipment may be necessary to achieve the identified functional outcomes. Additional equipment and devices that are not critical for the majority of

individuals at a specific level of injury may be required for some individuals. The equipment descriptions are generic to provide for variances in program philosophy and financial resources. Rapid changes and advances in equipment and technology will be made and therefore must be considered.

Health care professionals should keep in mind that the recommendations set forth in Appendix 38-1 are not intended to be prescriptive, but rather to serve as guidelines. The importance of individual functional assessment of people with SCI prior to making equipment recommendations cannot be overemphasized. All durable medical equipment and adaptive devices must be thoroughly assessed and tested to determine medical necessity to prevent medical complications (e.g., postural deviations, skin breakdown, or pain) and to foster optimal functional performance. Electronic aids to daily living (EADL), the new name for environmental control units, and telephone modifications may be needed for safety and maximal independence, and each person must be individually evaluated for the need for this equipment. Disposable medical product recommendations are not included in this document.

- **FIM™.** Evidence for the specific levels of independence provided in Appendix 38-1 relies both on expert consensus and data from the FIM™ in large-scale, prospective, and longitudinal research conducted by NSCISC. FIM™ is the most widely used disability measure in rehabilitation medicine. Although it may not incorporate all of the characteristics of disability in individuals recovering from SCI, it captures many basic disability areas. FIM™ consists of 13 motor and 5 cognitive items that are individually scored from 1 to 7. A score of 1 indicates complete dependence, and a score of 7 indicates complete independence. The sum of the 13 FIM™ motor score items can range from 13, indicating complete dependence for all items, to 91, indicating complete independence for all items. FIM™ is a measure usually completed by health care professionals. Different observers, including the patient, family members, and caregivers, can contribute information to the ratings. Each of these reporters may represent a different type of potential bias. It should also be noted that, although the sample sizes of FIM™ data for certain neurological level groups are quite small, the consistency of the data adds confidence to the interpretation. Other pertinent data regarding functional independence must be factored into outcome analyses, including medical information, patient factors, social participation, quality of life, and environmental factors and supports.

In Appendix 38-1, FIM™ data, when available, are reported in three areas. First, the expected FIM™ outcomes are documented based on expert clinical consensus. The second number reported is the median FIM™ score, as compiled by NSCISC. The interquartile range for NSCISC FIM™ data is the third set of numbers. In total, the FIM™ data represent 1-year postinjury FIM™ assessment of 405 survivors with complete SCI. The sample size for FIM™ and assistance data is provided for each level of injury. Different outcome expectations should clearly apply to different patient subgroups and populations.

Some populations are likely to be significantly older than the referenced one. Functional abilities may be limited by advancing age (Penrod, Hedge, & Ditunno, 1990; Yarkony et al., 1988).

- **Home modifications.** To provide the best opportunity for individuals with SCI to achieve the identified functional outcomes, a safe and architecturally accessible environment is necessary. An accessible environment must take into consideration, but not be limited to, entrance and egress, mobility in the home, and adequate setup to perform personal care and homemaking tasks.

Appendix 38-1 Expected Functional Outcomes

Level C1-3

Functionally relevant muscles innervated: Sternocleidomastoid; cervical paraspinal; neck accessories
Movement possible: Neck flexion, extension, rotation
Patterns of weakness: Total paralysis of trunk, upper extremities, lower extremities; dependent on ventilator

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 15; Assist = 12

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	**Med**	**IR**
Respiratory	• Ventilator dependent • Inability to clear secretions	• Two ventilators (bedside, portable) • Suction equipment or other suction management device • Generator or battery backup			
Bowel	Total assist	Padded reclining shower-commode chair (if roll-in shower available)	1	1	1
Bladder	Total assist		1	1	1
Bed mobility	Total assist	Full electric hospital bed with Trendelenburg feature and side rails			
Bed, wheelchair transfers	Total assist	• Transfer board • Power or mechanical lift with sling	1	1	1
Pressure relief, positioning	Total assist; may be independent with equipment	• Power recline and/or tilt wheelchair • Wheelchair pressure-relief cushion • Postural support and head control devices as indicated independent with equipment • Hand splints may be indicated • Specialty bed or pressure-relief mattress may be indicated			
Eating	Total assist		1	1	1
Dressing	Total assist		1	1	1
Grooming	Total assist		1	1	1

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level C1-3

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Bathing	Total assist	• Handheld shower • Shampoo tray • Padded reclining shower-commode chair (if roll-in shower available)	1	1	1
Wheelchair propulsion	Manual: Total assist Power: Independent with equipment	• Power recline and/or tilt wheelchair with head, chin, or breath control and manual recliner • Vent tray	6	1	1–6
Standing, ambulation	Standing: Total assist Ambulation: Not indicated				
Communication	Total assist to independent, depending on workstation setup and equipment availability	• Mouth stick, high-tech computer access, environmental control unit • Adaptive devices everywhere as indicated			
Transportation	Total assist	Attendant-operated van (e.g., lift, tie-downs) or accessible public transportation			
Homemaking	Total assist				
Assist required	• 24-hour attendant care to include homemaking • Able to instruct in all aspects of care		24*	24*	12–24*

*Hours per day

Level C4

Functionally relevant muscles innervated: Upper trapezius; diaphragm; cervical paraspinal muscles
Movement possible: Neck flexion, extension, rotation; scapular elevation; inspiration
Patterns of weakness: Paralysis of trunk, upper extremities, lower extremities; inability to cough, endurance and respiratory reserve low secondary to paralysis of intercostals

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 28; Assist = 12

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Respiratory	May be able to breathe without a ventilator	If not ventilator free, see C1–C3 for equipment requirements			
Bowel	Total assist	Reclining shower-commode chair (if roll-in shower available)	1	1	1
Bladder	Total assist		1	1	1
Bed mobility	Total assist	Full electric hospital bed with Trendelenburg feature and side rails			
Bed, wheelchair transfers	Total assist	• Transfer board • Power or mechanical lift with sling	1	1	1

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level C4

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data

Pressure relief, positioning	Total assist; may be independent with equipment	• Power recline and/or tilt wheelchair • Wheelchair pressure-relief cushion • Postural support and head control devices as indicated • Hand splints may be indicated • Specialty bed or pressure-relief mattress may be indicated			
Eating	Total assist		1	1	1
Dressing	Total assist		1	1	1
Grooming	Total assist		1	1	1
Bathing	Total assist	• Shampoo tray • Handheld shower • Padded reclining shower-commode chair (if roll-in shower available)	1	1	1
Wheelchair propulsion	Power: Independent Manual: Total assist	• Power recline and/or tilt wheelchair with head, chin, or breath control and manual recliner • Vent tray	6	1	1–6
Standing, ambulation	Standing: Total assist Ambulation: Not usually indicated	• Tilt table • Hydraulic standing table			
Communication	Total assist to independent, depending on workstation setup and equipment availability	Mouth stick, high-tech computer access, environmental control unit			
Transportation	Total assist	Attendant-operated van (e.g., lift, tie-downs) or accessible public transportation			
Homemaking	Total assist				
Assist required	• 24-hour care to include homemaking • Able to instruct in all aspects of care		24*	24*	16–24*

*Hours per day.

Appendix 38-1 **Expected Functional Outcomes** *(continued)*

Level C5

Functionally relevant muscles innervated: Deltoid, biceps, brachialis, brachioradialis, rhomboids, serratus anterior (partially innervated)
Movement possible: Shoulder flexion, abduction, and extension; elbow flexion and supination; scapular adduction and abduction
Patterns of weakness: Absence of elbow extension, pronation, all wrist and hand movement; total paralysis of trunk and lower extremities

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 41; Assist = 35

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	**Med**	**IR**
Respiratory	Low endurance and vital capacity secondary to paralysis of intercostals; may require assist to clear secretions				
Bowel	Total assist	Padded shower, commode chair, or padded transfer tub bench with commode cutout	1	1	1
Bladder	Total assist	Adaptive devices may be indicated (electric leg bag emptier)	1	1	1
Bed mobility	Some assist	• Full electric hospital bed with Trendelenburg feature with patient's control • Side rails			
Bed, wheelchair transfers	Total assist	• Transfer board • Power or mechanical lift	1	1	1
Pressure relief, positioning	Independent with equipment	• Power recline and/or tilt wheelchair • Wheelchair pressure-relief cushion • Hand splints • Specialty bed or pressure-relief mattress may be indicated • Postural support devices			
Eating	Total assist for setup, then independent eating with equipment	• Long opponens splint • Adaptive devices as indicated	5	5	25–55
Dressing	Lower extremity: Total assist Upper extremity: Some assist	• Long opponens splint • Adaptive devices as indicated	1	1	1–4
Grooming	Some to total assist	• Long opponens splints • Adaptive devices as indicated	1–3	1	1–5
Bathing	Total assist	• Padded tub transfer bench or shower-commode chair • Handheld shower	1	1	1–3
Wheelchair propulsion	Power: Independent Manual: Independent to some assist indoors on uncarpeted, level surface; some to total outdoors	Power: Power recline and/or tilt with arm drive control frame with hand rim modifications assist Manual: Lightweight rigid or folding	6	6	5–6

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level C5

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Standing ambulation	Total assist	Hydraulic standing frame			
Communication	Independent to some assist after setup with equipment	• Long opponens splint • Adaptive devices as needed for page turning, writing, button pushing			
Transportation	Independent with highly specialized equipment; some assist with accessible public transportation; total assist for attendant-operated vehicle	Highly specialized modified van with lift			
Homemaking	Total assist				
Assist required	• Personal care: 10 hours per day • Home care: 6 hours per day • Able to instruct in all aspects of care		16*	23*	10–24*

*Hours per day.

Level C6

Functionally relevant muscles innervated: Clavicular pectoralis; supinator; extensor carpi radialis longus and brevis; serratus anterior; latissimusdorsi
Movement possible: Scapular protraction; some horizontal adduction, forearm supination, radial wrist extension
Patterns of weakness: Absence of wrist flexion, elbow extension, hand movement; total paralysis of trunk and lower extremities

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 43; Assist = 35

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Respiratory	Low endurance and vital capacity secondary to paralysis of intercostals; may require assist to clear secretions				
Bowel	Some to total assist	• Padded tub bench with commode cutout or padded shower-commode chair • Other adaptive devices as indicated	1–2	1	1
Bladder	Some to total assist with equipment; may be independent with leg bag emptying	Adaptive devices as indicated	1–2	1	1
Bed mobility	Some assist	• Full electric hospital bed • Side rails • Full to king standard bed may be indicated			

Appendix 38-1 **Expected Functional Outcomes** *(continued)*

Level C6			FIM™/Assistance Data		
	Expected Functional Outcomes	**Equipment**	**Exp**	**Med**	**IR**
Bed, wheelchair transfers	Level: Some assist to independent Uneven: Some to total assist	• Transfer board • Mechanical lift	3	1	1–3
Pressure relief, positioning	Independent with equipment and/or adapted techniques	• Power recline wheelchair • Wheelchair pressure-relief cushion • Postural support devices • Pressure-relief mattress or overlay may be indicated			
Eating	Independent with or without equipment except cutting, which is total assist	Adaptive devices as indicated (e.g., U-cuff, tenodesis splint, adapted utensils, plate guard)	5–6	5	4–6
Dressing	Independent upper extremity; some to total assist for lower extremities	Adaptive devices as indicated (e.g., button hook; loops on zippers, pants, socks; Velcro® on shoes)	1–3	2	1–5
Grooming	Some assist to independent with equipment	Adaptive devices as indicated (e.g., U-cuff, adapted handles)	3–6	4	2–6
Bathing	Upper body: Independent Lower body: Some to total assist	• Padded tub transfer bench or shower-commode chair • Adaptive devices as needed • Handheld shower	1–3	1	1–3
Wheelchair propulsion, standing, ambulation	Power: Independent with standard arm drive on all surfaces Manual: Independent indoors; some to total assist outdoors Standing: Total assist Ambulation: Not indicated	Manual: Lightweight rigid or folding frame with modified rims Power: May require power recline or standard upright power wheelchair Hydraulic standing frame	6	6	4–6
Communication	Independent with or without equipment	Adaptive devices as indicated (e.g., tenodesis splint; writing splint for keyboard use, button pushing, page turning, object manipulation)			
Transportation	Independent driving from wheelchair	• Modified van with lift • Sensitized hand controls • Tie-downs			
Homemaking	Some assist with light meal preparation; total assist for all other homemaking	Adaptive devices as indicated			
Assist required	• Personal care: 6 hours per day • Home care: 4 hours per day		10*	17*	8–24*

*Hours per day.

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level C7–C8

Functionally relevant muscles innervated: Latissimusdorsi; sternal pectoralis; triceps; pronator quadratus; extensor carpi ulnaris; flexor carpi radialis; flexor digitorum profundus and superficialis; extensor communis; pronator/flexor/extensor/abductor pollicis; lumbricals (partially innervated)
Movement possible: Elbow extension; ulnar/wrist extension; wrist flexion; finger flexion and extension; thumb flexion/extension/abduction
Patterns of weakness: Paralysis of trunk and lower extremities; limited grasp release and dexterity secondary to partial paralysis intrinsic muscles of the hand

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 38; Assist = 35

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	**Med**	**IR**
Respiratory	Low endurance and vital capacity secondary to paralysis of intercostals; may require assist to clear secretions				
Bowel	Some to total assist	• Padded tub bench with commode cutout or shower-commode chair • Adaptive devices as needed	1–4	1	1–4
Bladder	Independent to some assist	Adaptive devices as indicated	2–6	3	1–6
Bed mobility	Independent to some assist	Full electric hospital bed or full to king standard bed			
Bed, wheelchair transfers	Level: Independent Uneven: Independent to some assist	With or without transfer board	3–7	4	2–6
Pressure relief, positioning	Independent	• Wheelchair pressure-relief cushion • Postural support devices as indicated • Pressure-relief mattress or overlay may be indicated			
Eating	Independent	Adaptive devices as indicated	6–7	6	5–7
Dressing	Independent upper extremities; independent to some assist lower extremities	Adaptive devices as indicated	4–7	6	4–7
Grooming	Independent	Adaptive devices as indicated	6–7	6	4–7
Bathing	Upper body: Independent Lower extremity: Some assist to independent	• Padded transfer tub bench or shower-commode chair • Handheld shower • Adaptive devices as needed	3–6	4	2–6
Wheelchair propulsion	Manual: Independent all indoor surfaces and level outdoor terrain; some assist with uneven terrain	Manual: Rigid or folding; lightweight or folding wheelchair with modified rims	6	6	6
Standing, ambulation	Standing: Independent to some assist Ambulation: Not indicated	Hydraulic or standard standing frame			

(continued)

Appendix 38-1 **Expected Functional Outcomes** *(continued)*

Level C7–C8

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Communication	Independent	Adaptive devices as indicated			
Transportation	Independent car if independent with transfer, wheelchair loading and unloading; independent driving modified van from captain's seat	• Modified vehicle • Transfer board			
Homemaking	Independent light meal preparation and homemaking; some to total assist for complex meal prep and heavy housecleaning	Adaptive devices as indicated			
Assist required	• Personal care: 6 hours per day • Home care: 2 hours per day		8*	12*	2–24*

*Hours per day.

Level T1–T9

Functionally relevant muscles innervated: Intrinsics of the hand including thumbs; internal and external intercostals; erector spinae; lumbricals; flexor/extensor/abductor pollicis
Movement possible: Upper extremities fully intact; limited upper trunk stability; endurance increased secondary to innervation of intercostals
Patterns of weakness: Lower trunk paralysis; total paralysis lower extremities

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 144; Assist = 122

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Respiratory	Compromised vital capacity and endurance				
Bowel	Independent	Elevated padded toilet seat or padded tub bench with commode cutout	6–7	6	4–6
Bladder	Independent		6	6	5–6
Bed mobility	Independent	Full to king standard bed			
Bed, wheelchair transfers	Independent	May or may not require transfer board	6–7	6	6–7
Pressure relief, positioning	Independent	• Wheelchair pressure-relief cushion • Postural support devices as indicated • Pressure-relief mattress or overlay may be indicated			
Eating	Independent		7	7	7
Dressing	Independent		7	7	7

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level T1–T9

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Grooming	Independent		7	7	7
Bathing	Independent	• Padded tub transfer bench or shower-commode chair • Handheld shower	6–7	6	5–7
Wheelchair propulsion	Independent	Manual rigid or folding lightweight wheelchair	6	6	6
Standing, ambulation	Standing: Independent Ambulation: Typically not functional	Standing frame			
Communication	Independent				
Transportation	Independent in car, including loading and unloading wheelchair	Hand controls			
Homemaking	Independent with complex meal prep and light housecleaning; total to some assist with heavy housekeeping				
Assist required	Homemaking: 3 hours per day		2*	3*	0–15*

*Hours per day.

Level T10–L1

Functionally relevant muscles innervated: Fully intact intercostals; external obliques; rectus abdominis
Movement possible: Good trunk stability
Patterns of weakness: Paralysis of lower extremities

FIM™/Assistance Data: Exp = expected FIM™ score; **Med**= NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 71; Assist = 57

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Respiratory	Intact respiratory function				
Bowel	Independent	Padded standard or raised padded toilet seat	6–7	6	6
Bladder	Independent		6	6	6
Bed mobility	Independent	Full to king standard bed	7	7	6–7
Bed, wheelchair transfers	Independent				
Pressure relief, positioning	Independent	• Wheelchair pressure-relief cushion • Postural support devices as indicated • Pressure-relief mattress or overlay may be indicated			

Appendix 38-1	Expected Functional Outcomes *(continued)*

Level T10–L1

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Eating	Independent		7	7	7
Dressing	Independent		7	7	7
Grooming	Independent		7	7	7
Bathing	Independent	• Padded transfer tub bench • Handheld shower	6–7	6	6–7
Wheelchair propulsion	Independent all indoor and outdoor surfaces	Manual rigid or folding lightweight wheelchair	6	6	6
Standing, ambulation	Standing: Independent Ambulation: Functional, some assist to independent	• Standing frame • Forearm crutches or walker • Knee, ankle, foot orthosis (KAFO)			
Communication	Independent				
Transportation	Independent in car, including loading and unloading wheelchair	Hand controls			
Homemaking	Independent with complex meal prep and light housecleaning some assist with heavy; housekeeping				
Assist required	Homemaking: 2 hours per day		2*	2*	0–8*

*Hours per day.

Level L2–S5

Functionally relevant muscles innervated: Fully intact abdominals and all other trunk muscles; depending on level, some degree of hip flexors, extensors, abductors, adductors; knee flexors, extensors; ankle dorsiflexors, plantar flexors.
Movement possible: Good trunk stability; partial to full control lower extremities.
Patterns of weakness: Partial paralysis lower extremities, hips, knees, ankle, foot

FIM™/Assistance Data: Exp = expected FIM™ score; **Med** = NSCISC median; **IR** = NSCISC interquartile range
NSCISC Sample Size: FIM™ = 20; Assist = 16

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Respiratory	Intact function				
Bowel	Independent	Padded toilet seat	6–7	6	6–7
Bladder	Independent		6	6	6–7
Bed mobility	Independent				
Bed/wheelchair transfers	Independent	Full to king standard bed	7	7	7
Pressure relief/positioning	Independent	• Wheelchair pressure-relief cushion • Postural support device as indicated			

Appendix 38-1 Expected Functional Outcomes *(continued)*

Level L2–S5

	Expected Functional Outcomes	Equipment	FIM™/Assistance Data		
			Exp	Med	IR
Eating	Independent		7	7	7
Dressing	Independent		7	7	7
Grooming	Independent		7	7	7
Bathing	Independent	• Padded tub bench • Handheld shower	7	7	6–7
Wheelchair propulsion	Independent on all indoor and outdoor surfaces	Manual rigid or folding lightweight wheelchair	6	6	6
Standing/ambulation	Standing: Independent Ambulation: Functional, independent to some assist	• Standing frame • Knee-ankle-foot orthosis or ankle-foot orthosis • Forearm crutches or cane as indicated			
Communication	Independent				
Transportation	Independent in car, including loading and unloading wheelchair	Hand controls			
Homemaking	Independent complex cooking and light housekeeping; some assist with heavy housekeeping				
Assist required	Homemaking: 0–1 hour per day		0–1*	0*	0–2*

*Hours per day.

Rheumatoid Arthritis, Osteoarthritis, and Fibromyalgia

Alison Hammond

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe key features of rheumatoid arthritis, osteoarthritis, and fibromyalgia.
2. Identify clinical sequelae that interfere with meeting occupational performance goals.
3. Select assessments to optimize occupational performance for clients with rheumatoid arthritis, osteoarthritis, and fibromyalgia.
4. Describe interventions to enable clients to continue, resume, and/or adopt new occupational performance goals.
5. Describe methods of helping clients understand and adopt self-management methods during occupational performance.

Many people with rheumatoid arthritis (RA), osteoarthritis (OA), and fibromyalgia (FM) find performing everyday activities painful, tiring, and frustrating, affecting their well-being. Occupational therapy aims to

- improve clients' ability to perform daily occupations (i.e., activities and valued life roles in work, the home, in leisure, and socially)
- reduce pain and fatigue
- prevent losses of function
- improve or maintain psychological status
- help people self-manage their condition and successfully adapt to disruptions in lifestyle
- achieve occupational balance.

Those with participation restrictions have poorer psychological outcomes, which is linked with poorer physical outcomes. Maintaining or increasing participation is the goal of therapy (American Occupational Therapy Association [AOTA], 2008). Treatment enables behavioral change by using self-management approaches such as ergonomics (joint protection techniques), fatigue management, orthoses (if applicable), stress management, and increasing physical activity. Occupational therapists see clients with RA, OA, or FM mainly as outpatients or community patients.

RHEUMATOID ARTHRITIS

RA is an autoimmune, chronic inflammatory disease affecting joints. Symptoms are symmetrical, polyarticular pain and swelling; early morning stiffness; malaise; and fatigue. It also affects the eyes, skin, lungs, heart, gastrointestinal system, kidneys, nervous system, and blood. There is no cure, but earlier diagnosis and start of medication help prevent or slow effects.

RA affects about 1.5 million people in the United States (Helmick et al., 2008). Prevalence is 0.5%–1.0%. Peak onset is at age 40–70 years. Some 60% are of working age when diagnosed (Symmons et al., 2002). Usually, onset is slow, with hands and feet affected first. Onset is rapid for 20%: waking up one morning with multiple painful, stiff and swollen joints, and they may be admitted via the Emergency Department.

Etiology and Pathophysiology

Genetic, hormonal, environmental, and lifestyle factors contribute to developing RA. Joint damage can occur within months of symptom onset. Changes include the following:

- Synovitis, i.e., thickening of the synovial membrane with increased synovial fluid (swelling). The pressure resulting stretches nociceptors in surrounding tissues, causing pain.

- Protein-degrading enzymes released from inflammatory cells. Inflammatory tissue (pannus) invades bone and cartilage at the joint margins. Chondral and subchondral erosions develop.
- Continued, prolonged joint swelling stretches and weakens ligaments and capsules, disrupting joint stability.
- Muscle mass is lost (cachexia) as inflammatory processes affect muscles and the metabolism.
- Inflammatory proteins (e.g., tumor necrosing factor alpha) are released, causing marked fatigue.
- Abnormal movement occurs in joints with weakened ligaments and disrupted structures. Joint deformity may occur.

Joint Involvement and Natural History

The upper limb joints affected are the wrists (85% of people with RA), metacarpophalangeal (MCP) joints (80%), elbows (70%), proximal interphalangeal (PIP) joints (65%), and shoulders (60%). In the lower limb, knees (80%), ankles (70%), metatarsophalangeal (MTP) joints (70%), and hips (30%) are affected. Additionally, the cervical spine (35%) and temporomandibular joint (25%) can be affected (Arthur & Hill, 2006).

The natural history of RA varies considerably. Three disease courses have been identified:

1. Monocyclic: About 20% have one episode ending within 2–5 years of initial diagnosis and not reoccurring. Early diagnosis and/or aggressive treatment with disease-modifying antirheumatic drugs (DMARDs) can help achieve this.
2. Polycyclic: About 75% experience fluctuating disease activity over the course of the condition. RA can last many years.
3. Progressive: In 5% RA continues to rapidly increase in severity and is unremitting (Centers for Disease Control and Prevention [CDC], 2012).

Management of Rheumatoid Arthritis

Medical management aims to suppress inflammation rapidly to prevent or limit joint damage, thereby limiting pain and fatigue. The earlier the person starts DMARDs, the better the outcome. Methotrexate is the drug of choice. Combination therapy (e.g., methotrexate, and/or leflunomide, sulphasalazine, or hydroxychloroquine) is recommended in moderate to severe disease (Singh et al., 2012) and has better outcomes than monotherapy, with no difference in drug tolerability or toxicity (National Institute for Health and Clinical Excellence [NICE], 2009). If DMARDs are ineffective, or there are poor prognostic indicators, biologic drugs are considered (e.g., etanercept, infliximab, or adalimumab) (Singh et al., 2012). In the last

5 years, increasingly early, aggressive use of combination DMARD therapy and biologics have improved outcomes of those newly diagnosed.

Multidisciplinary team (MDT) management, self-management, and condition education are essential. Ergonomic education, exercise, and fatigue management are key components. From an early stage, some 60% have hand and activities of daily living (ADL) problems, and 28%–40% stop work within 5 years of diagnosis (NICE, 2009). Once unemployed, they are unlikely to return to work (Verstappen et al., 2004). This suggests that two-thirds could benefit from OT for hand and activities of daily living (ADL) difficulties, and at least a third could benefit from work rehabilitation (NICE, 2009). Clinical guidelines for the management of RA (including nonpharmacological management) have been produced in Europe (Combe et al., 2007) and the United Kingdom (NICE, 2009).

OSTEOARTHRITIS

OA is the most common form of arthritis and one of the leading causes of pain and disability worldwide. OA is a clinical syndrome of joint pain linked with degenerative joint changes. OA affects 27 million adults in the United States (CDC, 2012). Symptoms are joint pain, initially on activity, which reduces with rest. Over time, pain becomes persistent and disturbs sleep. Pain arises from stretching of nociceptors in the joint capsule caused by focal synovitis, from increased vascular pressure in subchondral bone, and from spasm of surrounding muscle. Stiffness occurs after sleep or prolonged inactivity (called the gel phenomenon). This usually lasts 5–30 minutes and reduces with movement. There is no cure.

Etiology and Pathophysiology

There are multiple risk factors:

- Genetic (heritability accounts for 40%–60% of hand, knee, and hip OA)
- Constitutional factors (more common in women, with age, and with higher body weight)
- Biomechanical factors (e.g., joint injury, greater occupational or leisure use of a joint, reduced muscle strength, joint laxity, or misalignment)

Any synovial joint can develop OA, but structural changes do not always cause symptoms. OA is a metabolically active, dynamic process involving all joint tissues (cartilage, bone, synovium, capsule, ligaments, and muscle). Pathophysiological changes include fibrillation, loss of articular cartilage, and remodelling of adjacent bone with new bone formation (osteophytes). Focal synovial membrane inflammation can occur because of irritation from osteophytes and other joint changes. These changes suggest OA is a repair process, which

is initially effective, resulting in a structurally altered but symptom-free joint. However, continued damage or ineffective repair means symptomatic OA results (NICE, 2008).

Joint Involvement and Natural History

The prevalence of symptomatic OA is:

- hand OA: 8% of people older than 60 years of age
- knee OA: 12% of people older than 60 years of age and 16% older than 45 years of age
- hip OA: 4.4% of people older than 55 years of age (CDC, 2012)

OA may affect one joint or be multifocal. It usually develops gradually. It is often accepted as part of getting older and as inevitably getting worse. However, different types of OA have different prognoses. People with interphalangeal (IP) joint OA (Heberden's and Bouchard's nodes) no longer have symptoms after a few years, although joint changes remain that can affect function. Thumb base OA frequently continues causing pain and disability. After 5 years of knee OA, about a third have improved, a third are the same, and a third have gotten worse. Why this is so is unclear, although obesity may be an important factor in worsening disease. Hip OA tends to have the worst outcome, with a significant number needing hip replacements after 1–5 years (NICE, 2008).

Management of Osteoarthritis

Core interventions are self-management and condition education, including local muscle strengthening exercise and aerobic exercise to improve fitness, weight-loss advice (if necessary), and ergonomics education. Acetaminophen and topical nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., ibuprofen gel) are recommended for pain relief. If necessary, oral NSAIDs may be prescribed. Capsaicin cream or intra-articular injections may be used if problems continue (NICE, 2008).

Amongst those seeking medical care, 82% reported difficulties with ADL (74% with hand OA and 83% with knee and multifocal OA). Problems include shopping (57% of participants), housework (43%), and dressing (21%) compared to 12%, 21%, and 13%, respectively, of age-matched controls (Fautrel et al., 2005). One in five with OA have to give up work or retire early because of their condition, and four out of five are in constant pain (Arthritis Care, 2004). This suggests that many could benefit from OT. Clinical guidelines for the MDT management of OA have been produced in the United States (Hochberg et al., 2012) and of knee OA (Jordan et al., 2003), hip OA (Zhang et al., 2005), and hand OA (Zhang, Doherty, & Leeb, 2007) in Europe (NICE, 2008).

FIBROMYALGIA

FM is neurogenic in origin and considered a disorder of the stress system following prolonged physical and/or mental overburdening. It is part of a spectrum of such disorders, including chronic fatigue syndrome. People experience chronic widespread pain, sleep disturbance, fatigue, and psychological distress. Other symptoms can include morning stiffness; tingling or numbness in hands and feet; headaches, including migraines; irritable bowel syndrome; and problems with thinking and memory (sometimes called "fibro fog"). It affects about 5 million adults in the United States. Prevalence is 2%–5%, and 80% are women (Arnold, Clauw, & McCarberg, 2011; CDC, 2012). FM seems to be underdiagnosed in men. Peak age of onset is 40–55 years, but it can occur at any age.

The American College of Rheumatology diagnostic criteria are pain lasting more than 3 months and of unknown origin, with a widespread pain index score of >9 out of 19 possible pain locations and symptom severity score of >9 out of 13 (including fatigue, cognitive, and somatic symptoms) (Wolfe et al., 2010). There can be long delays to diagnosis (average 5 years), resulting in poor management. Some health care professionals still do not consider FM to be a "real" condition, which causes distress and confusion to clients (Ablin et al., 2011).

Etiology and Pathophysiology

The cause of FM is likely to be multifactorial. Triggers include early life stressful events, physical trauma, catastrophic events, infections, and peripheral joint conditions (e.g., RA or OA). Predisposing factors may include a tendency to overexert physically and/or mentally. There can be familial associations, indicating that hereditary and social factors also play a role. Physical or psychological stresses can disrupt the hypothalamic-pituitary-adrenal pathway (i.e., the stress response mechanism in the brain) altering neuroendocrine functions. Functional magnetic resonance imaging shows FM is also associated with abnormal pain processing in the central nervous system. There is central sensitization of pain perception, with allodynia and hyperalgaesia, resulting in altered levels of neurotransmitters in pain pathways including increased substance P (increasing pain perception), reduced endorphins (increasing pain perception and reducing mood), and reduced serotonin (reducing sleep, mood, and cognition and altering circadian rhythms).

If C-size peripheral nerve fibers are repeatedly exposed to painful stimuli, there is progressively greater stimulation in the dorsal horn receptors in the spinal cord. This is known as "wind up" (pain is increasingly perceived at higher intensity over time). Substance P released in the dorsal horn cells can diffuse to synaptic connections in nearby myotomes, thus "spreading" pain perception to other uninjured sites. Pain wind up helps explain why some people with RA and OA go on to develop secondary FM. Appropriate use of pain medication is therefore important. Negative thoughts (fears, anxiety, depression, and poor self-efficacy) can also increase pain perception (Ablin et al., 2011).

Natural History

Community-based studies suggest that symptoms are relatively stable and quality of life improves as people with FM learn to cope with their condition. However, longitudinal studies of those referred to secondary care [rehabilitation] indicate that symptoms progress over a long period, remission is rare, and many are high users of health care services (Sallinen et al., 2009) (see Research Note 39-1).

Management of Fibromyalgia

Providing a diagnosis as soon as possible with a clear explanation about FM effects, the importance of self-management, and taking the person seriously are central to successful management. Three drugs are licensed for use in FM: pregabalin reduces the release of noradrenalin and substance P, improving pain, sleep, and fatigue; and milnacipran and duloxetine are dual reuptake inhibitors of serotonin and norepinephrine, improving pain, physical function, and fatigue. The side effects are generally mild. Tramadol also improves pain and physical function and is well tolerated.

Team management should provide multimodal therapy, because this is more effective than single therapies, and should include medication; exercise (moderate-intensity aerobic exercise including large body movements at least two or three times a week for at least 6 weeks; this can be water or land based, e.g., walking, Tai Chi); progressive strength training; cognitive-behavioral therapy (CBT); self-management education using CBT approaches such as stress, pain, and fatigue (sleep and pacing) management; relaxation; and ergonomics (Glombiewski et al., 2010; Hauser et al., 2009).

In a national community-based survey, 90% of women with FM reported difficulties in heavy household tasks and strenuous activities; 60% in light household tasks, carrying, climbing stairs, and walking over half a mile; and 25% in self-care (Jones et al., 2008). Work disability rates vary between 23% and 66% (Henriksson, Liedberg, & Gerdle, 2005). This suggests that many with FM can benefit from OT. Guidelines for the MDT management of FM have been produced by EULAR (Carville et al., 2007).

HAND INVOLVEMENT IN RHEUMATOID ARTHRITIS, OSTEOARTHRITIS, AND FIBROMYALGIA

Hand function is commonly affected in RA, OA, and FM. Therefore, understanding how the hands are affected helps appreciate the rationale behind interventions

Research Note 39-1

Abstract

Little is known about the long-term effects of fibromyalgia (FM) in everyday life or on work ability. A narrative interview study explored the experiences of work ability and functioning of 20 women with a long history of FM. Four types of experience were identified: confusion, coping with fluctuating symptoms, being "in between," and being over the edge of exhaustion. Severe pain and fatigue symptoms, combined with a demanding life situation and ageing, led to substantial decreases in work ability and functioning. Vocational rehabilitation or adjustments to work tasks were rarely seen or started too late to be effective. Exploring the women's life stories revealed perceived causes and consequences of FM related to work ability and disability. Such insights can be used in developing effective interventions to support work ability and avoid premature retirement in people with FM.

Implications for Practice

- Understanding the impact of FM from the client's perspective is essential. Qualitative studies provide valuable insights into how symptoms affect occupational performance. They help in understanding the barriers people may face from health care and social security systems in getting support and the possible negative attitudes of employers.
- Loss of work can lead to depression and anxiety in FM, making symptoms worse.
- In the occupational therapy process, the impact of FM on work must be assessed, and vocational rehabilitation must be provided. Ergonomic and fatigue management education are essential.
- Once unemployed, people with FM see a return to work as unrealistic. Early vocational rehabilitation to prevent work disability is essential.

used, such as ergonomics, exercise, and orthoses, and in explaining these to clients.

The Hand and Rheumatoid Arthritis

In women with early RA ($<$2 years), average losses are 20° of wrist extension, 30° wrist flexion, 15° MCP flexion, and 60% of normal power and pinch grip strength (Hammond et al., 2000). A third develop hand deformities (Eberhardt et al., 1990). There have been no recent studies of hand deformity development. The effect of earlier aggressive DMARD therapy may mean these losses now occur less. Deformities develop because of a combination of persistent synovitis, disrupted joint structures that alter joint mechanics, and both normal and abnormal forces over joints that arise from normal hand use (Adams et al., 2008). For example, power grip requires MCP ulnar deviation, especially in the fourth and fifth fingers, promoting ulnar deviation at weakened MCP joints. During lifting, external pressures in a volar or longitudinal direction increase strain on weakened wrist ligaments. Strong pinch grips increase intrinsic muscle pull, promoting imbalance at the IP joints (see Fig. 39-1).

Wrist Joint Changes

The ulnar side of the wrist is an early inflammation site. The triangular fibrocartilage is disrupted, allowing the proximal carpal row to rotate ulnarward. The distal row compensates by sliding radially, resulting in a gradually radially deviating wrist. Persistent synovitis promotes laxity of the wrist ligaments. Radioulnar ligament laxity allows rotation of the radius and ulna, with the ulnar styloid becoming more prominent. Extensor carpi ulnaris then displaces volarly, passing beneath the wrist joint axis, exerting a flexor pull. This, combined with wrist ligament laxity, and the natural volar incline of the distal radius, increases risk of wrist volar subluxation. Radial deviation at the wrist disrupts biomechanics of the extensor and flexor tendons, causing these to exert an ulnar pull at the MCP joints.

Figure 39-1 The hand and rheumatoid arthritis: synovitis at the wrist, metacarpophalangeal (MCP) and interphalangeal (IP) joints; swan-neck deformity in the third, fourth, and fifth fingers.

Metacarpophalangeal Joint Changes

Persistent synovitis weakens MCP collateral ligaments, volar plates, and dorsal hoods, leading to joint instability. The finger extensors can slip volarly and ulnarly, increasingly acting as weak flexors. Normal MCP joint features further contribute to ulnar deviation once joint structure is disrupted. These include (1) the flexor tendons normally approach the index and middle fingers from an ulnar direction exerting a significant ulnar torque, (2) the metacarpal head anatomically predisposes to tendons slipping ulnarward, and (3) the ulnar interossei exert a stronger pull than the radial ones.

Interphalangeal Joint Changes

Persistent synovitis can also disrupt positioning of the extensor tendon central slip and lateral bands at the PIP joints, allowing a Boutonniere deformity to develop. MCP joint inflammation can also cause protective spasms in the interossei, causing MCP flexion during finger extension (the intrinsic plus position), which further contributes to Boutonniere and swan-neck deformity development. Similar changes can result in Z deformity of the thumb.

The Hand and Osteoarthritis

The repair process in hand OA can lead to osteophyte formation at joint margins and focal synovitis in affected joints. Hand OA most commonly affects the DIP joints and carpometacarpal (CMC) joint. Bony enlargement and persistent synovitis can cause joint ligament laxity. Combined with forces exerted on the hands during daily use, deformities can result. At the PIP joints, bony enlargements are known as Bouchard's nodes, and at the

Figure 39-2 The hand and osteoarthritis: showing carpometacarpal (CMC); Bouchard's nodes (proximal interphalangeal [PIP] joint) and Heberden's nodes (distal interphalangeal [DIP] joint).

distal interphalangeal (DIP) joints, they are known as Heberden's nodes (Fig. 39-2). Mallet finger deformity results at the DIP joint if the distal extensor digitorum communis tendon attachment is disrupted by bony enlargement. The classic thumb deformity of squaring at the CMC joint, with Z deformity of the thumb, results from CMC joint adduction, MCP joint hyperextension, and IP joint flexion. Muscle wasting is noticeable in the thenar eminence, and finger, thumb, and wrist movement reduces (Bland, Melvin, & Hasson, 2000). People with combined finger and CMC OA have worse function. In women with hand OA, grip strength is only 57% of normal (Kjeken et al., 2005).

The Hand in Fibromyalgia

Hand function problems can be common in FM. They are due to hand pain, muscle weakness, and stiffness, resulting in poor grip. In women with moderate FM, hand grip strength was 19.3 kg of grip force, and in women with severe FM, hand grip strength was 16.9 kg compared to healthy women (29.5 kg) (Aparicio et al., 2011). There are no synovial or bony changes occurring in FM, and deformities do not develop.

ASSESSMENT AND EVALUATION

Assessment identifies clients' treatment priorities, their degree of motivation to use self-management approaches, and how their condition affects them. Treatment effectiveness can be evaluated if standardized, reliable, valid measures are used.

Initial Interview

Obtain information about the client's medical history and current medication from his or her medical records. For new clients, start with a brief explanation of OT because many, particularly in an early disease stage, may not be aware of the services occupational therapists provide. Explain that the initial assessment aims to identify key goals for therapy based on his or her needs. The interview includes

- a relevant past medical history, including comorbidities
- current medication information. For RA, knowing how long the person has been taking his or her DMARD or biologic drugs is helpful because, if started recently, functional gains may be expected. Ask about pain medication, when and how regularly, and note the client's attitude toward taking it.
- social history: whether they live alone or with others; type of house

The initial interview also focuses on occupational performance: ADL (personal and instrumental); rest and sleep; work (paid or volunteer); education (formal or informal); leisure, social, and community activities

(AOTA, 2008). For example, the Canadian Occupational Performance Measure (COPM) is a semistructured interview that focuses on activity limitations and participation. It takes 20–40 minutes to complete (Law et al., 2005). At the end, the person identifies the five most important problems he or she is experiencing in self-care, work, or leisure and rates each for importance, performance, and satisfaction with performance.

As problems are reported, explore why they are occurring: Is it due to pain? Fatigue? Stiffness? Physical limitations (e.g., in movement, strength, endurance)? Environmental factors (e.g., barriers, lack of equipment)? Psychological factors such as poor concentration, low mood, or lack of confidence (self-efficacy)? Performing specific activities because of fears of increasing pain and/or fatigue? Or a lack of information about alternatives?

Ask how clients spend a typical weekday and a typical weekend day. How much time do they spend in activity and in rest? Do they take regular rest breaks or keep pushing themselves even though fatigued? Have leisure activities become a rarity? How are they coping with competing demands of work and home life? What are they satisfied and dissatisfied about in their daily lives? How confident are they about managing difficulties they are experiencing? How much do they understand about why they are experiencing problems, about their condition, and what they could do themselves to make a difference? During the interview, gauge their mood, observe their body language, and listen carefully to their intonation and choice of words. This will help judge how ready and willing the person is to learn about self-management approaches, find solutions, and make changes.

Objective and subjective assessments are selected according to priority issues identified. Subjective assessments include patient-reported outcome measures. Interview may be more appropriate for some issues (e.g., intimate relations). An extensive review of rheumatology measures for body functions, activity limitations, participation, and personal factors was published by the ACR (2011). Some measures are described below and in Assessment Table 39-1.

Body Functions and Activity Limitations

Using self-reported questionnaires saves time and facilitates comprehensive evaluation.

The Evaluation of Daily Activity Questionnaire

The Evaluation of Daily Activity Questionnaire (EDAQ) is a detailed assessment (Nordenskiold, Grimby, & Dahlin-Ivanoff, 1998) now translated into English, updated with input from people with RA, OA, and FM, psychometrically tested in RA (Hammond et al., 2011, 2012) and being tested in OA, FM, and five other musculoskeletal conditions. Explain that the EDAQ helps clients identify their

own problems and priorities, enabling collaboratively finding solutions. The client completes it in his or her own time at home. There are three sections to this evaluation: body functions, activity limitations, and use of assistive devices.

Observation of ADL is more appropriate with those unable to self-report activity limitations because of severe comorbid cognitive problems and those post surgery as changing circumstances mean the client may not know his limitations. Interview is often more appropriate for those with low mood.

Activity Diaries

A diary of how the client spends a typical weekday and a typical weekend day, with each day divided into half-hour periods, helps identify occupational balance. Several designs exist. For example, the person can write his main activity each half hour, indicate on a scale of 0–10 the level of pain and fatigue experienced, and whether he took a rest.

Other Activity Limitation Patient-Reported Outcome Measures

- The Arthritis Impact Measurement Scale 2 (Meenan et al., 1992) is useful as an outcome measure, although lacking detail for treatment planning (10–20 minutes).
- The Health Assessment Questionnaire (HAQ) (Pincus et al., 1983). Scores are worsened if assistive devices are used, making it unsuitable as an outcome measure in OT. However, it is widely used in rheumatology clinics and useful for screening for OT (5 minutes).
- The Fibromyalgia Impact Questionnaire Revised (Bennett et al., 2009) specifically targets the issues affected in FM (5–10 minutes).

Mobility and Hand and Upper Limb Function

Overall movement can be assessed, if necessary, using the gait arms legs spine (GALS), a reliable, valid musculoskeletal screening examination (Plant et al., 1993) that takes 5–10 minutes to administer. There is a video posted online (http://www.youtube.com/watch?v=9jTZ03CbZm0) that shows the exam being conducted.

Hand and Upper Limb Assessment. In RA, a tender and swollen joint count can be conducted for hand splint assessment or to monitor progress over time. An online video (http://www.youtube.com/watch?v=RnvsbD6NKoc) shows this assessment performed as part of the Disease Activity Score 28 (Prevoo et al., 1995). Swelling in any condition can also be assessed using volumetry. In RA and OA, recording hand appearance, e.g., presence of joint swelling, pain, and deformity, on a hand chart is particularly useful, as is digital photography. Range of movement and appearance can be observed using the upper limb part of the GALS or using standard goniometric methods.

Assessment Table 39-1 | Summary of Assessments of Occupational Performance Related to Practice for Rheumatoid Arthritis, Osteoarthritis, or Fibromyalgia

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Evaluation of Daily Activity Questionnaire (EDAQ) (Hammond et al., 2011; 2012; Nordenskiold, Grimby, & Dahlin-Ivanoff, 1998)	Self-assessment of daily activity ability Ordinal (4-point) scale: 138 items in 14 domains; scores range from 0 to 24 or 56 depending on number of domain items	30–60 minutes	Correlations with HAQ r_s = 0.72–0.89; SF36 Physical function = −0.57 to −0.86	Internal consistency r_s = 0.89–0.97 Test–retest r_s = 0.54–0.87	Minimal detectable difference = 1.60–4.61	Strengths: Patient generated; very detailed; free Weaknesses: Length not acceptable to all
Workplace Activity Limitations Scale (WALS) (Gignac, 2005) http://www.acreu.ca/research/measures.html	Self-assessment of ability at work Ordinal (4-point) scale: scores range from 0 to 48; 12 items	5 minutes	Correlations with other work measures: RA Work Instability Scale, r = 0.77; Work Limitations Questionnaire, r = 0.61	Internal consistency determined by inter-item correlation coefficient = 0.81–0.86 Test–retest reliability not established Interrater reliability not established	Standardized Response Mean = −0.79–0.50	Strengths: Data have been collected in rheumatoid arthritis (RA) and osteoarthritis (OA) to date; free Weaknesses: Items based on literature review and did not include patients in scale development; psychometrics incomplete; not yet used as an end point in clinical trials
Michigan Hand Outcomes Questionnaire (Chung et al., 1998; Waljee et al., 2010) http://sitemaker.umich.edu/mhq	Self-assessment of hand function, appearance, pain and satisfaction Ordinal (5-point Likert) scale: 37 items in six subscales (overall hand function, activities of daily living (ADL), pain, work, aesthetics, and satisfaction with hand function. Scores converted to a 0 (worst) to 100 (best) scale.	30 minutes	In RA: correlations with Arthritis Impact Measurement Scales 2 (AIMS2) subscales r = 0.2–0.77, with highest for function, ADL, work, pain and AIMS2 physical function In OA: correlations with Cochin Hand Scale (r_s = 0.82) and hand strength (r_s = 0.5–0.65)	Internal consistency; intra-class correlation coefficient (ICC) = 0.75–0.94 in RA Test–retest ICC = 0.95 (RA) and 0.85 (OA)	Minimal Clinically Important Difference (MCID); pain subscale = 3; function = 11 and ADL = 13	Strengths: Good psychometric qualities in arthritis; includes appearance and satisfaction; useful postsurgery; free Weaknesses: Longer completion time
Measure of Activity Performance of the Hand (MAP-HAND) (Paulsen et al., 2010)	Self-assessment of hand function Ordinal (4-point) scale: 18 items of hand function; scores range from 18 (best) to 72 (worst)	3 minutes	Correlations with AIMS2 in RA: hand and finger function, r = 0.78; arm scale, r = 0.66; pain, r = 0.65 Unidimensional	Person Separation reliability index = 0.93. Test–retest ICC = 0.94	Not established	Strengths: Patient-generated items; quick; free Weaknesses: Needs testing in other conditions

Grip strength can be assessed using the Jamar® dynamometer, although this is less accurate for weak grip. Pinch strength can be measured with a B&L® pinch gauge, which is also reliable. Normative data are published for grip and pinch measured using the Jamar® and B&L® gauges (Crosby & Wehbe, 1994).

Reliable, valid hand assessments include the Grip Ability Test, which takes 5 minutes to complete and score and consists of pouring water from a jug, placing a paper clip on an envelope, and pulling Tubigrip® over the hand and forearm (Dellhag & Bjelle,1995); and the Sequential Occupational Dexterity Assessment (SODA) (Van Lankveld et al., 1996), which takes 15–20 minutes, if a more detailed assessment is required. Two self-report hand function measures are reviewed in the Assessment Table 39-1.

Participation

Measures of work and involvement in other valued roles are important in the rehabilitation of persons with arthritis or FM.

The Work Environment Survey–Rheumatic Conditions. A detailed semistructured interview, taking about 45 minutes, identifies problems experienced by working people, such as getting ready for and going to and from work, workplace access, completing job activities (physical, mental, and time demands), relationships with people at work, environmental factors, company policies, and work-life balance (Allaire & Keysor, 2009).

The Ergonomic Assessment Tool for Arthritis. The Ergonomic Assessment Tool for Arthritis (EATA) includes describing tasks, equipment used, a diary of typical activities at work during one day, work postures, work demands, and work station layout. It helps guide observation and recording during a work site visit and job analysis or can be conducted as an interview and/or client self-report (Backman, Village, & Lacaille, 2008).

For those who are unemployed, the Worker Role Interview identifies clients' perceptions of abilities and limitations, expectations of success, and enjoyment of and commitment to work (Braveman et al., 2005). An observational and functional assessment of work ability, the Functional Capacity Evaluation (FCE) describes the person's ability to perform work activities. FCE is an umbrella term, and there are several evaluation systems available: the WorkHab, Isernhagen Work Systems, and Matheson systems are examples (Gouttebarge et al., 2004).

Other Work Assessments. The RA-Work Instability Scale (Gilworth, Chamberlain, & Harvey, 2003) is a screening tool taking 5 minutes to administer. It has cut points identifying risk levels of work instability: <10 = low; 10–17 = moderate; and >17 = high risk, predictive of future work disability. People scoring 10 or more are recommended to receive work rehabilitation. The Workplace Activity Limitations Scale evaluates the degree of difficulties experienced during work tasks (Gignac, 2005). (See Assessment Table 39-1.)

Valued Life Activities Scale

The Valued Life Activities Scale is a brief measure of participation (33 items) that also includes some self-care items. Activities include leisure and social activities, work, travel, caring, household tasks, and gardening (Katz et al., 2009).

Educational and Psychological Assessments

Self-management education needs can be assessed using the Educational Needs Assessment Tool (Ndosi et al., 2011), which has 39 items and takes 5–10 minutes to administer. In RA, self-efficacy to use self-management approaches can be evaluated using the RA Self Efficacy Scale (RASE) (Hewlett et al., 2001). Other psychological measures are reviewed in the ACR (2011) outcome measures review.

INTERVENTIONS

Interventions are summarized in Procedures for Practice 39-1. Choice is guided by the priority occupational performance problems identified in assessment, the client's adjustment to the disease process, and his or her psychological status and self-management education needs. Occupational performance can be affected by limited

- knowledge of the condition and its progress
- knowledge and skills to adopt ergonomic approaches during occupational performance to reduce pain, fatigue, and joint strain
- energy to manage a full day of activity and ability to balance rest and activity
- range of movement and deformity
- muscle strength and endurance
- self-efficacy to use self-management approaches and to redesign lifestyle

Comprehensive OT programs sustain improvements in function (Helewa & Goldsmith, 1991; Steultjens et al., 2004) and increase self-management in early RA (Hammond, Young, & Kidao, 2004). Typically, key interventions are ergonomic approaches and fatigue management, self-management education, psychosocial support and cognitive-behavioral approaches to improve coping and reduce stress, hand and upper limb exercise, and orthoses.

Ergonomic Approaches

Ergonomic approaches include

- altering movement patterns and use of proper joint and body mechanics

Procedures for Practice 39-1

Comprehensive List of Occupational Therapy Interventions in Rheumatology

- Activities of daily living (ADL) rehabilitation
- Work rehabilitation: including on-site work assessments, ergonomics; work assistive devices; employer liaison; work environment adaptation; functional capacity evaluation; work hardening
- Avocational rehabilitation: voluntary work, adult education and leisure opportunities; modifying leisure activities
- Stress and pain management
- Relaxation training
- Communication and assertiveness training
- Counseling (may also include cognitive-behavioral therapy if the therapist has post graduate training)
- Family/carer liaison and support
- Advice on social security benefits and community resources
- Exercise for health and well-being (e.g., Tai Chi, yoga, swimming, walking, low impact dance programs)
- Self-management education (individual and group work) using cognitive-behavioral approaches
- Activity/role planning; goal clarification and setting
- Ergonomic education (joint protection); fatigue management.
- Assistive devices and adaptive equipment
- Orthoses (e.g., resting and working hand splints; elbow and neck orthoses)
- Hand and upper limb therapy and exercises
- Therapeutic activities
- Home assessment, recommendations for environmental and housing adaptations
- Mobility aids prescription (including wheelchair/powered aids); driving/transport advice
- Foot care advice and simple orthoses (e.g., metatarsal pads, arch supports, insoles)

From Hammond, A. (2004). What is the role of the occupational therapist? *Best Practice and Research in Clinical Rheumatology, 18*, 491–505; NICE, 2009.

- restructuring activities, work simplification, and altering the environment
- using ergonomic equipment and assistive technology
- activity pacing, planning, prioritizing, and problem solving to modify activities and routines (discussed in the Fatigue Management section)

Ergonomic approaches are also termed joint protection and energy conservation techniques. Joint protection was first developed in practice relating to RA and is now applied in practice with other rheumatic conditions causing joint or soft tissue pain and swelling (Cordery & Rocchi, 1998). Some conditions, such as FM and soft tissue rheumatisms, do not affect joints, so "ergonomics" is a more relevant term. How to provide self-management education to help people use ergonomic approaches enough in daily life to be effective is discussed at the end of this section.

Aims of Ergonomics

In inflammatory and degenerative rheumatic conditions (e.g., RA and OA), the aims of the ergonomics approach are to

- reduce pain during activity, and at rest, resulting from pressure on nociceptive endings in joint capsules, caused by inflammation and/or mechanical forces on joints
- reduce forces on joints: internal (i.e., from muscular compressive forces, e.g., during strong grip) or external (i.e., forces applied to joints whilst carrying or pulling/pushing objects)
- reduce secondary inflammation and subsequent strain on soft tissues resulting from excess (i.e., beyond tolerability) force on already inflamed and/or disrupted joints
- reduce loading on articular cartilage and subchondral bone
- help preserve joint integrity and reduce risk of development and/or progression of deformities

Additionally, in RA, OA, and FM, the aims of the ergonomic approach are to

- reduce pain resulting from overuse (i.e., beyond tolerability) of deconditioned muscles
- reduce fatigue, by reducing effort required for activity performance
- improve or maintain function

Ergonomics must be combined with exercise in order to maintain or improve muscle strength and endurance. Additionally, in RA and OA, exercise increases joint stability and improves the shock-absorbing capabilities of joints.

Evidence for Effectiveness of Ergonomics

Ergonomics is effective in RA and hand OA in reducing pain and improving function. However, effective teaching techniques must be used to help people make sufficient changes to gain benefits. (See the Self-Management Education section later for how to do this.) A number of randomized controlled trials (RCTs) of ergonomic education (joint protection) have shown education using cognitive-behavioral and/or self-efficacy–enhancing approaches is significantly more effective than traditional education. At 1 year, those receiving group behavioral education had significantly better use of joint protection, functional ability, reduced hand pain, general pain, and early morning stiffness than those receiving traditional education (Hammond & Freeman, 2001). Benefits continued for 4 years, and the behavioral group had fewer hand deformities (Hammond & Freeman, 2004) (see Evidence Table 39-1). An individual program, based on similar approaches, demonstrated at 3 months significant improvements in use of ergonomics and in

| Evidence Table 39-1 | | Best Evidence for Occupational Therapy Practice Regarding Rheumatic Diseases | | | | | |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical probability and effect size of outcome	Reference
Ergonomics (i.e., joint protection [JP])	Standard arthritis education program versus a JP program using educational, behavioral, motor learning, and self-efficacy–enhancing strategies	$n = 65$ (JP); $n = 62$ (standard) programs; RA: mean age: 50 years; 30 men, 97 women	JP: 4×2-hour weekly meetings JP training. Standard: $4 \times 2h$ weekly meetings (2.5 hours typical JP education + 5.5 hours re RA, exercise, pain management, foot care).	Randomized controlled trial Level: IA2a	Yes. At 4 years posttreatment, the JP group continued to have better joint protection adherence and activities of daily living (ADL) scores.	JP group significantly more improvement in ADL: $p = 0.04$, effect size, $r = 0.15$; and behavioral assessment: $p = 0.001$, $r = 0.27$ as compared to the control (standard) group	Hammond and Freeman (2004)
Work rehabilitation	Vocational rehabilitation (VR) and comprehensive occupational therapy versus usual care	VR/OT = 16; usual care = 16. RA: mean age = 50 years; 2 men, 28 women; all employed, but at risk for work disability.	VR/OT = 6–8 OT sessions: work rehab, splinting, education, ADL advice, ergonomics, work visit (and usual care). Usual care = medication and clinic visits	Randomized controlled trial Level: IB2a	Yes. At 6 months, there was significant reduction in work instability and improved functional ability and pain.	6 months: VR/OT group: Work instability $p = 0.04$, $r = 0.31$; COPM performance $p = 0.001$, $r = 0.55$; COPM satisfaction $p = 0.001$, $r = 0.55$; VAS (visual analog scale) pain $p = 0.007$, $r = 0.43$. These are medium to large effects.	Macedo et al. (2009)

self-efficacy (Niedermann et al., 2011). Furst et al. (1987) demonstrated that behavioral education was more effective than traditional in increasing the amount of daily activity people with RA were able to do. In hand OA, at 6-month follow-up, a hand joint protection intervention (based on the Looking After Your Joints Programme of Hammond & Freeman [2001]) led to significant improvements in hand pain, hand disability, global improvement, and self-efficacy (Dziedzic et al., 2011).

Ergonomic Methods

Hand ergonomics in RA includes changing movement patterns to limit strong grips, twisting movements, and sustained grips to reduce MCP forces; to limit lifting heavy objects and sustained wrist radial positioning to reduce wrist volar and radial forces; and to limit tight, prolonged key, tripod, and pinch grips to reduce volar and ulnar forces on the MCP, IP, and CMC joints. Approaches are similar in OA, although there is no need to emphasize reducing ulnar forces on the second through fifth MCPs, because these are not affected. The rapid hand function decline often seen in early RA and hand OA suggests that effective ergonomic education should be provided early to improve and maintain function or prevent problems. There is no need to "protect joints" in FM, because these are not affected, but ergonomic approaches help reduce forces on the hand that cause pain and help to compensate for weak grip.

Ergonomic Principles

Altering Movement Patterns and Use of Proper Joint and Body Mechanics. In hand activities, two hands can be used, and the load can be spread over the palmar surface (e.g., see Figs. 39-3 and 39-4). Movement patterns can be changed by, for example, turning a jar lid using the thumb, index, ring fingers, and thumb web space. The fingers are kept in correct anatomic alignment, and ulnar forces are avoided (Fig. 39-5).

Figure 39-4 Distribute load: using two hands to carry a kettle.

Objects should be kept closer to the body when lifting and carrying, and/or a stronger larger joint can be used. For example, avoid carrying a shopping bag using a hook grip in the hand. Instead use a bag with longer handles and put it over the shoulder (Fig. 39-6), or use a rucksack. Avoid prolonged sitting and standing. Change position regularly. For people with knee and foot pain, a perch stool reduces standing when preparing food or ironing. Work surfaces are within the reach envelope of the arms. Maintain efficient postures when working, e.g., avoid sitting with the head poking forward whilst working at a desk or reading. Book stands, writing slopes, and document holders help. Keep the back straight using supportive seating such as ergonomic office chairs and higher back, supportive sofas. Poor posture and positioning increases muscle fatigue and pain because greater energy is

Figure 39-3 Distribute load: using two hands to carry a mug.

Figure 39-5 Altering movement patterns: opening a jar.

Figure 39-6 Using a stronger, larger joint: carrying a bag.

Figure 39-7 Altering working methods: using a light jug to fill a kettle.

used to maintain biomechanically inefficient postures (see Procedures for Practice 39-2).

Restructuring Activities, Work Simplification, and Altering the Environment. Can an activity be done differently? For example, rather than taking a kettle to the tap, holding it whilst it fills and carrying it back across the kitchen, fill it with a lightweight jug instead (Fig. 39-8). Could shopping be done via the Internet to save driving, walking, and carrying bags? Reorder the sequence of tasks within activities to increase efficiency. Eliminate unnecessary tasks: Do all those items need to be ironed? Keep frequently used equipment within the reach envelope. Reorganize work areas to streamline work processes. Make work areas uncluttered. Locate equipment to promote correct joint positioning, e.g., keyboards. Raise or lower work surfaces to maintain good posture. Ensure storage is efficient, e.g., use stepped shelves in cupboards and sliding racks so jars, cans, and boxes are easily reached.

Using Ergonomic Equipment and Assistive Technology. Reduce the effort required by using ergonomic equipment or products with universal design, i.e., designed to be easy for all to use. There are many kitchen and household products available in stores and via the Internet (Figs. 39-7 and 39-9).

Procedures for Practice 39-2

Ergonomic (Joint Protection) Principles

- Respect pain
- Distribute load over several joints
- Reduce the force and effort required in activities
- Use correct patterns of movement
- Use good body positioning, posture and moving and handling techniques
- Use the strongest, largest joint available for the job
- Avoid staying in one position for too long
- Use ergonomic equipment, assistive devices, and labor-saving gadgets
- Pace activities: balance rest and activity, alternate heavy and light tasks, take microbreaks
- Use work simplification: plan, prioritise, and problem solve
- Modify the environment and equipment location to be ergonomically efficient
- Maintain muscle strength and range of movement

Modified from Cordery, J., & Rocchi, M. (1998). Joint protection and fatigue management. In J. Melvin & G. Jensen (Eds.), *Rheumatologic rehabilitation series: Assessment and management* (Vol. 1, pp. 279–321). Bethesda, MD: American Occupational Therapy Association; Hammond, A. (2010). Joint protection. In K. Dziedzic & A. Hammond (Eds.), *Rheumatology: Evidence based practice for physiotherapists and occupational therapists* (pp. 137–150). Edinburgh: Churchill Livingstone.

Figure 39-8 Using an ergonomic device: a jar opener.

FIGURE 39-9 Using an ergonomic device: an electric can opener.

For example, avoid lifting by using wheels: put shopping in a folding hand cart, easily kept in the boot of the car when not in use. Encourage people to consider features of good design when selecting products (see Procedures for Practice 39-3). For example, to avoid bending and kneeling, sit on a garden kneeler/stool when weeding. Wear cushioned, shock-absorbing insoles in shoes to reduce pressure on foot and knee joints when walking and standing. At work, use voice-activated software to reduce keyboarding and a wireless telephone headset or hands-free mobile instead of a handset.

Fatigue Management

Fatigue occurs in all three conditions. Causes can be physical: pain, increased physical demands because of altered joint biomechanics, deconditioning because of insufficient physical activity, and/or overdoing activities (the boom-bust cycle). In RA, the inflammatory process contributes to fatigue and also causes anemia and muscle cachexia. Psychosocial factors, e.g., depression, anxiety, helplessness, stress, poor self-efficacy, and poor social support (e.g., lack of understanding from family and friends),

---

Procedures for Practice 39-3

Selecting Ergonomic Products

- Lightweight, durable, compact
- Larger, nonslip handles
- Comfortable to hold and easy to maneuver
- Attractive and acceptable to the user
- Simple to operate; multipurpose (if appropriate)
- Reduces stress to all joints needed to operate the device
- Affordable

---

and work pressures contribute to fatigue. A variety of strategies help reduce fatigue, including ergonomic approaches at home and work, activity pacing, exercise, and stress management.

Activity Pacing, Planning, Prioritizing, and Problem Solving

Pacing. Many find taking a rest break difficult because it can be seen as "giving in." Rest "recharges the batteries," allowing people to keep going for longer. Rest recommendations include taking microbreaks for 30 seconds every 5–10 minutes or so, stretching and relaxing joints and muscles being most used, or taking a rest break for up to 5 minutes every 30–60 minutes. Frequency depends on fatigue severity. Rest breaks allow muscle recovery time. Help develop habits by using computer screen prompts or a kitchen timer or mobile phone alarm (or set to vibrate) to remind the person to take the rest break.

Planning. Balance activities to alternate between light, medium, and heavy tasks during the day and week. A "boom-bust" cycle is common, with people doing too much on good days and suffering the consequences for the next few. Breaking this habit requires attitudinal change. Many fear the consequences of failing to meet responsibilities. Activity diaries help people see boom-bust patterns. Use a diary with a line for each day of the week, each divided into 24 hours, showing 7 days on one page. The person completes this over a week, coloring the hours of high activity in red, medium in amber, and low in green, with rest colored blue. This graphically shows how they are overdoing activity and why they are fatigued.

Sleep Hygiene. A sleep diary helps identify why sleep is problematic. Solutions depend on problems and can include having a more supportive mattress and pillow (e.g., memory foam); establishing a regular bedtime and relaxing evening routine (e.g., listening to a relaxation recording, warm bath, or hot milky drink); avoiding stimulants (coffee, tea, alcohol, nicotine, and caffeinated soft drinks) several hours before bedtime; reducing stimuli in the bedroom (e.g., no TV or computer use), black-out curtains; and muted colors. Fatigue can also be aided by reducing stress and increasing physical activity (see later sections). At 6-month follow-up, an RCT of a multimodal fatigue management program in moderate to severe RA showed significant reductions in fatigue (Hewlett et al., 2011).

Self-Management Education: Applying Theory to Practice

Self-management education is problem focused and practical and emphasizes clients' ability to develop problem-solving skills and generate action plans. It includes

educational, behavioral, and cognitive approaches to influence health knowledge, attitudes, beliefs, and behaviors and to promote independence, maintain, or adjust life roles and address the psychological impact of disease (Iversen, Hammond, & Betteridge, 2010). Making changes to lifestyle is not easy. How it is applied in an ergonomics (i.e., joint protection, fatigue management, and hand exercise) program (the Looking After Your Joints Programme) is discussed below (Hammond & Freeman, 2001, 2004). Techniques can be applied to teach any self-management strategy.

The Transtheoretical Model

Identify the person's readiness to change and the benefits and barriers, both practical and psychological, to the person using ergonomics. People cycle through five stages of change when modifying health behaviors (Prochaska, DiClemente, & Norcross, 1992), with lapses at any stage possible. The stages are the following:

- Precontemplation: not knowing why or how to change or not wanting to.
- Contemplation: weighing the pros and cons of change.
- Preparation: starting to plan for change. Small steps are being taken, but they could easily remain "wishful thinking."
- Action: making changes and establishing new routines.
- Maintenance: keeping up the health behavior(s) for over 6 months.

To help identify a client's stage of change regarding pain management, during the initial assessment, ask

- "What do you do now to help manage your pain?"
- "Does pain and fatigue affect you doing activities you need and want to do in life?"

What does the response indicate? For example, "I take the tablets and keep on working through the pain" suggests the person is not self-managing effectively (precontemplation). Probe further to identify whether the person does not know what to do (limited knowledge), knows but lacks confidence to try other actions (poor self-efficacy), knows but does not believe anything else works (limited perceived benefit), or is angry/upset or denying the need to change (limited attitudinal change). This guides your choice of what to do next.

Precontemplation and Contemplation. If the person is not yet ready to make changes, cognitive and affective strategies are more important to use. Either (as relevant) provide small amounts of information incrementally about how, why, and what to do (increasing knowledge, perceived benefit, and self-efficacy) or discuss the person's attitudes toward having the condition and use counselling or motivational interviewing (attitudinal change) as relevant. See also Chapter 13 concerning motivational

interviewing. Encourage using self-evaluation and self-monitoring. Explore what activities and roles are important to the person: How are these affected by arthritis, what difficulties result (e.g., pain, fatigue, stiffness, or frustration)? How is the person's pain and fatigue at the end of the day or when doing activities he or she must do (e.g., work)? How will they be in a year or 5 years if things go on as they are or get worse? If resistance is encountered, roll with it (Mason & Butler, 2010). Encourage further self-reflection. This helps the person weigh up the pros and cons of change. Facing up to the negative consequences he or she fears for the future may prompt change. A technique then used in motivational interviewing is to ask

- How important is it for you to reduce these symptoms and continue these activities, on a scale of 0–10?
- How confident do you feel about making changes on a scale of 0–10?
- How ready are you to make changes on a scale of 0–10?

Zero means that the activity is not at all important or the person is not confident or ready. Ten means that the activity is extremely important or that the person is confident and ready (Mason & Butler, 2010). If the person's score is less than 7 for any of these questions, he or she is less likely to see the need for or be willing to change. If this is the case, explore what she thinks might increase these beliefs and her confidence in and readiness to use ergonomics; discuss that ergonomics and fatigue management are proven effective and the benefits gained, that is, reduced pain and fatigue, having more energy and ability to do what he or she needs and wants to in life (playing with the kids, working, running the home, and social activities), staying independent, reducing frustration, better physical and psychological well-being. Let the person discuss his or her concerns, which are commonly about negative self-image, embarrassment, not wanting to use assistive devices, wanting to remain as he or she is, not wanting to take the time to change, or concerns that using ergonomics makes tasks slower and more difficult.

Market ergonomics effectively. It can be perceived as excessive rest and giving up activity. Emphasize that it is adapting activities and movements to reduce strain or force on joints and soft tissues, just as in industry. Ergonomic practices do not mean stopping doing activities and appearing different, they mean change. Focus first on using altered working methods, planning, pacing, and restructuring activities (rather than assistive devices and splints). Such methods are less obvious, and many with arthritis strive not to appear different.

Change is a choice. The person may have good reasons for not using ergonomic approaches. There may be other priorities such as managing new medication, work, child care, increased exercise, or counseling. Ensure there are regular opportunities for people to be rereferred for education.

Preparation and Action. Identify the knowledge and skills the person has, emphasize that he or she has already started problem solving and will extend the amount and frequency of change to further reduce strain and pain. Teach some ergonomic skills specific to individual patient's priorities (e.g., in cooking). Teach self-monitoring: observing one's own behavior and how pain and fatigue are less when practicing an ergonomic method. This helps the person self-evaluate to determine whether change helps. Do not promote overly ambitious goals too soon. Engage family and friends in planning ergonomic changes, buying gadgets to help as presents, and reading advice leaflets to help support the client to change.

Once the person has started practicing techniques at home and work, use a coaching and educational-behavioral approach to teach ergonomic principles and their application across different activities. Motor learning approaches, with sufficient supervised practice and feedback, help psychomotor skill development. Teach

- task analysis: to help identify actions and activities to change
- problem solving: applying joint protection principles to generate new solutions, help overcome barriers, and prevent lapses
- goal setting: to regularly set and review action plans and identify internal rewards for meeting these

Workbooks, diaries, and action plans help recall of information and recording of activities, ergonomic behaviors practiced, and intentions to change. Increase and support self-efficacy by collaboratively developing a home program with the client to practice regularly.

Maintenance

Follow-up support can include telephone calls a few weeks or months later to check progress, booster sessions, and review of progress at rheumatology annual review appointments. Help clients be aware of how to cope with lapses.

Integrating Social Cognitive Theory

Increasing self-efficacy is key in teaching ergonomics. In the preparation, action, and maintenance phases, important strategies are the following (Bandura, 1977):

- Mastery experience: i.e., performing tasks successfully. Major barriers to change are altering automatic movement patterns and habitual daily routines. Provide sufficient practice of skills, with feedback, starting with simpler to more complex skills. Plan together how routines can change to accommodate extra practice and pacing.
- Vicarious experience (role modeling): watching others like ourselves successfully perform actions enhances our beliefs that we can also succeed.
- Verbal persuasion, i.e., encourage the person to try. Although widely used by health professionals,

supervised practice time and modeling are more effective. Persuasion is an adjunct.
- Reinterpretation of physiological signals, i.e., help people perceive differences in disease symptoms and increased symptoms (e.g., aches, fatigue, and joint swelling) from overdoing activities. Explain that symptoms from overdoing can be controlled through ergonomics and fatigue management.

Teaching in groups is very effective to enable modeling, problem solving, peer support, and ideas exchange, as well as being more efficient. Treating six patients in a 10-hour program takes less time than seeing each for 2 hours. Individuals get much more teaching time, which is significantly more likely to enable change.

Cognitive-Behavioral Approaches and Goal Setting

Change is the person's responsibility, but it is the therapist's responsibility to help him or her weigh the pros and cons of change and then provide effective interventions once the person decides to change. In preparation and action, goal setting and action plans support self-management. First, help clients identify long-term goals to aid motivation, for example, to be able to stay at work. Explain how ergonomics helps achieve this. Practicing with a therapist aids correct skill development, but continued home practice is essential for habit development. Help the person set a weekly action plan, including relevant short-term goals the person believes lead toward longer term goals. Short-term goals should state what, how much, when, how often, and the time frame. Plans must be achievable. Ask how confident the person is about achieving, on a scale of 0–10, each goal and the whole plan. If the answer is less than 7 for any or all, recommend the person review the plan to make it achievable. Failure reduces self-efficacy. Better to progress slowly and successfully. At the end of each session, help the person set an action plan until the next session. At the beginning of the next session, discuss progress toward meeting goals. If goals were not met, help problem solve about barriers.

Educational Approaches in Joint Protection

In the preparation and action phases, effective education techniques improve understanding and recall. Audiovisual aids are best kept simple. An A3 easel presenter portfolio (a table top presentation tool; e.g., see http://www.phillipsdirect.co.uk/a2-easel-presenter-portfolio-p-130.html), with preprinted sheets is cheap, informal, quick to set up, and very unlikely to go wrong. Group comments can be added to spare sheets. Help people remember by

- Using advance organizers: Before they come, send a booklet about ergonomics that they can read (e.g., the Arthritis Foundation's "Managing Your Pain" pages 15–17) (See Resources 39-1).

Resources 39-1

Patient and Professional Education

Arthritis Foundation

www.arthritis.org
Patient education brochures on conditions and self-management available for free download. Online store sells books with practical tips, e.g., "Good Living with . . ." Series (includes RA, OA, and FM). Branches in every state run exercise programs (e.g., *Tai Chi for Arthritis*, *Walk for Ease*, *People with Arthritis Can Exercise*, aquatic exercise) and organize arthritis self-management courses.

Arthritis Society of Canada

www.arthritis.ca
Includes sections about conditions and *Tips for Living Well*

American College of Rheumatology: Arthritis Health Professionals in Rheumatology

http://www.rheumatology.org
The clinical support section of the website includes standards of practice for rheumatology, bibliography of clinical guidelines and health assessments, and practice guidelines and patient resources. The education section includes access to some free educational materials.

American Occupational Therapy Association

www.aota.org
Patient education: *Tips for Living Life to the Fullest: Living with Arthritis* (2012).

Tai Chi for Arthritis

Self-help book

Lorig, K., & Fries, J. F. (2006). *The arthritis help book*. Cambridge, MA: De Capo Press.

- Simplification: Give a few key messages each session. Explain technical terms when necessary (e.g., inflammation). Use nontechnical words (e.g., bend rather than flex). Keep explanations short.
- Explicit categorization: Structure information to "tell them what you are going to tell them, tell them, and tell them what you told them." Summarize before and after each topic, and at the beginning and end of the session.
- Repetition: Ensure that key facts are repeated by paraphrasing. Ask the person to repeat back or paraphrase what he learned. Repetition is an important part of education for both facts and skills.

Psychomotor Skills Teaching Applied to Ergonomics

Ensure there is sufficient space, without obstacles. Check that your client(s) can see clearly. Move furniture, equipment, or people if need be. Have all the equipment you need to hand; be familiar with its use. Put anything not immediately required aside to avoid visual distraction. Explain why the skill is performed, its relevance to the client, objectives of the session, and how they will be participating. Teach skills using four steps:

1. Confidently demonstrate the whole skill at normal speed *without* commentary, providing a clear image of what is to be learnt, without distraction.

2. Demonstrate *with* commentary: break it down step-by-step. Use clear, *short* instructions. Too much information distracts.
3. Demonstrate whilst asking the person to tell you step-by-step what to do. Start/continue each step as a prompt if need be.
4. The person demonstrates the skill with commentary. Errors need correcting, but allow a few seconds for self-correction first. If not, provide prompts to identify errors. Tell the answer if the client is unsure.

This gives plenty of opportunity to watch and hear about new actions before doing it themselves. In a group, the last two stages can be shared amongst members (working in pairs or threes), each trying the skill in turn. Developing psychomotor skills helps clients successfully perform ergonomic actions correctly and integrate them into daily life. Repetition helps this. Simply knowing what to do and why does not necessarily lead to behavior change.

Teach skills gradually over three to four treatment sessions. Start with blocked practice of one part of an activity (i.e., repeating individual tasks such as opening a jar). Use self-monitoring. In RA and OA, highlight the hand limitations they already have (reduced grip strength, range of movement, any early deformities). Explain how deformities occur in RA and OA, e.g., forces on joints contributing to ulnar deviation in RA. Between sessions, ask them to self-monitor: watch movements during common

activities (e.g., making a meal, at work) as they normally do them. What forces occur? Is there aching, pain, or fatigue? Ask them to reflect and compare with ergonomic approaches they are learning. Could these help? In the second session, discuss their experience doing this. Often "the penny drops"; the clients begin to see the connection between ergonomic approaches and a reduction in pain and fatigue. Progress to whole practice, i.e., sequences of activities such as making a hot drink and snack meal, requiring more ergonomic methods to be integrated. OT facilities may mean practice is limited to cooking and household activities, but if possible, also try this process with work and leisure activities. Encourage the client to apply ergonomics in these in his or her action plan.

Physical Activity and Exercise

Ergonomic approaches are not used in isolation. Many with RA, OA, and FM have occupational performance problems because of reduced range of movement, muscle strength, and endurance. Exercise and physical activity are essential. Whilst tailored exercise programs are provided by physiotherapists, occupational therapists should explain the benefits of physical activity—how it reduces pain, improves fitness, and increases energy levels as muscle strength and aerobic capacity increase, and in RA and OA, how it helps protect joints as stronger muscles compensate for weakened ligaments. The occupational therapist helps clients to integrate physical activity into daily routines.

Occupational therapists should be able to confidently teach home exercise maintenance programs for range of movement, strength, and aerobic exercises, such as are described in widely available patient information booklets. Exercise programs should be recommended, such as the Arthritis Foundation's Walk with Ease program and the Tai Chi for Arthritis program (see Resources 39-1). People need advice tailoring exercise and activity to suit their changing ability and how to gradually progress, rather than overdoing it. People with FM especially should not do too much too soon, because sensitization means that incidence of delayed onset muscle soreness is high and can contribute to fear of exercising. Aerobic exercise programs are safe and effective in RA, OA, and FM. Those more physically active have less pain and fatigue, better function, and well-being (Busch et al., 2011; NICE, 2008, 2009). Refer to physical therapy for specialist advice.

Hand Exercises

Several trials demonstrate that exercise is effective in improving grip and pinch strength and hand function and reducing pain in RA. Two studies used intensive exercise (i.e., 10 repetitions, at least 15 minutes per day of resisted exercise using soft dough or therapeutic putty,

---

Procedures for Practice 39-4

A Home Hand Exercise Program

Find a comfortable position: support the arm to avoid shoulder aching. Warm up by moving the joints a little first and/or soaking in warm water for a few minutes. Exercise 3 days the first week, increasing repetitions and number of days over 2–4 weeks, to 10 repetitions most/every day.

Range of Movement

- Wrist extension/flexion
- Wrist pronation/supination
- Tendon gliding exercise
- Radial finger walk

Muscle Strength and Dexterity Exercise

Use a good handful of Play-doh® or therapeutic putty. Five minutes initially, gradually increasing to 10–15 minutes.

- Gently knead and squeeze
- Push fingers into dough and push out straight
- Pinch off dough with each finger/thumb in turn
- Roll into a sausage (two hands)
- Form a "ring doughnut" from the sausage. Put the fingers/thumbs in the hole; stretch out.
- Use an elastic band over fingers and thumb and stretch.
- Grip a 0.5-L (16.9-fl oz) drink bottle (with a "waist" filled with water or sand). Support the forearm. Lift bottle up and down slowly, first with palm facing down 10 times, and then with the palm facing up 10 times.

---

plus range of movement exercise). No adverse effects were reported (Brorsson et al., 2009; Ronningen & Kjeken, 2008). In hand OA, exercises can improve grip by up to 25% and reduce pain (Valdes & Marik, 2010). However, exercise must be sustained, otherwise the benefits are lost. A simple home program is described in Procedures for Practice 39-4 (see also Fig. 39-10). These exercises should be taught effectively, using the strategies discussed above to promote behavioral change. Exercise diaries and goal setting help people sustain exercising. Opportunities to remind people to restart, if they lapse, are essential.

Hand Orthoses

Splinting is used to

- reduce local inflammation
- reduce soft tissue and joint pain

FIGURE 39-10 Wrist exercise with a homemade weight.

- correctly position joints and improve joint stability
- improve hand function

Adherence to splint wear is variable and affected by belief in efficacy and quality of fit. People may believe splints cause muscle weakness and/or stiffness and therefore fear relying on them. An RCT demonstrated adherence with splint wear is significantly improved by how the therapist explains the splint's purpose, wear regimen, and whether he or she conducts a positive interaction with the client (Feinberg & Brandt, 1992). Hand exercises should be taught when providing splints, recommending the person does these most days.

Static Resting Splints

In RA, resting splints reduce localized pain and inflammation by providing support in an anatomically correct position at rest. They can be worn at night and/or during daytime rest periods. Trials give conflicting results. Adams et al. (2008) conducted an RCT, with 12-month follow-up, in early RA ($n = 116$). There were no significant differences in strength, hand function, or ulnar deviation progression as a result of using resting splints. However, by study end, adherence had reduced considerably. In contrast, Silva et al. (2008a), in an RCT with 3-month follow-up of 50 persons with established RA, identified significant improvements in pain, hand function, and grip and pinch strength. Adherence was good throughout the study. This suggests careful attention is needed to willingness to wear the splint and adherence. These splints are effective in established RA, but in early RA, acceptability may be less, or there may be only a short-term need until drug therapy reduces pain (Fig. 39-11).

Compression Gloves

Compression gloves can be prescribed for nocturnal pain in RA, OA, and FM and to reduce pain during daytime
FIGURE 39-11 A resting splint.

activities, because they are easily worn in activity. Several small RCTs indicate that gloves reduce pain and stiffness in established RA (McKnight & Kwoh, 1992; Oosterveld & Rasker, 1990). People with hand OA and FM also report reduced pain during night and day wear and improved function with day wear. There are no trials evaluating gloves in OA and FM.

Wrist Orthoses

Wrist orthoses are widely used in RA, and many designs are available. A close fit, not impeding MCP and thumb movement, is needed. They can be worn for nighttime pain relief if the person has wrist but not MCP or IP pain. Their main aim is to reduce torque during heavy tasks involving the wrist and to stabilize the wrist in a functionally effective position (i.e., 10°–15° of extension). RCTs show that wrist orthoses are effective in reducing hand pain (Kjeken, Moller, & Kvien, 1995; Veehof et al., 2008) but not improving grip strength or hand function. Their benefit is largely when being worn, and clients regularly report they are helpful for heavier activities, such as ironing, gardening, housework, and at work (Fig. 39-12).

Metacarpophalangeal Splints

MCP splints either are small palm-based splints or may also have a wrist and forearm component. They aim to

FIGURE 39-12 A wrist splint.

reduce medial force on the MCPs and maintain fingers in correct alignment. There is no evidence that they help prevent deformities because no trials have been conducted. One small study demonstrated that they maintained alignment and that function was easier in people with established RA with MCP deformities (Rennie, 1996).

Finger Splints

Swan-neck splints apply three-point pressure around the PIP joint to prevent PIP joint hyperextension and subsequent PIP flexion. They can be made or bought in thermoplastics or made in silver. The latter are more popular and adherence is better (Adams, 2010). Trials have demonstrated that they improve dexterity and hand function, although not pain or grip strength (van der Giesen et al., 2009; Zijlstra, Heijnsdijk-Rouwenhorst, & Rasker, 2004).

Thumb Splints

In RA and OA, thumb splints aim to reduce pain and improve function and grip. They may be a short, hand-based splint immobilizing the CMC joint only or a longer hand/forearm splint if pain extends to the wrist. A systematic review concluded that CMC joint splints for OA reduce pain and improve function and may help clients postpone or avoid surgery. Many prefer a short flexible splint to longer, more rigid versions (Valdes & Marik, 2010). A trial in RA identified that CMC splints significantly reduced pain (Silva et al., 2008b) (Fig. 39-13).

Effects of Combined Ergonomic and Exercise Interventions

Several RCTs evaluated combined interventions in RA. At 8-month follow-up, a 12-hour program of ergonomics, exercise, cognitive pain management, and relaxation, with monthly telephone follow-up, led to significant

FIGURE 39-13 A short carpometacarpal (CMC) splint.

improvements in pain, functional ability, and physical status (Masiero et al., 2007). At 1-year follow-up, the Lifestyle Management for Arthritis Programme (LMAP) (including ergonomics, exercise, and fatigue, pain, and stress management) led to significantly improved pain, functional and physical ability, self-efficacy, and psychological status compared to a group receiving standard arthritis education (Hammond, Bryan, & Hardy, 2008). In hand OA, at 1-year follow-up, a combined program of joint protection, hand exercises, and splinting led to significant improvements in pain, stiffness, and daily activities (Boustedt, Nordenskiold, & Lundgren, 2009).

Stress Management

Stress contributes to pain, fatigue, and poor psychological status. Managing stress is a key component for FM management especially and is often best addressed first. Explain the link between stress, pain, and fatigue and how stress can lower neurochemical levels, such as serotonin and noradrenaline, which help control sleep cycles and energy levels. In FM, these are already lowered, and stress makes the situation worse. Stress management methods help increase neurochemical levels. Effective stress reduction approaches include mindfulness therapy, relaxation, and CBT, combined with condition education (Glombiewski et al., 2010). Multimodal therapy is more effective. Undertaking additional training in such techniques can make a valuable contribution to OT, especially in FM.

Vocational Rehabilitation

Vocational rehabilitation (VR) can include

- job modifications or "accommodations" such as ergonomic changes (restructuring work tasks, assistive technology and adaptations, work station/place redesign, and splints)
- psychosocial and informational strategies (increasing confidence to ask for job modifications, work rights, statutory [imposed by law] VR service availability, and coping strategies)
- liaising with employers (about job and hours flexibility and better understanding of the condition), occupational health, and statutory services

Two OT studies in RA have demonstrated positive effects. An RCT with working people with RA ($n = 32$) randomized participants to both comprehensive occupational therapy and VR (work assessment, job modifications, help with daily living problems, ergonomic advice, splinting, and group education: provided over six to eight sessions) or a waiting list control group. At 6 months, self-perceived ability to manage self-care, work, and leisure, work instability, work satisfaction,

and pain significantly improved (Macedo et al., 2009) (see Evidence Table 39-1). A Canadian proof of principle study with people with RA ($n = 19$) evaluated a five-session group VR and self-management program plus an occupational therapy visit using the EATA to identify problems (Backman, Village, & Lacaille, 2008). At 1 year, 80% reported increased confidence in requesting job accommodations, 74% had requested at least one, and 71% of requests were implemented (Lacaille et al., 2008).

An RCT of a job-retention program with people with arthritis (RA, knee OA, systemic lupus erythematosus, or ankylosing spondylitis) led to significant reductions in job loss in the intervention group compared to the control group. The intervention group received two 1.5-hour individual VR sessions including a structured interview (the Work Experience Survey–Rheumatic Conditions [WES-RC]). Barriers were prioritized, potential solutions were discussed, and action plans were developed. Information on employment rights and guidance on disclosing arthritis to employers and asking for job accommodations were given (Allaire, Li, & La Valley, 2003). The intervention was provided by VR counsellors, but occupational therapists could provide a similar intervention.

CLINICAL OUTCOMES

The interventions described assist clients in adapting their lifestyle to improve self-management and occupational balance. Changing habits and routines is not easy. On average, adherence rates are about 50% for many interventions. Providing patient education about the condition, motivational interviewing, and counselling to help people prepare for change, followed by effective self-management education, takes time. But without doing so, we are wasting time if people do not follow the advice given. Delivering interventions effectively is a priority.

case example
Ms. B.: Preparing to Return to Work with Rheumatoid Arthritis

| | **Clinical Reasoning Process** | |
Occupational Therapy Assessment Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Ms. B. is 45 years old and has a 3-year history of rheumatoid arthritis (RA). She is stable on disease-modifying antirheumatic drugs (DMARDs). At her last 6-monthly rheumatology appointment, she complained of increasing right wrist, metacarpophalangeal (MCP), and shoulder pain (she is right handed) and pain in her feet. She is a full-time fourth-grade schoolteacher, and her work is affected, although she has not taken time off work. She lives in a first floor, one-bedroom apartment.	Understand the patient's diagnosis or condition	"Ms. B. has mild inflammatory RA affecting hands, feet, and shoulder. Her work problems might be walking around school because of foot pain, using a personal computer (PC), marking books because of hand pain, writing on the whiteboard because of her arm problems, and interacting with schoolkids because of fatigue."
	Know the person	"She enjoys teaching, wants to continue working, and is keen to help herself. A good candidate for self-management education and work rehabilitation."
Reason for Referral to Occupational Therapy Ms. B. was referred by her rheumatologist for assessment of hand function, help with work problems, and self-management education. Ms. B. wants to keep working full time.	Appreciate the context	"How much is she affected by fatigue? Does she have energy for leisure and social life?"
	Develop provisional hypotheses	"She is likely to do well as she is motivated to keep working, enjoys her job, and is keen to learn."

Assessment Process and Results

Ms. B.'s priority is work. She was assessed using the Work Environment Survey—Rheumatic Conditions (WES-RC) and an activity diary. Every day, she regularly uses an interactive whiteboard and PC, moves round the classroom helping small groups of children and bends to do so. She drives to work and has a full briefcase to carry to the car. She buys lunch at the school cafe. Work takes all her time and energy. She buys ready meals (although likes cooking) and has let her housework go. She does not like this but has supportive friends who help out. She spends weekends recovering, and the pain reduces, but she is often still tired. Her sleep is disturbed by hand pain at night. Her pain and fatigue is much less during school vacations. The pain, fatigue, and having given up some leisure activities gets her down at times, but teaching helps keep her positive.

Physical examination of Ms. B.'s hands, wrist, shoulder and feet (using the gait arms legs spine [GALS]) and tender and swollen joint count showed a mild inflammatory process and no deformity. Bilateral grip strength was 19 kg (norm is 28 kg). On a Visual Analog Scale (VAS) for pain and for fatigue, Ms. B. scored 7 out of 10 for both after workday.

Ms. B. took the Evaluation of Daily Activity Questionnaire (EDAQ) home to complete (see Assessment Table 39-1). She had problems including, e.g., cooking (viz., opening jars, peeling vegetables, lifting pans), cleaning (viz., vacuuming), handicrafts, and going out socially.

Consider evaluation approach and methods	"Her joint swelling wasn't too bad, but poor grip strength, pain, and fatigue scores helped me understand why things are difficult. The activity diary showed which activities are painful, she doesn't rest much in the day, sleeps poorly, and doesn't do a lot at weekends. The WES-RC and EDAQ identified activities she has difficulty with."
Interpret observations	"Her joint pain and inflammation seem aggravated by resisted activities, regular shoulder elevation using the whiteboard, and regular standing. Overuse is a likely cause as at weekends and vacations she has less pain and fatigue. Her mood is likely to improve if her job is made easier, and she can do more things in the home and during her leisure time."

Occupational Therapy Problem List

1. Right wrist, MCP, shoulder, and foot pain worsen during the work day, especially using the interactive whiteboard and PC and standing a lot.
2. Difficulty with home maintenance.
3. Difficulty preparing meals.
4. Limited leisure activities.
5. Poor sleep because of nocturnal hand pain.

Synthesize results	"If Ms. B. continues to overdo activity and push through pain at work, it may get more difficult for her to continue working full time, look after her apartment, and cook for herself. Her leisure and social life are already seriously affected."

Occupational Therapy Goal List

1. Use ergonomic approaches to reduce wrist, MCP, shoulder, and foot pain during work, home, and meal preparation activities.
2. Use fatigue management (activity pacing) to reduce fatigue.
3. Wear right wrist orthosis during heavier activities and compression glove at night to reduce pain.
4. Perform hand exercises daily to improve grip strength and endurance.

Develop intervention hypotheses	"It can be difficult using ergonomic principles. Focusing specifically on her goals and helping her problem solve should help her cope in new situations as they arise. Educating Ms. B. about the positive effects of hand exercises and orthoses will help her understand why these help."
Consider the evidence	"She wants to keep teaching, so she is more likely to want to learn about making work and daily activities easier. She seems trapped in a cycle of fatigue, pain, and overwork and needs help tackling problems step by step, to increase her self-efficacy to manage RA. She is doing some things to help herself (**preparation** stage of change)."
Select an intervention approach	"I think I will use ergonomic and self-management education using cognitive-behavioral and self-efficacy enhancing approaches to facilitate change."
Consider what will occur in therapy, how often, and for how long	"Ms. B. will be seen in occupational therapy (OT) as an outpatient for five 1-hour sessions over 5 weeks. The sessions will focus on ergonomic teaching, problem solving, self-management, and provision of orthoses and hand exercises."

Intervention

1. Identify which activities are most important to Ms. B. to accomplish each day at work, home, and in the community. Identify long-term goals and set priorities together; teach how to action plan short-term goals.
2. Provide ergonomic education emphasizing self-analysis of activity, problem solving and practicing alternative methods to reduce joint stress. Practice each session.
3. Explore alternative equipment to operate the interactive whiteboard to reduce shoulder movement (e.g., light pens); alternative mouse and keyboard designs, use of voice-activated software to reduce keyboarding time.
4. Explore adapted equipment for carrying heavy briefcase: e.g., wheeled briefcase, folding hand cart. Discuss use of online assessment with kids to reduce marking and getting books home.
5. Explore using a stool with wheels around classroom to scoot between tables and save standing/bending.
6. Discuss fatigue management: pacing activities, microbreaks. Discuss goals to practice and how to fit into routines.
7. Review meal preparation activities; teach ergonomic methods; and review equipment available in shops to reduce wrist and MCP stress, e.g., easy jar and can openers, Good Grip® knives.
8. Review driving: padded steering wheel, hand and arm positioning.
9. Identify and fit appropriate right wrist splint, fit right compression glove. Explain wearing time of orthoses and purpose. Train in appropriate donning, doffing, and general care.
10. Teach intensive hand exercise program (range of movement and strength): practice and grade up weekly.
11. Review adapative equipment to help with handicrafts.

Assess the patient's comprehension	"We easily identified long- and short-term goals, and she is used to the concept of action planning. Finding ergonomic approaches makes sense to her."
Understand what she is doing	"Ms. B. is finding it hard to break habits during classroom activities; wonders how the kids will respond."
Compare actual to expected performance	"Using ergonomic methods and equipment, wearing glove at night and wrist splint at home (but not work), and finding pacing hard at school, pain and fatigue scores were reduced to 4 out of 10 at the end of the day. Exercise was well tolerated, and grip increased to 23 kg."
Know the person	"Ms. B. is well motivated and has made a number of changes. She is willing to continue to change."
Appreciate the context	"Pacing is difficult in school; I recommend she adds some 'quiet time' work-alone activities to most lessons (5 minutes), e.g., doing online tests that automatically score. She can take microbreaks while the children are completing these activities."

Next Steps

Discuss continuing to set weekly action plans. Schedule review appointment in 6 weeks to evaluate effect of changes at work and home, and give opportunity to raise problems not solved herself. Discuss how managing with pacing at school and attitude to splint wearing. Telephone after further 4 weeks to discuss progress. Then discharge and recommend that she contact occupational therapy via rheumatology if she needs help in future.

Anticipate present and future patient concerns	"Possible continuing problems are pacing and accepting wearing the wrist splint at school. I will encourage Ms. B. to focus on how pacing will help her keep going for longer and be able to do more for the kids in the long run."
Analyze patient's comprehension	"Ms. B. understands all of the concepts well but still struggles to accept pacing because she always puts the children's needs first."
Decide whether he or she should continue or discontinue therapy and/or return in the future	"A review appointment in 6 weeks will encourage her to keep setting action plans and review progress. The final follow-up call will be to check whether changes have been embedded into routines."

Clinical Reasoning in Occupational Therapy Practice

Activity Analysis: Cooking

Ms. B. does very little cooking, mostly relying on ready meals and eating at the school cafeteria. The therapist taught ergonomic approaches during cooking skills but also wants Ms. B. to be able to apply ergonomic principles to finding solutions for herself in the future. How can she teach problem-solving skills? What tasks are involved in the activity of making a simple meal (soup and cheese on toast)? How can each task be made easier using ergonomic principles?

case example

Mrs. S.: Activities of Daily Living and Instrumental Activities of Daily Living with Osteoarthritis

	Clinical Reasoning Process	
Occupational Therapy Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Mrs. S. is 65 years old and lives with her husband in their own home. They owned and operated a small café for 25 years until they had to retire 5 years ago because the café site was redeveloped. Mrs. S. has bilateral knee pain and now can only walk short distances until she has to sit or lie down. She has pain in the right carpometacarpal (CMC) joint, especially when cooking, doing housework, and gardening (all of which she used to enjoy), but her husband now helps a lot. She has been having difficulty using the bath and toilet. She does not go out much. They have no children.	Understand the patient's diagnosis or condition Know the person	"Her medical records identify x-ray changes of joint narrowing in both knees, right CMC joint, and Heberden's nodes, with a diagnosis of osteoarthritis (OA). She is overweight (14 stones [196 pounds]), which will make her knee pain worse." "Mrs. S. used to be a sociable, busy person in the café. She now feels her arthritis has taken over and has given up many activities she enjoyed."
Reason for Referral to Occupational Therapy Mrs. S. was referred by her family doctor because of her difficulties in personal care, home activities, and gardening.	Appreciate the context Develop provisional hypotheses	"Her doctor thinks her pain is worse than expected considering the x-ray changes. He thinks psychosocial factors are contributing. He has advised about weight loss and exercise, but Mrs. S. does neither." "Her pain is being made worse by low mood (from being forced to retire, pain, and helplessness), being overweight (putting extra stress on knee joints), deconditioning, lack of physical activity and use of ergonomic approaches, and poor occupational balance."
Assessment Process and Results Mrs. S. was tearful during the initial interview. The Canadian Occupational Performance Measure (COPM) was used. (She did not have the concentration to do a self-report questionnaire). She identified her five most important activities as using the bathroom (bath and toilet), cooking, gardening, walking more, and getting out socially. She rated her performance between 2 and 4. She felt that there was little she could do to control pain and that she is relying too much on her husband (who has heart problems) because he helps lift her out of the bath, cooks, and does the housework. On a Visual Analog Scale for knee pain, her scores after walking short distances are 8 out of 10; her hand pain was 8 out of 10; her QuickDASH (Quick Disabilities Arm Shoulder Hand) hand function score was 70.5 out of 100 (see Chapter 9); right pinch strength (B&L® pinch gauge) was 1.5 (norm is 4.5 kg).	Consider evaluation approach and methods Interpret observations	"Mrs. S.'s low mood is the priority. She wants to do more but feels helpless. With help, she could identify goals. Her concern about overburdening her husband (who has health problems) is a motivator for change." "She doesn't know where to start without making the pain worse. She fears exercise and believes doing more will make her joints worse. "Many physical problems are due to poor grip and pinch strength and thumb/hand pain and reduced lower limb strength and endurance."
Occupational Therapy Problem List 1. Difficulties in activities of daily living (ADL) (toilet and bathing) because of knee pain, reduced mobility, and poor grip. 2. Difficulty with cooking because of poor grip and standing tolerance. 3. Difficulty with gardening: poor grip and standing tolerance, difficulty bending and kneeling, lack of stamina. 4. Reduced mobility: deconditioned and fearful of consequences of physical activity. 5. Limited social activities: because of low mood and poor mobility (was a very social person before retirement). 6. Lack of knowledge of self-management approaches: pain management, ergonomics, and physical activity.	Synthesize results	"If Mrs. S. continues as she is, her psychological and physical problems will get worse, her husband will have increasing difficulties, and he could have a heart attack."

Occupational Therapy Goal List

1. Use ergonomic approaches and adaptive equipment during personal care (toilet, bath), cooking, gardening and any other valued activities.
2. Increase occupational balance: engaging in more social, leisure, and community activities.
3. Perform hand exercises most days to increase hand muscle strength.
4. Increase physical activity to increase upper and lower limb muscle strength and endurance.
5. Wear a right CMC splint to reduce pain during activity.

Intervention

Session 1:

1. Motivational interviewing: explore pros and cons of changing/not changing. ("I am confident I can move her to preparation as her concern about husband's health is already beginning to overtake her own fears.")
2. Explain about OA and self-management, i.e., exercise and physical activity will not damage joints; can manage pain through ergonomic and other approaches.
3. Assess for toilet and bath aids; practice techniques.
4. Practice some ergonomic approaches in making a hot drink.
5. Home visit: fit bathroom aids and practice; do a kitchen and gardening assessment; discuss with Mrs. S. and husband how he can help Mrs. S. make changes; explore social, leisure, and physical activities they might both be interested in.

Sessions 2–5:

6. Practice ergonomic approaches and use of ergonomic equipment during kitchen activities (e.g., jar openers, Good Grip® knife and vegetable peeler, perch stool) and gardening activities (easy kneeler; long handled tools). Provide booklets with ideas on making house and garden activities easier.
7. Discuss activity pacing and help set weekly goals to gradually increase activity duration (household, gardening, and leisure activities).
8. Educate about importance of physical activity in reducing pain and improving muscle strength. Introduce to a walking program (loan pedometer to monitor activity). Introduce to Tai Chi (practice warm-up twice for 10 minutes). Set weekly goals to increase physical activity and locate a Tai Chi class to join.
9. Teach intensive hand exercise program (range of movement and strength; progress gradually)
10. Identify and fit appropriate CMC splint: explain wearing time and purpose. Train in donning, doffing, and splint care. Include splint use when practicing activities.

Develop intervention hypotheses	"Mrs. S. is stuck in a cycle of pain, fear about making it worse, and unhappiness because of not doing activities she enjoys. We'll have to take things step by step, in valued activity–related goals, and explore new activities. I will help her see change is possible."
	"She was forced to retire, she never planned her retirement, and OA got in the way of doing so. Her low mood is due to poor occupational balance, social isolation, fear, and pain."
Select an intervention approach	"I will use motivational interviewing to enhance change and educate about condition/self-management. As Mrs. S. moves to preparation/action, I will start ergonomic and self-management education using cognitive-behavioral and self-efficacy enhancing approaches."
Consider what will occur in therapy, how often, and for how long	"Mrs. S. will be seen in occupational therapy as an outpatient for five 1-hour sessions over 8 weeks, plus a home visit after the first session."
Assess the patient's comprehension	"Mrs. S. was surprised her pain was not made worse when trying ergonomic approaches and hand exercises and that the thumb splint made a difference."
Understand what she is doing	"She is doing more now; looks forward to Tai Chi (husband goes too) and chatting to class in the leisure center café after. She says it 'Feels like the old times.' Two class members used to go to their café!"
Compare actual to expected performance	"Hand and mobility pain scores improved to 4 out of 10, QuickDASH to 30.8, and pinch strength to 2.5 kg. Average daily steps increased from 2,000 to 4,500."
Know the person	"She is keen to learn more methods and is getting more confident. She is now looking for social groups they can join."
Appreciate the context	"Her husband is very supportive and keen to do things with his wife (e.g., Tai Chi). He read the booklets and is making changes to make things easier at home. He loves that Mrs. S. is more like her old self again."

Next Steps

Discuss with Mrs. and Mr. S. about setting weekly action plans to help continue making changes. Schedule a telephone review in 4 weeks to discuss progress, plans for future, and joining social group(s). Refer to physical therapy for knee exercises. Then discharge and recommend that they contact occupational therapy via family doctor if they need help in the future.

Anticipate present and future patient concerns	"Mrs. S. could lapse if her knee pain got worse or her mood lowers again (e.g., if husband's health got worse). Developing a social network will help provide support in future as they have no family."
Analyze patient's comprehension	"Her apprehension initially meant needing to start slowly and ensure she was 'on board.'" But once she decided to change, she gained confidence with my and her husband's support."
Decide whether he or she should continue or discontinue therapy and/ or return in the future	"A review call will give Mrs. and Mr. S. a goal to look forward to; they have been keen every week to tell me about progress. I am confident they will continue after discharge."

Summary Review Questions

1. List the primary differences between RA and OA.
2. Describe joint problems that can lead to diminished occupational performance for people with RA and OA
3. Besides joint problems, what other issues affect occupational performance for people with RA?
4. What are the major symptoms of FM that lead to diminished occupational performance?
5. What assessments can be used to evaluate occupational performance for people with RA, OA, and FM?
6. Describe ergonomic approaches in RA to prevent or restore occupational performance.
7. Describe a home hand exercise program suitable for people with RA or hand OA.
8. Name three resources for people with RA, OA, and FM to find alternate methods and assistive devices to improve occupational performance.
9. How does splinting help people with RA and OA improve occupational performance?
10. Describe strategies the OT can use to help people increase self-management.

Glossary

Allodynia—Pain in response to a normally nonpainful stimulus.

Bouchard's nodes—Hard, bony outgrowths at the PIP joints caused by OA.

Boutonniere deformity—Flexion of the PIP joint and hyperextension at the DIP joint.

Chronic fatigue syndrome—A condition characterized by persistent fatigue (lasting more than 6 months) not caused by ongoing exertion nor relieved by rest or known to be caused by other medical conditions. There can be multiple causes.

Disease-modifying antirheumatic drugs (DMARDs)—Drugs that affect the immune response or suppress the disease process (e.g., methotrexate).

Energy conservation techniques—Breaking up physically active periods with rest periods, resulting in increased amount of physical activity (Cordery & Rocchi, 1998).

Fibrillation—The initial degenerative changes in OA, marked by softening of the articular cartilage and development of vertical clefts between groups of cartilage cells.

Heberden's nodes—Hard, bony outgrowths at the DIP joints caused by OA.

Hyperalgaesia—Increased response to painful stimuli.

Joint protection techniques—The application of ergonomic principles in daily activities, work, and leisure to reduce internal and external stress on joints and soft tissues.

Mallet finger deformity—Deformity resulting from damage to the extensor tendon at the DIP joint.

Patient-reported outcome measures—Self-reported measures facilitating insight into the way patients perceive their health and the impact that treatments or adjustments to lifestyle have on their abilities and/or quality of life.

Stress system—The complex interplay between the nervous system and stress hormones. The hormonal system is known as the hypothalamic-pituitary-adrenal axis, a feedback loop by which signals from the brain trigger the release of hormones needed to respond to stress.

Swan-neck deformity—Hyperextension of the PIP joint and flexion at the DIP joint.

Synovitis—Inflammation of the synovial membrane (which lines synovial joint capsules, the function of which is to produce synovial fluid, which lubricates joints).

Volumetry—A water displacement measure of hand volume, conducted by inserting the hand to a specified depth in a measuring cylinder containing a specified amount of water.

Z deformity of the thumb—hyperextension of the interphalangeal joint and flexion of the MCP joint of the thumb.

Burn Injuries

Monica A. Pessina and Amy C. Orroth

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe differences between superficial, superficial partial-thickness, deep partial-thickness, and full-thickness burn injuries.
2. Explain the rationale for splinting and positioning programs for patients with burn injuries.
3. Outline occupational therapy treatment techniques for each phase of burn recovery.
4. Give examples of using activity as a modality in the acute and rehabilitation phases of burn recovery.
5. Describe potential complications and treatment strategies for hand burns.
6. Discuss the effects of a burn injury on a patient's psychosocial functioning.

pproximately 450,000 burn injuries that required medical treatment occurred in the United States in 2011, resulting in 3,000 fire- and burn-related deaths (American Burn Association [ABA], 2011). Thermal damage to the skin can be caused by fire, contact with a hot object or hot liquid (scald burn), radiation, chemicals, or electricity. According to statistics from 2001 to 2010, the majority of burns in adults occur in males (70%); the most common cause of burns is fire/flame (44%); and most burns occur in the home, followed by injuries in the workplace (ABA, 2011). These data also show that hot food and liquid spills are the most common source of burns to children. Approximately one-half of patients with burn injuries are admitted to regional burn centers designated by the American Burn Association; the remainder are treated at local or regional hospitals (ABA, 2011). Therefore, every occupational therapist should understand the principles of care and rehabilitation of patients with burn injuries. Treatment of these injuries requires a comprehensive approach by a qualified burn treatment team, including a skilled occupational therapist. This chapter explores the unique role of occupational therapy in treatment of burn patients, from the initial injury to the patient's return to independent function. Topics include various phases of burn rehabilitation, scar management, psychosocial issues, and reconstructive surgery. We hope to convey the unique and rewarding aspects of working with patients with burn injuries.

BURN CLASSIFICATION

In the past, burn depth was classified as first, second, or third degree. Today, the preferred classification system more accurately describes the level of cellular injury. The terms in use are superficial, superficial partial-thickness, deep partial-thickness, and full-thickness. Burns typically have mixed depths, which necessitates that the burn team carefully assess the appearance and progress of each area of the wound site. Disruption of any portion of the skin has the potential to interfere with its normal functions, which include temperature regulation, excretion, sensation, vitamin D synthesis, and acting as a barrier against infection and dehydration (Falkel, 1994). Occupational therapists may treat patients with all levels of thermal injury. It is important to differentiate among the classifications to plan appropriate intervention.

Superficial Burns

Superficial burns damage cells only in the epidermis (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994) (Fig. 40-1). These injuries are painful and red. With a well-nourished and intact epithelial bed at the base of the hair follicles, these injuries heal spontaneously within approximately 7 days and leave no permanent scar (Malick & Carr, 1982).

Superficial Partial-Thickness Burns

Superficial partial-thickness burns damage cells in the epidermis and the upper level of the dermis (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). The most common sign of a superficial partial-thickness burn is intact blisters over the injured area (Staley, Richard, & Falkel, 1994). Hair follicles remain intact, because these are found in the deeper layers of the dermis. In addition, these injuries are painful because of the irritation of the nerve endings in the dermal layer. Superficial partial-thickness burns heal spontaneously within 7–21 days and leave minimal or no scarring (Staley, Richard, & Falkel, 1994).

Deep Partial-Thickness Burns

Deep partial-thickness burns cause cell injury in the epidermis and severe damage to the dermal layer (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). These injuries appear blotchy, with areas of whitish color interspersed throughout the wound, which is the result of damage to the blood vessels in the dermal layer (Malick & Carr, 1982). The injury site is painful. Pressure sensation is intact, but light-touch sensation is diminished because of the relative locations of receptors for these modalities (Staley, Richard, & Falkel, 1994). Spontaneous healing of deep partial-thickness burns is sluggish (3–5 weeks) because vascularity in the dermal layer is impaired. Therefore, the risk of significant scarring is increased (Staley, Richard, & Falkel, 1994). For this reason, deep partial-thickness burns are often grafted to expedite healing and minimize scarring.

Full-Thickness Injury Burns

In a full-thickness injury, both the epidermis and the dermal layer are destroyed (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994). These wounds appear white or waxy because of the underlying adipose tissue and are inherently insensate because of the complete destruction of the dermal nerve endings (Malick & Carr, 1982). Full-thickness burns require surgical intervention, such as skin grafting (Malick & Carr, 1982; Staley, Richard, & Falkel, 1994), because there are no dermal elements to support the regrowth of epithelial tissue. Some burns, such as electrical burns, may damage structures below the dermis, including subcutaneous fat, muscle, or bone.

RULE OF NINES

The rule of nines is a commonly used technique to determine burn size in adults (Fig. 40-2). For example, if an adult received a burn that included the anterior and posterior surfaces of his right arm (9%), his anterior head and neck (4.5%), and his anterior chest (18%), then his total body surface area (TBSA) affected would be 31.5%. To determine the TBSA of a burn injury in children and infants, a modification of this technique, the Lund-Browder chart, is used. In addition, in
Figure 40-1 Cross section of the skin. (From Willis, M. C. [1996]. *Medical terminology: The language of health care*. Baltimore: Williams & Wilkins.)

both children and adults, it is a widely used estimate that the palmar surface of one's hand is approximately 1% TBSA. The burn percentage TBSA is used for the following:

- Calculating nutritional and fluid requirements
- Determining level of acuity to establish the level of medical treatment needed (i.e., admission to an intensive care unit)
- Classifying patients for use of standardized protocols

PHASES OF BURN MANAGEMENT AND REHABILITATION

Identifying specific phases of burn management helps to describe the role of occupational therapy for patients with burn injuries. These include the emergent, acute, and rehabilitation phases. Each of the phases, along with accompanying occupational therapy considerations, are described.

Emergent Phase

The emergent phase of a burn injury is considered to be from initial injury to approximately 72 hours after the burn (Grigsby deLinde & Miles, 1995).

Medical Management

During the emergent phase, the medical team attempts to stabilize the patient. This may include fluid resuscitation, establishment of adequate tissue perfusion by means of mechanical ventilation, and achievement of cardiopulmonary stability. Associated injuries, such as fractures, are also evaluated and treated during this time.

Inhalation Injury. An important consideration in the emergent phase is the possibility of an inhalation injury. Damage to the upper airway from inhaling either smoke or noxious gases results in an inhalation injury. This damages the respiratory epithelium and can impair gas exchange. Inhalation injuries can significantly increase mortality rate (Cioffi & Rue, 1991). Singed eyebrows, soot around the nares, and facial edema are indications of an inhalation injury (Cioffi & Rue, 1991). Diagnosis is confirmed by analysis of arterial blood gases, chest radiographs, and bronchoscopy. In addition, edema can quickly develop in the airway and constrict breathing. Therefore, patients with significant burn injuries are usually intubated (placed on mechanical ventilation) to maintain an open airway until the risk of airway closure caused by edema has diminished.
Figure 40-2 Rules of nines. (Reprinted with permission from Malik, M. H., & Carr, J. A. [1982]. *Manual on management of the burn patient*. Pittsburgh: Harmarville Rehabilitation Center.)

Escharotomy and Fasciotomy. Circulation can be compromised when burn injuries encircle a body segment. This is due to the inelasticity of the eschar (burned tissue) combined with increased internal pressure within fascial compartments. Local increase in pressure in the extremities compresses blood vessels and reduces blood flow (Sheridan et al., 1995). Symptoms of increased compartmental pressure include paresthesias, coldness, and decreased or absent pulses in the extremities. In the trunk, inelastic eschar can act as a corset, limiting lung expansion and preventing adequate respiration. In both cases, surgical intervention (escharotomy and/or fasciotomy) is required to relieve the pressure and prevent tissue death. An escharotomy is a surgical incision through the eschar, whereas a fasciotomy is a deeper incision extending through the fascia. Unless exposed tendon is present, the escharotomy region can be mobilized during therapy (Grigsby deLinde & Miles, 1995).

Dressings. After the initial burn assessment, the nursing staff applies dressings. The functions of dressings include protecting the wound against infection, maintaining contact between the topical agent and the wound, superficially debriding the wound, and providing comfort for the patient (Grigsby deLinde & Miles, 1995). Debriding is the

removal of devitalized tissue from the wound site. Types of topical agents vary widely, although most are wide-spectrum antimicrobials. Examples include mafenide acetate (Sulfamylon), silver sulfadiazine (Silvadene), and 0.5% silver nitrate solution (Duncan & Driscoll, 1991). As a rule, the nursing staff changes the dressings; however, by periodically participating in dressing removal and application, the occupational therapist makes opportunities to view the healing wounds. This allows the therapist to monitor healing and adjust the therapy program accordingly.

Infection Control. One of the functions of the skin is to act as a barrier against infection (Falkel, 1994). Therefore, a patient with a burn injury is susceptible to infection. It is essential that all staff, family, and visitors adhere to infection control procedures. This includes frequent hand washing, use of gloves when necessary, and avoiding cross-contamination through instruments and equipment (Procedures for Practice 40-1).

Procedures for Practice 40-1

Hand Hygiene

Proper hand hygiene, either by use of traditional hand washing with soap and water or the use of hand disinfectants, is essential in the reduction of infections for you and your clients. A study by Kampf and Löffler (2009) noted that nosocomial infection rates can be reduced as much as 40% by proper hand hygiene. A nosocomial infection is a hospital-acquired infection.

When to Perform Proper Hand Hygiene

- Before and after all patient contact
- After removing gloves used to perform a task involving contact with blood, body fluids, or infectious material
- After handling possibly infectious devices or equipment
- Before and after preparing and eating food

General Procedure for Hand Washing

- Dispense paper towel
- Push up long sleeves
- Wet hands and wrists
- Apply antiseptic solution or soap
- Use friction to clean between fingers, under nails, and palms and backs of hands; effective scrubbing lasts at least 20–30 seconds
- Rinse hands and towel dry
- Turn off faucet using paper towel
- Dispose of paper towel in appropriate trash barrel
- Waterless hand cleaner can be used if hand washing facilities are available

Contracture Formation

Patients with burn injuries are at significant risk for contractures. Wound contracture, a normal physiological response to an open wound (Greenhalgh & Staley, 1994; Jordan, Daher, & Wasil, 2000) combined with prolonged immobilization, creates an opportunity for permanent soft tissue contracture. Contractures tend to occur in predictable patterns, usually flexed, shortened positions (e.g., elbow flexion, shoulder adduction, or knee flexion) and can considerably limit the patient's ability to perform activities of daily living (ADL). For example, decreased elbow extension may limit the patient's ability to dress.

Occupational Therapy during the Emergent Phase

During the emergent phase, the occupational therapist performs a screen of the patient's needs. A full evaluation is deferred until after the emergent phase, when the patient is more medically stable. During the screen, the therapist notes the distribution of the burn and which joints are involved. This allows the occupational therapist to establish an appropriate splinting and positioning program. It is also during this time that the therapist begins collecting information regarding the patient's functional status before admission, including interests and social supports.

Occupational therapy intervention in the emergent phase focuses on the prevention of early contracture formation through the use of splints and positioning programs. It is ideal to initiate occupational therapy intervention as early as 24–48 hours after burn, because collagen synthesis and contracture formation begin during the initial response to thermal injury (Dewey, Richard, & Parry 2011; Jordan, Daher, & Wasil, 2000).

Splinting. Ideally, splints are fabricated and applied in the initial visit, and a positioning program is established and communicated to the team. Table 40-1 describes common contracture patterns, antideformity positions, and appropriate splints. Generally, any joint involved in a superficial partial-thickness injury or worse has the potential for contracture and is usually splinted. Splint wearing times are determined by the patient's ability to use the involved extremity. That is, a decrease in active movement indicates the need for increased splint wearing time. For example, a heavily sedated patient cannot perform active movement and therefore requires splinting at all times except for therapy and dressing changes. An alert patient who can use his or her affected extremity for functional tasks, such as self-feeding or prescribed exercises, may require the use of splints only at night. Splints are applied over the burn dressing and secured with either gauze wrap or Velcro® straps. Although splinting is considered the standard of care in burn treatment, there is a paucity of evidence to support its use (Richard & Ward, 2005). Validation of the practice of splinting for the prevention of contracture is a research area that may be addressed by occupational therapists in the future.

Positioning. Antideformity positioning, which is used as an adjunct to splinting for prevention of contractures, can be initiated in the first visit. For example, if a patient is

---

Table 40-1 **Anticontracture Positioning by Location of Burn**

Location of Burn	Contracture Tendency	Anticontracture Positioning and/or Typical Splint
Anterior neck	Neck flexion	Remove pillows; use half-mattress to extend the neck; neck extension splint or collar
Axilla	Adduction	120° abduction with slight external rotation; axilla splint or positioning wedges; watch for signs of brachial plexus strain
Anterior elbow	Flexion	Elbow extension splint in 5°–10° flexion
Dorsal wrist	Wrist extension	Wrist support in neutral
Volar wrist	Wrist flexion	Wrist cock-up splint in 5°–10° extension
Hand dorsal	Claw hand deformity	Functional hand splint with MP joints 70°–90°, IP joints fully extended, first web open, thumb in opposition (safe position; see Chapter 37)
Hand volar	Palmar contracture Cupping of hand	Palm extension splint MPs in slight hyperextension
Hip-anterior	Hip flexion	Prone positioning; weights on thigh in supine; knee immobilizers
Knee	Knee flexion	Knee extension positioning and/or splints; prevent external rotation, which may cause peroneal nerve compression
Foot	Foot drop	Ankle at 90° with foot board or splint; watch for signs of heel ulcer

unable to be fitted with a custom wrist extension splint, supporting the hand on a rolled pillow can, at least temporarily, maintain appropriate joint position. Elevating the upper extremities can also help to minimize upper extremity edema. Elevation can be done with foam wedges, pillows, or specialized arm troughs attached to the bed. A risk of upper extremity elevation is the potential for brachial plexus strain. Symptoms of brachial plexus strain include tingling, numbness, and cold fingers.

Acute Phase

The acute phase begins after the emergent phase and continues until the wound is closed, either by spontaneous healing or skin grafts (Grigsby deLinde & Miles, 1995). The acute phase can last several days to several months, depending on the extent of the burn and the amount of grafting required. For example, a patient with a 10% TBSA may have an acute phase of 1 week, during which the patient is mobile and undergoes one excision and grafting procedure. However, a patient with a 70% TBSA burn may be in the acute phase for several weeks, during which the patient is in an intensive care unit and undergoes many grafting procedures to close the wounds.

Support and Psychosocial Adjustment in the Acute Phase

All patients with burn injuries, regardless of age, exhibit some of the same psychological responses, including withdrawal, denial, fear of death, regression, anxiety, depression, and grief (Wright, 1984). In addition, various factors can influence a burn patient's psychological status. These include emotional trauma arising from the hospital stay, the length of the hospital stay, adjustment to physical changes, adjustment to others' reactions, and location and depth of the burn injury (Baker et al., 1996; LeDoux et al., 1996). The psychosocial challenges of burn patients vary as the patient moves through each stage of physical recovery (Weichman & Patterson, 2004). Patients in the acute stage deal with issues of depression and anxiety and may begin to exhibit signs of both acute and post-traumatic stress disorder. Also at this time, any preinjury psychopathology may become more apparent (Weichman & Patterson, 2004).

LeDoux et al. (1996) state that the burn team can foster healthy coping strategies while working with the burn patient by using these techniques:

1. Identify strengths that each patient can emphasize, reminding him or her of the strength already involved in surviving a painful and frightening experience.
2. Validate sadness and fear.
3. Assist patient to achieve goals; this helps to show hope for the future.
4. Instill a belief that the patient can succeed.

Team Communication

Communication with all members of the team, including the patient and the patient's family and/or support system, throughout hospitalization is essential. During this acute phase, collaboration between the occupational therapist and the burn team is essential for several reasons, including the following (Pessina & Ellis, 1997):

1. Alerting the team to developing contractures and response to therapeutic intervention.
2. Planning for perioperative splinting.
3. Clarifying range-of-motion orders based on graft integrity.
4. Teaching the team about environmental modifications or communication systems.
5. Advocating on the patient's behalf regarding eventual outpatient needs.

Medical Management

Skin grafting, which occurs primarily in the acute phase, is required when the dermal bed is sufficiently destroyed to prevent or significantly impair spontaneous regrowth of the epithelial tissue (Grigsby deLinde & Miles, 1995). If reepithelialization of the burn site has not occurred within 14 days of the injury or is not expected, grafting would be considered (Kagan & Warden, 1994). Skin grafting is generally performed for all full-thickness burns and for large, deep partial-thickness burns. Skin grafting entails both excision of necrotic (dead) tissue and the placement of skin or a skin substitute over the wound bed.

Types of Grafts. A variety of grafting procedures are available to the burn team. According to the size of the burn and the medical stability of the patient, the team may opt to use one or more of the graft types described next.

Autografts. Skin harvested from an unburned area of the patient is an autograft. Split-thickness autografts, the most frequently used, are taken at the level of the mid-dermis (Institute for Healthcare Quality [IHQ], 1997; Staley, Richard, & Falkel, 1994). Donor sites are ideally selected for the best match of color and texture to the affected area. As donor sites produce mild scarring, their location, when possible, is in an inconspicuous site, such as the upper thigh. The harvested skin can be left as a solid sheet (sheet graft) or perforated to increase surface area (meshed graft) (Staley, Richard, & Falkel, 1994). Meshing allows the surface area of the harvested skin to cover up to four times the original area. Both sheet and meshed grafts have advantages and disadvantages. A sheet graft has the best cosmetic outcome and is thus preferred for the face and hands (Hazani, Whitney, & Wilhelmani, 2012). Infection and the development of hematoma under a sheet graft, however, can cause complete graft loss and

require regrafting. A meshed graft, although less cosmetically appealing (the meshed pattern is retained permanently), covers large areas when the donor site is limited. In addition, meshed grafts allow drainage of blood and exudate, which prevents hematomas and improves graft adherence (Hazani, Whitney, & Wilhelmani, 2012).

Temporary Grafts. In cases of extensive burn injuries, where there is not sufficient donor skin to cover all of the affected area with autograft, the burn team may opt to use temporary grafts until the donor site has healed sufficiently for reharvesting. These temporary dressings are either biologic, such as allografts or xenografts (from cadaver and bovine skin, respectively) or synthetic, such as Biobrane® composed of nylon and silastic. These dressings aid in wound management by decreasing infection, stimulating healing and preparing the wound bed for autograft skin, decreasing pain, and protecting exposed tendons, nerves, and blood vessels (Halim, Khoo, & Mohd Yussof, 2010).

Occupational Therapy during the Acute Phase

During the acute phase, the occupational therapist performs a detailed initial evaluation. This includes a thorough chart review to determine the history of the wound and associated injuries. Previous medical history is also important. Associated diagnoses that may limit occupational performance, such as psychiatric illness, diabetes, or lung disease, are to be noted and accounted for during occupational therapy treatment planning. Areas specifically assessed by the occupational therapist during the initial evaluation include client factors (e.g., mental functions, cognitive skills, communication and social skills, sensory functions, neuromusculoskeletal and movement-related functions, joint mobility/stability, and muscle strength/tone/endurance) and ADL and instrumental activities of daily living.

Evaluation can consist of observation during task performance and interviews with patient and family. The potential for permanent scarring and disfigurement may cause significant anxiety and limit the patient's ability to participate in rehabilitation. Thus, early assessment of the patient's support systems allows the therapist to identify resources that may aid in early patient motivation and goal setting.

Because of the acute medical nature of many burn injuries, occupational therapy intervention in the acute phase focuses on capacities and abilities such as range of motion and strength. These are addressed through continued splinting, positioning, exercise, and functional activity. Whenever possible, activities in treatment should reflect each patient's interests. For example, using sports analogies to encourage performance in active range of motion may benefit one patient, while using images of nature and music may benefit another. Other potential treatment activities include environmental modifications, pain remediation, environmental adaptation, and patient and family education. In the acute phase, the individual's ability to participate in treatment related to self-care and functional retraining is often limited by complex medical issues. These areas are addressed in detail during the rehabilitation phase.

Splinting and Positioning. During the acute phase, the splinting and positioning programs established in the emergent phase are continually monitored and adjusted. Splinting schedules are adjusted according to the individual's ability to participate in an exercise and positioning program. For example, if a patient consistently uses an affected elbow for self-feeding and ADL during the day, decreasing the wearing time for the elbow splint to nights and rest periods is appropriate. Conversely, a patient who cannot follow through with an exercise and positioning program because of impaired alertness or poor motivation should wear a splint continuously except for dressing changes and therapeutic activity. It is imperative to check all splints often to ensure proper fit and function (Dewey, Richard, & Parry, 2011). In addition, teaching the nursing staff proper fit and application of splints can decrease the potential for complications (Pessina & Ellis, 1997).

Exercise and Activity. In the acute phase, splinting and positioning are used in combination with exercise and activity (Schneider et al., 2012). Exercise is especially important to control edema and prevent muscle atrophy, tendon adherence, joint stiffness, and capsular shortening (Dewey, Richard, & Parry 2011; Harden & Luster, 1991). Exercise types include passive range of motion, active range of motion, active assistive range of motion, and functional activity. If the patient cannot participate in active exercise or activity because of poor medical status or impaired level of alertness, passive range of motion is indicated. Active exercise is encouraged whenever possible, however (Burke Evans et al., 1996; Wright, 1984), and it is the role of the therapist to guide the patient toward function. Within a single treatment session, a patient may participate in all of these forms of exercise. In fact, functional activities may be used to improve active range of motion. For example, ring toss games are entertaining and easily adapted by changing height and distance to meet upper extremity range of motion goals. Exercise and activity programs are performed up to five times daily (Wright, 1984). Contraindications to exercise include exposed tendons, recent autografts (approximately 5–10 days), acute medical complications, and fractures (Dewey, Richard, & Parry, 2011; Grigsby deLinde & Miles, 1995; Staley, Richard, & Falkel, 1994). In addition, periodic inspection of the wound by the occupational therapist is essential to determine status of wound healing and skin integrity as related to tolerance of the exercise program.

Perioperative Care. The 5–10 days after a skin graft procedure is the perioperative period. A patient with a large burn injury may make many trips to the operating room for skin grafting. Each surgical procedure begins a new perioperative stage. For example, a patient needing grafting on the trunk, arms, and legs may make three trips to the operating room, with each successive area requiring proper perioperative care. The role of the occupational therapist in the perioperative period is to fabricate custom splints to immobilize the newly grafted areas in antideformity positions. Ideally, splints are fabricated immediately prior to or during surgery and applied at the conclusion of the surgery. These splints usually stay in place, along with the primary dressing, for 5–10 days (Dewey, Richard, & Parry, 2011; Grigsby deLinde & Miles, 1995). During this time, range-of-motion exercises are contraindicated to allow for graft adherence. After the primary dressing is removed, the burn team assesses the graft adherence, and a determination is made regarding the appropriateness of resuming exercise.

Pain Management. The occupational therapist must address pain issues that arise during treatment. Many patients in intensive care cannot verbalize a subjective response to manipulation, such as during dressing changes or exercise. In these cases, the therapist monitors objective responses to pain, such as blood pressure, heart rate, and respiratory rate, and adjusts the treatment accordingly. If necessary, the time of the treatment may be changed to allow pain medication to be administered. Decreased repetitions and increased rest breaks during exercise sessions may also be appropriate. Other techniques used to manage pain throughout recovery include distraction strategies, relaxation techniques, and preparatory information (informing/preparing the client regarding procedures to be performed) (Connor-Ballard, 2009). Activity context and emotional state can also affect perception of pain (Dubner & Ren, 1999). Recently, the effectiveness of virtual reality distraction for reducing pain associated with burn injuries has been reported (Hoffman et al., 2011).

Environmental Adaptation. Beginning in the acute phase and throughout recovery, the occupational therapist provides modified call buttons and bed controls, voice-activated telephone systems, and modified utensils (Fig. 40-3) and self-care items. These modifications, combined with patient, staff, and family education, can increase a patient's sense of control and independence. The development of environmental modifications is limited only by the patient's motivation and the therapist's creativity.

Patient and Family Teaching The occupational therapist provides members of the patient's support system with guidance regarding ways to interact with and support the patient during recovery. They may be encouraged to make tape recordings and posters or to bring in favorite music or

Figure 40-3 Modified utensils can increase independence in the acute phase.

foods. They may need to learn new ways to touch or comfort their loved one. In addition, the family and friends provide a source of information regarding the patient's vocational and avocational roles and available community resources if the patient cannot communicate this information. An educated family and/or support system can be an important asset for ensuring follow-through of exercise and splinting programs and for encouraging participation in functional activities (Duran-Coleman, 1991).

Discharge Planning

Because hospital stays are generally short, discharge planning begins as soon as possible after admission (Fletchall & Hickerson, 1995; Rivers & Jordan, 1998). Many patients in the acute phase are discharged directly home or leave a burn center for continued care on a rehabilitation unit. Elements to consider during discharge planning are the availability of community resources for outpatient or follow-up care, support systems available to the patient, and physical demands of the home environment. When patients who have sustained major burns cannot return to the hospital where they received acute care, it is important for the inpatient occupational therapist to establish a relationship with a therapist in the patient's community to ensure continuity of care throughout the rehabilitation phase. In accordance with the knowledge and experience of the community therapist, the discharging therapist provides appropriate literature and written, photographic, and/or videotaped descriptions of the rehabilitation program. This establishes a communication channel for the community therapist so questions and concerns can be addressed in a timely manner. Whenever possible, all authorization from third-party payers should be established prior to discharge (Fletchall & Hickerson, 1995) to avoid delays in the initiation of outpatient therapy. If a patient cannot be discharged directly to home, transfer to an inpatient rehabilitation facility is

appropriate; again, early communication with the receiving therapist is necessary to ensure continuity of care. Regardless of the discharge setting, well-briefed patients are best able to advocate for appropriate care.

Rehabilitation Phase

The rehabilitation phase follows the acute phase and continues until scar maturation (Rivers & Jordan, 1998). Scar maturation can take 6 months to 2 years (Rivers & Jordan, 1998; Staley, Richard, & Falkel, 1994). It is considered complete when the scar becomes pale and the rate of collagen synthesis stabilizes (Grigsby deLinde & Miles, 1995). The level of direct involvement of the occupational therapist during this extended time is varied. It may range from daily inpatient treatment to weekly outpatient treatment to annual clinic visits.

Occupational Therapy during the Rehabilitation Phase

During the rehabilitation phase, the occupational therapist continues to assess capacities and abilities such as range of motion and strength. In addition, functional assessments specific to self-care and homemaking are valuable in guiding treatment planning and preparing for discharge. The overall goal of occupational therapy intervention during this phase is to facilitate the patient's return to his or her previous level of occupational performance. Patients are encouraged to take increasing responsibility for their care, including helping to establish meaningful goals. In addition to range of motion and strength, occupational therapy also focuses on activity tolerance, sensation, coordination, scar management, and self-care and home management skills.

Range of Motion. In the rehabilitation stage, the patient continues to benefit from daily stretching routines established in the acute phase of care. In the early part of this phase, the rate of collagen synthesis is increased (Staley, Richard, & Falkel, 1994), requiring the patient to stretch frequently throughout the day. As the scar matures and collagen synthesis slows, frequency of stretching should be reduced. At all times, skin integrity must be monitored during stretching to prevent tearing. Massage using a non–water-based cream should precede stretching to help prevent dry skin from rupturing (Rivers & Jordan, 1998). An appropriate stretch consists of bringing the tissue to the point of blanching, or becoming pale, and holding it in that position for several seconds. The patient should report tension but not pain. Overzealous stretching can result in tissue tears and edema, which increase joint stiffness. Stretching is initially performed by the occupational therapist. With training, however, the patient and/or caregiver can also complete stretching routines.

Strength. Resistive exercise and graded functional activities can improve strength. Patients may be taught an independent exercise program with resistive rubber ribbon or tubing, such as Theraband®, to increase proximal upper body strength. Functional activities can also be graded to increase strength. For example, patients may gain strength as they perform self-care activities with increasing demands, as when progressing from sitting to standing for hygiene activities.

Activity Tolerance. A key feature of rehabilitation is mobilizing the patient as much as possible, thereby increasing his or her activity tolerance. For an inpatient, this includes increased time spent out of bed and trips to the gym and off the nursing unit. Activity time can be increased by 15 minutes every 2 days, if there is no evidence of fatigue. Fatigue can be monitored by patient self-report and clinician observation. For an outpatient, this may mean resuming leisure activities and going on community outings.

Sensation. Newly healed skin and grafted skin may be hypersensitive, which can significantly limit functional performance. Hypersensitivity can be addressed effectively by systematic desensitization. This can be achieved by asking the patient to manipulate objects with varying textures in the environment. Initially, the patient practices holding soft textures, such as cotton balls or lambswool, and then progresses to manipulating objects with rougher textures, such as Velcro® or burlap. A formal system such as the Downey desensitization program (Barber, 1990) can be used (see Chapter 22).

Coordination. Coordination can be impaired by a variety of factors, including limited range of motion, strength, or sensation. Coordination can be improved through the use of selected progressive tasks designed to challenge the patient's skills. For example, a patient may be asked first to take lids off large jars and then smaller containers (Fig. 40-4).

Figure 40-4 Coordination can be addressed with the use of simulated or actual functional tasks.

The patient may also trace large letters or patterns before attempting fine motor writing tasks such as working a crossword puzzle from the newspaper.

Scar Management. Scar tissue formation is a natural response to wound healing (Grisby deLinde & Miles, 1995). It begins in the emergent phase and may take up to 2 years to mature (Jordan, Daher, & Wasil, 2000). A hypertrophic scar is an aberration of the normal healing process and presents as a red, raised, and inelastic scar (Dewey, Richard, & Parry, 2011) (Fig. 40-5). A hypertrophic scar contains an increased number of fibroblasts as compared to normal skin, and the collagen fibers are arranged in a nodular as opposed to parallel fashion (Abston, 1987). The cause is thought to be a disruption in the balance between collagen synthesis and lysis (Grigsby deLinde & Miles, 1995). The tendency for hypertrophic scarring is unique to each individual. In general, patients with large amounts of pigment in the skin and young patients are most prone to hypertrophic scarring. Hypertrophic scarring is also inversely related to the depth of the initial burn wound (Staley, Richard, & Falkel, 1994). In addition to being cosmetically unappealing, hypertrophic scars can limit functional skills by restricting joint range of motion.

Occupational Therapy Assessment of Scars. The Burn Scar Index (Vancouver Scar Scale) is the most widely used standardized scar assessment tool and is used to rate the pliability, vascularity, height, and pigmentation of scars (Sullivan et al., 1990). Used periodically, the Burn Scar Index can help guide the occupational therapist in determining effective scar management and evaluating the stage of scar maturation. Other assessments include the Patient and Observer Scar Assessment Scale (Draaijers et al., 2004) and the Matching Assessment of Scars and Photographs (Masters, McMahon, & Svens, 2005).

Occupational Therapy Intervention for Scar Management. The occupational therapist attempts to prevent or limit the development of hypertrophic scars. Treatment methods include a combination of techniques, including massage, pressure therapy, and the use of specialized inserts.

Massage. Massage may be useful in reducing scar contracture (Roh, Seo, & Jang, 2010; Staley, Richard, & Falkel, 1994). Scar massage is initiated when it is determined that the injured area can withstand slight friction. In addition, scar massage maintains suppleness, often at risk as normal sweat and oil gland function is disrupted. Scar massage also aids in desensitization. Scar massage is performed several times daily with deep pressure (enough to blanch the scar temporarily) in either a circular pattern or perpendicular to the long axis of the scar. Lotion is used during massage to reduce friction. Perfume-free lotions are preferred to decrease potential irritation to newly healed skin. Initially, scar massage is the responsibility of the occupational therapist so that skin integrity and tolerance can be monitored. Once an established routine has been developed, the therapist teaches the patient and/or caregivers to assume responsibility for daily scar massage.
Figure 40-5 **A.** Hypertrophic scars on neck. **B.** Hypertrophic scars on hand. The hypertrophic scar on the dorsum of the hand causes claw hand deformity.

Figure 40-6 Gentle pressure is applied using Coban™ and Tubigrip™.

Pressure Dressings and Garments. Pressure dressings and garments are another form of scar management that has been advocated in the literature (Chang et al., 1995; Li-Tsang, Zheng, & Lau, 2010; Ward, 1991). The flattened, smooth, supple appearance of the scar after application of pressure has been reported clinically, but objective support has been inconclusive (Bloemen et al., 2009; Grigsby deLinde & Miles, 1995). The occupational therapist initiates

the application of gentle pressure via Tubigrip™, elastic bandage wraps, Coban™, or Isotoner® gloves (Fig. 40-6). Initially, pressure dressings are applied for 2-hour intervals. Wearing time is gradually increased by 2-hour increments until 24-hour wear is tolerated. Tolerance is determined by lack of blisters or open areas. At this point, increased pressure using customized products such as Jobst® or Bioconcepts™ garments is indicated (Fig. 40-7). Staley, Richard, and Falkel (1994) suggest that the application of 25 mm Hg of pressure is ideal to aid in collagen organization, which ultimately helps decrease scar tissue formation. Custom garments cause notable shearing during application and removal and thus should be used only when the skin is healed sufficiently to withstand these forces. Wearing of custom garments continues until the scar is inactive, or mature, as described earlier. The therapist's role is to initiate the ordering of custom garments and oversee their use. Most providers of custom garments send trained personnel to measure the patient for custom fitting. For facial burns, the patient may use a transparent facial orthosis secured by elastic straps to provide even pressure distribution. These orthoses are usually fabricated by a specially trained orthotist at the request of the therapist.

Inserts are often used in conjunction with pressure garments. They may be constructed from products such as Otoform®, or closed cell foam (Fig. 40-8, A & B). Their purpose is to increase pressure in concave areas, such as the web spaces and the sternoclavicular depression. Silicone inserts have also been demonstrated to be effective in improving some characteristics of hypertrophic scars
Figure 40-7 Custom pressure garments can be worn while performing simulated functional activity.
Figure 40-8 **A.** Use of Otoform® insert. **B.** Without insert.

(Ahn, Monafo, & Mustoe, 1989), although the mechanism of action remains to be determined. The design of a scar management program is determined by the available resources, careful clinical observation, and the patient's ability to comply with the program (Evans & McAuliffe, 1995). Periodic outpatient visits to occupational therapy or an established burn clinic throughout the rehabilitation phase allow for monitoring and adjustments of the scar management program.

Self-Care and Home Management Skills. If neuromuscular limitations impede the patient's performance of functional tasks, the therapist may provide adaptive equipment, such as built-up handles for impaired grasp or long-handled utensils for decreased elbow flexion. Teaching adaptive techniques, such as performing certain activities using two hands for extra support, may also improve function.

Patient and Family Teaching. Patients and their family members should understand the rationale for each of the splints and techniques used in their care. They participate in the development of goals, so that they are invested in achieving them. Skin care is an important element in discharge teaching. Patients practice monitoring their skin for breakdown and caring for their skin, including the daily use of a moisturizer. They learn to use a sunscreen with an SPF of at least 15 (reapplied frequently) if they anticipate exposure to the sun (Staley, Richard, & Falkel, 1994). In addition, patients should have a basic understanding of wound healing and tissue response to exercise and scar management techniques.

Support and Psychosocial Adjustment during the Rehabilitation Phase. Although the patient and family typically focus on survival immediately after injury, many other issues arise during rehabilitation. According to Weichman and Patterson (2004), patients in the rehabilitation phase face challenges in three areas: physical (such as decreases in function), social (such as body image and changing roles), and psychological (such as anxiety and depression). The increase in activity in the rehabilitation phase not only assists physical rehabilitation but also assists patients to discover how their injury affects their daily lives. Emotional reactions to the realization of loss may produce a wide range of behaviors, such as crying or expression of anger. In addition, guilt or embarrassment regarding the injury may lead the patient to withdraw. Patients may also have responses related to post-traumatic stress disorder, such as flashbacks.

One of the most difficult challenges for the burn therapist is caring for patients as they grieve for a functional limitation or alteration in body image (Pessina & Ellis, 1997). The occupational therapist supports the patient by encouraging questions and verbalization of feelings about the burn injury (Pessina & Ellis, 1997). The occupational therapist also chooses treatment activities to restore confidence and self-esteem. Group activities provide opportunities for socialization and sharing of concerns in a safe environment (Summers, 1991). Given the extensive contact with the patient throughout all phases of recovery, the occupational therapist is in a unique position to identify and address psychosocial issues, but collaboration with other specialists on the burn team (e.g., nursing staff, family members, social workers, and psychologists) is essential.

Potential Complications

In addition to the potential for soft tissue contractures and loss of joint range of motion, other complications may occur in any phase of burn recovery.

Pruritus

Pruritus (persistent itching) is a common complication (IHQ, 1997; Staley, Richard, & Falkel, 1994), presumably caused by nerve regeneration. It usually resolves within 2 years of the initial injury (Poh-Fitzpatrick, 1992). The use of compression garments, skin moisturizers, cold packs, and medications such as antihistamines may alleviate itching (IHQ, 1997).

Microstomia

Patients with facial burns in the area of the mouth are at risk for oral commissure contracture (microstomia) (Rivers & Jordan, 1998), which is tightening of the musculature around the lip area that limits mouth opening. In extreme cases, urgent surgical revision is required. This risk is exaggerated if the patient has undergone prolonged periods without eating or speaking because of intubation or respiratory compromise. In addition to daily scar massage, the therapist can teach the patient facial stretching exercises, such as yawning or grinning widely and pursing lips together. The exercises can be combined with the wearing of a microstomia splint to stretch the oral commissure. The splint may be worn as tolerated, usually starting with 10 minutes and gradually increasing to 60 minutes twice a day. These devices can be purchased or constructed by the occupational therapist. The cognitive level of the patient is an extremely important factor in use of a microstomia device because of the risk of an unexpected airway emergency. For example, a heavily sedated or confused patient may attempt to swallow the device.

Heterotopic Ossification

Heterotopic ossification, or myositis ossificans, is the development of new bone in tissues that normally do not ossify. It occurs in up to 13% of patients with major burns

(Dutcher & Johnson, 1994). The most common location in the burn-injured population is the elbow, although the shoulder, knee, and hip can also be affected (Dutcher & Johnson, 1994). Heterotopic ossification causes pain, swelling, and rapid loss of range of motion. The therapist must be aware of the symptoms and alert the team so treatment options, including medications and surgery, can be discussed. *Safety Message: Aggressive range-of-motion exercise is contraindicated.*

Heat Intolerance

Heat intolerance is caused by loss of sweating, because split-thickness skin grafts do not contain sweat glands (Grigsby deLinde & Miles, 1995; Rivers & Jordan, 1998). To compensate for this, patients may sweat excessively in remaining unburned areas. Patients in extremely hot climates may require additional air conditioners in the home to maintain comfort (Rivers & Jordan, 1998). The lack of sweat glands also makes healed grafts susceptible to extreme dryness (Grigsby deLinde & Miles, 1995; Staley, Richard, & Falkel, 1994), and patients are encouraged to use moisturizing cream often throughout the day.

RECONSTRUCTIVE SURGERY

An important element in burn recovery is the planning and execution of reconstructive procedures. Despite diligent efforts by the burn team and patient, contractures may develop. Reconstructive surgery can be useful in correcting these deformities. Surgery is typically performed once the scar tissue is mature; however, it may be necessary to perform reconstructive surgery before scar maturation if a severe functional deficit is present (Robson et al., 1992). For example, an axillary contracture, which limits abduction to 80°, may significantly interfere with dressing and hygiene. A surgical procedure, a Z-plasty, can be performed to elongate soft tissue (Robson et al., 1992; Staley, Richard, & Falkel, 1994). A skin graft to cover the deficit may be necessary once the contracture is released.

Occupational Therapy Related to Reconstructive Procedures

When results of functional assessment suggest that the patient's progress toward his or her self-management goals has ceased because of a contracture, the occupational therapist communicates to the burn team the possible need for surgical release of the contracture.

Postoperatively, the occupational therapist provides a custom splint to immobilize and protect the graft in its new lengthened position. After approximately 10–14 days, the therapist initiates an exercise program beginning with gentle active range of motion and progressing to more aggressive exercise and activity as skin integrity tolerates.

Pressure therapy over the newly grafted area minimizes scarring. This includes the use of a pressure garment and an insert fabricated to match the contours of the new graft.

RETURN TO WORK

Returning to work before final scar maturation preserves function and improves the patient's self-concept (Rivers & Jordan, 1998). During the initial evaluation in the acute phase, the occupational therapist gathers information regarding the work history of the patient and specific job demands the patient previously encountered daily. With this information, the occupational therapist can guide treatment activities to prepare for return to the previous level of functioning. For example, if the patient was employed as a mechanic prior to injury, tool use should be incorporated into treatment activities as soon as possible. Patients may require job retraining if the extent of the injury renders the original job demands now unrealistic. In this case, the occupational therapist works with the patient and employer to explore appropriate job modifications.

Return-to-work parameters are ideally based on the percentage of body surface area affected, whether the job requires the use of the affected body part, and the depth of the burn (IHQ, 1997). Fletchall and Hickerson (1995) investigated the effectiveness of a daily 6-hour outpatient program beginning immediately after discharge. Patients in this program, with burns to the upper extremity and hands averaging less than 25% of TBSA, returned to work in an average of 8 weeks; patients in a similar population who participated in traditional outpatient therapy returned in an average of 19 weeks. In addition, the experimental program was shown to reduce the overall costs to the health care payer (Fletchall & Hickerson, 1995). Assignment of a case manager early during the inpatient phase also facilitated the progression from rehabilitation to return to work (Fletchall & Hickerson, 1995).

In addition to physical limitations, burn survivors may encounter psychosocial barriers to returning to the work. These include nightmares, flashback, concern regarding appearance and depression. Patients exhibiting these symptoms may benefit from psychological intervention that, when started early in their recovery, may enable them to return to work sooner (Esselman et al., 2007).

SPECIAL CONSIDERATIONS FOR HAND BURNS

Hand burns resulting in significant functional limitations occur quite frequently. The high rate of injury to the hand is because individuals use their hands to protect themselves or to extinguish the fire (Tanigawa, O'Donnell,

& Graham, 1974). Dorsal hand burns occur more frequently than palmar injuries (Tanigawa, O'Donnell, & Graham, 1974). As previously noted, significant edema usually occurs in response to thermal injury. This pulls the hand into a position of deformity (Sheridan et al., 1995) characterized by thumb adduction, digital metacarpal hyperextension, interphalangeal joint flexion, and flattening of the palmar arches (Wright-Howell, 1989). If this position is maintained, the result is joint contracture and severe functional limitation.

Evaluation of Hand Burns

A comprehensive hand evaluation includes determination of whether range-of-motion limitations are due to joint stiffness, intrinsic muscle tightness, extrinsic muscle tightness, or inelasticity of skin. Other factors that limit hand flexibility and decrease range of motion include pain, bulky dressings, exposed tendons, and the presence of eschar, which is inelastic. Once the clinician determines the cause of range-of-motion limitations, an effective treatment plan can be devised.

Treatment of Hand Burns

The occupational therapist must provide appropriate splinting and exercise programs to prevent contracture and expedite functional use of the burned hand. The appropriate splinting position of the hand is described in Table 40-1. In this position, the collateral ligaments of the metacarpophalangeal (MP), proximal interphalangeal (PIP), and distal interphalangeal joints are positioned at length, preventing ligamentous contracture so that maximum digital range of motion is preserved.

Two distinct options exist for thumb position. Radial abduction maintains the first web space at maximum length. We prefer palmar abduction, however, because this is a position of function. Hand burns are typically dorsal. When present, a deep palmar burn can lead to palmar contracture. In this case, a volar hand extension splint is appropriate. When using this position, however, careful monitoring of MP flexion is critical to prevent shortening of the collateral ligaments. Unfortunately, evidence is lacking regarding specific splint positions and schedules. According to Richard and Ward (2005), "Controversy about splinting in burn care is not based on the rationale for and success of splinting, but exists because of the paucity of validation of its use" (p. 392). A list of splinting options for the conditions previously discussed follows (see Chapter 16 for splint illustrations):

- Dynamic PIP extension splint such as LMB™, or banana splints for PIP stiffness: start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.
Figure 40-9 Dynamic flexion splint and pressure glove combination.

- Dynamic flexion splint in which the MPs are blocked in full extension while the IPs are passively flexed (for intrinsic muscle tightness): start 10 minutes three times a day, increase wearing time as tolerated, not to exceed 60 minutes at a time.
- Forearm-based dynamic flexion splint that offers composite MP-IP flexion (Fig. 40-9) (for extrinsic extensor tightness or inelastic skin that limits composite flexion): start 10 minutes three times a day, increasing as tolerated but not to exceed 40 minutes.
- Volar forearm-based static extension splint (for extrinsic flexor tightness): wear at night.
- Forearm-based dynamic extension splint (for extrinsic flexor tightness): wear periodically during the day, starting with 10 minutes three times per day and progressing to 45 minutes as tolerated.

Often, individuals do not present with a single limitation; rather, a combination of factors limits the individual's range of motion. The clinician must determine which factor is the primary source of dysfunction and treat accordingly. Appropriate splints are always used in conjunction with exercises, functional activities, and scar management techniques. Splints should never be used to the extent that they limit or prevent performance of ADL.

Potential Complications of Hand Burns

Normal hand anatomy can be characterized by a balance of levers and pulleys that work harmoniously to achieve motion. Damage to this balanced network results in significant functional limitations.

Extensor Tendon Injury

Extensor tendon injury is often associated with dorsal hand burns because they lie superficially on the dorsal

Figure 40-10 Boutonniere deformity.

Figure 40-11 C-splint in radial abduction.

aspect of the hand. Limitations can be due to direct thermal injury or tendon ischemia (Wright-Howell, 1989). Because of the close proximity of structures, the formation of scar tissue can greatly limit tendon excursion and create imbalance. This can result in contracture development. Boutonniere (Fig. 40-10) and swan-neck deformities are the result of extensor tendon damage (Evans & McAuliffe, 1995; Rosenthal, 1995; Wright-Howell, 1989).

Web Space Contractures

Web space contractures can be due to overgrafting of the web spaces, muscle shortening (contracture of the adductor pollicis brevis resulting in a first web space contracture), joint stiffness, or skin graft contracture in a normal response to tissue healing. Splints, scar management, and exercise are effective treatment modalities. First web space contractures (between the thumb and index finger) respond well to a web space C-splint (Fig. 40-11) that is lined with Otoform®, a silicon gel sheet. This is usually worn at night for 6–8 hours. During the day, the individual performs stretching, massage, and functional activities that encourage full range of motion of the affected area. For example, an individual with a first web space contracture is asked to pick up containers or game pieces of various sizes, using palmar abduction to promote full abduction of the thumb. A dynamic splint with an insert that exerts pressure over the second, third, and fourth web spaces can be appropriate for digital web space contractures. Another option is the addition of web space inserts under a Jobst® or Isotoner® glove.

OUTCOME STUDIES

Long-term outcomes and quality of life after major burn injuries are of significant concern to those working in the field of burn rehabilitation. A research tool that has been established to address this issue is the Burn Specific Health Scale (BSHS) (Blalock, Bunker, & DeVellis, 1994). This scale is a 31-item instrument that includes items in seven categories: simple functional abilities, work, body image, interpersonal relationships, affect, heat sensitivity, and treatment programs.

Kildal and colleagues (2004) performed an outcome study using a brief version of the Burn Specific Health Scale (BSHS-B) and the Coping with Burns Questionnaire to determine the relationship between coping strategies, burn injury characteristics, social and economic status, and long-term functional outcome. Data were collected from 161 adult survivors of burn injury. The authors concluded that, for most patients, extensive use of avoidant coping and low use of emotional support were related to the lowest long-term functional outcomes. This suggests that early attempts should be made to guide patients toward the most effective coping strategies.

Another study investigated hand function after acute hand burns (Sheridan et al., 1995). The study examined 659 patients with a total of 1,047 hand burns. It was reported that normal function was resumed in 97% of patients with superficial injuries and 81% of patients with deep dermal or full-thickness injuries. Of the patients with severe injuries, which included tendon damage or joint capsule or bone involvement, only 9% had normal function, whereas 90% were able to compensate for this and independently perform ADL (Sheridan et al., 1995).

Another study published by Sheridan et al. in 2000 investigated the long-term outcome of children surviving major burn injuries (>70% TBSA) using a validated quality-of-life scale administered an average of 14 years postinjury. The authors reported that most children had a satisfying quality of life. The majority of the subjects (72%) were either full-time students or gainfully employed. Statistical analysis revealed that key factors such as early

return to pre-burn activities and comprehensive burn care that included experienced multidisciplinary aftercare played an important role in recovery (Sheridan et al., 2000). The authors are careful to note that, "Children who survive massive burns will have major cosmetic and functional impairments that can never be completely corrected" (Sheridan et al., 2000, p. 73).

When outcomes were assessed in adult survivors of severe burn injuries, the results were similar (Druery et al., 2005). Using an abbreviated form of the BSHS to assess function and quality of life in adults surviving burns >40% TBSA, it was determined that the majority of these burn survivors developed functional independence and a good quality of life (Druery et al., 2005).

Although evidence is growing that patients who sustain burn injuries can expect generally positive outcomes, little evidence is available to guide the occupational therapy clinician in choosing specific treatment approaches and modalities. The lack of evidence in this field prevents a formal assessment of evidence related to occupational therapy practice. It highlights the need of occupational therapists to participate in outcome-based research related to the treatment of patients with burn injuries. As specialists in the evaluation and treatment of function, occupational therapists have a responsibility to continue to enhance the knowledge base in this area (see Resources 40-1). Evidence Table 40-1 shows evidence of benefits of occupational therapy for patients with burns.

FUTURE DIRECTIONS

Exciting progress has occurred in regards to reconstruction techniques for the burn patient. Recent advances include hand and face transplants. To date, 18 successful face transplants have occurred worldwide (Singhal, Pribaz & Pomahac, 2011), and patients have undergone unilateral and bilateral hand transplants as well. In both cases, clients must undergo a rigorous evaluation process to determine appropriateness. Rejection is a constant concern

with these individuals, because current protocols require that transplant recipients must stay on a lifelong immunosuppressive medications to prevent transplant rejection. These medications can have significant side effects including increased risk of cancer and organ toxicity. The major goals of face and hand transplants include functional and sensory improvements; however, the potential impact they have on an individual's life satisfaction, body image, and social interaction cannot be overlooked. As occupational therapists, focused on functioning in daily activities, we can assist these patients through the use of splinting, exercise, and environmental adaptations to maximize functional independence.

Evidence Table 40-1 | Best Evidence for Occupational Therapy Practice Regarding Burns

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Effects of pressure therapy (PG), silicone gel sheeting (SGS), and combined therapies (CTG) on hypertrophic scar	Four groups (PG, SGS, CTG, and control group); blinded assessment of hypertrophic scar at five time intervals: pretreatment; at 2, 4, and 6 months during treatment; and 1 month after treatment using various validated instruments	One hundred four patients mean age 21.8 ± 18.7 years (scar size of <16 cm²) with baseline Vancouver Scar grade of >5	Application of garment and/or silicone 24 hours per day (except bathing or 15 minutes of daily massage)	Randomized, double blind, prospective controlled clinical trial Level IB1a	CTG most effective for improving thickness of scar after 2 months. CTG and PG both resulted in improved thickness after 6 months, with CTG showing greatest change. SGS most effective in relieving pain and pruritus.	Using two-way repeated analysis of variance, all noted significant effects, p values ≦ 0.001	Li-Tsang, Zheng, & Lau (2010)
Inpatient burn rehabilitation	Standard of care rehabilitation program. Tested range of motion (ROM) of shoulder, elbow, hip, and knee Hand function assessed via Jebsen Hand Function test Balance assessed using Berg balance scale	Eleven inpatients in regional burn hospital All subjects >18 years of age	All subjects received physical & occupational therapy for 3 hours daily five times per week	Prospective one-group, pre- post-test pilot study Level IIIC3c	Demonstrated improvement in ROM by 64% as well as improvement in hand function and balance in response to rehabilitation intervention	Significant improvements in ROM, hand function, and balance from admission to discharge ($p < 0.05$).	Schneider et al. (2012).

case example
Mrs. J.: Burn Rehabilitation

Clinical Reasoning Process

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mrs. J. is a 42-year-old woman who sustained a 45% total body surface area (TBSA) burn as a result of a house fire. She presented to the emergency department with superficial and superficial partial-thickness burns to her face and neck and deep partial- and full-thickness burns to both upper extremities and hands (dorsal aspect only), chest, and proximal aspect of her bilateral lower extremities. She also sustained an inhalation injury and was intubated and sedated. She was admitted to the intensive care unit. No significant medical history was reported. Split-thickness skin grafts (STSGs) were performed to her chest and upper thighs 3 days after admission. STSGs were performed to her arms and hands 10 days after admission. After skin grafting was complete, Mrs. J. was extubated and moved to a private room. She was on a regular diet and could walk independently. She was noted to be withdrawn and was concerned regarding her ability to care for her 3-year-old daughter. Her husband and sister were present and supportive throughout her hospitalization.	Understand the patient's diagnosis or condition Know the person	"STSGs have the potential for contracture, which means we will have to work hard to ensure full return of her upper extremity function. In addition, STSGs may result in some scarring, which means a scar management program will need to begin as soon as possible." "From the pictures her family has brought in, it seems she took great pride in caring for her daughter—doing her hair, getting her dressed, etc. I can work with her to create goals related to care for her daughter that will be motivating for her and will reassure her that she will, in fact, be able to resume care for her child. Also, it appears that Mrs. J. has good family support. I wonder how available her husband and sister will be now that Ms. J. is beginning rehabilitation. It seems that often, after the acute crisis is over, many family members need to return to their jobs, at least to some extent."
Reason for Referral to Occupational Therapy Mrs. J. was referred to occupational therapy (OT) during the acute phase to prevent contractures that might result in deficits in occupational functioning, to provide patient and family education, and to address psychosocial sequelae related to the burn injury.	Appreciate the context Develop provisional hypotheses	"I am going to suggest regular team meetings to discuss goals and monitor Mrs. J.'s progress. It will be important for the team to recognize if she is becoming more withdrawn or depressed. I will also need to know what services will be available as she prepares for discharge. I anticipate that occupational therapy intervention can help in many aspects of recovery, from restoring performance skills, such as range of motion (ROM), to returning to important life roles such as caring for her family."
Assessment Process and Results The following assessment was performed on transition to the rehabilitation phase: Assessment of wound healing: Immature scar noted on bilateral forearms and dorsum of both hands Assessment of cognitive/social status: Awake and alert for several short periods throughout the day; also noted to appear withdrawn, not seeking social interaction Biomechanical assessment: ROM and strength: Decreased elbow flexion, decreased grasp (metacarpophalangeal [MP] flexion limited) and decreased upper extremity strength bilaterally Role and interest assessment: Ability to care for daughter is of primary importance Functional assessment: Observed having difficulty using utensils and difficulty using nurse call button and observed to fatigue easily	Consider evaluation approach and methods Interpret observations	"Mrs. J. receives many services throughout the day and has limited activity tolerance. In my experience, observational methods are the most efficient way to gather assessment information during this phase of burn recovery." "Mrs. J.'s limited ROM is not unexpected at this stage of recovery. Fortunately, these patients usually respond well to occupational therapy treatment. In addition to working to remediate her biomechanical limitations, I would like to try to quickly improve her independence in activities by issuing some adaptive equipment. This may help her feel more in control and less dependent."
Occupational Therapy Problem List • Unable to feed or dress independently because of impaired strength and ROM in both upper extremities • Impaired ability to care for her daughter • Withdrawn behavior • Activity tolerance limited to 5 minutes	Synthesize results	"Biomechanical limitations are affecting her ability to perform tasks independently. Before the fire, Mrs. J. was so competent and in control of her activities that I'm sure her current functional status is contributing to feelings of dependence and poor self-esteem."

Occupational Therapy Goal List

- Mrs. J. will use splinting, positioning, exercise, and activity to prevent loss of ROM in her upper extremities.
- Mrs. J. will be able to perform 10 repetitions of active assistive ROM of bilateral upper extremities.
- Mrs. J. will improve ability to grasp utensils by increasing flexion in her right MP joints from 40° to 75°.
- Mrs. J. will eat 90% of her meal independently, using adaptive equipment as needed.
- Ms. J. will be able to comb her daughter's hair for 5 minutes while sitting independently.
- Mrs. J. will cope with anxiety and withdrawal by attainment of goals and through increased knowledge of the burn recovery process.

Develop intervention hypotheses	"I believe that through the use of carefully selected activities, Mrs. J. will regain basic skills, as well as quickly gain confidence in her ability to perform tasks that are important to her."
	"Splinting is not fully evaluated in the literature, yet it is the standard of care. So I will carefully evaluate and document the effects of my splinting program and modify my intervention accordingly."
Select an intervention approach	"The most limiting factors in her task performance are her biomechanical limitations. Therefore, I need to address these as a priority. However, I will accomplish biomechanical goals by using activities that also address psychosocial needs."
Consider what will occur in therapy, how often, and for how long	"In my experience, occupational therapy treatment six times a week is appropriate for the remainder of Mrs. J.'s acute hospitalization (2–3 weeks). Initially, she may be frustrated and discouraged. However, I expect that, with the proper motivation, she will quickly regain function. This means that her goals will need to be continually reviewed and adjusted appropriately. I really want her to know that she is part of setting the goals for treatment, so she can take pride in her achievements in therapy."

Intervention

OT occurred six times a week. Bilateral elbow and hand splints were fabricated. Adaptive equipment, such as modified call button and built-up utensils, were provided. The therapist encouraged the family to bring in recordings of get-well messages that Mrs. J. could listen to with headphones. Mrs. J. was taken to the OT gym as much as possible, and private time with her daughter was added to her daily schedule.

Understand what she is doing Know the person Appreciate the context	"Mrs. J. is slowly beginning to ask me and the other team members appropriate questions regarding her treatment. She is demonstrating beginning awareness of the course of recovery and expected outcomes from this type of injury. She is smiling more and appears more open as she realizes that she will be able to resume activities that are meaningful to her. Her family is responding well to her new brightness. This is a nice cycle that is further motivation for Mrs. J."

Next Steps

As the scars matured, Mrs. J. was provided with both verbal and written instructions regarding scar management and skin care. As discharge neared, a local therapist was contacted to follow Mrs. J. three times a week.

Anticipate present and future patient concerns	"As Mrs. J. transitions to home, she may be initially fearful of being home again, but we will plan close follow-up to quickly address any new issues that arise. Also, as she becomes more competent in her daily activities, her focus may shift to concerns about her appearance. She will likely have many questions in the next few months. I believe that the more she knows about the scar maturation process and scar management treatments, the more empowered she will feel. A burn garment will be needed, and I will order it prior to discharge, so trials can begin under the supervision of an experienced therapist."
	"I will need to be sure that I have opened the lines of communication with her local therapist who may also have questions about types of treatment, appropriate goals, and so on."
Decide whether the patient should continue or discontinue therapy and/or return in the future	"In addition to local follow-up, I would like to see Mrs. J. in the burn clinic in 1 month to assess outpatient care and provide additional recommendations as needed."

Clinical Reasoning in Occupational Therapy Practice

Poor Functional Grasp

In therapy, Mrs. J. has been making steady gains in range of motion of her wrist and digits, and her grasp strength has improved as well. However, she has difficulty performing functional tasks such as holding a utensil for eating or buttoning her shirt. Her hand grafts are well healed with no remaining open areas, and her available range of motion for these tasks seems sufficient. What methods might the therapist use to determine what is limiting functional performance?

Summary Review Questions

1. In your own words, what is the primary goal of burn care?
2. How is the role of the occupational therapist unique to the burn team?
3. Describe key differences between superficial, superficial partial-thickness, deep partial-thickness, and full-thickness burns.
4. What splinting and positioning program would you establish for a patient who is intubated in the intensive care unit with deep partial-thickness burns to the axilla, elbow, and wrist?
5. How would your approach differ with the same patient awake and alert?
6. Describe the correct positioning for a deep dorsal hand burn and explain the anatomical justification behind your answer.
7. What factors would you consider when designing a scar management program for your patient?
8. As the occupational therapist on the burn unit, how would you help to address the psychosocial issues of your patients?
9. List five complications you might encounter as your patient recovers from a significant burn injury.
10. What might you, as an occupational therapist, find difficult about treating a patient with a burn injury? How would you address these issues?

Glossary

Antideformity positions—Positions opposite to common patterns of deformity used to prevent contractures.

Blanching—Applying sufficient pressure to interrupt blood flow temporarily: an assessment of capillary flow rate.

Debriding—Removing eschar and loose or necrotic tissue to prevent infection and promote healing.

Deep partial-thickness burn—Thermal injury that destroys cells from the epidermis to the deep dermal layer.

Dermis—Layer of skin below the epidermis that contains blood vessels, nerve endings, hair follicles, and sweat and oil glands; supports the regrowth of new epithelial tissue.

Epidermis—Most superficial layer of the skin; acts as a barrier. It is continually sloughed and replaced.

Eschar—Burned tissue.

Full-thickness burn—Thermal injury in which the epidermis and dermis are destroyed.

Superficial burn—Thermal injury that involves only cells in the epidermis.

Superficial partial-thickness burn—Thermal injury in which the epidermis and upper portion of the dermal layer are destroyed.

Wound contracture—Part of normal healing in which myofibroblasts in the wound bed contract to minimize the skin defect.

Z-plasty—Surgical procedure in which a Z-shaped incision is made and tissue is transposed to increase tissue length.

Amputations and Prosthetics

Sarah Mitsch, Lisa Smurr Walters, and Kathleen Yancosek

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Design treatment programs for preprosthetic and prosthetic management of upper limb amputations.
2. Discuss upper limb amputation levels and respective prosthetic systems and components.
3. Discuss treatment program considerations for persons with lower limb amputations.
4. Describe the psychological implications of amputation and the therapeutic management.
5. Discuss challenges of treating individuals with multiple limb loss.

Amputation can result from several causes including trauma, vascular disease, tumors, infection, or congenital limb deficiencies that present as missing or partially developed limbs. This chapter addresses adults with acquired amputation, that is, amputations that occurred after birth.

INCIDENCE, LEVELS, AND CLASSIFICATION OF AMPUTATION

There are nearly two million people living with limb loss in the United States (Ziegler-Graham et al., 2008). Annually, more than 185,000 persons in the United States have amputations, with the ratio of arm to leg amputations estimated to be 1:3 (Goodney et al., 2009). Some 57% of upper limb amputations are transradial, that is, below the elbow through the radius and ulna. Trauma rather than disease is the primary cause (close to 75%) of upper limb amputations in adults, with injury occurring primarily to males aged 15–45 years in work-related accidents (Esquenazi, 2004). Upper limb amputations can also result from other causes, such as gunshot wounds and electrical burns. Disease is the primary reason for lower limb amputations, with peripheral vascular disease and diabetes being the most common causes in people older than 60 years of age (Dillingham, Pezzin, & MacKenzie, 2004). An increasing prevalence of diabetes as well as continued overseas combat military operations is causing an overall increase in amputation rates (Darnall, 2009; Johannesson et al., 2009; Rayman et al., 2004). As of January 2012, over 1,400 military service members have sustained limb loss as a result of the wars in Iraq and Afghanistan, with over 200 service members sustaining an upper extremity amputation (Harvey, Loomis, et al., 2012).

When amputation is necessary, the surgeon's aim is to preserve as much limb length as possible and still retain healthy skin, soft tissue, blood supply, sensation, muscles, bones, and joints (Smith, Michael, & Bowker, 2004). A residual limb that is pain free and functional is the final surgical goal.

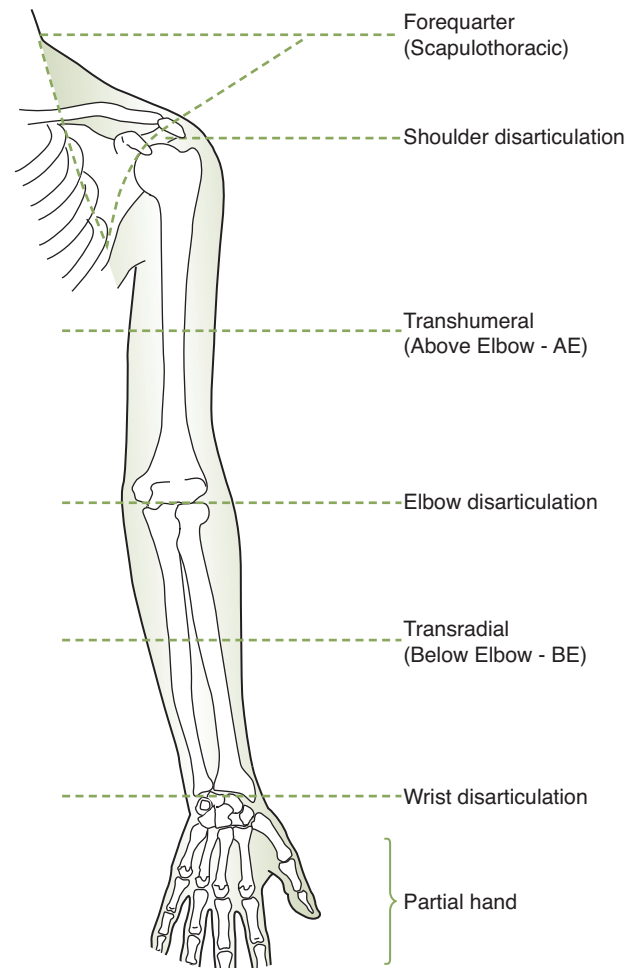
The levels of upper extremity amputation are illustrated in Figure 41-1. The term forequarter describes an amputation of the arm, scapula, and clavicle. The term transhumeral describes an amputation through the humerus; transradial describes an amputation through the radius and ulna. The level of amputation may affect the use of a prosthesis. The higher the upper extremity amputation, the more difficult it will be to use a prosthesis because fewer joints and muscles are available to control the prosthesis. Furthermore, the weight of the prosthesis is greater, and more complex systems are needed for active control. Therefore, for a variety of reasons, a patient may choose not to be a full-time prosthetic user in his or her daily activities (Biddiss & Chau, 2007).


Figure 41-1 Levels of amputations.

REHABILITATION: A TEAM APPROACH

The members of the professional team are the physician, prosthetist, occupational therapist, physical therapist, and the patient. The social worker, psychologist, and vocational counselor should be consulted as needed. Patients are always active, equal members of the team and must be given the opportunity to explain their needs, preferences, and goals. The occupational therapist is essential to the rehabilitation process, because he or she works so closely with patients after their amputation.

PREPROSTHETIC THERAPY

The preprosthetic therapy program occurs from the postsurgical period until the patient receives a temporary (test) or permanent prosthesis. This is a preparatory time for both physical and emotional healing.

Postoperative Care

Postoperative care, required immediately after surgery, addresses wound care, maintenance of skin integrity, joint

mobility, reduction of edema, prevention of scarring, and control of pain (Smurr et al., 2008). Outpatient therapy can be provided in a rehabilitation unit, rehabilitation center, or an outpatient clinic. Future inpatient admissions may be necessary for infections, revisions, or other complications that may or may not delay prosthetic fitting and training.

Phantom Limb Sensation

Therapists must reassure the patient that after an amputation, he or she will likely continue to experience sensations in the missing limb. This is called "phantom limb sensation" and is common among individuals with limb loss (Eichenberger et al., 2008). The perception of the presence of the amputated limb is a universal phenomenon that is remarkably real to the patient. The cause of phantom limb sensation is still not clearly understood, and research into it is continuing. Phantom limb sensation is most common in adults with traumatic amputations, although it has been known to occur in aplasics (persons with congenital limb absence) (Price, 2006). According to Melzack (1989), the neural system exists within the brain even when the body input is cut off by amputation. These perceptions are strongest with amputations of upper extremities, and the hand and fingers are felt more vividly than the arm.

With time, the patient may feel that the distal portions of the phantom limb have moved closer to the site of the amputation; this is called "telescoping." Phantom limb sensation often remains, and ordinarily, the patient accepts it. The patient may view it as an annoyance if the sensation is mild burning or tingling or may find it useful, as when learning myoelectric control for externally powered prostheses. Open discussion and ongoing patient education regarding this common phenomenon are imperative.

Phantom Limb Pain

Phantom limb pain is even less clearly understood, and its causation and management remain controversial; again, research continues (Hompland, 2004). This pain can be felt as extremely intense burning or cramping sensations or shooting pain in the residual limb and is most common in traumatic amputations. At least 90% of individuals with limb loss experience phantom limb pain (Chan et al., 2007). Central nervous system changes and peripheral nervous system damage are thought to be causes of phantom limb pain (Flor, Nikolajsen, & Jensen, 2006), whereas psychological factors have been identified as triggers to phantom limb pain (Desmond & MacLachlan, 2006).

Often, pain increases with stress. The therapist is advised to avoid emphasizing pain when possible. Treatments for those with severe pain include analgesics and surgery, such as nerve blocks and neurectomies. In the

rehabilitation setting, limb percussion (See Chapter 22), ultrasound, and transcutaneous electrical nerve stimulation (TENS) have been used (Smurr et al., 2008). Acupuncture, psychotherapy, hypnotherapy, and relaxation techniques have also been used. No one approach, however, has proven to be clearly successful. Using both a team approach and a patient-centered approach to find the best pain relief methods for the patient and to integrate them into the overall treatment plan is recommended.

Mirror therapy is another available treatment option to explore for treating phantom limb pain. Over 15 years ago, Ramachandran and Rogers-Ramachandran (1996) published a key article on the novel use of a mirror for the treatment of phantom limb pain. Albeit a small case report, 60% of their subjects had an improvement in phantom limb pain with the use of mirror therapy. In 2007, Chan et al., published the first randomized, sham-controlled trial on the use of mirror therapy versus imagery therapy for phantom limb pain in lower extremity amputees. The results were impressive: 100% of those performing mirror therapy experienced improvement in phantom limb pain, whereas 89% of those who switched to mirror therapy from the two sham-controlled conditions also experienced improvement.

The use of mirror therapy is now widely accepted as standard therapy for limb amputation (Weeks, Anderson-Barnes, & Tsao, 2010). The process of mirror therapy involves the use of a mirror placed at midline and against the patient's chest or groin depending on the level of amputation that is being addressed. The residual limb is placed behind the mirror and the intact limb is placed in front of the mirror, so that the patient observes the reflection of the intact limb in the mirror. The mirror should be placed close enough to the body to obstruct view of the residual limb as shown in Figure 41-2. The patient is then
Figure 41-2 A patient with a transhumeral amputation performing mirror box therapy. Position the mirror at the patient's midline with the residual limb behind the mirror. Instruct him to continuously look at the reflection of the intact limb while performing mirror box therapy.

directed to focus on the reflection of the intact limb in the mirror during the process. He or she is instructed to place the intact limb in the position that the residual limb feels as though it is in. As tolerated, the patient should slowly move the intact limb and attempt to move the phantom limb through motions that do not elicit pain in the phantom or residual limb. The patient is encouraged to perform movements that he or she is capable of doing with the phantom limb and at a speed that requires attention but does not create a challenge. Typically, the therapist will observe movement in the residual limb when the patient feels able to move the phantom limb. It is recommended that mirror therapy be conducted in a quiet environment to reduce distractions.

Oftentimes, patients beginning mirror therapy will fatigue easily, so it is not uncommon for the patient to initially only tolerate 8–12 minutes. Patients should be encouraged to work up to 15–20-minute sessions daily over a 4-week period as part of their home program. Encourage patients to perform mirror therapy daily and as needed when phantom limb pain is disruptive to daily activity, including sleep. Daily use of a visual analogue scale and tracking of the number and duration of phantom pain episodes are recommended to determine whether mirror therapy is beneficial.

Psychological Aspects of Limb Loss

Upper limb loss results in a change in the ability to grip, feel, and manipulate objects; physically engage in social interaction; and communicate through gestures. This loss can profoundly influence the person's body scheme, self-esteem, and sense of efficacy (Desmond, 2007). Limb loss affects not only physical function but also the patient's competence and satisfaction in life roles: self-maintenance, family, and home; self-enhancement, such as engaging in leisure and community activities; and self-advancement as a worker or student (see Chapter 1) (Murray, 2005). Reactions to amputation are as complex as the unique nature of each human, and an individual's personality and belief system may influence how he or she responds to limb loss. Often, an early response is shock and disbelief; furthermore, when both upper extremities are amputated, a feeling of helplessness is common. In a review of the literature relating to psychosocial adjustment to amputation, Horgan and MacLachlan (2004) found that depression rates in amputees are higher than general population rates for up to 2 years postamputation. Anxiety rates were also higher but seemed to readjust to comparable general population rates after 1 year. Sometimes the patient may project negative feelings onto the therapist, family members, and friends. What can the occupational therapist do? The therapist should encourage open discussion, develop a relationship based on trust and respect, and work with the other treatment team members to facilitate the patient's psychological adjustment and reintegration into previous roles.

- Give the patient information. Explain the therapy process and establish realistic goals and outcomes. This can clarify the patient's expectations and reduce fear and anxiety. The therapist can prepare the patient during the preprosthetic phase by showing various prostheses that are appropriate to the amputation level and discussing prosthetic components. The therapist must listen to the patient and understand his or her life roles and future goals. A collaborative relationship between therapist and patient fosters a sense of trust and control for the patient.
- Introduce the patient to a peer visitor who has a similar amputation to facilitate discussion on stages of recovery, the rehabilitation process, and problem-solving strategies. Recommend that the patient attend local amputee support groups and research appropriate available Internet resources.
- Provide the patient with reference material; topics can include information on coping and adjusting to the amputation, information on prosthetic options, tips on how to manage one's activities of daily living (ADL) independently, and a list of organizations as resources (Resources 41-1).
- Communicate with (and, when necessary, refer the patient to) the psychologist, spiritual counselor, and other team members throughout the psychosocial adjustment periods of survival, recovery, and reintegration after limb loss described by Van Dorsten (2004).

Preprosthetic Program Guidelines

Occupational therapy (OT) during the preprosthetic period for the upper extremity includes providing emotional support, ensuring maximal limb shrinkage and shaping, desensitizing the residual limb, maintaining range of motion and strength, facilitating independence in ADL, and change of dominance.

Provide Emotional Support

Establish an ongoing supportive, trusting relationship with the patient and family to facilitate open discussion (see Chapter 14). Collaborate with the team regarding the patient's needs and refer the patient for additional services if needed.

Instruct in Limb Hygiene and Expedite Wound Healing

- Instruct the patient to wash the limb daily with mild soap and dry it thoroughly (after clearance from the surgeon to get the residual limb wet).
- Provide basic wound care such as wound cleansing or debridement.
- Use creams to massage at the scar line to decrease scar adhesions.

Maximize Limb Shrinkage and Limb Shaping

The goal is to shrink and shape the residual limb so that it is tapered at the distal end; this allows for optimal prosthetic fit. The following interventions can be used to achieve this goal.

- Elastic bandage. The patient is taught to wrap the limb in a figure-of-eight pattern and is expected to do so independently unless physical or cognitive limitations prevent it. In this case, a family member, friend, or caregiver is instructed in the process. The residual limb must be wrapped in a figure-of-eight diagonal configuration, with the most pressure applied at the end of the limb. *Safety Message: The limb must never be wrapped in a circular manner, as this causes a tourniquet effect and restricts circulation.* The bandage must conform firmly to the limb and be wrapped in a distal to proximal direction (Fig. 41-3). The wrap should
Figure 41-3 Wrapping technique for transhumeral amputation. Repeat diagonal turns as necessary to cover the limb with no constriction.

be worn continuously and reapplied immediately if it loosens. *Safety Message: The patient is advised to remove the bandage two to three times daily to examine the skin for any redness or excessive pressure.* A clean bandage should be applied at least every 2 days. Bandages can be washed with mild soap and laid flat to dry but not squeezed or machine dried.

- Elastic shrinker. Another option is an elasticized sock or shrinker. If the shrinker loosens, a smaller shrinker size will be needed. Shrinkers should be worn when not wearing the prosthesis and while sleeping in order to maintain residual limb shaping and size.
- Early postoperative prosthesis. The early postoperative prosthesis is strongly recommended for bilateral upper extremity amputations (Uellendahl, 2004) to reduce dependency for self-care activities. This temporary prosthesis may facilitate acceptance and use of the permanent prosthesis. Studies support the premise that early fitting and prosthetic training ensure acceptance of the prosthesis and its use (Fletchall, 2005; Lake & Dodson, 2006). If an early postoperative prosthesis is chosen by the team as an intervention, it is imperative that there is daily communication among the patient, occupational therapist, and prosthetist in order to maintain proper fit and use, including necessary, often daily, adjustments to improve function.

Prosthesis Wear Schedule

Early in this phase, it is important to begin patient and family education on the wear time and wear schedule of the prosthesis. Wear time is a gradual process after the initial fitting. It is important in the beginning to limit wear of the prosthesis to approximately 15–30 minutes and then remove it to check for skin integrity. Gradually, the daily wear time will increase as tolerance and skin integrity improves. The schedule will be set by the therapist and the prosthetist.

Desensitize the Residual Limb

Desensitization of the residual limb is necessary to prepare the patient's residual limb to tolerate touch and pressure in preparation for fitting the socket. This goal can be met through the following interventions (see also Chapter 22).

- Residual limb wrapping or wearing of a shrinker.
- Percussion (tapping, rubbing, and vibration) over the residual limb.
- Massage to prevent or release adhesions and soften scar tissue.
- If there are no contraindications, the patient may bear weight on the end of the limb against various surfaces. These surfaces are graded from very resilient, such as soft foam, to variously resistant and textured, such as layers of felt, a bucket of rice, and a mound of clay.

Maintain or Increase Range of Motion and Strength of the Limb

A physical conditioning program is instituted to increase or maintain the range of motion of all joints proximal to the amputation. Increasing muscle strength of the residual limb and shoulder area are also important to address. Include the contralateral side if limitations are noted. For patients with high-level amputations, a shift of weight and center of gravity can occur. Core strengthening will promote postural control, balance, and endurance and prevent asymmetry. Mobilization of the limb also increases circulation and reduces edema. This conditioning regimen should be practiced at home. Encourage the patient with unilateral limb loss to incorporate the residual limb into bilateral tasks during daily activities. Patient education on the risks of overuse of the contralateral limb should be discussed, especially if the patient elects to do all tasks one-handed. Those risks include biomechanical overuse syndromes, learned nonuse of the amputated side, and reduction of the cortical representation of the amputated part.

Facilitate Independence in Activities of Daily Living

It is important that the patient develop skills to be proficient with and without a prosthesis in his or her ADLs. A patient may only have one prosthesis; therefore, there may be times when the patient does not have the prosthesis and will still have to complete daily tasks without it.

Change of Dominance

For persons with amputation of the dominant limb, change of dominance activities, such as handwriting, must receive special attention (Yancosek & Howell, 2011). Although the patient will instinctively use the remaining extremity for ADL, the therapist can introduce a wide variety of activities and provide tips for one-handed techniques or recommend adaptive equipment (Yancosek, 2008) for home management, communication, desk activities, and community participation (see Chapters 25–27). A 6-week handwriting program, *Handwriting For Heroes*, is commercially available and has been tested with nonimpaired and impaired adults and shows promising results for handwriting skill development (Yancosek & Gulick, 2008).

Bilateral Amputation

Establishing some level of independence is essential for the patient with bilateral upper extremity amputations, and this must be addressed promptly to lessen feelings of dependency and frustration (Yancosek, 2011). If the patient has enough length in one of the residual limbs,

immediately provide the patient with a universal cuff, which is useful for holding a utensil or toothbrush; this is a temporary substitute for grasp. Inserting a small pencil into the universal cuff with eraser end downward can be used to operate cell phones, telephones, and allow for text messaging. For patients with smartphones, a stylus with thermoplastic, silicon, elastic, or neoprene tip can be fabricated to be mounted around the residual limb; however, the stylus must have direct contact with the skin to receive the natural electric charge from the skin in order to effectively operate the smart phone.

Early fitting with a temporary prosthesis on at least one limb is by far the best approach. Adapted devices may be needed to assist the patient in performing basic self-maintenance tasks, such as eating, toileting, grooming, and dressing (Davidson, 2002). For patients with high-level amputation, specifically designed prostheses may be helpful for accomplishment of critical tasks, for example eating (Hung & Wu, 2005). Use of the feet should be encouraged if at all possible, and other modifications of performance can be suggested, such as use of the chin, knees, and teeth (Edelstein, 2004). The therapist and patient can analyze tasks and solve problems together. Typically, the longer residual limb will be chosen as the dominant extremity.

CHOOSING THE PROSTHESIS

As a member of the team, the occupational therapist contributes to the recommendation for the upper limb prosthesis. The therapist has come to know the patient in some depth during the preprosthetic program and can contribute information regarding the patient's social and cultural contexts (Procedures for Practice 41-1).

Procedures for Practice 41-1

Choosing the Prosthesis

Consider these factors:

- Residual limb: length, range of motion, skin integrity, strength
- Preference for cosmesis and function
- Hand dominance
- Prior level of function and activity levels
- Activities at work, home, school, community and recreational interests
- Patient goals, motivation, and attitude
- Financial coverage: health care insurance, ability to pay privately, and alternative funding sources
- Cognitive abilities to learn to use various components

The occupational therapist and prosthetist educate the patient about upper extremity prosthetic systems appropriate to the level of amputation. A candid discussion needs to occur between the patient, therapist, and the prosthetist about the different types of prostheses and terminal devices (TDs) and the advantages and disadvantages of each system. This discussion assists the patient in establishing realistic expectations of the prosthesis and its function.

Prosthetic Systems

The most common upper extremity prosthetic options currently available are body-powered (BP), externally powered, hybrid, activity-specific, and passive prostheses. A BP system uses motions from the body, proximal to the amputation, to operate a TD. Tension is produced from the contralateral limb, and the scapulohumeral motions are transferred to a TD through a cable. An externally powered system uses power external to the body for operation. These devices are more commonly known as myoelectric systems. Myoelectric systems require electrical signals produced from muscle contractions to operate powered elbow and electric TDs. A hybrid system is a combination of a BP and externally powered components. This type of system often includes a BP elbow and a myoelectrical TD. This system is often an option for patients with elbow disarticulation or transhumeral amputations. An activity-specific prosthesis is designed for a specific function or activity. A passive prosthesis is another option. It is endoskeletal, contoured to the shape of the arm and covered with resilient foam. It is often lightweight, contains an internal pylon shaft, and is designed with the physical characteristics of the natural arm and hand. There is no functional component to a passive prosthesis. These prostheses are available to replace any part of a limb, from a single digit to a whole arm (Leow, Pho, & Pereira, 2001). Each option has specific socket designs for each level of amputation, as well as harnessing and suspension options, and available TDs

Socket Designs

Transradial Amputation. The residual limb is encased in the socket of the prosthesis with total contact. A standard forearm socket encases the full length of the residual forearm but can be modified to allow for more active pronation and supination if the patient has a long residual limb as well as for more elbow flexion and extension. The supracondylar socket (modified Muenster) is a frequent choice for the short transradial limb; the proximal brim grips the humeral lateral and medial epicondyles and the posterior olecranon (Fig. 41-4). Additionally, the

Figure 41-4 Body-powered transradial prosthesis with a modified Muenster socket and a standard voluntary opening hook.

Figure 41-6 Standard transhumeral prosthesis. 1, axilla loop; 2, Northwestern University (NU) ring; 3, lateral support strap; 4, control attachment strap; 5, elastic anterior support strap; 6, socket; 7, elbow lock cable; 8, turntable; 9, internal elbow lock unit; 10, lift loop; 11, housing; 12, cable; 13, wrist unit; and 14, TD. (Illustration by Gregory Celikyol.)

supracondylar design is widely used for the myoelectric prostheses because it is self-suspending and thus requires no harnessing (Fig. 41-5).

Transhumeral Amputation. The conventional socket edge is generally just near or above the acromion, depending

on residual limb length. If rotational stability is of concern there are other variations to socket design that the prosthetist may consider. An example of a transhumeral BP prosthesis is shown in Figure 41-6.

Shoulder Disarticulation and Forequarter Amputation. Most socket designs at this level consist of a plastic laminated shoulder cap or frame socket with carbon fiber reinforcements. Another choice is an endoskeletal passive arm that is lightweight and contains an internal pylon shaft.

Figure 41-5 Myoelectric transradial prosthesis shown with a carbon fiber socket and without a terminal device.

Harness and Other Control System Options

The harness serves two purposes: (1) to suspend, or hold, the prosthesis firmly on the residual limb and (2) to allow for force (through body motions) to be transmitted to the control cable on a BP or hybrid system. Several types of harnesses are available to include figure-of-eight, figure-of-nine, and chest strap. A new alternative option to harnessing for a BP prosthesis is the cutaneous anchor technology available through Single-Handed Solutions (Resource 41-1). This kit system uses movement from the same side of the body as the residual limb to activate the

prosthesis, thus eliminating the need for body motion from the contralateral side through a harness.

Wrist Units. The wrist rotation unit provides a means to attach the TD to the forearm. It also provides an important function: the TD can be rotated to positions of supination, pronation, or midposition before engaging in an activity. This is termed prepositioning and is an important substitute movement for reduced or absent active forearm rotation. Common types of wrist units include the constant friction wrist unit and quick change units.

Wrist flexion units provide the user with the ability to manually flex at the wrist often at neutral, 30° of flexion, or 50° of flexion. Wrist flexion units are indispensable for the person with bilateral amputations because of their usefulness in reaching the midline for toileting, dressing, and eating.

Elbow Units

Two kinds of elbow units are available for the BP transhumeral prosthesis: (1) an internal elbow locking unit for a standard or short transhumeral amputation and (2) an external elbow locking unit for a long transhumeral or elbow disarticulation amputation. Manual elbow components are also available with a locking mechanism. For a shoulder disarticulation prosthesis, the elbow lock can be activated using a chin nudge lever, a manual elbow lock mechanism, or through myoelectric control.

For an above-elbow externally powered prosthesis, the elbow is controlled by electromechanical switches or by myoelectric control. There are numerous types currently available. Depending on the company's design specifics, some elbows can be matched with certain available externally powered wrist and hand components and TDs. Each unit will have a charging mechanism such as an internal or external battery. Battery life can vary between products and manufactures.

Body-Powered Terminal Device Prehensors

TD prehensors for a BP prosthesis can be classified as operating by a voluntary opening (VO) mechanism or voluntary closing (VC) mechanism. The fingers of a VO device remain closed by springs for a mechanical hand or by rubber bands for a hook. The force of pinch on the hook can be increased by adding rubber bands, approximately 1 pound for each band, or by adjusting the spring mechanism for the hands. In a VC mechanism, the amount of pinch force is decreased or increased by the amount of tension the patient applies on the cable to close the TD. Patients should be made aware of the advantages of a hook over a hand, including precision grasp for small items; a minimally obstructed view, making it easier to visualize the object for grasp or release; and light weight.

The choice of a hand TD would be made by a person who values cosmesis over function.

Voluntary Opening Terminal Devices. The VO hook is widely used and can vary in size. Hooks are made of aluminum, titanium, or stainless steel; some have rubber-lined fingers. The lining provides a firm grip and prevents slippage. Many available hooks can withstand the rigors of heavy mechanical activity and are able to facilitate holding tools in activities. The VO mechanical hands operate similarly to the VO hooks except that, in the hand, the thumb and first two fingers open when the cable is pulled. These fingers oppose in a three-point prehension pattern.

Voluntary Closing Terminal Devices. A VC TD has strong variable prehension and is controlled by the amount of force the individual can exert. It is possible that a grasp of more than 30 pounds can be attained. This TD may be appealing for individuals who are active in sports, heavy physical work, or recreational activities. A VC mechanical hand has a thumb that can be manually adjusted and locked in two positions to achieve a 1.5- or 3-inch opening.

Electrically Powered Terminal Device Prehensors

The electrically powered prehensors are heavier (approximately 1 pound) but provide stronger pinch force (approximately 20–40 pounds) than the BP TDs. Examples of these are shown in Figure 41-7. These devices are activated through myoelectric or switch control. The two speed systems are (1) digital control (constant speed), in which muscle contractions cause opening and closing at a given speed; and (2) proportional control (variable speed), in which the speed and pinch force increase in proportion to the intensity of muscle contraction.
Figure 41-7 Examples of externally powered prehensors. On the left is the Ottobock System Electric Hand (Otto Bock, Minneapolis, MN) with a cosmetic cover. On the right is the Electric Terminal Device by Motion Control, Inc. (Salt Lake City, UT).

Electric Hands. The Sensorhand Speed by Ottobock has a motor in the hand mechanism that drives the thumb and first two fingers as a unit to provide palmar (three-point) prehension. The hand automatically increases force on an object if it detects slippage by a sensor in the thumb. There are multiple other electric hand devices being developed, tested, marketed, and manufactured. The ultimate goal of these types of devices is to have individual articulating digits to include an opposable thumb and multiple grips, pinch, and grasp patterns available that allow users to better master everyday tasks.

Electric Hooks. The Ottobock electric Greifer TD is only available in one size, and its two "fingers" move symmetrically in opposition to one another for precision pinch, whereas a more proximal, expanded contact area provides for a cylindrical grasp (Figure 41-8). This device may be chosen when the activity requires prehension force up to 40 pounds.

Myoelectric Control and Terminal Devices. There are numerous myoelectrically controlled TDs available, and each has advantages and disadvantages, but it is often up to the user to decide which TD he or she finds most useful and functional. It is beyond the scope of this chapter to elaborate on all available types of myoelectic TDs because technology quickly advances, and control schemes vary based on TD function and user preference. It is important that the therapist consult the patient's prosthetist to understand the capabilities and control mechanisms of the specific TD the user has received in order to effectively train the patient to operate the myoelectric TD.

Myoelectric Site Testing and Training. Muscle site testing is necessary for patients choosing a myoelectric prosthesis. This testing results in choosing the optimal location for

Figure 41-9 Myoelectric site training during the preprosthetic training phase at midline. The electrodes are placed on the patient's biceps and triceps myosites. The electrode leads are connected to a universal carbon fiber demonstration socket with an Ottobock System Electric Hand (Minneapolis, MN) with a standard hand shell covering the terminal device. Use of the demonstration socket allows the patient to experience what it is like to control an actual myoelectric terminal device. This patient is practicing grasp and release with a foam block; use of this type of object is often for practicing proportional control during grasping.

the control site or sites. The goal is to find a site where the patient can hold a steady contraction for at least 1–2 seconds and relax for that time. Ordinarily, the agonist and antagonist are chosen, such as wrist extensors and flexors for transradial amputation and biceps and triceps for transhumeral amputation. It is possible to use only one muscle to control two functions: a strong contraction controls one function, and a weaker contraction controls another; relaxation turns the system off; however, this system is difficult to learn and use without error. There is a wide variety of alternative control setups that can be programmed by the prosthetist.

During muscle site testing and training, skin electrodes are strapped to the residual limb or encased in a test socket. A myotester such as Myolab II by Motion Control, Inc. (Salt Lake City, UT) or Myoboy® by Ottobock, a biofeedback computer program (see Chapter 19), or an electronic demonstration hand is used to provide feedback (Fig. 41-9). Once the optimal electrode placement for control of the prosthesis is determined, the user practices with the feedback device to operate the electronic motor on command. See Chapter 13 for teaching and learning principles and practices.

Cosmetic Gloves

Prosthetic hands will have some type of rubberized covering or gloves. These gloves are available in a variety of colors and sizes to cover mechanical, electric, and passive hands. The glove needs to be replaced when damaged.

A stock production glove is one type of covering available. The skin color choices are made from a selection of sample swatches to match skin tones. These polyvinyl

Figure 41-8 Ottobock (Minneapolis, MN) Greifer terminal device. The Greifer on the left has the interchangeable standard hooks and is in open position. The Greifer on the right has interchangeable extended hooks and is in the closed position.
Figure 41-10 A. An individual with a left partial hand amputation. **B.** The same individual with a left-hand custom-sculpted and painted silicone glove. This custom glove is designed to resemble the intact hand.

chloride (PVC) gloves are the least expensive but are susceptible to staining from contact with such items as newsprint, clothing dyes, and ballpoint ink. The glove can deteriorate with extreme temperature and when exposed to sunlight.

A silicone covering is more expensive than PVC. A wider range of color choices is available, and details, such as veins, are painted on the glove to render a more realistic covering. These silicone gloves can withstand extremes of temperature and do not stain as easily as those made of PVC.

A custom-sculpted and painted silicone glove, also called an anatomical cover, truly attempts to replicate the individual's remaining hand (Fig. 41-10, A & B). To make the glove, the remaining hand is cast in silicone, which duplicates its contours in great detail. It is then reversed. A cosmetic restorationist adds to the realistic appearance of the hand by painting the glove and adding veins and other features. This glove is more costly than the stock production gloves.

Bilateral Upper Extremity Prostheses Considerations

Individuals with bilateral upper extremity amputations present unique challenges when selecting the prosthetic systems. Many factors influence this selection and frequently a combination of systems is selected: for example, a system that includes a BP prosthesis with

a hook as one system and a myoelectric system with an electric hand as the other system. There is no ideal setup for all individuals with bilateral upper extremity amputations. It is recommended to listen to the patient and his or her needs and goals and also consult with other team members for other perspectives. In the end, the patient will select the system best for him or her (Fig. 41-11, A & B).
Figure 41-11 A. A patient with bilateral upper extremity amputations using final prosthetic sockets. This picture demonstrates this individual using his prostheses to peel a banana. This activity requires a high level of proportional control to hold the banana without crushing it as well as a high level of skill to control the prosthesis and terminal device while peeling the banana. This individual has a through-elbow amputation on his right and is wearing a body-powered prosthesis with the N-Abler V Series Body-powered Five Function Wrist by Texas Assistive Devices, LLC (Brazoria, TX). On his left, he has a transradial amputation and is wearing a myoelectric prosthesis with an ETD by Motion Control, Inc. (Salt Lake City, UT) with a flexion wrist component. **B.** Bilateral upper extremity prosthetic test socket system. This patient has a myoelectric test socket on the left with a Dynamic Arm and Griefer from Otto Bock (Minneapolis, MN). The test socket is made of a clear heavy thermoplastic and is used until the individual's limb volume has stabilized. On the right, the individual has a body-powered test socket with the N-Abler V Series Body-powered Five Function Wrist by Texas Assistive Devices, LLC (Brazoria, TX).

The Final Choice: A Discussion

"In the upper extremity, the prosthesis meets its greatest challenge. Here the lost function can only be imitated. . . . We must fit the prosthesis not only to the patient's limb but to his whole personality" (Kessler, 1947, p. 5).

Comfort and function have long been accepted as important factors in the acceptance and use of the prosthesis by the patient. Studies have attempted to reveal additional predictor variables of prosthetic use. In one study of 107 upper limb amputees, 56% wore a prosthesis for approximately 11 hours per day for an average of 24 days per month; this study identified longer length of the residual limb, the absence of phantom limb pain, and married status as variables associated with use of a prosthesis (Raichle et al., 2009). Military service members from current conflicts have higher than previously recorded acceptance and use rates that may be a result of improved comfort and function of prostheses (Gailey et al., 2010; McFarland et al., 2010; Reiber et al., 2010). The patient's desire for a prosthesis is strongest after surgery and may wane as time passes, particularly for those with unilateral amputations, because compensatory one-handed techniques are typically quickly mastered. The patient with bilateral upper extremity amputations needs to function and therefore is likely to accept and use one or both prostheses in order to achieve some level of independence. Therapists may also be involved in evaluating the patient's satisfaction with the prosthesis using standardized measurement tools as well as measuring performance while using a prosthesis (Resnik & Borgia, 2011).

What defines a success? The definition is unique to the individual. When the prosthesis is viewed as necessary or meaningful for any activity, such as leisure activities, or for cosmesis, it has added to the quality of life and thus can be seen as successful. A patient with a unilateral amputation may use the prosthesis for particular activities, such as for sports, and these interests can change with time. The end goal is for self-selection of the type of prosthesis for activities and tasks that facilitate the highest level of independence and competency in life roles that are meaningful to the patient. However, this does not always assume prosthetic use in all daily activities. It is the team's responsibility to present all the options to the patient.

Although prosthetic use is the goal, another important discussion topic is the risk for development of a musculoskeletal overuse syndrome in the neck/upper back, the shoulders, and the remaining limb (Ostlie et al., 2011).

PROSTHETIC TRAINING PROGRAM

Initial Stage of Prosthetic Training

The initial stage of treatment can generally be covered in one or two therapy sessions. Procedures for Practice 41-2 has treatment guidelines for this stage.

Procedures for Practice 41-2

Treatment Guidelines for Initial Stage of Prosthetic Training

- Evaluate to determine roles, tasks, and activity needs and preferences.
- Evaluate the prosthesis.
- Explain program goals to the patient.
- Describe the functions of each component; give the patient an illustration of the prosthesis with components labeled.
- Teach the patient to don and doff the prosthesis.
- Discuss the wearing schedule with the patient.
- Teach limb hygiene care.
- Teach care of the prosthesis.
- Begin controls training using the terminal device.

Evaluation of the Prosthesis

The therapist evaluates the prosthesis before training begins. The evaluation is to determine (1) compliance with the prescription, (2) comfort of fit of the socket and harness, (3) satisfactory operation of all components, and (4) appearance (features) of the prosthesis and its parts. If the patient is fitted with a myoelectrically controlled prosthesis, it is important that the therapist have a good understanding of the prosthetic control setup in order to direct prosthetic controls training. Control setup refers to how the patient switches between modes (i.e., elbow control, wrist control, and hand open and close). The therapist should contact the prosthetist if there are any questions about the prosthesis setup.

First Therapy Session

Generally, patients with unilateral amputations attend therapy on an outpatient schedule several days a week; therefore, the first visit is important. The initial goal is to minimize negative experiences in order to facilitate future acceptance and use of the prosthesis. In addition to evaluation of the prosthesis, the following must also be covered during the first visit: (1) donning and removing the prosthesis, (2) wearing schedule, and (3) hygienic care of the residual limb if the patient did not receive preprosthetic care in the clinic.

Donning and Removing the Prosthesis. Donning and doffing of the full prosthetic system as independently as possible is critical to prosthetic use. The full prosthetic system includes (1) residual limb sock, (2) prosthetic donning liner, (3) alcohol-based lubricant gels, or powder, (4) prosthetic socket, and (5) harnessing as appropriate (Smurr et al., 2008).

Figure 41-12 Transradial myoelectric prosthetic donning method with pull sock. This method can also be used to don transhumeral level myoelectric prosthesis. **A.** Don the pull sock over the residual limb. **B.** Pull the laynard of the pull sock through the socket opening. **C.** Pull the pull sock completely through to ensure good skin contact.

There are a number of different methods for donning and doffing the BP prosthesis, but the two most common methods are (1) the coat method and (2) the pull-over method. To use the coat method, the residual limb is inserted into the socket, which is held in place with the intact hand, with the harness and axilla loop dangling behind the back. The intact arm reaches behind and slips into the axilla loop; a forward shrug of the shoulders positions the prosthesis in place. For the pullover method, the patient places the prosthesis in front of him or her, and the intact arm is placed through the axilla loop while the residual limb is placed into the socket. Both limbs are raised to lift the prosthesis and harness over the head as the harness falls into place. Initially, the prosthesis can be placed on a bed or dresser to support it as the patient slips into the prosthesis. When donning a myoelectric prosthesis, the patient may use a pull sock on the residual limb that helps to guide the residual limb into the socket and is pulled through an opening in the socket and allows for good skin and socket interface (Fig. 41-12, A–C). To allow for the highest level of independence of donning and removing the prosthesis, the patient, therapist, and prosthetist may need to collaborate to determine the simplest or most ideal method.

Wearing Time. The patient must increase wearing time gradually to develop tolerance to the socket and harness or type of suspension. The initial wearing time may be two to three 15–30-minute sessions spread out over the course of a day. Each time the prosthesis is removed, the residual limb must be examined for excessive redness or irritation and must not be reapplied until any

redness subsides. *Safety Message: Redness that does not disappear after approximately 20 minutes should be reported to the prosthetist for adjustment of the prosthesis.* Otherwise, prosthetic wearing time can be increased in 30-minute increments until the prosthesis can be worn all day. The importance of gradually increasing the wearing time cannot be overemphasized, particularly for patients with decreased sensation and scar tissue (Smurr et al., 2008).

Limb Hygiene. The residual limb is enclosed in a rigid socket where excessive perspiration can macerate the skin. Therefore it is important to instruct the patient to inspect the residual limb each time the prosthesis is removed to look for any skin changes or areas of irritation and to wash the residual limb daily with mild soap and lukewarm water and pat dry. If the patient experiences excessive sweating with the wear of the prosthesis, it is recommended the patient and therapist discuss this with the prosthetist. This discussion may identify any socket modifications or socks, liners, or special antiperspirant formulas that may be worn with the prosthesis without compromising the fit and suspension and without interfering with myosite electrodes. Alternative strapping methods for suspension may also be examined.

Operational Prosthetic Knowledge: Componentry and Maintenance

Componentry Knowledge. With all prostheses, the patient must obtain and demonstrate knowledge of prosthesis componentry terminology and a general understanding

of proper prosthetic maintenance. The prosthestist will provide education on the componentry and maintenance, and the therapist should reinforce this education during therapy. Basic common terminologies include but is not limited to (1) socket and harness design; (2) component identification, operation, and care; (3) types of TDs; (4) type of control system used; and (5) basic prosthesis mechanics. The goal is for the patient to be able to articulate problems to the prosthetist and therapist using correct terminology if the prosthesis malfunctions.

Care of Prosthesis. Mild soap and warm water are recommended for daily cleaning of the interior of the socket to remove any residues of powders, lubricants, and perspiration. It can also be wiped with rubbing alcohol every several weeks. The patient must be cautioned about agents that may stain or damage gloves. If using hand sanitizer, caution against using those with an added fragrance. The hook is rugged, but care must be taken during work in areas where there is excessive dirt, grease, or water. The patient must be especially careful with powered components and know which components must avoid contact with water or which are water resistant. Other special concerns are care of the batteries, methods of charging the batteries, and operation of the on/off switch.

Regardless of the type of prosthesis, basic prosthetic maintenance procedures that the patient is expected to become proficient with include (1) socket daily maintenance (i.e., daily cleaning and socket inspection), (2) routine battery charging procedures appropriate for the prosthesis, (3) component maintenance (i.e., routine cleaning and lubrication), (4) harness adjustment, and (5) rubber band replacement and cable system changes for BP prosthesis (Smurr et al., 2008). The therapist is responsible for ensuring the patient is appropriately trained and achieves maximal independence in all of the above procedures and can complete each task proficiently within his or her everyday environment.

Intermediate Stage of Prosthetic Training

The therapy program for the prosthesis is addressed in two phases: (1) prosthetic controls training and (2) prosthetic functional use training. Please refer to Figures 41-13 and 41-14 for schematic overview of controls training for BP and myoelectric prostheses by level of amputation.

Prosthetic Controls Training

Therapy for BP controls training begins with teaching the operation of each control, beginning with the TD. The therapist guides the patient to practice repetitive activation of each component. Transradial prostheses have a single control system that activates the TD

by cable pull. Patients are instructed to activate the TD (Fig. 41-15) through humeral flexion and scapular abduction (protraction). Transhumeral prostheses have a dual control system for the TD and elbow. The motions required to lock and unlock the elbow are a combination of scapular depression, and humeral extension and abduction (Fig. 41-16). Chest expansion can also be useful for patients with higher level amputations or with nerve involvement or other injuries impacting the residual limb; however, harnessing may need to be adjusted to capture this motion (Atkins & Edelstein, 2006). TD activation is achieved in the same manner as with the transradial controls except that the elbow must be locked. The patient with a transhumeral prosthesis may also have to learn to use the turntable to rotate the arm medially and laterally. For very short transhumeral amputations, the prosthetist may fit the patient with a shoulder joint as well, so the user should be trained how to position the shoulder to better accommodate specific activities.

Currently, myoelectric prostheses are frequent choices for prosthetic systems. Ideally, the patient has already received muscle site controls training during the preprosthetic period. When a myoelectric tester is used (a biofeedback unit can also be used), the goals are to isolate muscle contractions and increase muscle strength (see Chapter 20). Figure 41-17 depicts a two-state transradial system whereby two separate muscle groups are used to operate the TD. The intent is to choose muscles that physiologically closely correspond to the outcome motion and also produce strong electrical signals when contracted. It is also essential that the contractions can be isolated from one another. Cocontraction may be used to switch between functions (i.e., wrist rotation and TD control). Wrist extensors and flexors are commonly chosen to achieve opening and closing of the TD. For transhumeral amputations, the common choices are the biceps and triceps. For higher level amputations, as in shoulder disarticulation or forequarter amputations, the choices for control may be pectoralis or infraspinatus.

The therapy program begins with evaluation of the prosthesis, with special emphasis on the control system. Additional factors to be addressed with externally powered prostheses include the following:

- Are the electrodes aligned along the direction of the muscle fiber and placed over the site offering the best muscle control potential?
- Is there good contact between the electrodes and the skin? An imprint should be visible on the skin when the prosthesis is removed but should not be deep enough to cause irritation.
- Can the patient open and close the hand in various planes?
- If there is an internal battery, can the patient manage the battery charging strategy?

Controls Training for Body-Powered Prosthesis by Level of Amputation

Wrist disarticulation and transradial amputation (components include harness, cable and TD)

↓

Apply/Remove TD

↓

Demonstrate rotation of TD, if available

↓

Grasp and release with TD:
-through full range
-open to 1/3, 1/2, and 3/4 range

Elbow disarticulation and transhumeral amputation (components include harness, elbow lock cable, elbow flexion and TD control cable)

↓

Demonstrate unlocking/ locking of elbow

↓

Position and lock elbow to 1/3, 1/2, and 3/4 range

↓

Demonstrate free swing of elbow

↓

Position turntable component for internal/external rotation

Mimic motions of therapist for elbow and TD control

↓

With prosthesis positioned and locked in midline:
– Grasp objects of similar size, weight and density and transfer from one area to another in standing position (Same as above but in sitting position)
– Progress to grasping and releasing objects of various shapes, sizes, and densities in standing and in sitting

↓

Progress to grasping and releasing objects placed to the right/left of midline and at varying heights (encourage proper body mechanics)

↓

Have user grasp objects of various textures and densities without crushing (i.e. cotton ball, Styrofoam cup, potato chip)

↓

Have user complete functional unilateral and bimanual tasks with appropriate prepositioning, control and skill with the prosthesis

*Note: This diagram does not include shoulder disarticulation or forequarter amputation. Many people with these levels of amputation are unable to generate necessary motions to produce excursion through the harness and cables to operate a body-powered system, therefore they are rarely seen clinically.

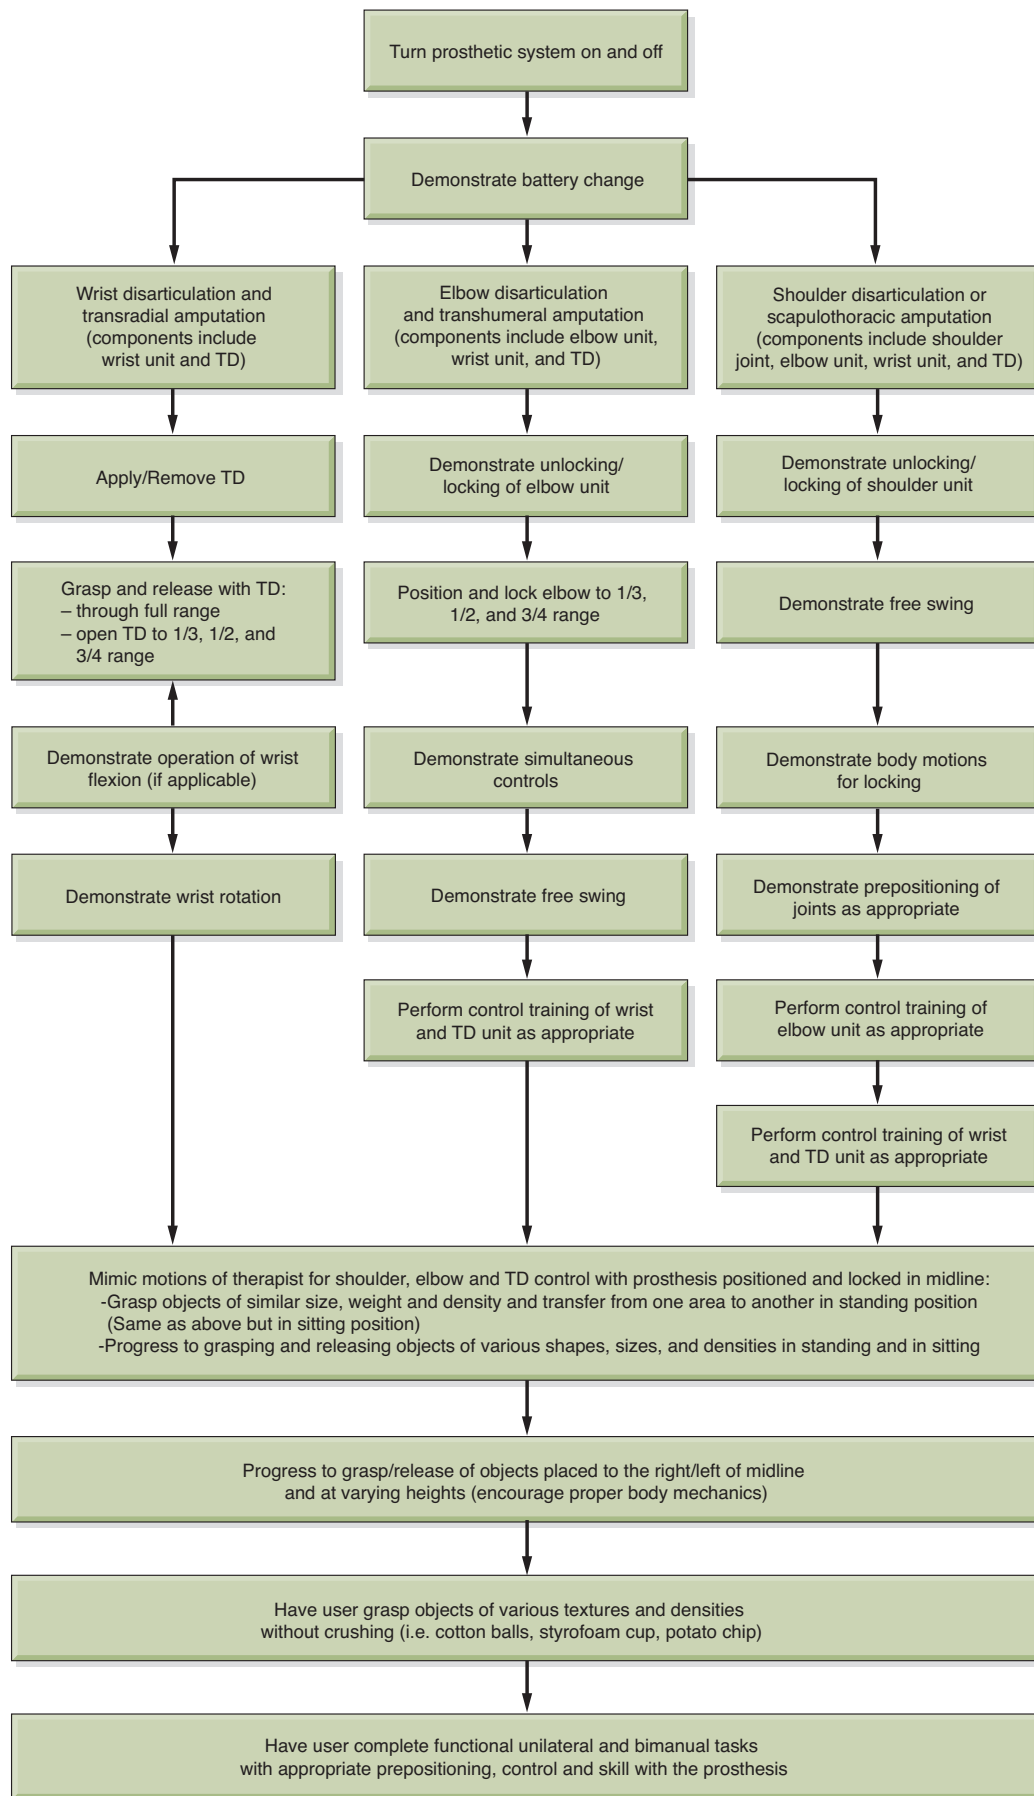
Figure 41-13 Controls training for body-powered prosthesis by level of amputation. TD, terminal device.


Figure 41-14 Controls training for myoelectric prosthesis by level of amputation. TD, terminal device.
Figure 41-15 Teaching activation of voluntary opening (VO) terminal device (TD). With elbow locked, the therapist guides the patient's upper arm forward to open TD. (Illustration by Gregory Celikyol.)

- If there is an external battery, can the patient remove and replace the battery with ease?

The therapist should consult with the prosthetist for guidance with any concerns with system setup and operation.

Practice in control drills requires instructing and coaching the patient in patterns of reach, grasp, and release of objects that vary in weight, size, texture, and
Figure 41-16 Motions (*arrows*) necessary to lock or unlock the elbow of a transhumeral prosthesis. **A.** Abduction with depression. **B.** Extension. **C.** Combined movement pattern of extension, depression, and abduction. (Illustration by Gregory Celikyol.)

configuration. Ordinarily, the sequence is from large, hard objects to smaller, softer, and more fragile ones. These assortments are subject to the therapist's ingenuity and the patient's interests. Initially, objects are placed on a tabletop for prehension practice; they are then transported to various locations in the room. The therapist instructs the patient to determine the most natural and efficient position for the TD before grasping an item and to rotate it in the wrist unit. This is called prepositioning the TD.

Eventually, the therapist instructs the patient to perform motion patterns in different planes away from midline through the functional envelope, such as overhead, at tabletop, and at floor level. The functional envelope refers to the area of space in which the patient can operate the upper limb prosthesis. Overhead use is the most difficult because of the harnessing system; overhead use is particularly difficult, sometimes impossible, for individuals with high amputations. The person with bilateral amputations may have a harness system that is bilaterally attached; therefore, the patient must practice relaxing the musculature on the contralateral side while using one prosthesis.

Prosthetic Functional Use Training

Spontaneous, automatic skillful prosthetic use is a goal for functional use training, particularly with bimanual tasks. Another is completion of activities within a reasonable length of time while using minimal extraneous movement and energy expenditure. Figures 41-18 to 41-25 show functional tasks. The therapist encourages patients to analyze and see similarities among situations and reminds them of relevant principles. This prepares the patient to respond with a sense of control in unpredictable situations.

A person with a unilateral amputation can be expected to use the prosthesis primarily for sustained holding or for stabilization. Table 41-1 suggests how some activities can be accomplished; Yancosek (2011) offers additional task suggestions. A key component to successful training is deliberate practice using the prosthesis for realistic, functional tasks. A landmark study by Lake in 1997 that has never been replicated revealed that individuals who received prosthetic training surpassed those who did not in efficiency of use, skill, and spontaneity.

Several factors affect the degree of independence of the person with bilateral amputations, the major one being the level of amputations. Some adaptations may be necessary for those with high-level bilateral amputations. These adaptations may range from a simple buttonhook or dressing frame—a stand in which coat hooks are inserted to hold clothing—to high-tech solutions, such as electronic aids for daily living and computers controlled
Figure 41-17 Myoelectric prosthesis, a two-state system in which two separate muscle groups operate the terminal device. **A.** 1, The muscle contracts and creates an electrical signal that can be measured in microvolts (1 millionth of a volt). 2, The EMG signal is detected by the surface electrode. 3, The EMG signal is processed by the electronics and transmitted to the electronic relay in the hand. **B.** 1, When the electronic relay receives an EMG signal from the wrist flexors, the circuit is complete, and the electricity from the battery runs the motor to close the hand. 2, When the relay receives an EMG signal from the wrist extensors, the motor runs in the opposite direction to open the hand. (Illustration courtesy of Jack Hodgins, CPO, Kessler Institute for Rehabilitation, West Orange, NJ.)

Figure 41-18 An individual using a body-powered prosthesis to play a tabletop game. Using the prosthesis as the primary mover during the game requires a high level of prosthetic control and skill. This type of activity would be appropriate during advanced prosthetic training.

Figure 41-19 The practice of holding a bottle of water with a myoelectric prosthesis and electric hand is an excellent functional activity to learn proportional control and build individual confidence in the prosthesis.

Figure 41-20 Individual with final hybrid prosthesis drinking from a water bottle. This demonstrates prosthetic integration into activity.

by breath, voice, or mouthstick. The therapist is advised to encourage foot use when patients show potential and are agile. Persons who have developed this ability at an early age have a high degree of independence. Feet have the advantage of having sensibility, which serves well in all activities and surpasses prosthetic use.

Figure 41-21 Practicing bimanual tasks with a myoelectric prosthesis and electric hand. This individual changing a diaper and dressing a doll using his prosthesis as an assist.

Figure 41-22 Practicing folding laundry with a myoelectric prosthesis with electric hand to learn to integrate the device during bimanual tasks.

Final Stage of Prosthetic Training: Instrumental Activities of Daily Living

In the final stage, prosthetic functional use skills are further developed, and daily living activities that are more demanding are introduced. Discharge planning should include exploration of vocational and recreational interests, driving, the use of public transportation, community reintegration, and adaptive sports. Visits to the community, home, school, and work are strongly advised. This brings the patient and therapist into the actual environment, away from simulated, static settings of a clinic. Patients may be encouraged to attend an amputee peer support group. These groups vary in their goals, but most provide a forum wherein people can interact and share experiences. Many groups provide ongoing educational programs on new prosthetic developments or on sports and recreational activities. See Resources 41-1 for organizations that may have local chapters.

Figure 41-23 Cutting vegetables using a body-powered prosthesis and a myoelectric prosthesis. It is important for the a patient with bilateral upper extremity amputations to learn how to hold a knife in the terminal device for functional activities such as cutting.

Figure 41-24 Tying military boots with a body-powered prosthesis. The individual is using the hook as an assist to hold the lacing during this task.

Figure 41-25 Assembling a mock weapon using a myoelectric prosthesis with a wrist rotator and wrist flexion component. This is a meaningful and purposeful activity for service members.

Sports and Recreation

Increasing numbers of individuals with amputations are pursuing recreational and sporting activities, and as a result, several customized prosthetic sockets and components are available for sports and recreational activities. Figures 41-26 to 41-29 show activity-specific sockets and activity-specific TDs used to facilitate participation in sports activities. The Internet is a good source of information for this and related topics.

Driving

Driving is of considerable importance in today's society. Many patients are eager to return to driving following

---

Table 41-1 **Suggested Approaches for Functional Activities: Unilateral Upper Limb Amputation**

Task	Prosthesis	Sound Limb
Eating		
Cut food	Hold fork	Cut with knife
Butter bread	Stabilize bread	Spread toward body
Fill glass from faucet	Hold glass	Turn knob or lever
Carry tray	TD in midposition to hold	Hold in midposition
Peel fruit	Stabilize with TD	Peel
Dressing		
Don and doff shirt or blouse	Don: prosthesis in sleeve first; doff: remove sound arm first	Don: sound arm last; doff: remove prosthesis last
Put clothing on hanger	Hold hanger	Place clothing on hanger
Buckle belt	Stabilize belt	Push belt through buckle
Tie bow	Stabilize lace	Manipulate and make loops
Button cuff on sound side	Use buttonhook (or sew on button using elastic thread)	Hold cuff in place with fingertips while using buttonhook
Use zipper	Hold fabric with TD	Pull zipper
Desk skills		
Write	Stabilize paper	Write
Insert letter in envelope	Hold, stabilize envelope at end	Insert letter and seal
Use phone, dial, take notes	Hold receiver: TD or with chin and shoulder	Dial and write
Draw line with ruler; use paper clip	Stabilize ruler; hold paper	Draw line; apply clip
General skills		
Take bill from wallet	Hold wallet or stabilize on table	Manipulate wallet and remove bill
Wrap and unwrap package	Stabilize box and paper	Manipulate box, paper; tie
Thread needle	Hold needle	Thread needle

TD, terminal device.

Figure 41-27 Commercially available activity-specific prosthesis with golf-ing attachment terminal device.

either an upper and/or lower limb amputation. Safe and independent driving involves a complex interaction of multiple systems to include one's physical, visual, cognitive, and behavioral abilities. When appropriate, the therapist makes the referral for a comprehensive driving assessment. The driving rehabilitation specialist will do a thorough chart review, patient interview, and clinical assessment, which may include a behind the wheel eval-uation. The driving rehabilitation specialist will make recommendations for any needed adaptive equipment or vehicle modifications. For example, a spinner knob or driving ring may be recommended for patients with a unilateral upper extremity amputation. Installation of a left-foot accelerator bar and pedal may be necessary for a person with a right lower extremity amputation. Hand controls can be installed for patients with bilateral leg amputations (see Chapter 26). There are companies available that may be consulted to do van conversions for patients who require multiple adaptations. Patients are encouraged to contact their state licensing agency or department of motor vehicles to determine whether there are any limitations or driving restrictions for those indi-viduals with amputations.

Figure 41-29 An individual with a short transhumeral amputation mountain biking wearing a custom activity-specific prosthesis. (Courtesy of Disabled Sports USA, Rockville, MD.)

Figure 41-30 An individual with a transradial amputation completing the 9-Hole Peg Test using a test socket with wrist rotation and flexion wrist components as well as the Motion Control ETD by Motion Control, Inc. (Salt Lake City, UT).

OUTCOME ASSESSMENTS

A special interest group of rehabilitation professionals called the Upper Limb Prosthetic Outcome Measures (ULPOM) group was formed to address the need for validated outcome measures for amputees (Hill et al., 2009). These specific instruments are needed because traditional dexterity assessments (e.g., Box and Blocks, 9-Hole Pegtest, and Purdue Pegboard) do not provide meaningful data for patients with amputation using a prosthesis for fine motor movements. Anecdotally, occupational therapists may use these traditional assessments to assess changes in performance pre- and postprosthetic training (Fig. 41-30); however, they are inadequate for determining true outcomes of the effectiveness of prosthetic interventions. Clinicians who frequently treat patients with upper limb amputations are interested in compiling normative data on this specialized patient population and developing the evidence base for intervention selection; therefore, they need more valid measuring instruments. Although more work is needed in

the area of outcome assessments for patients with upper limb amputation, there are five assessments worthy of consideration and use. Assessment Table 41-1 provides information on these assessments.

DISCHARGE PLANNING

At discharge, the team will educate the patient and the family on the process of follow-up with the clinic if occupational therapy is needed for future therapy, questions, or any other issues that may arise. The patient may continue an ongoing relationship with the prosthetist and return for modifications or if a new prosthesis is needed. As patients return to their occupational roles and lives, their needs may change, and in the future they may want to explore different prosthetic options and TDs for different activities. When new devices are received, more therapy and training in occupational therapy may be needed.

PARTIAL HAND AMPUTATIONS

As with any amputation, the surgeon performing a partial hand amputation attempts to preserve length with intact sensibility. At this level, retaining residual digits with adequate skin coverage and some degree of mobility and sensation is far superior to any prosthesis and is the goal. The principles of preprosthetic therapy (discussed earlier) apply to this level of amputation as well. Devices available for persons with partial hand amputations can be described as cosmetic, passive functional, or active functional prostheses.

Assessment Table 41-1 Summary of Outcome Assessments for Prosthetic Use by Upper Extremity Amputees

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Trinity Amputation and Prosthesis Experience Scales-Revised (TAPES-R) (Gallagher & MacLachlan, 2000)	A self-report instrument that consists of three scales (psychosocial adjustment, activity restriction, and satisfaction with the prosthesis), each one containing three subscales (Gallagher et al., 2010). Higher scores indicate greater levels of the factor measured.	Not reported	Face validity in that subscales resembled what they intended to measure (Gallagher & MacLachlan, 2000). Construct validity as compared to the World Health Organization Quality of Life Questionnaire ($r \geq 0.618$), the Impact of Event Scale ($r \geq 0.26$), and the Trait Meta Mood Scale ($r \geq 0.337$) (Gallagher & MacLachlan, 2000).	All scales showed good internal consistency. Chronbach's $\alpha \geq$ 0.89 (Gallagher et al., 2010), as did the subscales: prosthesis satisfaction: $\alpha = 0.94$, activity restriction: $\alpha = 0.72$–0.94, psychosocial adjustment: $\alpha = 0.788$–0.907 (Desmond & MacLachlan, 2005). Interrater and test–retest reliability not reported.	Not reported	Strengths: The patient can complete on his own and mail the results back. Available free from http://www. psychoprosthetics.ie/tapes-r.html Weaknesses: The psychometrics are incomplete.
Assessment of Capacity for Myoelectric Control (ACMC) (Hermansson et al., 2005; Hermansson, Bodin, Eliasson, 2006)	The ACMC is administered and scored on clinical observations of the myoelectric prosthesis user (Hermansson et al., 2005). It measures the ability to use a myoelectrically controlled prosthesis for bimanual tasks on 30 items in four different areas: gripping, holding, releasing, and coordinating between hands. Each person's performance is rated on a 4-point capability scale: 0 = not capable, 3 = spontaneously capable.	Not reported	Validated for ages 2–57 years. Determined to have internal scale validity by Rasch analysis (Hermansson et al., 2005).	Intrarater reliability was excellent ($\kappa = 0.81$) in the experienced raters; interrater reliability was fair ($\kappa = 0.60$) in the experienced raters (Hermansson, Bodin, Eliasson, 2006).	Not reported	Strengths: Patient performs a functional task of choice & Rasch analysis determines patient's score in relation to difficulty of task (Wright, 2009). Intra-rater reliability is also a strength. Weaknesses: Administering this assessment requires substantial training and clinical experience. The scores must be entered into the ACMC database and converted to interval-level linear measures, using the Rasch measurement analysis in the ACMC website (http://acmc.se/).

Assessment Table 41-1 | Summary of Outcome Assessments for Prosthetic Use by Upper Extremity Amputees *(continued)*

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Orthotics and Prosthetics User Survey (OPUS) (Heinemann, Bode, & O'Reilly, 2003)	A paper and pencil measure of upper extremity and lower extremity functional status, health-related quality of life, and client satisfaction with prosthesis/orthosis and services.	Not reported	Rasch analysis determined the survey possesses good internal consistency and construct validity (Burger et al., 2008; Heinemann, Gershon, & Fisher, 2006). Content validity based on input from patients, orthotists, prosthetists, physical therapists, occupational therapists and physiatrists.	Not reported	Not reported	Strengths: Modules exist for upper and lower extremity function. The instrument is copyrighted to maintain integrity but is available free of charge from Dr. Heinemann (a-heinemann@northwestern.edu) Weaknesses: No psychometric data available, including intra-rater reliability.
The Southampton Hand Assessment Procedure (SHAP) (Light, Chappell, & Kyberd, 2002)	Assesses the use of an upper limb prosthesis with 8 object manipulation and 14 ADL tasks. A functionality profile and an index of function are generated.	20–30 minutes	Content validity established by expert peer review.	Test–retest reliability and interrater reliability were established using analysis of variance and 95% confidence intervals.	Not reported	Strengths: One-hour training Available from http://www.shap.ecs.soton.ac.uk/index.php Weaknesses: A kit must be purchased or an evaluator hired. Psychometric data were not provided.
Activities Measure for Upper Limb Amputees (AM-ULA) (Resnik et al., 2013) Copies of the measure are available free of charge. Contact: Linda.Resnik@va.gov	The AM-ULA is an 18-item observational measure of activity performance for adults with upper limb amputation that considers task completion, speed, movement quality, skillfulness of prosthetic use, and independence in its rating system. Items are graded on a scale of 0–4 with 0 = unable, 1 = poor, 2 = fair, 3 = good, and 4 = excellent. A summary score is obtained. The potential scores range from 0 to 40.	30–45 minutes. More time may be needed for persons with more proximal level amputations.	Content: Occupational and physical therapists with expertise in rehabilitation of adults with upper limb amputation identified and refined content, scoring elements and criteria. Convergent: The AM-ULA was moderately correlated with most dexterity tests and with self-reported function. Known Group Validity: Subjects with more distal levels of limb loss had better scores than those with more proximal levels (p < 0.01).	Test–retest reliability: One study reported ICCs of 0.88–0.91. Interrater reliability: One study reported ICCs of 0.84–0.89 Internal consistency: Cronbach's α values were 0.89–0.91. (Resnik et al., 2013)	Sensitivity to change has not been reported to date. Minimum detectable change (MDC) 90 was 3.7 points MDC 95 was 4.4 points	Strengths: The AM-ULA is appropriate for users of all types of upper limb prosthetic devices and addresses the need for a validated performance-based measure of activity for adults with upper limb amputation.

ICC, intraclass correlation; ADL, activities of daily living.

Figure 41-31 An example of a final prosthesis for an individual with a partial hand amputation using ProDigits™ by Touch Bionics, Inc. (Hilliard, OH).

Some patients with a partial hand amputation may want a prosthesis that closely replicates the look of the hand and provides dexterity as well. Although cosmetic hand coverings are truly artistic endeavors, once they fit over the residual hand, tactile sensation is lost, which limits function. The passive functional prosthesis may be a highly specialized device that is task specific, or it may be a simple post to provide opposition. ProDigits™ (Touch Bionics, Hillard, OH) provide myoelectic control for partial hand amputations, specifically those with transmetacarpal level amputations (Fig. 41-31). Each ProDigit™ by Touch Bionics, Inc. (Hilliard, OH) is a self-contained finger that is individually powered through remote electrodes called force-sensitive resistors, more commonly known as FSRs. The prosthetist determines which setup will work best for the patient. Ultimately, these devices provide fine motor pinch, touch, grasp, and pointing that the patient had previously lost as a result of amputation (Harvey, Potter et al., 2012).

MANAGEMENT OF LOWER LIMB AMPUTATIONS

As previously mentioned, the primary reason for lower extremity amputations is disease. Patients may have a primary diagnosis of diabetes or vascular disease with secondary complicating factors that affect therapy, such as sensory deficits, kidney disease, cardiovascular disease, chronic infection, respiratory disease, and arthritis. Other factors influencing function and safe performance of ADL are impaired vision and memory deficits. The therapeutic program for patients with lower limb amputations requires collaboration between the physical therapist and occupational therapist. This may occur in the acute care setting immediately following amputation, in an outpatient clinic, or in the patient's home.

Both therapists will perform an evaluation of the patient. The physical therapist is responsible for limb wrapping, core and lower limb strengthening exercises, range of motion, preprosthetic, prosthetic, and gait training. Initial patient treatment sessions by both disciplines

may focus on ADL to include patient and family education on wound care, limb wrapping, bed mobility, transfers, and basic wheelchair propulsion and management skills. Safety is a major concern with lower limb amputations, particularly for patients with other comorbidities. Patient and family are educated on safety precautions with specific activities such as transfers. Treatment sessions may include safe transfers from the wheelchair to the bed, toilet, furniture, and car. Early patient education on desensitization of the residual limb is also addressed.

The occupational therapist may also include other self-maintenance skills, such as kitchen tasks, housecleaning and bed making during the treatment sessions. Home and community visits with the patient may be indicated. During standing activities and ambulation, special attention is paid to balance, posture, and equal weight bearing through both lower extremities. This may be challenging for certain individuals and the therapist should use visual or verbal cues if necessary. The physical therapist or the occupational therapist will teach fall recovery to the patient and the family because safety after amputations is always important.

The occupational therapist may recommend home modifications and equipment to the patient and family. Equipment often includes a transfer tub bench or shower chair for use while showering and bathing and safety arm rails around the toilet. These rails provide a means of arm support that assists with lowering to the toilet and coming to the standing position safely.

The primary surgical or medical team will clear the patient to start wearing a shrinker on his or her lower residual limb prior to receiving the first prosthesis. The patient needs to be educated on the proper shrinker donning techniques and care of the shrinkers and liners. The shrinkers should have no wrinkles, and seams should not be over bony areas or the scar. The patient must inspect the skin on the residual limb everyday to check for any changes in skin integrity before and after shrinker, liner, or prosthetic wear. If the patient has difficulty inspecting the residual limb, a long-handled mirror may be used to assist.

The physical therapist will assess and recommend the lower extremity prosthetic wearing schedule, the amount of assistance required, and assistive devices needed, as well as readiness for any standing or ambulation activities. A patient needs to be able to don and doff the lower extremity prosthesis independently. If unable, a family member needs to be educated and able to demonstrate the proper technique in donning and doffing the prosthesis. The occupational therapist continues to address ADL with the patient both with and without the prosthesis. The occupational therapist works with the patient to identify how to incorporate the prosthesis into daily activities while assessing energy, effort, balance, transfer, and mobility skills. Energy conservation methods should be included in the program. It is important to recognize

that energy expenditures are affected by limb amputation and prosthetic ambulation. The percentage increase in energy costs of prosthetic ambulation is 9%–28% for unilateral transtibial, 40%–60% for a unilateral transfemoral, 41%–100% bilateral transtibial, and 280% for bilateral transfemoral amputations (Shah, 2010).

MULTIPLE LIMB LOSS

Individuals with multiple limb loss present a unique set of challenges for the rehabilitation and prosthetic teams. With the U.S. military "surge" in 2010, there was a twofold increase in the number of service members evacuated from the theater of operations who had sustained triple and quadruple limb amputations (Anderson et al., 2012). This created a need for additional rehabilitation expertise in treating individuals with multiple limb amputations. Early focus is on basic ADL such as eating, bathing, toileting, and transfer techniques along with core strengthening and residual limb preprosthetic exercises. Early application of a prosthesis for at least one limb fosters adaptation and learning. It is highly recommended to have a team meeting with all team members, including the patient and family, regarding initial focus of rehabilitation, achievable goals, and progression of prosthetic training for both upper and lower extremity amputations (Harvey et al., 2012a).

The rehabilitation team and patient must discuss initial mobility options such as ambulating with or without wearing a upper limb prosthesis (Yancosek, Schnall, & Baum, 2008), use of an electric wheelchair versus a manual wheelchair for mobility, and the direct effects mobility choices have on areas such as home modifications and vehicle selection. As the patient progresses and is fitted with various prosthetic systems, it is imperative for the entire team to have open communication in how specific therapies are progressing to achieve the patient's goals and obtain higher levels of independence in both ADL and instrumental activities of daily living (IADL). General considerations that will influence rehabilitation for this subset of the amputee population include (1) increased body temperature secondary to reduced body surface area; (2) increased risk of joint contractures, weight gain, deconditioning, and bone resorption as a result of immobility; (3) unique pain management needs given architectural changes to the musculoskeletal system; (4) psychosocial issues, such as the importance of body image acceptance and return to work; and (5) likely ongoing medical risks, such as cardiovascular disease, metabolic dysfunction, musculoskeletal pain, and arthritis (Davidson, 2002; Naschitz & Lenger, 2008; Ostlie et al., 2011).

The therapeutic program must be structured to meet the patient's needs. As the patient masters the basics of prosthetic control systems and practices their use in activities, with the therapist's guidance as a facilitator, the patient chooses tasks that he or she values. The approach of analyzing tasks and problem solving on how best to use this tool, the prosthesis, regardless of its complexity, serves the patient well throughout life.

EMERGING TRENDS IN PROSTHETICS

Research and development activities increase during times of armed conflict, as is currently the case with military operations. As a result, attention is focused on the increase in numbers of amputations in a young, previously healthy population, whose members will hopefully live long, productive lives using prosthetic devices.

Recent improvements in lower extremity prosthetic devices related to materials include improved suspension sleeves and gel interfaces that directly contact the skin. The use of carbon fiber, urethane, and titanium combined with improved mechanical and microprocessor components has advanced the state of the art for lower extremity prosthetics (Harvey et al., 2012b). Innovations such as the iWalk BiOM (Bedford, MA) allow plantar flexion in a lower limb extremity prosthesis by way of on-board sensors relaying information to actuators during gait.

The next area of promise is in using pattern recognition to allow for a more natural (instinctive) control of the prosthesis. The C-leg from Ottobock (Minneapolis, MN) has a microprocessor (computerized) knee and has stumble recovery capability that improves static and dynamic balance in response to perturbation. Ottobock has also developed new computerized leg prostheses, the Ottobock X2 (microprocessor knee), and the Genium™ Bionic Prosthetic System, which offer features for more athletic wearers who wish to ambulate backward or on uneven terrain, carry weighted loads, or run without stopping to change settings. To address the frequent problem of low back pain common to lower extremity amputees, the Ossur Power knee (Aliso, Viejo, CA) produces knee extension and limits the physiological and mechanical work for the amputee. Regeneration and purposeful directing of biomechanical energy within a prosthesis shows promise for improved control options for individuals with lower limb amputations (Au, Berniker, & Herr, 2008; Ha, Varol, & Goldfarb, 2011; Hitt et al., 2010).

Developments in upper limb prosthetics include the capability to perform (limited) isolated digit motions and some natural actions such as "reflexive responses" triggered by sensors in the prosthetic hand that detect slip and automatically adjust grip, thereby reducing the mental load required of the user to visually monitor grasp. Although no commercial electric shoulder is currently available, LTI has developed an electric lock actuator to lock the manually positioned shoulder. Wrist flexion and rotation units are available on both BP as well as electric TDs. Motion Control (Salt Lake City, UT) has

a mechanical flexion/rotation component to incorporate with the electric TD.

Current Research Topics

The surgical approach called osseointegration requires the implantation of a titanium peg fixed to the bone to which a prosthesis can be attached. This approach reportedly has been successful for lower limb amputations and has further potential for upper limb prosthetics. If successful in higher level upper limb amputations, the need for suspension is eliminated because it provides a stable fixation for prosthetic attachment. It has the added advantage of enhanced proprioceptive feedback from the artificial limb. This has been a treatment option in Sweden since 1980 (Hagberg & Branemark, 2009), but the practice is still under investigation in the United States (Shelton et al., 2011) and is not currently approved by the Food and Drug Administration.

Targeted muscle-reinnervation (TMR) is a surgical technique to increase the number of myoelectric control sites available in a higher level amputation. After limb loss, the brachial plexus and peripheral nerves may remain intact in the residual limb. This procedure takes advantage of expendable regions of remaining muscle by denervating and reinnervating sections of tissue. When successful, this can result in myoelectric sites that correlate physiologically with prosthetic functions: the radial nerve innervates musculature that contracts when the subject attempts to extend the elbow; the distal radial nerve reinnervated area contracts to open the hand; the median nerve area contracts to close the hand (Kuiken et al., 2009). Additionally, while undergoing TMR, targeted sensory reinnervation can be undertaken to allow some sensory nerves from the amputated limb to be directed to chest skin (Kuiken et al., 2007). This results in perceived touch of the missing limb at nearly normal ranges and can be used for sensory feedback within a prosthesis. Early indications suggest that sensory reinnervation may be tapped to enhance control of multiple functions in the artificial arm (Kuiken et al., 2004). There is an existing OT protocol for amputees who have undergone TMR that should be used when working with these specific patients (Stubblefield et al., 2009).

Currently, surface EMG (electromyography) will only allow up to four channels of control in the forearm, but 18 extrinsic muscles supply the hand and wrist. Development is proceeding on implantable myoelectric sensors (IMES) small enough to be injected, with the hope of extending myoelectric control to multiple degrees of freedom in the hand simultaneously (Weir et al., 2003).

The Defense Advanced Research Project Agency (DARPA) Revolutionizing Prosthetics program has set its mission "to create a fully functional (motor and sensory) upper limb that responds to direct neural control, within this decade" (DARPA, 2012). DARPA has teamed with DEKA Integrated Solutions Corporation (Manchester, NH) and Johns Hopkins Applied Physics Laboratory (APL) (Laurel, MD) to meet its mission. This partnership has resulted in advances in socket design, electronics, componentry, signal processing, and implantable devices that can produce arm control for those with limb loss or other neurologic conditions affecting upper extremity function.

As of the time of this publication, the DEKA Arm System is still in the research and development phase and is not commercially available. The intent of the DEKA Arm System is to provide a device with capabilities far exceeding those in available prostheses. It includes a flexible socket design for improved comfort, up to 18° of freedom, 10 of the degrees powered, depending on level of amputation, multiple hand and pinch grips, and versatile control inputs (Resnik, 2010). The expectation is that this device will offer greater function, improved comfort, control scheme design flexibility, and more intuitive control for the user.

The goal of the DARPA APL arm project was to determine whether it was possible to operate a prosthetic arm by direct brain control. In September 2011, the first human volunteer was able to move a DARPA-funded arm through mind control. This accomplishment sets the stage for clinical trials to begin over the next several years. Future advances in engineering, medicine, and prosthetics promise technical improvements in the fit and function of prosthetics.

Vascularized composite allotransplantation (VCA) is an emerging field that has presented the option of hand transplantation to potentially replace and restore tissue, function, and nearly normal aesthetics after limb loss. According to the American Society of Transplantation (2011), "VCA refers to the transplantation of multiple tissues such as muscle, bone, nerve and skin, as a functional unit (e.g., a hand, or face) from a deceased donor to a recipient with a severe injury." As of July 1, 2011, 46 patients worldwide had received 66 hand transplants (American Society of Transplantation, 2011).

Currently, most hand transplantations occur as part of approved clinical trials, and thus an extensive medical, surgical, and psychological screening process determines eligibility. The procedure and rehabilitation is costly and complex (Lanzetta, Dubernard, & Petruzzo, 2007). There are inherent risks associated with hand transplantation such as immunosuppressive therapies and possible rejection of the transplant. However, the transplanted hand may not only restore the natural cosmetics of the physical hand but may also provide psychological recovery to the individual's sense of wholeness and normalcy after limb loss. The functional results of VCA are by no means immediate and require dedicated time for intensive rehabilitation (Dubernard et al., 2003; Lee et al., 2011). There still exists considerable controversy over the risk-to-benefit ratio of undergoing hand transplantation (Schneeberger, Ninkovic, & Margreiter, 2008), and the therapist working

with a patient with an amputation does well to study this topic because it may be of interest to the patient who may seek guidance in considering all his or her options. After treating five patients with eight transplanted hands, the occupational therapists at the University of Pittsburgh Medical Center outlined a rehabilitation protocol to assist other therapists facing such challenging patients (Pace & Macguire, 2011).

CONCLUSION

Rehabilitation of an individual with an amputation requires a holistic approach that addresses the psychosocial adjustment to limb loss as well as the physical recovery (Hannah, 2011). This approach includes working with the patient to achieve tolerance to wearing and efficiency in using a pros-

thesis to facilitate participation in activities and occupations. The therapist needs to understand the technology available to this population, which means communicating with the prosthetist and other team members to make decisions about prosthetic selection. Rehabilitation progresses across time to accommodate the phases of adjustment, acceptance, healing, recovery, and ultimate mastery of skills needed to achieve higher levels of function and independence. The field of prosthetics is rapidly developing and necessitates therapists to stay abreast of emerging technologies; however, keystone principles of occupation-based, patient-centered rehabilitation remain the foundation for a successful rehabilitation experience. The occupational therapist operating from a biopsychosocial perspective is poised to help an individual that has an amputation adjust, adapt, and facilitate success (Borrell-Carrio, Suchman, & Epstein, 2004).

case example
Z.M.: A Military Service Member with Multiple Limb Amputations

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information Z.M. is a 25-year-old active duty right-hand–dominant married male injured while deployed to Afghanistan. Z.M. is an infantryman with 5 years of service. This was his second deployment. He was on foot patrol with his unit and stepped on an improvised explosive device. As a result, he sustained bilateral transtibial and right transradial amputations. He was treated and then transferred to a U.S. military treatment facility. Z.M. spent 2.5 months as an inpatient before his discharge to an outpatient facility. He currently resides in on-campus apartment housing with his wife of 3 years and their 1-year-old son. As an inpatient, he received daily occupational therapy and physical therapy for preprosthetic training for both his upper and lower extremity amputations. He was discharged from inpatient rehabilitation with a tub transfer bench, a rental power wheelchair, and a rental manual wheelchair. The power chair allows him increased independence and mobility from where he is living to the hospital and in the hospital. If he is traveling by vehicle, the manual chair can be stored in the vehicle, and he will be pushed by his family once they arrive at their destination.	Understand the patient's diagnosis or condition	"Z.M. is an individual with three amputated limbs. He lost his dominant hand. I have several individuals on my caseload currently with similar injuries. One of my other patients was in Z.M.'s unit and injured 2 months prior to him."
	Know the person	"Z.M. has a strong military background. He excelled on both of his deployments and was respected by his peers and unit. He had planned to make the military a career, serve 20 years, and then retire. Although he has a positive attitude, I know there may be stress in his family related to their understanding of his injuries and the impact the injuries may have on his future. With these types of injuries, there are changes initially in occupational roles. His wife is caring for both him and their son and attending all his medical appointments with him. They do have strong family support."
Reason for Referral to Occupational Therapy Z.M. will transition to outpatient OT for continued amputee care, preprosthetic training, prosthetic training, wheelchair mobility, community reintegration, adaptive sports, and driving.	Appreciate the context	"I will be Z.M.'s occupational therapist for the duration of his rehab here. I have worked with his physical therapist and his prosthetist with multiple prior patients, and we all have a good multidisciplinary approach. I think Z.M. has the potential to do very well and be both an upper extremity and lower extremity prosthetic user in his daily activities. He should be fitted soon with all of his initial sockets."

Assessment Process and Results

During his initial outpatient appointment, the goals and expectations of the patient and his family were determined. Z.M.'s activities of daily living (ADL) status was evaluated, including the current level of assistance needed to complete tasks (e.g., donning and doffing upper and lower extremity shrinkers) and his primary means for mobility and transfers. Also evaluated was the extent of education he and his family has received about the amputee care program. During the evaluation, he reported that his pain usually is 3 out of 10 and is usually in his legs. He does report having phantom pain at night.

| Consider evaluation approach and methods | "I need to understand and observe Z.M.'s functional levels now before he gets his prostheses in order to develop my treatment plan. I am sure there will be tasks that Z.M. will find easier to complete with his upper extremity prosthesis, and I need to work with Z.M. to identify which tasks and in what sequence he performs these tasks." |

"Z.M. arrived in the clinic in his power wheelchair. His wife accompanied him. They stated that he still needs assistance with bathroom transfers and all ADL areas. He states he is compliant with shrinker wear and is very excited for his fitting for his upper and lower extremity prostheses this week."

Occupational Therapy Problem List

1. ADL dependent.
2. Need to change upper extremity dominance.
3. Active range of motion (ROM) deficit of right elbow, bilateral knees.
4. Passive ROM deficit of right elbow.
5. At risk for contractures of right elbow and bilateral knees.
6. At risk for falls.
7. Weakness of abdominal muscles and back muscles.
8. Activity tolerance limited to decreased conditioning.
9. Unable to ambulate.
10. Unable to independently transfer from wheelchair to toilet, bed, bath, or chair.
11. Unable to perform tasks one handed.

| Synthesize results | "Like many of my patients with multiple limb loss, Z.M. has many areas that need to be addressed, which may be overwhelming at times both for Z.M. and for me as a therapist. I need to engage Z.M. during each therapy session about his functional levels and review what he is working on outside of therapy." |

Occupational Therapy Goal List

Long-term goal: Z.M. will be independent in ADL and instrumental activities of daily living (IADL) with and without his prostheses and be a community ambulator with least restrictive assistive device in 12 months. Initial short-term goals:

1. Z.M. will be able to be moderately independent in his ADL.
2. Z.M. will be able to independently don and doff his shrinkers, liners, and sockets.
3. After completing his wear schedule, Z.M. will be able to wear his upper extremity prosthesis for 6–8 hours and use it for functional activities.
4. Z.M. will complete the *Handwriting for Heroes* change of dominance program.
5. Z.M. will attend two community reintegration events each month (e.g., attend lunch and a movie with community reintegration group).
6. Z.M. will attend his unit's redeployment ceremony in 4 months and will stand to welcome his unit back from deployment.

| Develop intervention hypotheses | "Z.M. appears to be learning how to control his upper extremity prosthesis quickly. I can use principles of learning with practice of functional activities to improve his independence in activities of daily living tasks." |

| Select an intervention approach | "I selected controls training tasks in the clinic that allowed Z.M. to master control of his body-powered and myoelectric prostheses for grasping, holding, releasing, and reaching for various objects. I increased the difficulty when appropriate and added bilateral tasks. Finally, I simulated daily living tasks in the clinic as well as instructed Z.M. to use his prosthesis at home in activities." |

| Consider what will occur in therapy, how often, and for how long | "Z. M. will attend both occupational and physical therapy daily Monday through Friday for at least an hour in each for approximately the next year. He will also have multiple appointments with both his upper and lower extremity prosthetists for casting, fitting, and adjustments of his sockets. I have the ability to discuss any problems or issues with the multidisciplinary team weekly at our outpatient meeting for all of our patients. Encouraging participation in community reintegration both with his peers and his family early is important. Attending the redeployment ceremony is an important military tradition and will be beneficial psychologically for Z. M., his family, and his unit." |

Intervention

Z.M. is expected to be compliant with his daily therapy appointments. His military job while here is to heal and progress to higher levels of function and independence. His daily OT sessions may vary day to day in the activities, tasks, and focus. Once fitted with his initial upper extremity preparatory prosthesis, focus will be on increasing prosthesis wearing time, donning, doffing, and controls training with various terminal devices. These activities may be performed while sitting in his wheelchair or while standing as he progresses in his wearing schedule for his legs. Mirror therapy will be used to decrease pain.

Know the person

Appreciate the context

"Z.M. performed well during his preprosthetic training as an inpatient and continued as an outpatient. He is able to demonstrate isolated control of his forearm flexors and extensors and understands how these movements will eventually help him control his myoelectric prosthesis. Z.M. is highly motivated in therapy and has good family support."

Next Steps

1. Continue to assess and improve ADL and transfer status.
2. Facilitate community reintegration and adaptive sports participation.
3. Begin vocational exploration.
4. Discuss driving and vehicle options and refer for evaluation.
5. Arrange for him to discuss the pros and cons of returning to military duty versus military retirement with military unit, his therapists, and his family.
6. Identify needed future home adaptations.
7. Provide patient and family education concerning advances in prosthetic components.

Anticipate present and future patient concerns

Decide whether he or she should continue or discontinue therapy and/ or return in the future

"Z.M. has the potential and motivation to do very well and be able to become very independent in his ADL and IADL. He wants to return to his previous level of function and be able to participate in leisure activities that he enjoyed previously such as fishing, running, and skiing. As he progresses and improves in function, it is very important that all members of the treatment team, including Z.M., are communicating well and identifying any issues that may arise. Z.M. has verbalized an intention to remain in the service after rehabilitation; however, he also states that he will continue to evaluate his functional levels and his ability to perform his military duties with his prostheses. He also values the future needs of his family in this important decision."

Clinical Reasoning in Occupational Therapy Practice

Prosthesis Training

Z.M. demonstrated effective use of his body-powered and myoelectric prostheses but verbalizes that he is challenged by current child care tasks that he would like to be able to do with his son, such as changing diapers, dressing, and preparing food and bottles. How can the therapist incorporate these concerns into the treatment program?

Summary Review Questions

1. Why is a shrinker used on the residual limb?
2. What are the most common causes of acquired upper and lower limb amputations?
3. What are the types of upper extremity prosthetic systems?
4. Which body movements are required for a patient using a body-powered prosthesis?
5. How does myoelectric control work?
6. What is the purpose of controls training and use training?
7. What are tasks a therapist might start with for functional (use) training with a prosthesis?

8. Why might an individual reject a prosthesis?
9. What is the role of the occupational therapist in the rehabilitation of the patient with lower extremity amputations?
10. What is TMR? How does this improve control of a prosthesis?
11. What are the challenges of treating a patient with multiple limb loss?

Glossary

Acquired amputation—Surgical amputation after birth as a result of trauma or disease.

Actuators—Motorized mechanisms or signals that activate a device or system.

Body-powered (BP) prosthesis—Person's own effort through body motion is used to apply tension on the control cable to activate the TD and/or the elbow unit.

Externally powered or myoelectric prosthesis—Electric or other motor that provides impetus to move the prosthesis or terminal device.

Functional envelope—The area of space in which the patient can operate an upper extremity prosthesis.

Hybrid prosthesis—Combines BP and myoelectric-powered control to operate the system; only available for prostheses for transhumeral amputations or elbow disarticulation amputations.

Myoelectric prosthesis—Has electrodes embedded in the prosthetic socket that pick up electromyographic signals that activate prosthetic components to open, close, or move.

Preprosthetic therapy program—Period from the postsurgical procedure until a test-socket (temporary prosthesis) or the permanent prosthesis is received.

Terminal device (TD)—Prosthetic hook, hand, or other prehensile device that is inserted into the wrist unit of the prosthesis.

Transfemoral amputation—Amputation across the axis of the femur; previously called above knee (AK).

Transhumeral amputation—Amputation across the axis of the humerus; previously called above elbow (AE).

Transradial amputation—Amputation across the axis of the radius and ulna; labeled by the larger of two adjacent bones; previously called below elbow (BE).

Transtibial amputation—Amputation across the axis of the fibula and tibia; labeled according to the larger of two adjacent bones; previously called below knee (BK).

Visual analogue scale—A straight line 10-centimeter scale with 0 centimeters meaning no pain and 10 centimeters meaning the worst pain imaginable; the patient marks a point along the scale that matches the amount of pain.

Voluntary closing (VC) mechanism—TD that remains open until tension is applied to the control cable for grasp.

Voluntary opening (VO) mechanism—TD that remains closed until tension is applied to the control cable to open it.

Cardiac and Pulmonary Diseases

Nancy Huntley

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Recognize the signs and symptoms of exercise/activity intolerance.
2. Identify the common cardiac diagnoses and their treatment in occupational therapy.
3. Understand various cardiac and pulmonary diagnostic studies and how these tests assist with treatment planning in occupational therapy.
4. Know the controllable risk factors for heart disease and ways to ameliorate their effect.
5. Be able to instruct patients with pulmonary disease in breathing techniques.
6. Know resources for further guidelines in cardiac and pulmonary rehabilitation.

INCIDENCE OF CARDIAC AND PULMONARY DISEASE

Between 1998 and 2008, the mortality rate from cardiovascular disease (CVD) decreased by 30.6% (American Heart Association [AHA], 2012). However, CVD remains the leading cause of mortality, causing one out of every three deaths in the United States (AHA, 2012). According to Summary Health Statistics for U.S. Adults 2010, 12% of Americans have been told by a health professional that they have heart disease, and 6% have been told they have coronary heart disease. There is a positive correlation between advancing age and increased incidence of heart disease (Schiller et al., 2010).

Pulmonary disease is also a significant cause of death in the United States. Chronic obstructive pulmonary disease (COPD) is the third leading killer of Americans (American Lung Association, 2012). Lung disease is not only a killer; it is also chronic and significantly alters the lives of those who have it. Of people with COPD, 50% say that the disease limits their ability to work, and 70% say it limits their ability to do normal daily exertion (American Lung Association, 2008).

Even though a clinician is not working in either cardiac or pulmonary rehabilitation, the diagnosis of cardiac or pulmonary disease in a patient's medical history has implications for the occupational therapist's treatment plan. For instance, a patient may carry the primary diagnosis of a recent stroke. If that stroke occurred shortly after coronary artery bypass surgery, certain precautions should be taken to protect the patient's sternum. When the patient has a history of heart disease, the therapist should also routinely measure heart rate and blood pressure both at rest and with activity to determine his or her cardiovascular response to rehabilitation. The occupational therapist must therefore be aware of these disease processes and know how they will influence treatment.

HEART DISEASE

Heart disease may be due to a blockage of the coronary arteries, diseases of the heart muscle, or structural anomalies of the heart. A myocardial infarction (MI), or heart attack, is death of the heart muscle caused by lack of blood flow caused by an obstruction of a coronary artery by thrombosed plaque or spasm. The patient's clinical history, along with several diagnostic tests, is considered when diagnosing a heart attack. The patient may first have an onset of symptoms known as acute coronary syndrome (ACS), which indicates acute myocardial ischemia and encompasses unstable angina, non-ST elevation myocardial infarctions (non-STEMIs) and ST elevation myocardial infarctions (STEMIs) (Kim, Kini, & Fuster, 2008). The patient may first have symptoms such as chest pain or pressure, which may radiate to the teeth, jaw, ear, arm, or midback. These symptoms may be accompanied by diaphoresis, shortness of breath (SOB), nausea, vomiting, and/or fatigue. The patient may present with one or more of these symptoms, and the severity and intensity varies from person to person. (Not everyone who has these symptoms will have a heart attack, but it helps to triage them to the appropriate treatment.) An electrocardiogram (EKG) will show where the damage to the heart muscle occurred. Meanwhile, blood tests for certain structural proteins and cardiac enzymes will confirm a heart attack and give an idea of the amount of damage done to the heart muscle.

If a person realizes he or she is having a heart attack, it is important to seek treatment immediately. It has been demonstrated in numerous multicenter trials that aggressive treatment with angiographic revascularization and antiplatelet drugs produces better results (Kim, Kini, & Fuster, 2008). The greatest benefit, especially with large heart attacks, is when treatment is initiated within the first 60–90 minutes after symptom onset (Antman, 2008). The sooner the patient receives treatment, the more heart muscle can be saved.

The left ventricle is the main pump of the heart. It pumps the blood from the heart to the rest of the body. Because the left ventricle does more work, it has a higher oxygen requirement than the rest of the heart. It is usually the first area of the heart to suffer from any coronary artery perfusion deficiency.

Types of Myocardial Infarction

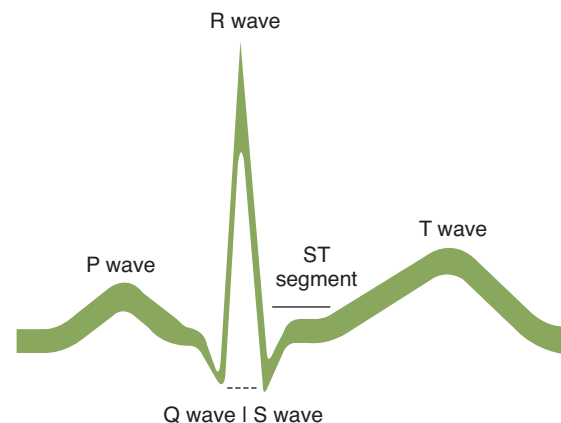
In evaluating an MI, an EKG is an important adjunct in determining the location of the MI and the severity of the infarction (see Fig. 42-1). An MI that involves all three layers of the heart muscle is called transmural, and


Figure 42-1 Basic EKG. (Google Images, 2012.) P wave reflects when the atria contract, the R wave reflects the ventricular contraction, and the T wave represents when the heart is repolarizing. If the ST segment is elevated, it is significant for myocardial injury. If the ST segment is depressed, there is myocardial ischemia. If there is a Q wave one-third the depth of the R wave, the patient has had a previous myocardial infarction.

it usually produces ST elevation on the EKG. It is referred to as an ST elevation MI, or STEMI. Most of these MIs will later produce a Q wave over EKG leads affected by the MI (Antman & Braunwald, 2008). A Q wave is an identifying characteristic showing where damage occurred. In STEMIs, the size of the infarct is important. If the STEMI is large or if the STEMI is small to moderate in a person with previous STEMIs, the prognosis is poor (Antman, 2008). An anterior STEMI is considered the most serious because of the large amount of muscle mass lost and decrease in the effectiveness of ventricular pumping action (Meyers, 2005). (See Definition 42-1 for a review of common diagnostic procedures.)

When the thrombus in the coronary artery is incomplete, less damage is done, and it is called a non-ST elevation MI or a non-STEMI. The majority of these MIs do not develop a Q wave. These MIs are called non-STEMIs or non–Q wave MIs (Antman & Braunwald, 2008). Although the immediate prognosis is better in patients with a non-STEMI, their future risk is often higher for death or further cardiac events because of a history of previous heart events, comorbidities or because of the extent of their underlying heart disease (Cannon & Braunwald, 2008).

Blockage in the left main or left anterior descending artery of the heart will cause damage to the front of the left ventricle and is called an anterior MI. When the right coronary artery is involved, the back and bottom of the left ventricle are damaged; this is called an inferior MI. The circumflex artery feeds the lateral wall of the heart, and blockage in this artery results in a lateral MI (Fig. 42-2).

Angina pectoris is heart pain caused by a temporary inadequate supply of blood to the heart muscle. Angina might be described as pain, aching tightness, or pressure. It is usually diffuse and located in the midchest, but it may radiate to the midback, teeth, ear, jaw, or arm. Typically, angina comes on with increased activity and is relieved with rest. Some people, however, may develop angina after a heavy meal or while resting. Nitroglycerin, taken by pill or spray under the tongue, usually relieves angina quickly. Angina is an indication of coronary artery disease (CAD); it is not uncommon to have angina after a heart attack. If the frequency or intensity of angina changes, the physician should be notified.

Percutaneous coronary intervention (PCI) or angioplasty is a procedure used to improve the blood flow through an occluded artery and reduce the symptoms of angina. Angioplasty requires the insertion of a catheter into the coronary artery at the site of the occlusion. On the end of the catheter is a balloon that is inflated until the arterial walls, at the point of the occlusion, are pushed out to allow more blood flow through the area. When just angioplasty is done on a blood vessel, the restenosis rate is high. Of patients with angioplasty, 30%–50% will experience restenosis within the first year (Shaffer, 2008). Currently, a stent,

which resembles a spring in a ballpoint pen, is usually used with the balloon. The stent lies over the balloon, and when the balloon is inflated, the stent opens and imbeds itself in the artery wall, forming a structure to keep the artery open. Stents without drugs are called bare metal stents. Stents with drugs coating them are called drug-eluting stents. When a bare metal stent is used, the success of the procedure increases to about 70%–80% (Popma, Baim, & Resnic, 2008). When a drug-eluting stent is used, the restenosis rate drops to less than 5% (Baim, 2010). Getting a patient who is having an MI quickly to the catheterization lab for an angioplasty/stent to the involved artery is now considered the standard of care. For each 30 minutes of delay in having a PCI after the onset of symptoms, there is an 8% increase in 1-year mortality (Antman, 2008).

For those patients whose lesions are too calcified to insert the angioplasty catheter, another procedure is available. It is called atherectomy. In atherectomy, the catheter inserted into the coronary artery has a rotating blade that cuts out the plaque. As it cuts the plaque, suction pulls the plaque through a tube and out of the body. Arthrectomy is usually followed with stent placement (Barsness & Murphy, 2007).

Open Heart Surgery

Open heart surgery is a procedure that usually involves a sternotomy that allows the surgeon to work on the heart. There are several types of open heart surgery.

Coronary artery bypass graft (CABG) is the replacement of occluded coronary arteries with artery or vein grafts. The patient is first put on a heart lung machine so that the heart can be stopped while the surgeon works and oxygenated blood will continue to be pumped through the body. The harvested grafts are then attached to the aorta and reconnected below the occlusion in the coronary artery. Sometimes the mammary artery, which comes directly off the aorta, is dissected from its original destination and used as a graft. Another arterial graft is the radial artery. Arteries are preferred as grafts, because they stay patent longer than vein grafts. Vein grafts are harvested from the legs.

Valve replacement and/or repair may be necessitated by destruction of a heart valve caused by disease or congenital malformation. If the surgeon is unable to repair the valve, it is replaced with a prosthetic or tissue valve. Prosthetic valves are very durable and last a lifetime. If a prosthetic valve is used, patients will have to take thrombolytics for the rest of their lives. The thrombolytics will prevent blood from clotting as it goes through the valve. A tissue or biothesis valve is from humans or pigs. These valves do not require the patient to be on thrombolytic therapy. Bioprosthetic valves last at least 15 years for 94% of the patients with an aortic valve and for 78% of

Definition 42-1

Common Diagnostic Studies for Heart Disease

Blood Tests

Blood tests are usually drawn on patients with symptoms of a probable heart attack. The cells of the heart contain isoenzymes and structural proteins, which are specific to that organ. Death of the heart's cells causes those isoenzymes and structural proteins to be released into the bloodstream where an increase in their levels can be measured. CPK MB is an isoenzyme that shows up in the blood within 6 hours after a heart attack and peaks in 24 hours (Davis, 2008). Troponin I and troponin T are two structural proteins whose levels rise with heart damage. Troponin I is the preferred structural protein to examine because of its specificity and sensitivity for myocardial ischemia (Blue Verrier & Hargrove Deelstra, 2010). Troponin levels start rising after 3–6 hours and stay elevated for up to 14 days, allowing detection of a myocardial infarction (MI) in patients who wait to seek treatment (Davis, 2008).

Natriuretic peptides BNP and pro-BNP are neurohormones made in the left ventricle, whose values increase in the bloodstream with ventricular wall stress. BNP is a strong diagnostic tool in CHF and a predictor of clinical outcomes in CHF, unstable angina, and non-STEMIs (Cannon & Braunwald, 2008).

Stress Echocardiogram

A stress echocardiogram is an exercise test usually conducted on a treadmill. Before starting the test, an ultrasound recording is taken of the function of the heart at rest. The patient is then exercised to his or her maximum capacity. After exercising, another ultrasound recording of the heart is done to show how the heart responds to work. It will show whether the heart muscle and valves work normally under pressure or if some parts respond suboptimally. It is also possible to measure how much blood the heart ejects with each beat. This number is the ejection fraction (EF).

A normal EF is >60%. A person is mildly impaired with an EF of 50%–59%. A person with an EF of 40%–50% has moderate impairment. An EF below 40% is considered significant impairment. The lower the EF, the higher the risk the patient has for further events and complications. In most cardiac conditions, the EF is a strong predictor of outcome and is helpful in determining treatment (Connolly & Oh, 2012). The EF does not always accurately reflect an individual patient's ability to work, but the EF is helpful as a starting point for making appropriate exercise and activity recommendations and precautions.

Stress echocardiography is approximately 85% accurate in predicting CVD depending on the cohort of the study (ACSM, 2010a). When a stress test is given without the echo, the accuracy is reduced to 75% in predicting heart disease, but patient's maximum exercise capacity and maximum heart rate with exercise are known.

Nuclear Stress Test

A nuclear stress test is conducted with a 12-lead electrocardiogram (EKG) as patients exercise to their maximum capacity on a treadmill. During this test, the patient is injected with a radioactive isotope when the patient feels only able to exercise for one more minute. The patient is then placed under a special instrument called a scintillation camera, which can detect the presence of the radioactive isotope in the heart muscle. This isotope has special properties, which allows it to be readily picked up by healthy myocardium cells, more slowly by cells with poor perfusion, and not at all by infarcted myocardium. Those areas with restricted blood flow may eventually "fill in" with the radioactive isotope, and these areas are said to have a reversible defect. Areas that do not "fill in" are infarcted, and the deficit is permanent (Nishimura et al., 2010). Because this process may take several hours, the nuclear test usually involves an initial scan, with another scan administered 2–3 hours later.

Transesophogeal Echocardiography

A transesophageal echocardiography (TEE) involves intubating the esophagus with a TEE ultrasound probe to visualize the cardiac structures such as the condition of the valves, both native and prosthetic; tumors; atrial septal defects; and congenital anomalies (Scordo, 2008).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive technique that uses radio waves, magnets, and computers to create pictures of the heart. It provides diagnostic information about the blood vessels, tissue, size of MI, the condition of valves, and neoplasms (Soine & Crawley, 2010). Often, contrast dyes are used with it.

Computed Tomography

In computed tomography (CT), the patient is surrounded by a 360° gantry of x-ray tubes, which gives excellent pictures of the coronary arteries and veins, valves, and patency of stents and picks up tumors and congenital abnormalities (Soine & Cawley, 2010). It is often used to assess coronary artery disease (CAD) in the symptomatic patient. When used for diagnosis of CAD, it has a 95% sensitivity, 60%–85% positive predictive value, and a 99% negative predictive value (Vora, 2011). There is radiation exposure with CT, and contrast dyes may be used with it.

Coronary Angiography

Coronary angiography is currently the most definitive test in the diagnosis of CAD. A catheter is inserted into a blood vessel in the groin and threaded back into the heart, and a radiopaque dye is injected through it into the coronary blood vessels. The extent of the obstruction in any coronary blood vessel can be visualized. A blockage must be greater than 70%–75% of the lumen to be considered significant. A lesion greater than 50% in the left main artery is considered equivalent to two-vessel disease. The length of coronary artery lesion(s) is also taken into consideration. In addition, heart valve function, ventricular wall motion abnormalities, and some heart defects can be detected (Paganda & Paganda, 2011).
Figure 42-2 Coronary arteries. Location of damage to the heart depends on which coronary arteries are blocked. (From Willis, M. C. [1996]. *Medical terminology: The language of health care.* Baltimore: Williams & Wilkins.)

the patients with a mitral valve, before they need to be replaced (Acar & Theodore, 2010).

Differently invasive bypasses or valve surgery are new techniques in which the bypass or valve replacement operations are done through small incisions (minimally invasive bypass) or are performed on a beating heart. In both cases, the patient is not put on a heart lung machine used during a standard bypass operation (Sabek, Bansilal, & Lyle, 2008). Minimally invasive surgery is done through several small incisions made between the ribs. In bypass surgery done on a beating heart, the patient has a sternotomy, but special instruments stop the heart from beating for a few seconds so the surgeon can sew the new bypass graft to the native coronary artery. In both types of differently invasive surgeries, the recovery time is much less than usual. However, the skill level to do both these operations is high, and they are generally done only when the arteries in the front of the heart are being bypassed or on the aortic valve.

Atrial septal defects are the most common type of congenital defect (Marelli, 2011). About 30% of people with atrial septal defect will develop symptoms in the third decade of life, but 75% will have symptoms by their 50s (Moons et al., 2008). When the heart has been attempting to compensate for a defect for a long time, it may become enlarged, and the patient may complain of fatigue and SOB. The current standard of practice is to repair these heart defects before the patient has significant symptoms or sustains myocardial damage.

Other Heart Diagnoses and Procedures

Congestive heart failure (CHF) describes the inability of the heart to function as an effective pump. The heart muscle becomes stretched beyond its ability to contract efficiently, resulting in the collection of fluid in the lungs or the extremities. In Western civilization, 60%–65% of cases of CHF are caused by CAD (Francis, Wilson Tang, & Walsh, 2012). CHF may also result from a number of other disease processes such as hypertension, incompetent valves, and cardiomyopathy (CM). Patients with CHF experience SOB and fatigue and may have an increase in weight and

Safety Note 42-1

Signs and Symptoms of Congestive Heart Failure

- Sudden gain in weight
- Inability to sleep lying down flat
- Persistent dry hacking cough, often with white frothy sputum
- Shortness of breath with normal activity
- Swelling in ankles or feet or legs
- Fatigue with activity
- Lack of appetite
- Difficulty focusing one's attention

Two organizations dominate the administration and policies of cardiac rehabilitation. One is the American Association of Cardiovascular and Pulmonary Rehabilitation (AACVPR), which published the book *Guidelines for Cardiac Rehabilitation and Secondary Prevention Programs*. Government agencies and third-party payers use this publication to determine appropriate cardiac rehabilitation policies and procedures. The second is the American College of Sports Medicine, which has multiple publications of use for those working in cardiac rehabilitation. Both organizations offer continuing education courses in cardiac rehabilitation. Together these two organizations shape the practice of cardiac rehabilitation.

a dry hacking cough. Often, they complain of coughing or being SOB in a recumbent position (see Safety Note 42-1 for signs and symptoms). The B-type natriuretic peptide (BNP) is a lab test routinely drawn to differentiate CHF from other causes of SOB (Hollenberg & Parrillo, 2010). The number of medication treatment options for patients with CHF has increased significantly, yet the mortality rate for CHF is high. Of those with CHF, 50% will die within 5 years (AHA, 2012).

CM refers to diseases of cardiac muscle. The three main types of CM are dilated, hypertrophic, and restrictive (Wynne & Braunwald, 2010). According to the American Heart Association Heart and Stroke Update (2012), dilated CM is the most common type of cardiomyopathy. Many diseases can cause dilated CM, but symptoms are an enlarged heart with decreased pumping capacity that usually results in CHF (Mestroni et al., 2012). Depending on the cohort of the study, 10%–50% of those people presenting to the hospital with CHF died within the first year (Hare, 2008). Approximately one-fourth of patients with dilated CM, for unknown reasons, improve or stabilize over time (Wynne & Braunwald, 2010). However, the most reliable predictor of a poor outcome is the decreased pumping function of the left ventricle as expressed by a low ventricular ejection fraction (EF) (Mestroni et al., 2012).

CARDIAC REHABILITATION

Cardiac rehabilitation usually involves a multidisciplinary team. Doctors, nurses, occupational and physical therapists, exercise physiologists, dieticians, chaplains, psychologists, and social workers may all play a part in the patient's recovery. Doctors, dieticians, chaplains, psychologists, and social workers perform their conventional roles

in treating the cardiac patient. None of the other allied health professionals, however, are trained specifically to work in cardiac rehabilitation, and all need additional training. Geographical tradition and availability of staff seem to determine what role each allied health professional plays. Members of each discipline use their own special skills in dealing with patients with heart disease, but their job expectations and responsibilities may essentially be the same. (See Resources 42-1 for information on organizations that develop policies and certifications in cardiac rehabilitation and Evidence Table 42-1 for the best evidence for cardiac rehabilitation.)

Occupational therapists are invaluable when treating the patient with heart disease. Therapists are able to evaluate and analyze the patient's activities of daily living (ADL). The therapist can then assist patients in modifying activities, if necessary, so that they can resume those activities they previously enjoyed. The occupational therapist's expertise in the rehabilitative process and knowledge of comorbid diseases is extremely important when evaluating and adapting treatment for the individual needs of the patient. Patients who have undergone lifestyle changes and experienced life-threatening diseases also benefit from occupational therapy intervention to help with psychosocial adjustment to their new situation.

Evidence Table 42-1 | Best Evidence for Cardiac Rehabilitation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Phase II cardiac rehabilitation (CR)	Two groups of women with syndrome X. One group was assigned to symptom monitoring and the other group attended a phase II CR program and symptom monitoring program.	Sixty-four women, 57.3 ± 8.6 years, who had chest pain and normal coronary arteries (syndrome X)	The cardiac rehab group received 8 weeks of exercise and symptom monitoring. The other group monitored symptoms for 8 weeks.	Randomized controlled trial. Level: 1B2a	Those who received CR showed improvements in exercise tolerance, quality of life, psychological morbidity, symptom severity, and cardiovascular risk. These improvements were not found in the symptom monitoring group.	Statistically significant differences between CR and symptom monitoring groups in terms of decreased symptom severity ($p = 0.009$, $r = 0.17$), hospital anxiety ($p = 0.008$, $r = 0.21$), depression ($p = 0.004$, $r = 0.24$), SF-36 physical functioning ($p = 0.006$, $r = 0.20$), and pain ($p = 0.028$, $r = 0.18$) and increased exercise tolerance on shuttle walk test ($p < 0.001$, $r = 0.32$).	Asbury et al. (2008)
Any form of supervised or unsupervised structured exercise program compared to a control group	Inpatient, outpatient, or community-based setting exercise program	6,111 patients	Varied from study to study. The minimum was 2 weeks with a minimum follow-up of 12 weeks	Systematic review and meta-analysis of 34 randomized, controlled trials Level: I	Yes, patients in exercise-based cardiac rehab programs had a lower rate of reinfarction, cardiac, and all-cause mortality.	Reduction in all-cause mortality (odds ratio [OR]) = 0.74; 95% confidence interval [CI] = 0.58–0.95) Reduction in cardiac mortality (OR = 0.64); lower risk of reinfarction (OR = 0.53); 95% CI = 0.38–0.76	Lawler, Filion, & Eisenberg (2011)

Any form of supervised or unsupervised structured exercise program (compared with usual care)	Inpatient, outpatient, or community- or home-based setting exercise program either with or without psychosocial and educational interventions	8,940 patients	Varied from study to study. Median intervention time was 3 months.	Meta-analysis of 48 trials Level: I	Yes, significant reduction in all-cause mortality and total cardiac mortality, a significant reduction in total cholesterol and triglycerides and systolic blood pressure, and lower self-reports of smoking	Reduction in all-cause mortality (OR = 0.80; 95% CI = 0.68–0.93) Reduction in cardiac mortality (OR = 0.74; 95% CI = 0.61–0.96) Reduction in total cholesterol level (weighted mean difference = −0.37 mmol/L; 95% CI = −0.63 to −0.11 mmol/L) Reduction in total triglyceride level (weighted mean difference = −0.23 mmol/L; 95% CI = −0.39 to −0.07 mmol/L) Reduction in systolic blood pressure (weighted mean difference = −3.2 mm Hg; 95% CI = −5.4 to −0.9 mm Hg) Reduction in smoking (OR = 0.64; 95% CI = 0.50–0.83).	Taylor et al. (2004)

Risk Factors for Heart Disease

One of the main goals of all phases of cardiac rehabilitation is primary and secondary prevention of heart disease. Primary prevention refers to efforts to prevent the development of heart disease. Primary prevention efforts are usually limited to health fairs and lecture series because health insurance currently does not cover its cost. Those costs are borne either by a sponsor (i.e., a hospital) or by charging admission. Therefore, most of the therapist's efforts are directed toward secondary prevention. Secondary prevention pertains to efforts designed to stop or slow the progression of heart disease. Improving an individual's risk factor profile is the method used by therapists for secondary prevention of heart disease.

Ten risk factors increase one's likelihood of developing CAD. The three risk factors that are not controllable are age, family history, and gender. With advancing age, an individual is at greater risk for heart disease. A family history of a first-degree relative, such as father, mother, brother, or sister, developing heart disease before age 55 years for males and before age 65 years for females increases one's risk (Johns Hopkins Health Alert, 2010). If one's father has premature heart disease, a man's risk doubles and a woman's increases by 70% (AHA, 2012). The risk of developing heart disease for both men and women doubles when another sibling has the disease (AHA, 2012). Men are more likely to develop heart disease 10–15 years earlier than women, but as women approach menopause, they lose the protective effect of estrogen, and their risk of heart disease increases (Stewart, 2008). Although heart disease is commonly considered a male problem, it is an equal opportunity killer. It remains the number one cause of death for both men and women (AHA, 2012).

Controllable Risk Factors

The risk factors that one can control are smoking, hyperlipidemia, hypertension, sedentary lifestyle, obesity, diabetes, and psychological stress.

Smoking is a major modifiable risk factor that contributes to heart disease in multiple ways. The incidence of heart disease is two to four times higher in people who smoke than in nonsmokers (Sohn et al., 2010). Smoking damages the endothelial lining of the coronary arteries, making them more susceptible to plaque formation. Nicotine causes vasoconstriction of the arteries and increases heart rate. Smoking makes the heart more susceptible to lethal ventricular arrhythmias and predisposes it to coronary artery spasm (Ridker & Libby, 2008). Carbon monoxide in cigarette smoke binds with the hemoglobin faster than oxygen, resulting in less oxygen being distributed to the tissues. Nicotine alters the metabolism of fats, increasing the levels of atherogenic low-density lipoprotein (LDL) cholesterol and decreasing the levels of the heart-protective high-density lipoprotein (HDL) cholesterol. Smoking also causes the blood to coagulate more quickly and promotes thrombus formation (Ridker & Libby, 2008). Even those who are regularly exposed to secondhand smoke at work or home have a 25% increase in their risk of CVD (AHA, 2012). However, if a person quits smoking after their first MI, the benefits accrue quickly. Within a year, their risk for heart disease drops by 50%. Their risk continues to decline over time, so that after 15 years of smoking abstinence, their risk of coronary heart disease is equal to someone who has never smoked (Sohn et al., 2010).

Hyperlipidemia or a high lipid level is a major risk factor among Americans. It has been determined that a total cholesterol level below 200 mg/dL is desirable. LDL or "bad" cholesterol is acceptable below 130 mg/dL for those without risk factors for heart disease. LDL should be below 100 for those at risk of heart disease, and LDL should be below 70 for those with known CAD. HDL or "good" cholesterol of less than 40 mg/dL for men and 50 mg/dL for women significantly increases the risk of heart disease. Triglycerides should be under 150 mg/dL to be considered normal (Mayo Clinic, 2012). Cholesterol levels may be lowered through a low-fat diet, regular aerobic exercise, and weight loss. If these options are unsuccessful, the physician will put a patient on a lipid-lowering drug. Others are put on lipid lowering drugs because they inherit an inability to metabolize lipids normally. They have very high lipid levels in their blood because they manufacture high levels of their own cholesterol. According to multiple trials on lipid-lowering drugs, these medications decrease the risk of heart disease by lowering blood cholesterol (Blaha et al., 2012).

The American Heart Association Heart and Stroke Update (2012) classifies blood pressures greater than 140/90 at rest as being hypertensive. Hypertension causes damage to the arterial walls and causes increased myocardial oxygen consumption because of the need for the heart to do more work against high pressures (Medline Plus, 2012). People with hypertension have a two- to fourfold higher risk of heart disease and heart failure than normotensive individuals (Dennison, Miller, & Cunningham, 2010). Other than taking medication, individuals can improve their blood pressure by weight loss, eating a low fat diet, reducing sodium intake, eating lots of fruits and vegetables, regular aerobic exercise, moderation in alcohol intake, and controlling other risk factors for CAD (Blaha et al., 2012).

Sedentary lifestyle is a risk factor for heart disease. The relative risk of a sedentary lifestyle for heart disease is comparable to the risk associated with smoking, hypercholesterolemia, and high blood pressure (Sohn et al., 2010). Regular physical exercise assists with weight control, lowers blood pressure, and improves the lipid profile and glucose tolerance (Ridker & Libby, 2008). The Centers

for Disease Control and Prevention (CDC) and the American College of Sports Medicine (ACSM) recommend that adults get 30 minutes or more of moderate physical activity on most and preferably all days of the week (CDC, 2008). Results of a meta-analysis of multiple studies suggested that patients who undergo cardiac rehabilitation exercise training after an MI have 25% reduction in cardiovascular and all-cause mortality (Clinical Knowledge Summaries, 2007). Because of the effect of exercise on the heart, circulatory system, and other risk factors, aerobic exercise is an effective weapon against heart disease.

In the United States, 68% of adults are overweight or obese (AHA, 2012). Obesity is now the second leading preventable cause of death (Burke et al., 2010). Obesity is closely related to and influences negatively a number of risk factors for heart disease such as hypertension, diabetes, hyperlipidemia, and physical activity. The distribution of body fat is important in disease promotion. Central or abdominal obesity is linked to increased risk of CAD (Warzeski et al., 2008). The loss of even 5%–10% of one's weight, however, can have a positive influence on risk factors such as hypertension, lipid levels, and sleep apnea (Warzeski et al., 2008).

Diabetes has long been recognized as a risk factor for heart disease. The incidence of type II diabetes has doubled in the past 30 years and parallels the increase in obesity (AHA, 2012). Women who have diabetes lose the protective effect of their hormones against heart disease, and their risk of CAD is significantly higher than that of nondiabetic women (Sweeney, 2010). Compared to people who do not have diabetes, people with diabetes have two to four times the death rate from heart disease (AHA, 2012). Keeping blood sugar levels in good control through medication, diet, and exercise reduces macro- and microvascular disease in patients with type I and type II diabetes and thus reduces the risk of heart disease (Cade, 2008).

Stress is also considered to be a risk factor for heart disease, but its effect is difficult to quantify. Several studies have shown that depression, low social support, and stress increase one's risk for CAD and other adverse life events (O'Connell-Edwards, York, & Blumenthal, 2008). Chronic stress negatively affects the cardiovascular system by increasing the heart rate, blood pressure, blood lipid levels, and blood clotting. Managing chronic stressors with relaxation techniques or through behavioral change is helpful in eliminating or minimizing the effect of stress on the body.

As part of secondary prevention, the therapist must direct considerable energy toward educating the patient regarding the significance of these risk factors and methods of ameliorating them. Education may take place in one-on-one sessions, such as with the patient while doing a home program, or with groups of patients before, during, or after exercise.

Inpatient Cardiac Rehabilitation or Phase I

The goals of inpatient cardiac rehabilitation are to prevent muscle loss from bed rest, monitor and assess the patient's ability to function, instruct the patient in appropriate home activities, educate the patient about individual risk factors, and teach methods to lessen these risks.

Therapists treat each patient at least once a day and usually twice daily as soon as the patient's medical status has stabilized, often within the first 24–48 hours after admission. Hospital stays for coronary events have declined significantly in the past 10 years. The average stays are 1 day for the uncomplicated non-STEMI, 2–3 days for STEMIs, and 3–7 days for open heart surgery.

The occupational therapist working in cardiac rehabilitation initiates therapy on a one-on-one basis so that the therapist can interview the patient regarding lifestyle and assess the patient's cardiovascular response to exercise. During exercise, physical measurements of heart rate, blood pressure, EKG response, and symptoms are noted. Occupational therapists working in cardiac rehabilitation need to take an EKG reading course. See Procedures for Practice 42-1 for instructions regarding blood pressure measurement and pulse taking.

Although programs vary in the type of exercise done, many begin with mild calisthenics for 2-minute bouts followed by a 1-minute rest for people post bypass or those with CHF. Initially, the total time of the calisthenics added together is 4–8 minutes, depending on the patient's tolerance. As the patient progresses, the amount of time the patient may spend doing calisthenics typically increases to 8–10 minutes. Hall walking, treadmill, and/or stairs are added to those with surgery and CHF as soon as they can tolerate it. With patients who have had non-STEMIs, STEMIs, or percutaneous transluminal coronary revascularization (PTCR)/stents, the therapist usually starts with hall walking or treadmill and may add stair climbing. Other modalities, such as NuStep® and bicycle ergometer, may be added to all of the diagnoses as tolerated (Fig. 42-3). Regardless of the modality used, each is started gradually (treadmill walking at 0.8–2.5 mph or less for about 3–15 minutes) with progression based on the patient's tolerance and diagnosis. It is important for the therapist to assess the patient's heart rate, blood pressure, EKG, and symptoms to establish the patient's tolerance for exercise (see Safety Note 42-2).

Home Programs

Each patient is given a home program before discharge from the hospital. The type of program given is individualized to the patient and his or her particular diagnosis. The general components of a home program are activity and exercise guidelines, work simplification, pacing, temperature precautions, social activity, sexuality, signs and symptoms of exercise intolerance, and/or a discussion of risk factors. Depending on the diagnosis, certain aspects

Procedures for Practice 42-1

Measuring Blood Pressure and Pulse

Measuring Blood Pressure

1. Wrap blood pressure cuff 1 to 1.5 inches above the antecubital space.
2. The cuff should be wrapped smoothly and firmly around the arm.
3. The bladder of the cuff should cover 80% of the arm circumference.
4. Palpate the brachial pulse on the medial aspect of the arm.
5. Place the stethoscope over the pulse.
6. Close the valve on the inflation ball.
7. Inflate the cuff 20 mm Hg greater than the point where you hear the pulse obliterated.
8. Slowly open the valve on the inflation ball so the mercury or arrow drops at the rate of 2–3 mm per second.
9. The first sound heard is the systolic pressure; make a note of that number.
10. Continue to listen until the pulse starts to muffle and finally disappears.
11. The point at which the pulse disappears is the diastolic pressure; make a note of that number.
12. Be sure to listen for 30 mm Hg longer to make sure you heard the exact last pulsation.
13. Completely deflate the cuff and remove from the patient (Berman & Snyder, 2012).

To be considered normal, blood pressure must be under 140/90 at rest. Systolic blood pressure should rise with exercise. Diastolic blood pressure should stay the same or drop slightly. With exercise, diastolic blood pressure should not increase more than 10 mm Hg compared with resting. The blood pressure response of patients with a history of high blood pressure is likely to be exaggerated with exercise.

Pulse Taking

1. Locate indentation on lateral side of wrist about 0.5 inch proximal to the wrist crease.
2. Palpate the radial artery with the index and middle finger.
3. Count the number of pulsations for 10 seconds.
4. Multiply that number by six to determine the number of beats per minute.
5. Notice if the pulse is regular or irregular.
6. Also note any "skipped" or early beats.

A normal heart rate (HR) range at rest is between 60 and 100 beats per minute (bpm). Someone who is very fit, such as a runner, may have a heart rate in the 40s or 50s. After open heart surgery, a patient often has a heart rate in the low 100s. It is not uncommon for patients who have valve repair or replacement to develop a rapid heart rhythm called atrial fibrillation. This rhythm is usually controlled with medication or by cardioversion. *Safety Message: If the patient's HR is uncontrolled and is 120 bpm or higher at rest, exercise is contraindicated.*

Figure 42-3 Patients exercising in inpatient cardiac rehabilitation to maintain muscle tone and endurance. The exercises also allow the therapist to evaluate the patients' cardiovascular response to light-to-moderate activity while they recuperate from significant myocardial infarction, congestive heart failure, or open heart surgery.

Safety Note 42-2

Signs and Symptoms of Exercise Intolerance

- Chest pain or pain referred to the teeth, jaw, ear, or arm
- Excessive fatigue
- Shortness of breath
- Light-headedness or dizziness
- Nausea or vomiting
- Unusual weight gain of 3–5 pounds in a 1–3-day period

If a Patient Needs to Take Nitroglycerin

A patient with chest pain or angina, who has a prescription for nitroglycerin, should try a nitroglycerin pill under the tongue. If the chest pain has not disappeared within 3–5 minutes, another nitroglycerin pill should be tried, and 911 (or the within-hospital emergency number) should be called. The patient may take a third nitro pill after another 5 minutes if he or she needs it. The doctor should be notified when the patient first has angina or if there are changes in the frequency or intensity of episodes of angina. Notify the physician if other symptoms of exercise intolerance persist after resting.

of the home program are emphasized or minimized. The information should be pertinent to the patient's lifestyle, including favorite activities, work, and/or hobbies with suggestions for resuming these activities.

Open Heart Surgery Home Program Patients who have had open heart surgery are given directions that are more specific. They are in pain and under the influence of analgesics, which may affect retention of information. They are told specifically what to do and what to avoid. They are also given information on stretches and mild exercises to assist in incisional pain management. In these patients, the sternum has been broken, and it must be treated like any other broken bone. Surgical patients are to avoid lifting, pushing, or pulling greater than 10 pounds for 6–12 weeks. Therapists should make recommendations for alternative ways of doing activities to avoid one-sided pulling. For example, when pulling open a heavy door, it is desirable to use two hands, or when picking up a heavy coffeepot, put one hand covered with an oven mitt on the bottom of the pot and the other hand on the handle. Patients who complain of feeling sternal shifting or clicking are told to try to avoid the activity that causes it and to stop any upper extremity (UE) exercises. Usually, the clicking goes away with just a little care. Be aware that individual surgeons have their own views regarding the exact length of time to avoid lifting and the amount of arm activity they will allow. Walking schedules that increase gradually, such as 1 minute per day for those very deconditioned or 2–5 minutes a day for those with small MIs, are issued. Patients are also given information regarding the possible emotional and physical responses they may expect during the healing process, such as easy fatigability or depression. Patients are encouraged to express their affection and intimacy. After open heart surgery, it is generally suggested that patients wait 6–8 weeks before resuming sexual intercourse (Levine et al., 2012). When patients initially resume sexual intercourse, they may wish to try positions that avoid strain on the sternum, such as side-lying or sitting in a chair facing each other.

Congestive Heart Failure Home Program Patients with CHF and/or CM often have limited endurance. Their home program puts heavy emphasis on pacing and work simplification. It also includes a mild exercise program. Information regarding their diagnosis is given to help these patients understand that overexertion could put them back into heart failure. Signs and symptoms of CHF are included to alert the patient to signs of worsening medical status (see Safety Note 42-1).

Myocardial Infarction Home Program The home program of a patient who has had an STEMI will tend to highlight how to evaluate activity/exercise and determine the correct energy expenditure during the patient's recovery.

Definition 42-2

METs

METs, or metabolic equivalents, are a unit of measure used to describe the amount of oxygen the body needs for a given activity. One MET is equal to oxygen consumption at rest or 3.5 ml of oxygen per kilogram of body weight per minute (ACSM, 2010b). Extensive oxygen consumption tests have been done on a number of activities, and a small sampling of activities is included in Table 42-1. These values are still approximate because they do not take into account environmental factors or skill. The more the body moves and has to work against resistance, the higher the MET level.

Healing of the heart muscle takes about two to four weeks depending on the amount of damage sustained. Patients are usually asked to restrict their activities to the 2–4-MET range during this time (Definition 42-2 and Table 42-1). Pacing and work simplification may also be explained. This is especially important when the patient has had a significant amount of heart damage. A walking or biking exercise schedule is issued. Depression and sexuality are discussed because certain cardiac medications can play a significant role in mood as well as sexual function and desire. Patients should be told that, if there is a change in sexual ability or desire after their cardiac event, they should talk to their doctor to explore the role of any new medications in those changes. The AHA suggests that post-MI patients who can tolerate activities between 3 and 5 METs without symptoms, are ready to resume sexual intercourse (Levine et al., 2012).

Angioplasty Home Program Patients admitted for ACS and who have revascularization PCI are usually seen for home instruction. The goal of this home program is to teach risk factor recognition and patient awareness of ways to modify these risks. An aerobic exercise program positively affects most risk factors for heart disease. Therefore, a variety of ways to exercise are discussed, with the goal of finding one or several modes of aerobic exercise that might interest the patient. For example, if the patient chooses walking, options such as mall walking, treadmill and video walking programs, and outdoor walking are explored. Patients are given instruction in how to start an exercise program and taught how to assess their physical response to exercise using the Borg Rating of Perceived Exertion (RPE) Scale (ACSM, 2010a) and heart rate monitoring, if appropriate. Again, the therapist reviews signs and symptoms of exercise intolerance. Stress reduction techniques may be covered, and other resources for stress reduction are given. If the patient is a smoker, his or her willingness to quit is

Table 42-1 MET Values for Various Activities

Home	Leisure and Vocational	Exercise and Sports
1.0–2.5 METs		
Sweeping floors Dusting Straightening up Serving food Table setting Knitting and crocheting Putting away groceries Making bed Standing quietly in line Mowing lawn with a riding mower Sexual activity (general, moderate effort) Dressing and undressing Sleeping Watching TV Dish washing Bathing–sitting Changing light bulbs Hairstyling–standing	Power boating Fishing from boat Pumping gas Typing, computer Sitting for light office work Card playing, sitting Board games Playing piano or organ Driving tractor Sewing with a machine Driving an auto or truck Sitting to study, read, or write Casino gambling–standing	Walking at slow pace Playing catch with a baseball or football Horseback riding, walking
2.6–4.0 METs		
Child care bathing and grooming Walk, run, and play with children (moderate) General house cleaning Walking downstairs Sweeping garage or sidewalk Raking lawn Walking and carrying load of 15 pounds	Pitching horseshoes Home auto repair Planting seedlings and shrubs Playing the drums Home wiring or plumbing Feeding small farm animals Standing doing light-to-moderate effort Bartending–standing Walking and picking up yard Sailing Motorcycle riding	Very light stationary biking Weight lifting of light-to-moderate effort Stretching, yoga Golf using a cart Snowmobiling Walking at moderate speed Water aerobics Walking pushing a wheelchair Bicycling (<10 mph) Activity videos moderate effort (i.e., Wii Fit™ aerobics and weight training) Curves™ exercise for women
>4.0–6.0 METs		
Major house cleaning, such as washing windows, vigorous effort Moving furniture Scrubbing floors on hands and knees Cleaning gutters Painting the outside of house Painting and wallpapering inside of house Weeding or cultivating Walking carrying a 15-pound load	Laying carpet or tile Slow wood chopping Farming, feeding cattle Carpentry on outside of house Carpentry, refinishing surfaces Hunting–general Road building, carrying heavy loads Roofing Golf, carrying clubs	General calisthenics, moderate effort Shooting hoops Softball, fast or slow pitch Low-impact or dance aerobics Dodgeball or hopscotch Bicycling (10–11.9 mph) Walk/jog (with jogging part less than 10 minutes) Elliptical, moderate effort
6.0–10 METs		
Carrying groceries upstairs Moving household items in boxes Shoveling more than 16 pounds per minute (heavy) Walking or standing with objects weighing 50–74 pounds	Farming, bailing hay Concrete masonry Moving heavy objects such as furniture Firefighter carrying hoses	High-impact aerobics Running 10–12 minutes/mile Basketball game Jump roping Race walking Swimming laps at a moderate pace Bicycling at moderate pace (>12 mph)

Roitman (Ed.), *ACSM's resource manual for exercise testing and prescription* (pp. 656–667). Baltimore, MD: Williams & Wilkins.

assessed. If the patient is in the planning or action phase of quitting, information regarding the effects of nicotine on the body is given, as well as assistance in planning how to beat the urge to smoke and resources for support groups. All information is written so that the patient may refer to it later.

Patients with PCI, MI, CABG, or valve replacement or repair are all referred to outpatient cardiac rehabilitation to continue skilled monitoring of exercise and risk factor education and modification. Patients who have CHF are not covered by Medicare for outpatient cardiac rehabilitation.

Discharge Planning

Discharge planning begins early because of shortened hospital stays. The cardiac occupational therapist provides information regarding the level of physical function the patient tolerates at discharge. The therapist also makes recommendations for further therapies and gives input regarding the possible need for home health or extended care facility.

Outpatient Cardiac Rehabilitation or Phase II

Outpatient cardiac rehabilitation is a multifaceted program of EKG-monitored exercise and education for secondary prevention of heart disease. Outpatient cardiac rehabilitation is designed to

1. Continue medical surveillance and assessment of an individual's cardiovascular response to exercise
2. Limit the physiological and psychological effects of heart disease
3. Instruct on risk factors for heart disease and how to reduce their impact
4. Maximize psychosocial and vocational status.

Patients are usually started in outpatient cardiac rehabilitation 1–2 weeks after discharge from the hospital. The program runs 3 days a week for 8–12 weeks. Often, the therapist must take a careful history to determine risk stratification based on the patient's EF, hospital course, heart rate and blood pressure response, symptoms, and/or possible EKG changes with exercise. Risk stratification refers to determination of the patient's risk for further cardiac events based on the past medical history.

After assessing the patient's risk stratification, the therapist will need to determine the appropriate exercise intensity using one of the following means. The therapist could determine 50%–85% of the patient's maximum age-adjusted heart rate (MAHR) (see Procedures for Practice 42-2 regarding how to calculate MAHR). If, however, the patient is on a beta blocker medication, such as Toprol or Metoprolol, his or her heart rate response will be blunted, making the heart rate calculation inaccurate. Using the Borg RPE Scale is an additional way to measure the patient's tolerance of

Procedures for Practice 42-2

Determining the Maximum Age-Adjusted Heart Rate

1. Take the number 220.
2. Subtract the patient's age.
3. The difference is that patient's maximum age-adjusted heart rate (MAHR).
4. To establish his or her exercise heart range, multiply the MAHR by 50%–85% to obtain the heart rate for exercise.

For example, a 50-year-old patient's MAHR would be 170 (220 − 50). To determine the exercise heart rate, multiply 170 by 0.50 and 0.85. The 50-year-old patient's exercise heart rate range is 85–149 bpm.

exercise. The patient is usually asked to rate the intensity of the exercise on the Borg RPE Scale. Initially, the patient should try to keep the score between 11 and 13; later in the rehabilitation program, a score between 12 and 15 may be appropriate (ACSM, 2010a). The patient's cardiovascular response and/or symptoms all assist in formulating the exercise prescription.

The exercise goal varies per individual depending on the function of his or her heart and physical condition. Usually, those with good heart function and physical condition achieve between 5 and 6 METs. The patient's previous vocational and leisure interests, however, must also be considered in determining the patient's exercise goal.

The elderly, those who are sedentary, or those who have low functional capacity can still benefit by increasing their maximum MET level. For example, a patient with MI and CHF may have a functional capacity of 2.5 METs after a hospitalization. If they can increase their MET level to 3.5–4 METs, they have significantly increased the number of activities or tasks they can do.

The two primary methods of achieving exercise goals are continuous and discontinuous exercise. For some, continuous exercise works well. For others, short bouts of exercise on various pieces of equipment followed by a short rest of 1–2 minutes are preferable.

The first goal is to increase the total duration of continuous exercise to at least 20–40 minutes. Later, intensity is gradually increased. The advantages of continuous exercise are that less equipment and space are needed and the exercise more closely mimics what the patient will be doing at home. The disadvantages are that only certain muscle groups are targeted on one piece of equipment and the patient is exposed to just one form of aerobic exercise.

In discontinuous exercise, the patient stays on one piece of equipment for one-half or one-third of the allotted exercise time. After finishing the time on one piece of

equipment, the patient then switches to another; this process may be repeated once or several times. The advantages of discontinuous exercise are that the patient is exposed to a variety of equipment, boredom is minimized, and multiple muscle groups are used. The disadvantages are that discontinuous exercise takes a lot of space and equipment, it is sometimes hard to coordinate patients shifting equipment at the same time, and it does not reflect what the patient will be doing for aerobic exercise at home. With both methods of conditioning, however, the patients can achieve the same MET levels over time.

In outpatient cardiac rehabilitation, a variety of exercise equipment may be used. Treadmills, bicycle ergometers, recumbent bikes, rowing machines, arm ergometers, and so on are used, depending on the patient's preference and to accommodate any existing orthopedic problem the patient may have. Weight training is usually started 1–2 weeks postevent if weights below 10 pounds are used. For instance, a patient post bypass might start with 1–3-pounds weights, whereas a patient post–non-STEMI might start at 5-pound weights and gradually progress upward. If the program starts with heavier weights such as 50% of one repetition maximum, the ACSM recommends waiting at least 5 weeks post-MI or bypass. Patients post percutaneous transluminal coronary revascularization (PTCR) may start 2–3 weeks postprocedure (ACSM, 2010). Prior to weight training, patients must meet certain criteria regarding their exercise capacity, blood pressure (BP) control, and heart rhythm (ACSM, 2010).

Risk factor modification is a key focus of outpatient cardiac rehabilitation. Therapists help patients identify their own risk factors and choose which risk factors they would like to try to modify or eliminate. Risk factor education occurs in a variety of ways. Some centers have specific times on various days where health professionals will lecture on a particular topic. Other hospitals have short education sessions before, during, or after exercise sessions. The goal of these educational sessions is to give patients the information they need to modify their risk factors.

Psychosocial issues must be evaluated with the patient who has heart disease. Depression post-MI is linked to negative outcomes (Madan & Sivarajan Froelicher, 2010). Many centers use standardized questionnaires to determine depression or anxiety such as the Beck Depression Inventory or the Center for Epidemiological Studies Depression Scale (ACSM, 2010b). The results of testing will indicate whether the patient needs referral to a chaplain, social worker, or psychologist based on their circumstance or preference.

Community-Based Phase III Cardiac Rehabilitation

Phase III is a community-based cardiac rehabilitation with larger groups of patients and fewer staff members per participant. Phase III programs are often located in community centers, school gyms, or YMCAs. Such programs may follow outpatient or phase II cardiac rehabilitation. Patients may skip phase II, however, and go directly to phase III if they are low risk and have been active in the past. Only a small percentage of patients go to phase III after phase II because it is generally not covered by insurance. Because reimbursement is difficult, it also means that these programs run on a very low budget and usually are lucky to break even.

A physician must refer a participant to a phase III program. Sometimes a stress test is required, or the physician establishes heart rate guidelines. Trained personnel monitor BP response and assist patients with monitoring their heart rate. EKG monitoring is typically limited to once per month. Goal setting for risk management continues, as does the education component, although the education may be more informal. Participants also enjoy the support and encouragement of others who have a common goal of reducing their incidence of heart disease.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

COPD is a combination of emphysema and bronchitis (American Lung Association, 2010). Emphysema is the progressive and irreversible destruction of the alveoli walls (American Lung Association, 2008). The walls of the alveoli have elastic fibers, and when these are destroyed, the lung loses some of its elasticity, resulting in air trapping. This air trapping reduces the ability of the lung to shrink during exhalation; the lung then inhales less air with the next breath (American Lung Association, 2010). Chronic bronchitis is defined as excessive sputum production and cough of at least 3 months in duration occurring 2 years in a row. This inflammation also causes the bronchial tubes to increase their production of mucus. The result of these processes is that the patient experiences sudden SOB and may wheeze or cough (Davis, 2012). Patients with COPD have characteristics of all these diseases (see Definition 42-3 for a description of pulmonary function tests). COPD is a chronic and progressive condition (American Lung Association, 2010). Medications and good health habits can lessen the symptoms and maximize function.

The feeling of breathlessness, called dyspnea, is a key feature of COPD. Damage to the lung results in a flattening of the diaphragm caused by hyperinflation. This flattening takes away the ability of the diaphragm to act effectively in assisting with expansion of the lungs during inspiration (Hill & Schmitt, 2010). To compensate for the lack of inspiratory pressure, patients with COPD tend to use their shoulder girdle muscles to expand their lungs, making it difficult to use those muscles in unsupported UE activities (Celli, 2009a).

Definition 42-3

Pulmonary Function Tests

- Patients are asked to exhale forcefully as much air as possible into a spirometer. The amount of air exhaled in 1 second is called the forced expiratory volume (FEV1). Age-related norms for the FEV1 are available (Celli, 2009b).
- Arterial blood gases are drawn to determine the lungs' ability to oxygenate blood, remove CO_2, and maintain the body's acid–base status (Tiep & Carter, 2009). It is helpful to draw blood gases before and after exercise to see how well oxygenation is maintained during activity.
- A pulse oximeter is a noninvasive test to determine the amount of oxygen in the blood. A probe is wrapped around a fingertip. A light shines through the finger, and the amount of light reaching the other side indicates the amount of oxygen in the blood. Hemoglobin is red, and the more hemoglobin in the blood, the less light is able to penetrate the fingertip (Tiep & Carter, 2009). The oximeter can occasionally give false readings. If the patient is anemic, wears nail polish, or has poor circulation, the pulse oximetry may be inaccurate. Often, the oximetry machine will also determine the patient's pulse. If the palpated pulse and the oximetry machine pulse match, it is likely that the oxygen saturation (O_2 Sat) will be accurate.

Dyspnea, fatigue, cough, and sputum production are part of the disease process. The effort of breathing takes so much energy that often COPD patients find themselves without enough energy to do their daily tasks, including ADL and vocational and leisure endeavors. They are unable to increase their ventilation enough to meet physiological demands. Because of the unpleasant sensation of SOB, patients reduce their physical activities, resulting in muscle weakness and the inability to use oxygen efficiently (Celli, 2009a).

Eating is an activity that is made difficult by lack of air. Maintaining adequate nutrition is a problem for many patients with COPD, and nutrition problems are independent predictors of mortality (American Association of Cardiovascular and Pulmonary Rehabilitation [AACVPR], 2011). Some patients lose weight because of the excessive energy costs of their breathing efforts. Others use steroids to reduce lung inflammation, resulting in weight gain, that contributes to additional problems (AACVPR). Weight gain exacerbates the problem of not having enough oxygen to metabolize food, and extra weight requires more oxygen to do any activity, including eating.

In a large study of over 7,400 people, individuals with COPD had a rate of depression slightly higher at 23.1% compared to those without COPD whose depression rate was 16.8% (Schneider et al., 2010). As with any chronic disease process, the changes in lifestyle, the struggle to accomplish normal daily activities, the fear of extreme SOB, and feelings of hopelessness all contribute to the depression that many patients with COPD feel.

PULMONARY REHABILITATION

The AACVPR sets standards of practice for pulmonary rehabilitation, which are used by insurers and the Joint Commission of Hospital Organizations. The AACVPR (2011) has published a book called *Guidelines for Pulmonary Rehabilitation Programs* to guide practice. It has also instituted a certification for pulmonary rehabilitation programs (see Resources 42-1). A team of health professionals, including doctors, respiratory therapists, dieticians, pharmacists, and occupational and physical therapists, is ideally involved in the pulmonary rehabilitation program. As with other diagnostic categories, the roles may overlap in reinforcing behaviors to enhance function.

Occupational therapy goals in pulmonary rehabilitation are patient centered and patient driven and may include

1. ADL evaluation and training to increase functional endurance
2. Instruction and training in appropriate breathing techniques with ADL
3. Evaluation and strengthening of the UE
4. Instruction in work simplification and energy conservation
5. Evaluation of the need for adaptive equipment
6. Assistance in adapting leisure activities
7. Education in stress management and relaxation techniques.

Evidence Table 42-2 lists the best evidence for occupational therapy practice regarding pulmonary rehabilitation.

Activities of Daily Living Evaluation and Training

Patients with COPD are often limited in their ability to perform their ADL because of dyspnea. It is common to have significant muscle wasting from disuse. The therapist should note the patient's breathing pattern during the ADL evaluation. Often, patients with COPD hold their breath, breathe shallowly and fast, or elevate their shoulders as they breathe. The amount of oxygen in the blood or **oxygen saturation (O_2 Sat)** with activity should also be measured by pulse oximetry (Procedures for Practice 42-3). If the O_2 Sat falls below 90% as the patient performs ADL, the use of oxygen with activity should be considered. If the patient does not have home oxygen, the physician should be informed of the patient's low O_2 Sat. Currently, the O_2 Sat must be below 88% to qualify for reimbursement for home oxygen from Medicare or other supplemental insurances (Crouch, 2009). As part of the

| Evidence Table 42-2 | Best Evidence for Occupational Therapy Practice Regarding Pulmonary Rehabilitation |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Eight studies evaluated a cognitive-behavioral– or psychotherapeutically based intervention, and one evaluated a taped progressive muscle relaxation.	Studies that had detailed psychologically based interventions for treatment of anxiety associated with chronic obstructive pulmonary disease (COPD)	Five hundred twenty-three patients with confirmed COPD. Four studies had patients with moderate-to-severe COPD, one had mild-to-moderate COPD, and others did not classify severity.	Varied from study to study in number of sessions and duration of each session	Systematic review and meta-analysis of nine studies Level: I	Yes. Meta-analysis found a small but significant reduction for anxiety, but only when compared within the intervention group, but not compared to control.	Significant decrease in pre- and postanxiety scores from eight studies (n = 222, CI = −0.419 to −0.141, p = 00004).	Baraniak & Sheffield (2011)
Compare effectiveness of short-term pulmonary rehabilitation with brief advice	Rehabilitation group: Patients came to hospital. Sessions included exercise and education. Brief advice group: Individuals were given instruction and advice on exercise along with a printed handout. They were asked to keep a record of their exercise.	One hundred three patients with severe COPD were randomly assigned to group program or advice program. Fifty-four were in the group program, and 48 were in the advice program.	Those in rehabilitation group were seen twice per week for 6 weeks. Advice patients received 1 hour of individual advice and education.	Randomized controlled trial Level: 1A2a Trial did not have blinded therapists or participants; difference in amount of intervention time.	Yes, the rehabilitation group increased the shuttle walking distance compared to the advice group.	Statistically significant differences between group rehabilitation program and brief advice groups at 3 months in terms of shuttle walking distance (34.1 m; 3.0 – 65.3 confidence interval; p < .05).	White et al. (2002)

Procedures for Practice 42-3

Breathing Techniques

Patients are instructed to practice these techniques while sitting in a relaxed position. After they become proficient using these breathing methods at rest, patients should try using them while doing pleasant activities such as reading or watching television. Finally, patients should try using one of these techniques while doing a task that is difficult, such as stair climbing (Coppola & Wood, 2009).

Pursed Lip Breathing

- Breathe in through your nose.
- With lips pursed, exhale air slowly.
- Try to take twice as much time to exhale as it did to inhale.

Active expiration is the contraction of the abdominal muscles during exhalation.

According to the AACVPR *Guidelines for Pulmonary Rehabilitation* (2011), abdominal or diaphramatic breathing is no longer used because of lack of evidence of efficacy. Instead active expiration is recommended.

functional assessment, measurements of heart rate and blood pressure should also be taken.

Breathing Techniques

It is important that the patient practice use of breathing techniques with ADL. After becoming familiar with pursed lip breathing and active expiration, the patient should attempt to use these breathing techniques while performing tasks that previously caused them to be breathless. The pulse oximeter helps to reinforce the improvement in the O_2 Sat with use of a breathing technique. Timing the breath with work is also helpful. For example, the patient should breathe out while pushing the vacuum cleaner, and breathe in while pulling the vacuum cleaner. Exhaling with the exertion of lifting is less taxing not only on the lungs but also on the cardiovascular system because it prevents the Valsalva maneuver (see Procedures for Practice 42-3 for breathing techniques).

Upper Extremity Function

UE muscle strength must be evaluated. Pulmonary patients are often on steroids, have systemic inflammation, are older and hypoxic, and therefore often have muscle weakness (American Association of Cardiac and Pulmonary Rehabilitation, 2011). Patients with COPD commonly use the accessory muscles of the shoulder girdle to help them breathe, which makes it difficult for them to use these muscles in unsupported upper extremity activity (Celli, 2009a). UE strengthening has been found to improve the quality of life by increasing the capacity to work and reducing the oxygen requirement of UE activity. Use of free weights, Theraband®, an arm ergometer, and other upper body strengthening techniques are all helpful in increasing upper body strength. Additional improvement in functional status is seen when leg training is added (Celli).

Work Simplification and Energy Conservation

Because their work capacity is significantly reduced, patients with COPD will benefit from instruction in work simplification and energy conservation. Bathing is a particularly strenuous activity because the hot humid air makes breathing difficult. Therapists encourage patients to use the ventilation fan or leave the door open while bathing to keep the humidity level down. Recommending the use of a chair in the shower and using a thick terry robe after showering instead of toweling off are two suggestions that are helpful in reducing energy expenditure. Unsupported UE activity is very fatiguing for patients with COPD. It is important to teach these patients to support their arms during UE activities such as hair combing or shaving. Sometimes, a machine like an electric toothbrush can be of assistance. Scheduling of activities that require more energy expenditure for the time following the use of a bronchodilator will also allow patients to accomplish more (AACVPR, 2011).

Not all patients with COPD will need adaptive equipment. As the disease progresses in severity, however, some adaptive equipment is useful (Fig. 42-4). Because bending

Figure 42-4 Using adaptive aids for self-care activities can be an effective way to conserve energy and maintain independence for those with cardiac or respiratory conditions.

over to tie shoes or put on pants may cause significant SOB, elastic shoe laces, a long-handled shoehorn, or a reacher to assist with putting on slacks may be helpful.

Promoting Self-Enhancement Roles

People with COPD tend to feel isolated. Just completing daily necessities takes so much energy that little, if any, is left for leisure activities. Many patients fear becoming very SOB in front of others or are embarrassed using oxygen. The occupational therapist can help the patient evaluate previously enjoyed activities and see whether those activities can be adapted to fit the current health status. Providing patients with information regarding programs or activities available in their community is also helpful. Sometimes, involving a helper or companion may make an activity more feasible.

Stress Management

The feeling of being unable to get enough air is truly frightening. Patients with COPD often experience a sense of panic with breathlessness. Teaching patients methods

to cope with extreme SOB can lessen their fear. Leaning forward and resting their arms on the table releases the diaphragm and makes breathing easier. Using pursed lip and/or active expiration helps to slow the pace of breathing so that the patient is not breathing shallowly and rapidly. A stress management technique such as visualization may help patients calm themselves by mentally transporting them out of the stressful situation. It is important that the patient practice these options prior to actually needing them. Having a well-practiced plan of action for the panic associated with breathlessness will give patients confidence in their ability to control the situation.

Heart disease and pulmonary disease, as the first and third leading causes of death, respectively, pose a major health problem. As either a primary or a secondary diagnosis, both heart disease and COPD require specialized attention in planning occupational therapy intervention. If a patient has a history of heart disease or COPD, the occupational therapy practitioner must assess the patient's cardiovascular response to activity or exercise. Precautions for the patient's cardiac or pulmonary problem must be incorporated into the treatment program.

case example
Mrs. H.: Cardiac Rehabilitation

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information	Understand the patient's diagnosis or condition	"Cardiomyopathy after pregnancy is rare. If she improves within the 6 months after diagnosis, she will probably be able to lead a normal life."
Mrs. H. is a married, 32-year-old full-time health worker and mother of a 3-year-old child. The day after the delivery of her second child, she suddenly developed a migraine headache. Her condition deteriorated quickly. She became very SOB and needed a rebreather mask with 10 L of oxygen to maintain her O_2 saturation. Her heart rate was 135–140 bpm. The next day, she was diagnosed as having an anterior wall myocardial infarction (MI). Several days later, her pulmonary edema had resolved, and she had a coronary angiogram. The angiogram showed normal coronary arteries and an ejection fraction (EF) of 25%–30%. She was subsequently diagnosed with a cardiomyopathy.	Know the person	"Mrs. H. will be a busy lady, working and taking care of two children younger than 3 years old. She works in the health care system and has some knowledge of health issues. Mrs. H. is used to a full-time income and taking care of herself, her home, and family. It must be stressful to have to rely on others to take care of something she normally did herself."
Initially, she was referred to inpatient cardiac rehab for general conditioning and instructions for appropriate activities at home. She had very limited endurance. She had a 10-pound lifting restriction, which, with a newborn, made her dependent on family and friends.		
She was seen by home health occupational therapy for several weeks. She was given exercises to increase her endurance and instructed in energy conservation techniques. Although she became somewhat stronger, she was still dependent on volunteers around the clock to do the majority of household tasks and take care of the children. This caused her a great deal of stress. Her therapist instructed her in stress management techniques and practiced them with Mrs. H.		

Reason for Referral to Cardiac Occupational Therapy Phase II

Mrs. H. was referred to outpatient cardiac rehabilitation for physical conditioning and education.

Appreciate the context	"I will talk with the husband to get his view of how things are going at home and get a feel for how supportive he is to Mrs. H. I will also need to consider whether Mrs. H. is getting secondary gain from all the attention."

Assessment Process and Results

Mrs. H. arrived in outpatient cardiac rehabilitation via wheelchair because she felt she was too weak to walk from the car and exercise. She was now doing her own self-care but still relied on volunteers for most of her household chores and caring for her children. She admitted she was stressed by her diagnosis, the number of volunteers in her home, and financial worries. She reported that she slept excessively and was exhausted with exercise. She also reported that she had a history of depression and complained of being somewhat depressed. She was able to walk slowly on the treadmill at 2.0 mph for 20 minutes with normal cardiovascular response. A recent echocardiogram revealed her EF to now be up to 50%.

Consider evaluation approach and methods	"Initially, Mrs. H. is allowed to demonstrate what she can comfortably do physically. After 20 minutes of walking, she still is tolerating the exercise well."
Interpret observations	"Mrs. H. does not seem to correlate her ability to easily walk 20 minutes at a strolling pace as indicative of her ability to do many household chores, such as dishwashing, folding clothes, making beds, etc. I will continue to assess Mrs. H. to see if she may need referral for psychiatric help for possible depression."

Occupational Therapy Problem List

- Low physical capacity for work less than 3 METs.
- Inability to engage in previous work and leisure pursuits because of decreased endurance.
- Possible depression over feelings of dependency and concern over cardiac diagnosis.
- Dependence on volunteers for most instrumental activities of daily living (IADL).

Synthesize results	"Mrs. H. seems to be overwhelmed with her diagnosis and has not assimilated that her heart function has now improved to near normal. With an exercise program to increase her physical capacity, she should be able to return to her job and all her IADLs. Stress management technique training will assist her to cope with difficulties caused by illness."

Occupational Therapy Goal List

- Learn to monitor physical response to exercise and activity through use of Borg RPE Scale and pulse monitoring.
- Gradually increase capacity for work through aerobic exercise and strengthening exercises (2–5 METs).
- Gradually resume household and leisure pursuits (1.5–5 METs).
- Learn to pace household activities.
- Learn stress management techniques to cope with difficulties caused by illness.
- Instruct patient in risk factors for heart disease.
- Identify patient's personal risk factors and ways to ameliorate their effects.
- Start a regular home aerobic exercise program.

Select an intervention approach	"As Mrs. H. increases her endurance, we can gradually shift her back to some of her household responsibilities of the same energy or MET level. In the meantime, learning stress techniques will help her handle her current situation. Education about her current health problem will help her understand that she is truly getting better." "Cardiac rehabilitation will concentrate on an aerobic exercise and strengthening program. Brief educational sessions will be conducted as she exercises or after the exercise session."
Consider what will occur in therapy, how often, and for how long	"Mrs. H. is highly motivated to improve, but conditioning takes time. I will see her three times a week for 6 weeks. During that time, I will help her understand the connection between workload on treadmill or exercise cycle and home activities. Together we can develop a plan on how she will start resuming household tasks. I will also instruct her in a home exercise program to assist in improving her conditioning. After exercising, we will practice some stress management techniques."

Intervention

As she regained physical strength through exercise, Mrs. H. could start resuming more of her usual activities and reduce her dependence on volunteers. Instructing Mrs. H. in how to assess her own physical response to exercise and activity gave her confidence that she was in control. Because Mrs. H. had difficulty with pacing, the therapist had her keep a diary of her daily routine. Later, they reviewed it, and the occupational therapist reviewed work simplification techniques and methods of pacing. The therapist also assigned her tasks within her current aerobic capacity to assist her in resuming her home responsibilities. Mrs. H. was also instructed in stress management techniques to help her deal with the stresses of her illness. Because of her previous history of depression, the therapist reviewed information about the relationship of depression and fatigue. The occupational therapist explored with Mrs. H. the possibility of seeking professional help and/or medication to deal with her depression. Additionally, Mrs. H. was instructed in the risk factors for heart disease. Her individual risk factors were identified, and information was provided on how to ameliorate their effects. As part of her risk factor reduction, Mrs. H. initiated a walking program.

Assess the patient's comprehension

Know the person

Appreciate the context

"Mrs. H. was a quick learner. As she fully understood that her heart function was near normal, she really started to gain confidence that her life could return to normal. However, she needed some concrete direction to translate what she was learning into action. Adding the additional home exercise program helped to increase her capacity more quickly, but depression was holding her back from making a complete recovery. Even with her health care background, she did not realize the effect of depression on her physically. With more information about depression, she was more willing to seek professional help."

Next Steps

Discharge from outpatient cardiac rehabilitation.

Decide whether the patient should continue or discontinue therapy and/ or return in the future

"Mrs. H. was making significant strides in returning to her previous activity level. She seemed to benefit significantly from activity modification, education, and information on heart disease. She had initiated a home walking program, and she planned to return to work within a month."

Clinical Reasoning in Occupational Therapy Practice

Implications of a Diagnosis

When treating Mrs. H., what signs or symptoms would cause you to discontinue treatment and/or call the doctor?

case example
Mr. M.: Pulmonary Rehabilitation

Clinical Reasoning Process

Occupational Therapy Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mr. M. is an 85-year-old male with a medical history of congestive heart failure (CHF), chronic obstructive pulmonary disease (COPD), and diabetes. He also has a history of coronary artery disease and has had a myocardial infarction in the past. He has been on home oxygen but reports he was not always using it despite it being prescribed. He lives alone in an apartment building with an elevator. Prior to this hospitalization, he had recently begun receiving home visits from a nurse and was getting food from Meals on Wheels™. Up until this point, he has been independent with dressing, toileting, bathing, laundry, and finances. He is ambulating without an assistive device but owns a front-wheeled walker and a wheelchair. He also stated that he owns a shower chair and has a handheld shower head but has not needed to use the shower chair for bathing. He does not drive and is provided with transportation by various family members. He is currently on 6 L of oxygen and is receiving steroids and inhalers to improve breathing. He states that he has had "a little" education for COPD/CHF management in the past. His goal was to return to his apartment after discharge from the hospital, to which he was admitted for increased shortness of breath (SOB). He was open to receiving more assistance from family or outside agencies if necessary.	Understand the patient's diagnosis or condition Know the person	"Mr. M. has been on 6 L of oxygen chronically at home and has other medical conditions that indicate to me that he likely has poor endurance and may have had some difficulty managing activities of daily living (ADL) at home." "The lack of Mr. M.'s use of energy conservation techniques and his prescription for oxygen during daily activities suggests that he would benefit from education in these areas. His daughter reports some forgetfulness in the patient, and therefore, I need to keep in mind that he may need to have education repeated and in written form, as well as hands-on practice and demonstration, for the most success in learning new information."
Reason for Referral to Occupational Therapy Mr. M. was admitted to the hospital because of increased shortness of breath. He was referred to occupational therapy for an evaluation and further treatment to improve efficiency with functional activities. Because Mr. M. lives alone, it is especially important that he be as independent as possible to allow him to reach his goal of returning to his apartment.	Appreciate the context Develop provisional hypotheses	"I believe that Mr. M. will benefit from the combination of education and adaptive equipment use, as well as exercise to improve his activity tolerance at home. I am hoping that as Mr. M. gets more competent and confident with using breathing techniques, he will be more inspired to combine them with adaptive equipment use to improve his efficiency. I am glad that he has a supportive family that is working to keep Mr. M. as independent as possible."
Assessment Process and Results Mr. M.'s assessment took place in his hospital room. He was on 6 L of oxygen via nasal cannula. He appeared to be comfortable at rest, but following activity, his oxygen saturations decreased to 85%. He was able to complete pursed lip breathing with cues, and his saturations increased to 93% after 90 seconds of rest and pursed lip breathing. His upper body strength and range of motion were within functional limits. He was able to demonstrate ability to physically complete grooming, dressing, and toileting independently but was limited by decreased endurance and rapid shortness of breath. He frequently had to stop what he was doing to rest and, for that reason, took extra time or chose not to complete some tasks. He was able to complete basic transfers and ambulate in his room with standby assistance and no assistive device. A basic cognitive screen indicated that Mr. M.'s cognition was intact. His daughter did report that he has been more forgetful lately.	Consider evaluation approach and methods	"My focus was primarily on Mr. M.'s functional status and assessing his level of fatigue during functional tasks. I did spend some time observing him completing activities of daily living (ADL) as well as interviewing him about his perceived level of fatigue and level of difficulty completing tasks. I monitored his oxygen saturations throughout our treatment sessions and observed his levels of dyspnea." "We discussed what ADL were a priority for him versus less important tasks, and we were able to narrow our focus and set specific goals."

Occupational Therapy Problem List

- Limited endurance affecting ADL performance
- Limited education of energy conservation and work simplification techniques and pursed lip and diaphragmatic breathing
- Decreased awareness of adaptive equipment resources and oxygen use
- Mild memory impairment

| Synthesize results | "It was apparent to me that Mr. M. was not conserving the maximum amount of his energy during certain functional tasks. Occasionally when he was fatigued, he would not complete grooming or hygiene tasks at all. I feel that, because he lives alone, we needed to focus on being able to complete his basic self-care activities efficiently and independently. At this point, he was not able to complete all self-care activities because of fatigue and shortness of breath." |

Occupational Therapy Goal List

(anticipated length of treatment: four or five sessions)
- Patient will be able to verbalize and demonstrate understanding of pursed lip breathing and active exhalation during functional activities by discharge.
- Patient will verbalize or demonstrate understanding of two or three work simplification and energy conservation techniques during self-care activities, community activities, and laundry and other homemaking tasks by discharge.
- Patient will complete tub transfer independently using adaptive equipment to increase activity tolerance by discharge.
- Patient will have all recommended adaptive equipment or resources for pursuing purchase of equipment by discharge.
- Patient will be independent with a 10–15-minute upper extremity exercise program while using pursed lip breathing to improve overall endurance and ability to tolerate ADL.

Develop intervention hypotheses	"I plan on providing Mr. M. with instruction on breathing techniques, energy conservation, adaptive equipment recommendations, and resources. This education will provide him with improved activity tolerance and give him a greater sense of independence. I believe that it is important to provide him with the opportunity to prioritize the importance of completing certain tasks and allowing him to participate in the goal-setting process."
Select an intervention approach	"My intervention will primarily focus on an adaptive approach with a focus on patient education."
Consider what will occur in therapy, how often, and for how long	"Mr. M. will likely only be hospitalized for 5–6 days, and therefore, we will need to strive to meet our goals in that time frame. I will focus mostly on completing functional tasks while providing education throughout the sessions. Written materials will also be provided, as well as family education when possible."

Intervention

Mr. M.'s treatment plan consisted of education for specific breathing techniques (pursed lip and active exhalation). He was instructed on how to incorporate these breathing techniques into his daily routine. He was then provided with more education in energy conservation and work simplification to allow him to be more efficient. Discussion about adaptive equipment needs took place, and recommendations were made. He was instructed in an upper extremity exercise program to increase endurance, and he was provided with a handout to encourage him to continue with the exercises after he was discharged. Mr. M. was provided with written instruction for all education because of memory impairments. Repetition and hands-on training were also provided whenever possible.

Providing education was key to allow Mr. M. to understand how to manage his COPD symptoms better. He was better able to manage his shortness of breath and fatigue during activities by using pursed lip breathing combined with work simplification and energy conservation techniques. Discussion about the benefits of adaptive equipment use and incorporation into Mr. M.'s daily routine has allowed him to complete more tasks independently and with less fatigue. He was in agreement with using a shower chair, handheld showerhead, and long-handled bath sponge to ease the burden that bathing once had been. Mr. M. elected to purchase a long-handled bath sponge from the hospital before discharge, and he already had a shower chair and handheld showerhead at his apartment. He was encouraged to use his oxygen for all activities, including showering, to maintain a desirable oxygen saturation level for his safety. By participating in a daily exercise program, Mr. M.'s endurance improved, which allowed him to complete his ADL with much less shortness of breath and fewer rest breaks. Mr. M. was seen for six sessions by occupational therapy. He met all of his established goals and was discharged back to his apartment

| Assess the patient's comprehension | "I could see the initial frustration that Mr. M. had when he was not fully able to complete tasks because of dyspnea. He was hesitant to try pursed lip breathing initially because he thought it was 'too confusing' and that he would 'forget how to do it.' However, with repetition and encouragement, he was able to quickly learn the technique and feel the benefits. Once we started to incorporate the use of adaptive equipment (such as a shower chair, handheld showerhead, and long-handled bath sponge), Mr. M. was appearing more positive and confident in his abilities. He really was a rewarding patient to work with because he dramatically improved with simple modifications to his routine." |
| Understand what he is doing | |

Next Steps

Discharge to his apartment with recommendation of home occupational therapy evaluation and to resume Meals-on-Wheels™ as was established previously.

Anticipate present and future patient concerns	"I am recommending a home occupational therapy evaluation to reinforce the use of adaptive equipment and oxygen in Mr. M.'s home setting. I feel that Mr. M. was able to fully appreciate the benefits of using pursed lip breathing and oxygen to extend his endurance. He was comfortable with the idea of using adaptive equipment and work simplification techniques incorporated into his everyday routine. He is confident in his abilities to complete his daily activities and to return to his apartment independently. His family is comfortable with his abilities to care for himself, and they feel he has the resources he needs to be successful."
Decide whether the patient should continue or discontinue therapy and/ or return in the future	

Clinical Reasoning in Occupational Therapy Practice

Implications of a Diagnosis

How could you show Mr. M. that using pursed lip breathing is effective in keeping the oxygen level in his blood at the proper levels? What would be an appropriate percentage of O_2 in the blood for someone with moderate-to-severe COPD?

Summary Review Questions

1. A person is admitted to the hospital with an acute STEMI. He is given thrombolytics to reverse clot formation in his coronary arteries, but the thrombolytics cause a cerebral bleed. In evaluating and treating for stroke-related deficits, what physiological parameters should the therapist take to measure the workload on the patient's heart? What factors might increase these parameters?

2. What cardiac symptoms might a patient who has a previous heart history exhibit if he or she were not tolerating the treatment you prescribed for the patient's current shoulder injury?

3. What symptoms would a person going into CHF exacerbation exhibit?

4. In reviewing a patient's medical record after hip replacement surgery, what cardiac diagnoses might influence your treatment? What cardiac diagnostic tests might provide information to help you make decisions about the severity of his or her heart disease?

5. Describe in detail the differences between a home program for a patient with a STEMI, a CABG, and an angioplasty. How would you customize the program for the individual?

6. Describe the different ways of conditioning an outpatient in cardiac rehabilitation. What are the advantages and disadvantages of each method?

7. List the risk factors for heart disease. What methods might an occupational therapist use to decrease a patient's risk for CAD?

8. Describe pursed lip breathing and active exhalation. How would you teach it to a patient with COPD?

9. If you were the only occupational therapist in a small rural hospital, where could you find information pertaining to the treatment of the patient with cardiac or pulmonary disease?

10. Develop a treatment plan for a patient with COPD, who is having problems with SOB while doing her ADLs.

Glossary

Acute coronary syndrome (ACS)—A term that includes unstable angina and myocardial infarction (MI), both non-ST elevation MI (non-STEMIs) and ST elevation MIs (STEMIs). This designation is used to triage and manage patients with symptoms of myocardial ischemia (Kim, Kine, & Fuster, 2008).

Angina pectoris—A temporary lack of blood flow to the myocardium, which causes the sensation of chest pain, fullness, tightness, or pressure. The pain or discomfort from angina can be referred to the teeth, jaw, back, ear, or arm. Angina is relieved with nitroglycerin or rest.

Atherogenic—Causing the development of plaque in an artery.

Atrial fibrillation—A rapid firing of cells in the atria of the heart with irregular response of the ventricles causing a fast irregular heart rhythm. With uncontrolled atrial fibrillation, the patient often feels short of breath and fatigued.

Cardioversion—Electrical shock delivered to the heart to stop a serious dysrhythmia, with the hope that the heart will restart in a normal sinus rhythm.

Diaphoresis—A cold clammy sweat that comes on suddenly.

Oxygen saturation (O$_2$ Sat)—Measurement of the amount of oxygen carried by the hemoglobin in the blood. A normal O$_2$ Sat is greater than 95%.

Sternotomy—A procedure used in open heart surgery where the sternum is split in half to allow the surgeon access to the chest cavity. After surgery, the sternum is wired together.

Dysphagia

Wendy Avery

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Discuss normal swallowing.
2. Identify types of dysphagia and their presentation.
3. Describe how to perform a clinical dysphagia assessment.
4. Employ basic compensatory and rehabilitative strategies to treat dysphagia.
5. Describe instrumental evaluation procedures for dysphagia.

Dysphagia, or difficulty with any stage of swallowing, interferes with functional independence for many recipients of occupational therapy services in many settings. Safe swallowing is a critical and life-supporting activity of daily living that is addressed by occupational therapists in many environments, including acute care and psychiatric hospitals, acute and subacute rehabilitation centers, outpatient clinics, nursing homes, home health settings, and schools. Dysphagia is prevalent in adult diagnostic groups often seen by occupational therapists, including in 81% of clients with acute stroke (Warnecke et al., 2008), 50% of those with Parkinson's disease (Crary & Groher, 2003), and 55% of the elderly presenting with pneumonia (Cabre et al., 2010).

Occupational therapists assist clients with dysphagia in rehabilitation of abilities that affect swallowing, including self-feeding, cognition, perception, sensory and motor skills, postural control, and in rehabilitation of or compensation for an altered swallowing mechanism. Clients with acute, chronic, congenital, and acquired dysphagias may all benefit from intervention. In some settings, experienced occupational therapists serve as the primary swallowing therapist (American Occupational Therapy Association [AOTA], 2011); in other settings, speech and language pathologists serve as the primary swallowing therapist. Even when occupational therapists are not the primary dysphagia therapist, their contribution to swallowing rehabilitation is significant, and an understanding of the anatomy and physiology of the swallowing mechanism is most useful. Dysphagia care may be provided by a multidisciplinary dysphagia team, often including the occupational therapist, attending or primary care physician, nurse, respiratory therapist, speech language pathologist, and specialty physicians including the radiologist. The patient as a self-advocate and consumer is also a member, as are caregivers.

This chapter introduces the entry-level skills required for the evaluation and treatment of dysphagia in adults. Independent intervention with the dysphagic patient requires advanced knowledge and skills on the part of the occupational therapy clinician. AOTA (2007) delineates entry-level and advanced-level skills in dysphagia care for occupational therapists and occupational therapy assistants. It should be noted that dysphagia care is an advanced practice area for occupational therapists (AOTA, 2007). The contents of this chapter are not a substitute for formal education and training in dysphagia care. Further information about dysphagia can be acquired by seeking advanced learning opportunities, researching new developments, attending workshops and conferences, and receiving mentoring.

NORMAL SWALLOWING

Deglutition is a complex process involving both volitional and nonvolitional behaviors. The cranial nerves
Figure 43-1 The oral, pharyngeal, and esophageal structures involved in swallowing. 1. The hard palate. 2. The base of the tongue. 3. The soft palate and uvula. 4. The vocal cords. 5. The laryngeal vestibule. 6. The hyoid bone. 7. The upper esophageal sphincter. (Adapted with permission from Groher, M. E. [1997]. *Dysphagia: Diagnosis and management* [3rd ed.]. Boston: Butterworth-Heinemann.)

execute the sensory and motor processes that constitute swallowing. Cortically mediated factors, including appetite, attitude, attention span, appreciation of food, and body position influence swallowing and must be considered in evaluation and treatment. Oral, pharyngeal, and esophageal structures involved in swallowing are shown in Figure 43-1.

The stages of swallowing include the preoral, oral preparatory, oral, pharyngeal, and esophageal stages (Definition 43-1). The preoral, oral preparatory, and oral stages are voluntary. The length of the oral preparatory stage varies with the type of bolus (Mendell & Logemann, 2007) and age (Logemann et al., 2002). Oral transit time, the length of time to accomplish the oral stage, is normally 1–1.5 seconds (Mendell & Logemann, 2007). The pharyngeal stage is involuntary, although volitional movements can alter it. Normal pharyngeal transit time is 1 second (Mendell & Logemann, 2007). Although the patient's position may affect the esophageal stage because of the effects of gravity, this stage is involuntary.

IMPAIRED SWALLOWING

Many disease processes and trauma cause dysphagia, including those that affect the central nervous system, peripheral nervous system, motor end plate, muscles, and other anatomical structures. Dysphagia can lead to

Definition 43-1

The Stages of Swallowing

Preoral Stage

The food is visually and olfactorily appreciated. This stimulates salivation, and there are preparatory movements of the mouth to ready the oral cavity to receive and mobilize the food or liquid. Spontaneous upper extremity movements occur as the person reaches for and grasps the utensil, cup, or finger food and brings it to the mouth.

Oral Preparatory Stage

The food is received and contained by the mouth. It is then formed into a bolus of food and mixed with saliva. Pureed or liquid boluses require little mastication and may briefly be held centrally in the mouth by the tongue and cheek musculature. If solid, the food may need to be bitten off to be contained in the mouth. The bolus is chewed in a rotary motion by the molars and is moved between the left and right molars. The buccal muscles contract to prevent food from pocketing between the cheeks and the teeth. Once masticated or formed, the bolus is brought to the center of the tongue.

Oral Stage

As the cheek and tongue muscles retain the bolus centrally in the mouth, the tongue squeezes it against the hard palate, moving it posteriorly to the level of the faucial arches.

Pharyngeal Stage

The soft palate elevates to close off the nasopharynx. The larynx and hyoid elevate and protract, minimizing the size of the laryngeal vestibule (its opening) as the epiglottis tips to cover the vestibule. Breathing stops (termed "swallowing apnea"), which reduces the possibility of aspiration or laryngeal penetration of food or liquid. The vocal cords close. Simultaneously, the pharyngeal constrictor muscles sequentially contract to propel the bolus through the pharynx. The elevation of the larynx causes the upper esophageal sphincter (UES) to relax, allowing the bolus to pass through it.

Esophageal Stage

The UES returns to its normal tonic state, and the bolus is transported through the esophagus via esophageal peristalsis and gravity. The lower esophageal sphincter relaxes, allowing the bolus to pass through into the stomach.

---

dehydration (Leibovitz et al., 2007), malnutrition (Foley et al., 2009), pressure ulcers (Westergren et al., 2001), and pulmonary complications caused by aspiration. These complications include aspiration pneumonia (Eisenstadt, 2010), airway obstruction (Eckberg & Feinberg, 1992), and death (Eisenstadt, 2010). The limited ability to participate in social and cultural activities because of chronic dysphagia can profoundly affect an individual.

Types of Dysphagia

Dysphagia occurs in three types: paralytic, pseudobulbar, and mechanical. Paralytic dysphagia results from lower motor neuron involvement that causes weakness and sensory impairment of oral and pharyngeal structures, including weakness or absence of the swallowing reflex. Pseudobulbar dysphagia results from upper motor neuron involvement, causing hypotonicity or hypertonicity of oral and pharyngeal structures and a slow or poorly coordinated swallowing reflex. Mechanical dysphagia is caused by loss of oral, pharyngeal, or esophageal structures; weakness; and/or sensory deficits caused by trauma or surgery. Pulmonary complications may complicate the presentation. Debility, lack of appetite, and poor overall nutritional status can affect a client's stamina and ability to participate in

dysphagia and overall rehabilitation (Safety Note 43-1 and Definition 43-2).

DYSPHAGIA ASSESSMENT

A dysphagia assessment involves two components, a clinical assessment and an instrumental evaluation.

Clinical Assessment

Clinical assessment of dysphagia must be thorough, with examination of all areas relevant to swallowing. It is best done using a reliable and valid tool (Latella & Meriano, 2010). A reliable and valid tool allows for accurate assessment and reassessment by different test administrators and ensures that each test item provides accurate assessment of performance components. The Dysphagia Evaluation Protocol (1997) is an example of a standardized assessment developed by occupational therapists. Figure 43-3 illustrates the use of a chartable form to document evaluation results.

History, Nutrition, and Respiratory Considerations

The clinician reviews the patient's medical and surgical history, with special attention to any diagnoses and procedures that are relevant to dysphagia. The patient

Safety Note 43-1

Pulmonary Concerns

Respiratory problems may contribute to dysphagia and vice versa because the respiratory and swallowing mechanisms share anatomy and physiology.

Secretion Management

The patient's airway must be clear of excessive secretions. Intermittent suctioning through the nose or tracheostomy may be needed to clear the airway. The swallowing therapist should work closely with nursing and respiratory staff to assess whether airway protection and the ability to maintain oxygenation are adequate. Personnel should be available to suction the airway as necessary.

Tracheostomy

A tracheostomy tube reroutes breathing through a stoma in the neck. Tracheostomy tubes may be temporary or permanent and are used to keep the airway open (Fig. 43-2). Tracheostomies provide easy access for suctioning or ventilator use but can cause or exacerbate dysphagia. They cause reduced smell and taste sensation because the patient is not breathing through the nose. Tracheostomy reduces the ability to clear the upper airway if laryngeal penetration occurs. It increases the risk of aspiration caused by pooling in the pharynx, delays trigger of the swallow reflex, decreases duration of vocal cord closure, and reduces laryngeal movement. An inflated tracheostomy cuff further reduces laryngeal elevation and increases the risk of silent aspiration (Ding & Logemann, 2005). An "open" tracheostomy, in which the tube is not covered or "capped," eliminates the subglottic pressure, reducing the force of the swallow response (Gross, Mahlmann, & Grayhack, 2003).

Mechanical Ventilators

Ventilators are machines that assist patients to breathe if they cannot do so on their own. Positive pressure ventilators may be used temporarily, to assist a patient through an acute illness, or chronically, for a patient with a long-term respiratory challenge. Positive pressure ventilators deliver breaths to patients through a tube in the nose or mouth or through a tracheostomy. Patients who use a ventilator to breathe via a tracheostomy may be able to eat by mouth.
Figure 43-2 A tracheostomy tube. Tubes come in different sizes and may come with or without the cuff as pictured. The pilot balloon is used to inflate the cuff with a syringe and indicates relative inflation of the cuff. The inflated cuff prevents food or secretions from falling further into the airway.

Breathing ceases during the swallow. A well-coordinated swallow is needed to interpose the swallow between inhalation and exhalation. Patients who have had mechanical ventilation for more than a week have been shown to have multiple swallowing deficits once the ventilator is removed (Macht et al., 2011). Patients who are ventilator dependent via tracheostomy are prone to aspiration during eating (Macht et al., 2011).

Definition 43-2

Clinical Dysphagia Presentation for Various Diagnostic Groups

This is not an exhaustive list of diagnoses prone to dysphagia; however, it includes those most often encountered.

Alzheimer's Disease: Pseudobulbar Dysphagia

- Decreased attention span and apraxia for swallowing and self-feeding may be seen.
- Oral and pharyngeal responses slow and a need for physical and verbal cues to self-feed are needed.
- Difficulty with self-feeding is common, and challenges with initiating the meal may be present (Edahiro et al., 2012).
- Agitation and behavioral challenges can hamper the eating process (Edahiro et al., 2012).
- Clients prefer sweet-flavored and pureed foods.
- Clients are prone to aspiration (van der Maarel-Wierink et al., 2011) and more difficulty with self feeding (Edahiro et al., 2012) in later stages of the disease.

Brain Injury: Pseudobulbar, Paralytic Dysphagia

- Type and severity of dysphagia in brain injury depends on the cause of the injury and location and size of brain lesions.
- Behavioral and cognitive problems affect self-feeding and swallowing.
- Abnormal pathological reflexes can affect oral and pharyngeal control.
- Increased or reduced muscle tone may cause decreased mouth opening, decreased lip closure, drooling, decreased tongue control, and pocketing of the bolus in the cheek (Logemann, Pepe, & Mackay, 1994; Mackay, Morgan, & Bernstein, 1999).
- Delayed pharyngeal swallow trigger, nasal regurgitation, decreased base of tongue movement, and decreased laryngeal elevation with resulting pharyngeal residue may be seen (Logemann, Pepe, & Mackay, 1994).
- Overall mealtime may be slow (Mackay, Morgan, & Bernstein, 1999).

Cerebrovascular Accident: Pseudobulbar and Paralytic

- Pharyngeal and laryngeal sensory deficits may occur in right and left hemispheric as well as subcortical strokes (Aviv et al., 1996).
- Symptoms vary with lesion location and size.
- Patients with right hemispheric stroke (pseudobulbar dysphagia) display mild oral transit delays and some delay in pharyngeal trigger and laryngeal elevation. The pharyngeal stage lasts longer, and there may be penetration of the larynx and aspiration (Robbins et al., 1993). There may be neglect or denial of swallowing problems,

and sensory loss can slow motor responses to bolus presence.
- Patients with left hemispheric stroke (pseudobulbar dysphagia) display delays in initiating the oral stage and in triggering the pharyngeal stage. The pharyngeal stage takes longer (Robbins et al., 1993). There may be apraxia for eating and swallowing.
- Patients with subcortical stroke (paralytic dysphagia) demonstrate mild oral transit delays and a delay in triggering the swallow. There is general weakness of pharyngeal swallow, as seen in reduced laryngeal elevation, reduced tongue base retraction, and unilateral pharyngeal weakness (Horner et al., 1991; Robbins et al., 1993). There may also be reduced upper esophageal sphincter (UES) opening (Horner et al., 1991).

Developmental/Intellectual Disabilities: Pseudobulbar, Paralytic Dysphagia

- Cerebral palsy (CP) and mental retardation, together or in isolation, may present deficits of bolus formation and transit, delayed swallow reflex, pharyngeal dysmotility, esophageal disease, and aspiration (Sullivan, 2008).
- Abnormal oral reflexes and oral hyposensitivity or hypersensitivity may be observed.
- Poor postural, head, neck, and limb control can affect swallowing.
- Behaviors such as eating too quickly and putting too much food in the mouth can affect efficiency and safety of swallowing (Samuels & Chadwick, 2006)

Head and Neck Cancer: Mechanical Dysphagia

- Swallowing problems with head and neck cancer vary with tumor type, size, and location.
- Bolus control and containment problems result from surgery to the lip (Nguyen et al., 2008).
- Resection of tumor from the floor of the mouth causes difficulty with bolus control, reduced laryngeal elevation, and its accompanying reduction in UES opening (Hara et al., 2003).
- Glossectomy, or removal of some or all of the tongue, causes difficult or absent bolus mobilization; a resection of the tongue base limits the elevation needed to initiate the pharyngeal swallow (Lazarus, 2006).
- Unilateral laryngeal cancer may require a vertical laryngectomy or hemilaryngectomy; this may cause reduced vocal cord closure, reduced posterior tongue movement, and reduced UES opening (McConnel & O'Connor, 1994).
- Supraglottic laryngectomy reduces glottic closure, laryngeal elevation, and opening of the UES (McConnel & O'Connor, 1994).

Definition 43-2 *(continued)*

- Extensive cancer of the larynx necessitates a total laryngectomy, which separates the foodway and airway tracts and creates a permanent anatomical tracheostomy. Although aspiration is no longer a threat, there is reduced movement through the pharynx, remaining laryngeal tissue, and esophagus (Maclean, Cotton & Perry, 2009).
- Adjunctive radiation therapy causes edema in areas adjacent to the radiation field, fibrosis, and reduced salivary flow, causing dry mouth or xerostomia.
- Radiation therapy combined with chemotherapy without surgery can reduce tongue base movement, laryngeal elevation, and pharyngeal range of motion and speed (Lazarus et al., 1996).
- Radiation therapy combined with surgery can cause longer oral transit time, increased pharyngeal residue, and reduced UES opening (Pauloski, 2008).

Multiple Sclerosis: Pseudobulbar, Paralytic Dysphagia

- Dysphagia symptoms vary with location of plaques in the central and peripheral nervous systems. Dysphagia worsens with disease progression (Poorjavad et al., 2010).
- Weakness of the oral structures and the neck muscles may be seen (Poorjavad et al., 2010).

- Delayed pharyngeal swallow and weakness of pharyngeal contractions may be seen (Poorjavad et al., 2010).

Neoplasms of the Brain: Pseudobulbar, Paralytic Dysphagia

- Dysphagia may be due either to a tumor or to metastasis in the brain or to medical or surgical interventions.
- Symptoms vary with the location and extent of the client's neoplasm and interventions, and symptoms may be similar to those found in clients with stroke (Wesling et al., 2003).

Parkinson's Disease: Pseudobulbar Dysphagia

- Impulsiveness and poor judgment can affect swallowing.
- Jaw rigidity, abnormal head and neck posture, impaired coordination of tongue movements and mastication. Mastication and orofacial motions are affected (Bakke et al., 2011) along with tongue control (van Lieshout, Steele, & Lang, 2011). Alterations in the pharyngeal aspect of the swallow occur (Noyce et al., 2012) including pharyngeal residue and delayed pharyngeal elevation. Abnormal head, neck, and trunk posture along with difficulty coordinating upper extremity movements for self-feeding are seen.
- Feeding and swallowing may be too slow and laborious to allow sufficient nutritional intake.
- Orofacial fatigue may make eating and swallowing more difficult as a meal progresses (Solomon, 2006).

and caregiver also provide information about any history of swallowing disorders. Specific signs and symptoms and modifications in behaviors relevant to mealtime are noted, as are changes in food intake and weight loss. The current nutritional sources are recorded, including the length of time the patient has been **NPO**, or not eating by mouth, if applicable. The therapist also documents any cultural and religious dietary preferences and practices. Information regarding respiratory status is gathered from the hospital chart and staff, including the presence of a tracheostomy and/or mechanical ventilation, and the level of independence with secretion management.

Assessment of Cognitive, Perceptual, and Physical Abilities

Important cognitive and perceptual considerations include the level of alertness and arousal, orientation, ability to attend to a **feeding** session or meal, ability to follow multistep commands, and any visual deficits or unilateral neglect. The clinician notes the patient's

insight into his or her dysphagia and observes head, neck, trunk, and limb control and endurance for being out of bed at mealtimes. The ability to self-position and self-feed and need for or use of adaptive eating equipment are assessed.

Assessment of Oral and Pharyngeal Abilities

Once direct physical assessment begins, the clinician must observe universal precautions to prevent exposure to pathogens for both the clinician and the patient (Safety Note 43-2). Then the occupational therapist assesses oral and pharyngeal control including tone, range of motion, strength, and sensation of the lips, tongue, jaw, and cheeks and any abnormal oral reflexes. To assess pharyngeal control, the therapist observes soft palate movement, gag reflex, vocal quality, and volitional cough. A stethoscope may be used to listen for pooling of fluid above the level of the vocal cords, as pooled liquids resonate during breathing. The therapist rates the patient's hunger and level of enthusiasm for a snack or meal.

Evaluation Protocol

RECORD FORM

Client name: Doe, John DOB: 1/1/40 Age: 73 Date: 1/1/13
Physician: Dr. Smith Location: bedside Type of service: Neuro
Type of eval ☑ Initial ☐ Re-eval Assistive or postural devices used: wheelchair.
Diagnosis: (L)CVA, (R) hemi Date of onset: 12/29/12 Reason for referral: dysphagia
Last oral feeding: breakfast Clinician/Title: Wendy Avery, MS OTR/L

HISTORY AND OBSERVATIONS

Feeding History

Normal preexisting function? ☑ No ☐ Yes

When did change occur? Describe change.
Coughing c̄ all textures p̄ CVA

Has consistency of food changed? ☐ No ☑ Yes

When, and how did client compensate? MD
ordered thick puree

Has food intake changed? ☐ No ☑ Yes

When, and how? poor oral intake

Weight loss? ☑ No ☐ Yes

Number of lbs: _____ When? _____

Other changes: _____

Nutritional Status

Nutritional Route:
☐ NPO ☑ PO

Alternative feeding method used:
☐ NGT ☐ PEG ☐ TPN ☑ Other: IV for fluids

Current diet:
☐ Regular ☑ Other: thick puree

Special dietary requirements:
☐ No concentrated sweets ☐ Low salt ☐ Kosher
☐ Other: None

Respiratory Status

Auscultation of pooling? ☑ No ☐ Yes
Suctioning required? ☑ No ☐ Yes

Frequency: _____ Route: _____

Tracheostomy? ☑ No ☐ Yes

Type: ☐ Cuffed ☐ Cuffless
☐ Fenestrated Size: _____

Position of cuff:
☐ Fully inflated ☐ Partially inflated ☐ Deflated

Comments: _____

Ventilator? ☑ No ☐ Yes ☐ Cannot be removed

Weaning parameters: _____

Receiving chest physical therapy? ☑ No ☐ Yes

Type of treatment: _____

Comments: _____

General Status

Alertness:
☑ No deficit ☐ Partial deficit ☐ Moderate/Severe deficit

Follows directions:
☑ verbal ☐ gesture
☑ 3-step ☐ 2-step ☐ 1-step ☐ Unable

If client responds to fewer than 3-step directions, note reason
for difficulty: _____

> If the client has difficulty with two- or three-step directions,
> see Alternative Administration Protocol section of the manual
> for information about continuing the evaluation.

Recognizes swallowing problems:
☑ Good insight ☐ Partial insight ☐ No insight

> Record the appropriate rating of this item after observing
> client's performance during the Feeding Trial portion of
> the evaluation.

Perceptual/Cognitive observations:
☑ No deficit ☐ Partial deficit ☐ Severe deficit

Comments: _____

Physical Status

Assistance needed to attain and maintain position:
☑ Independent ☐ Minimal/Moderate assistance
☐ Maximal assistance

Comments: _____

Head and neck control
Range of motion: ☐ Normal ☑ Impaired
Manual muscle testing: ☐ Normal ☑ Impaired
☐ Nonfunctional for eating

> If head and neck control is nonfunctional for eating, stop the
> evaluation and refer to the Manual for additional information.

Upper-extremity control
for self-feeding: ☐ Normal ☑ Impaired
☐ Nonfunctional

> Record rating for upper-extremity control during the feeding trial.

Comments: ↓ tone (R) neck, needs cues
to keep head erect, decreased
(R) u/e tone for utensil manipulation

Laryngeal elevation   ☑ Normal   ☐ Impaired   ☐ Absent
Voice quality after swallow   ☐ Normal   ☐ Impaired   ☑ Absent (was not present pre-swallow)
Auscultation:
　Audibility of upper esophageal sphincter: ☐ No   ☐ Yes
　Pooling   ☐ No   ☐ Yes
　Comments: Delay in trigger of pharyngeal swallow response

Repetitive swallows   ☐ No   ☑ Yes   Number of swallows: 1
Cough reflex   ☑ No   ☐ Yes
　　☐ Before swallow   ☐ During swallow   ☐ After swallow

Other Observations:
O₂ saturation remained at 96% before, during, + immediately after feeding trial

During the feeding trial, record the patient's recognition of swallowing problems and upper extremity control for self-feeding.

Comments:
Pt is aware of inability to swallow fluids and chewable solids. He required hand-over-hand assistance to load spoon and bring to mouth. Able to hold rigid cup c̄ two hands to bring to mouth and sip.

3

Figure 43-3 *(continued)*

IMPRESSIONS

Summary

This 73 y o gentleman is s/p CVA c̄ ⓡ hemi and aphasia. He shows reduced oral tone and control of ⓡ tongue and cheek. He manages soft, formed boluses c̄ extra time for oral manipulation and a slowed swallow response. No pooling or coughing was noted after swallowing. There were no clinical signs of aspiration or laryngeal penetration.

Functional Level (Physical and verbal assistance needed for positioning, hand-to-mouth movements, and swallowing):

Pt was able to self-feed c̄ hand-over-hand guiding to use utensil but was able to use cup Ⓘ with both hands. He needed verbal cues to prepare his tray to eat and supervision to transfer to wheelchair to eat.

Intermittent supervision at meals and snacks and assistance to self-feed c̄ right hand is recommended.

Recommendations/Plan:

☐ NPO (No food by mouth)
☐ Nutrition consultation: _____
☑ Videofluoroscopy TO assess safety with fluids
☐ Prefeeding program
☑ Special positioning, Adaptive equipment: Seated in chair to eat
☐ Mealtime supervision ☐ Constant ☐ Intermittent ☐ Set-up
☑ Diet recommendation: Thick puree, trial thick fluids
☑ Other: Short-term goals
   ① Trial of honey thick fluids
   ② Tolerate soft chewables without s/s of aspiration
   ③ Ⓘ techniques to maintain lip closure + prevent food pocketing
   ④ Ⓘ vocal cord adduction exercises
   ⑤ Modified Ⓘ self-feeding c̄ adaptive equipment

4

Figure 43-3 *(continued)*

✚ Safety Note 43-2

Precautions for the Therapist and Patient

The swallowing therapist stays close to the patient during eating and is exposed to oral secretions and respirations. Likewise, the patient is exposed to pathogens on the therapist's clothing and hands and in the therapist's respiratory tract. Universal (also called "standard") precautions should be used. The use of gloves is mandatory anytime the therapist touches the face or inside the oral cavity.

Dysphagia patients are prone to difficulty with airway obstruction and aspiration during eating. For the safety of the patient, the swallowing therapist should be trained in suctioning of the airway, the Heimlich maneuver, and cardiopulmonary resuscitation.

Signs and Symptoms of Potential or Actual Aspiration

Although laryngeal penetration or aspiration may be silent, occurring without overt warning signs and symptoms, the following indicate that it may occur or be occurring. If observed during a dysphagia evaluation, these signs or symptoms can indicate that a feeding trial should not be initiated or should be discontinued. Specific items of concern are as follows (Avery-Smith, Rosen, & Dellarosa, 1997):

1. The patient cannot remain awake for the clinical evaluation.
2. The oral and/or pharyngeal sensation and motion assessment reveal poor ability to manipulate and contain the bolus.
3. The bolus remains in the mouth, and the patient cannot initiate or complete the oral preparatory stage within a reasonable time.
4. There is excessive coughing or choking before, during, or after swallowing.
5. There is no swallow response once the oral stage is completed.
6. There is a change in voice quality, often wet, or no voice after swallowing.
7. Severe pooling or wetness is heard on auscultation or by the naked ear; secretions are poorly managed.
8. Silent aspiration is suggested by a change in the patient's color and/or respiratory rate, increased congestion on auscultation of the chest, and/or a reduction in oxygen level in the blood as recorded by pulse oximetry.

The Feeding Trial

Interventions that maximize performance can be initiated before the feeding trial begins (Procedures for Practice 43-1). The safest food textures are chosen for the trial. Easy-to-manage foods and thick fluids are attempted first, especially if the patient has been NPO and/or has a diagnosis or clinical picture that suggests a high risk of aspiration. During the oral stage, the clinician observes bolus containment, formation, propulsion, and mastication. During the pharyngeal stage, the clinician assesses laryngeal elevation, voice quality after swallow, repetitive swallows, and cough reflex. The therapist should observe for signs and symptoms of laryngeal penetration or aspiration, especially during the first feeding trial (Safety Note 43-2). The evaluation concludes with a summary, recommendations, and a plan (Latella & Meriano, 2010).

Specific techniques are helpful during the feeding trial. Auscultation (listening) to the swallow with a stethoscope held lateral to the larynx (Fig. 43-5) can reveal the efficiency and safety of the oral and pharyngeal stages (Borr, Hielscher-Fastabend, & Lücking, 2007). Gentle palpation of the neck (Fig. 43-6) during the swallow reveals symmetry, strength, and speed of oral

pharyngeal movement and may be done simultaneously with auscultation. Use of a pulse oximeter, a noninvasive monitoring device that measures the patient's oxygen saturation in the bloodstream, may be effective in assessing whether aspiration or respiratory difficulties are occurring (Salvador et al., 2009). Normal oxygen saturation in the bloodstream falls in between 93% and 98%; a level below 92% after swallowing suggests aspiration. If the patient can self-feed, palpation and auscultation may be done simultaneously. If the patient needs help to self-feed, auscultation and guiding with hand-to-mouth efforts may be done simultaneously.

Recommendations and Plan

Once the clinical evaluation is complete, recommendations and a plan are formulated. As seen in Figure 43-4, recommendations may include whether eating by mouth is advisable, whether an instrumental evaluation is advised, whether a nutritional consultation with a dietitian is needed, recommended diet type, mealtime positioning and supervision, adaptive equipment, and type and amount of assistance. Evaluation of the patient is ongoing, and with additional information from clinical observations, instrumental evaluations, and input from

Procedures for Practice 43-1

Preparation for Eating

Prior to the feeding trial portion of an evaluation and snacks or meals, measures must be taken to optimize the patient's swallowing performance. Because these strategies do not involve ingestion of food, they are indirect therapy techniques.

- Provide a quiet environment to encourage concentration.
- Position the patient upright in a chair to minimize the risk of aspiration. The feet should be supported, and the arms should be free for self-feeding. Patients with pseudobulbar dysphagia may need special attention to positioning before eating and special positioning devices; they may need assistance to maintain head and neck alignment and facilitation to stimulate oral and pharyngeal motions prior to and during eating (Fig. 43-4).
- Complete oral hygiene activities before the trial because this stimulates sensation and range of motion in oral structures.
- Present a simplified visual array of food and utensils for the patient with visual neglect and/or other visual deficits. Anchors, colorful cues to call attention to the side of the plate, are helpful for patients with neglect.
- Present appetizing, culture-specific foods, utensils, and tableware.
- Provide adaptive equipment and/or use hand-over-hand guidance to facilitate self-feeding.
- Provide simple explanations and one-step verbal directions if necessary.
- If the patient eats too quickly or is confused by multiple food choices, present one food at a time.
- Use small-bowled utensils and verbal or manual assistance to load just a teaspoon-sized bolus. Pinch the straw to limit the amount of liquid consumed or use a covered cup with a small opening.

Figure 43-4 Using the half-nelson position to assist with head and neck control. The therapist can also assist with jaw, cheek, and lip control at the same time.

other dysphagia team members, the treatment plan and goals change.

Instrumental Evaluation

Clinical assessment goes hand in hand with instrumental evaluation, which uses imaging and diagnostic studies to provide critical information about the unseen parts of the oral, pharyngeal, and esophageal stages of swallowing. Various types of instrumental evaluations for dysphagia are discussed in Definition 43-3. These evaluations are usually performed by physicians, often together with the occupational therapist. Aspiration of food or fluid may be silent (Leder, Suiter, & Green, 2011). Imaging studies, such as **videofluoroscopy**, and **fiberoptic endoscopic evaluation of**

swallowing (FEES) are needed to identify aspiration, but they may not identify aspiration in all instances, because client skills can vary, and the testing situation in the radiology suite may not reliably approximate an actual eating situation. However, these studies do provide important information about the quality of the swallow and the efficacy of compensatory therapy techniques used during swallowing.

DYSPHAGIA INTERVENTION

Remedial and Compensatory Goals

One consideration in treatment is remedial versus compensatory goals. Remedial, also referred to as "rehabilitative" treatment, focuses on restoring a normal level of

Figure 43-5 Auscultation of the swallow using a stethoscope. The therapist may be able to facilitate head position and guide self-feeding while listening to the sounds of the swallow.
Figure 43-6 Palpation of the neck during swallowing. The first finger is under the chin, the second finger is at the base of the tongue, the third finger is over the thyroid cartilage, and the fourth finger is at the base of the throat. A very light touch should be used so as not to inhibit motion.

Definition 43-3

Instrumental Evaluation of Swallowing

Instrumental evaluation uses technology, including the following.

Electromyography

Electrodes are placed either into the muscle via a small needle or on the skin over a muscle to record contractions of the muscle. Surface electrodes have been used to assess aspects of oral bolus management in neurological dysphagia patients and pharyngeal, laryngeal, and esophageal activity (Stepp, 2012).

Fiberoptic Endoscopic Evaluation of Swallowing

A fiberoptic laryngoscope, a narrow flexible tube with a small camera on its tip, is introduced through the nose into the nasopharynx, where structures including the palate, pharynx, and larynx are viewed for assessment of anatomy and movement. Food is administered in different consistencies to observe posterior oral and pharyngeal function and airway protection during eating.

Manometry

A catheter with transducers to measure pressure is introduced into the esophagus. The force, timing, and sequence of the esophageal contractions are measured.

Scintigraphy

A radioactive isotope is mixed with food. As the bolus is swallowed, a gamma camera tracks the radioactive particles. This test measures the speed of bolus transit and can accurately measure the amount of bolus that is aspirated.

(continued)

Definition 43-3 *(continued)*

Ultrasonography

An ultrasound transducer held under the chin produces images of oral and pharyngeal stages of swallow, revealing the mobility of structures and boluses swallowed.

Videofluoroscopy

The patient is seated between a movable camera and a fluorescent screen. Radiographic images of oral, pharyngeal, and esophageal structures are delivered to a screen from the camera as barium or barium-impregnated fluids and foods are swallowed. The images are recorded on videotape or DVD. Figure 43-7 illustrates a videofluoroscopic image of the oral, pharyngeal, and upper esophageal structures. Swallowing pathology and the effectiveness of compensatory swallowing techniques and positions can be observed. The patient may be positioned in a lateral and/or anteroposterior position to view structure and function from both perspectives. Videofluoroscopies are often repeated to assess progress. A swallowing therapist is usually present to ensure that the test reproduces compensatory maneuvers and food textures being used and to ensure that it mimics real eating as accurately as possible. In some instances, the swallowing therapist may perform the videofluoroscopy. Therapists assisting with or performing videofluoroscopies must be expert swallowing clinicians; they must be fully trained in use of the equipment and procedures used in videofluoroscopy. Videofluoroscopy of swallowing may also be known as "modified barium swallow" or "MBS."
Figure 43-7 A videofluoroscopic image of the oral, pharyngeal, and esophageal structures. (Videoprint image courtesy of Bette Pomerleau, MS, SLP, and Ray Autiello, LPN, RT, of Universal Mobile Services, Haverhill, MA.)

swallowing function. Potential for partial or full recovery is anticipated when goals are strictly remedial. This approach may be used with an acute stroke patient for whom complete or near complete recovery is anticipated. Compensatory treatment circumvents impairments with the use of alternative strategies and techniques. These techniques are used when full recovery is not anticipated, for example, for a patient with advancing Parkinson's disease. Compensatory techniques may also be used to enable a safe, functional swallow prior to recovery of normal swallowing, for example, with a patient with an acute pneumonia for whom full recovery is anticipated. Table 43-1 discusses compensatory and remedial interventions for specific swallowing deficits. Compensatory swallowing maneuvers and their indications are discussed in Procedures for Practice 43-2, and instrumental interventions are explained in Definition 43-4. Goals may be remedial and then change to compensatory once a plateau in function is reached.

Indirect and Direct Therapy

Another consideration is the type of therapeutic techniques used. Indirect therapy addresses the prerequisite abilities or the capacity to swallow without ingestion of food or liquid. Patients who are at high risk for aspiration often begin with indirect therapy only. Indirect therapy can include range of motion, strengthening, and coordination exercises for weak or hypotonic oral and pharyngeal musculature; strengthening of pharyngeal and laryngeal structures; techniques to reduce or stimulate sensitivity of oral musculature; and techniques to improve the pharyngeal swallowing response. Indirect therapy also involves increasing the patient's level of arousal to implement treatment, and manipulating the environment to optimize behaviors that affect swallowing (see Procedures for Practice 43-1).

Direct therapy rehabilitates prerequisite abilities or the capacity to swallow during therapeutic snacks or meals. This involves exercises and/or the use of compensatory swallowing maneuvers that include ingestion of food. Indirect therapy may continue once direct therapy has begun. An individualized treatment plan usually includes a selection of direct and indirect techniques. The complexity of interventions depends on the ability of the patient and/or caregiver to process complex information. Treatment techniques may be evaluated by videofluoroscopy or fiberoptic endoscopy to assess their efficacy, especially in the pharyngeal stage, where the effects of techniques are unseen. Although not discussed in depth here, optimizing self-feeding skills is an important goal to address together with swallowing goals. Although not yet proven in the literature, the sensory inputs and motor patterns used for self-feeding are probably related to those used in the partly voluntary swallow, and facilitating both skills enhances each.

Progression of Diet with Swallowing Therapy

As indirect therapy begins, some patients may receive all nutrition, hydration, and medication via a nonoral source, such as intravenous or gastrostomy tube feedings. As the patient recovers the ability to swallow without laryngeal penetration or aspiration, direct therapy with the therapist present begins during snacks and progresses to meals. As improvement continues and the patient learns compensatory techniques, he or she may progress to eating under the supervision of nursing personnel and trained significant others and then progress to eating independently. Calorie counts are initiated by the dietitian to assess the adequacy of oral intake. Once food intake improves and calories are consistently sufficient, nonoral feeding sources may be used only for hydration and/or medication. Finally, as the patient improves and fluids and medications are safely ingested by mouth, the use of nonoral feeding sources can be discontinued. Diet textures are upgraded as skills develop. Depending on the diagnosis and potential for recovery, patients may level off at any point in the described progression (Procedures for Practice 43-2).

Dysphagia Diets

Dysphagia diets are designed to provide stepwise gradation of food and fluid textures that are matched to the patient's improving oral and pharyngeal skills. A diet of mechanical soft foods (foods that have been chopped or ground) that form a moist, cohesive bolus and thickened fluids may reduce the incidence of aspiration compared with pureed foods and thin fluids (Groher et al., 2006). Specific textures and flavors can stimulate optimal oral and pharyngeal motion; for example, sour flavors may stimulate swallowing responses (Pelletier & Lawless, 2003). Patients may have strong preferences; those with dementias may prefer sweet flavors and reject foods that require chewing. Dysphagia diets for most patients follow this general progression:

1. Thick purees, such as pudding and applesauce
2. Very soft moist chewables, such as soft cooked vegetables, fruits, and soft pastas
3. Drier chewables, such as cookies and breads
4. Foods requiring biting, firmer chewables such as meats, and mixed textures like cereals and milk or pills and water.

The progression of fluids advances thus:

1. No fluids at all
2. Honey-thick fluids
3. Nectar-thick fluids
4. Thin, flavored fluids
5. Water

Table 43-1 **Compensatory and Remedial Interventions for Specific Problems**

Patient Problem	Compensatory Intervention	Remedial Intervention
Swallowing apraxia		Provide a natural mealtime setting; enhance self-feeding skills to facilitate oral skills; provide a variety of boluses to stimulate oral movements
Weakness of cheeks, lips	Provide soft solids and thick fluids for easy oral manipulation; place food at back and stronger side of mouth; tilt head toward stronger side; massage cheek to prevent pocketing; hold lips closed; inspect mouth after meals to check for residue	Use tapping, vibration, and quick stretch to stimulate movement (refer to Web Chapter C for further information on these interventions); provide range-of-motion and stretching exercises progressing to resistive sucking and blowing exercises
Abnormal oral reflexes	Avoid stimuli that provoke rooting, bite, tongue thrust, sucking, or hyperactive gag reflexes; elicit movements antagonistic to undesirable reflex (for example, encourage mouth opening to weaken bite reflex); seat patient with body well supported to minimize proximal extensor tone, which can provoke abnormal distal movements and reflexes	
Facial, intraoral hypersensitivity		Provide systematic desensitization to face and intraoral area; if sensory defensiveness affects whole body, a program of graded sensory stimulation to body should precede stimulation to oral area, followed by careful introduction of food; use systematic desensitization with guided imagery to reduce muscle tone and anxiety regarding eating and mouth
Oral hyposensitivity	Place bolus on more sensitive areas of mouth; use warmer or colder bolus and flavorful food to stimulate sensation (Logemann et al, 1998); use heavy or viscous boluses	Sensory diet providing heightened tactile and proprioceptive input to intraoral structures may stimulate sensation and movement before and during a meal or snack
Reduced lingual control	Introduce diet requiring little oral manipulation, including soft solids and thick fluids; use posterior and/or lateral placement of food on stronger side; inspect mouth for residue after meals	Introduce active and passive tongue range-of-motion exercises, activities; provide quick stretch to tongue with tongue depressor or gloved fingers; provide articulation and tongue strengthening exercises (Robbins et al., 2005)
Slow oral transit time	Use cold boluses to hasten oral transit time (take care in case they melt into a difficult-to-manage liquid) sour boluses, such as those infused with lemon juice, can speed oral manipulation	
Delayed swallow	Use a sour bolus to reduce swallow delay (Logemann et al., 1998); try chin tuck to enhance airway protection; increase bolus volume and viscosity to reduce pharyngeal delay time (Bisch et al., 1994)	Try thermal-tactile stimulation: stroke anterior faucial arches with iced laryngeal mirror (Fig. 43-8) which hastens initiation and overall speed of swallow immediately after application (Rosenbek et al., 1996)
Reduced laryngeal elevation	Use Mendelsohn maneuver to prolong elevation of the larynx or chin tuck to elevate larynx; use supraglottic or super-supraglottic swallow to clear or minimize any material in airway	Use "Shaker" exercises (a program of capital flexion exercises) to strengthen suprahyoid musculature and prolong opening of the upper esophageal sphincter (UES) (Shaker et al., 2002)
Reduced laryngeal closure	Use supraglottic or super-supraglottic swallow to enhance airway protection (Logemann et al., 1998) or chin tuck to elevate and close off larynx	Introduce vocal cord adduction exercises (Logemann et al., 1998)
Tracheostomy	Occlusion of tracheostomy tube minimizes aspiration and improves swallow biomechanics (Logemann, Pauloski, & Colangelo, 1998); use of one-way speaking valve can decrease frequency of aspiration (Dettelbach et al., 1995); chin tuck may be useful	

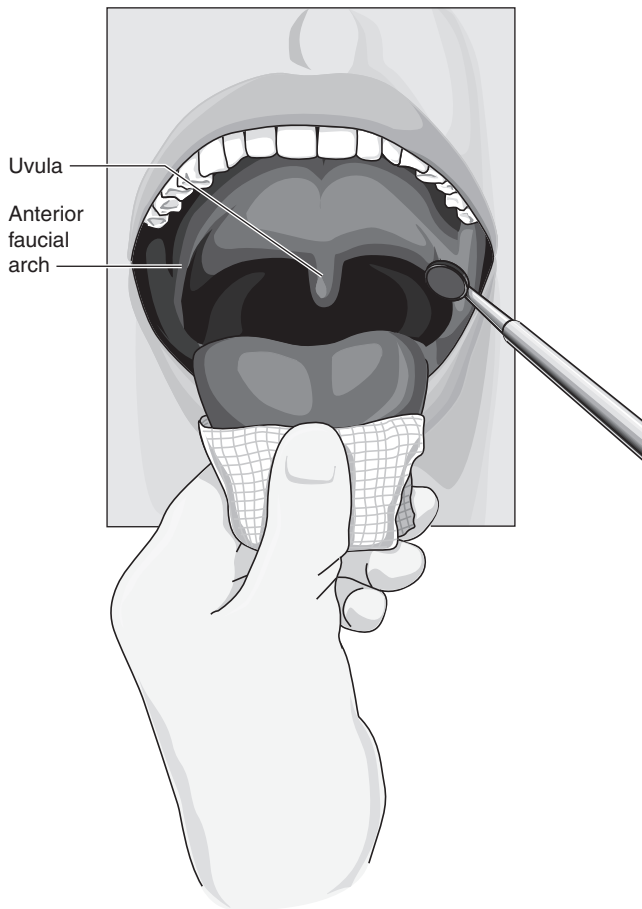
The swallowing therapist typically has to try several interventions, preferably with the assistance of videofluoroscopy, to assess which techniques work most effectively. Clinicians should work under the guidance of an experienced therapist when using a technique that is new to them.


Figure 43-8 Thermal-tactile stimulation of swallow. An iced laryngeal mirror is used to stroke the faucial arches to elicit or improve strength of the swallowing reflex.

Uvula

Anterior faucial arch

Fluids are easily thickened with commercial thickeners, which can be mixed with hot or cold beverages. Unthickened or "free" water is sometimes provided to dysphagia clients on the assumption that consuming small amounts of water creates little risk of pneumonia and can improve hydration (Carlaw et al., 2011). However, occupational therapists always comply with the patient-specific swallowing program, providing liquids only as designated. Because bacterial pathogens in the mouth may be aspirated into the lungs, meticulous oral hygiene before and after meals is needed with any oral intake to reduce the risk of pneumonia (Yamaya et al., 2001). It is important that all caregivers know and understand an individual patient's diet so that no foods or fluids are provided that are not allowed.

Patient and Caregiver Training

Although the occupational therapist alone may carry out treatment, the plan for intervention also includes education of the patient, nursing staff, and caregivers. The patient and family should understand the cause of and prognosis for the patient's dysphagia and the importance of strategies to be carried out at home. It may be helpful to have the patient view

the videofluoroscopy or fiberoptic endoscopy to fully comprehend his or her condition and the benefits of compensatory techniques. Mealtime positioning, adaptive equipment, and the type and amount of assistance must be taught to caregivers. Meal preparation practice and community outings can reinforce diet modifications, enhance patient and family education in various settings, and motivate the patient.

EFFECTIVENESS OF DYSPHAGIA INTERVENTION

Numerous studies cite the effectiveness of dysphagia intervention in both acute and chronic populations. More recent research is focusing on efficacy in the form of systematic reviews. One systematic review revealed that dysphagia interventions in acute stroke reduced incidence of aspiration pneumonia (Foley et al., 2008). Another demonstrated that compensatory swallowing and head positioning maneuvers can be effective in neurological populations (Ashford et al., 2009). Evidence Table 43-1 lists evidence for the benefits of occupational therapy interventions for dysphagia.

Studies have also evaluated the efficacy of specific intervention techniques in diagnostic cohorts. For instance, Logemann et al. (2008) concluded that providing honey-thick fluids was the most effective technique in eliminating aspiration in a population with Parkinson's disease and dementia. Other examples of proven therapeutic techniques to manage dysphagia are presented earlier in the chapter.

Although much research focuses on how well interventions eliminate aspiration from a clinical perspective, other studies evaluate how dysphagia interventions can improve the patient's quality of life. The SWAL-QOL and the SWAL-CARE tools assess quality of life and quality of care/patient satisfaction, respectively (McHorney et al., 2002). Since the publication of these and similar assessments and their publication in other languages, studies have been introduced to assess quality of life and care of patients with dysphagia around the world.

As the emphasis on evidence-based medicine and rehabilitation advances, clinicians must keep abreast of new knowledge. Useful resources on dysphagia care for both beginning- and advanced-level swallowing therapists are noted under Resources 43-1. The author encourages the reader to explore further learning and expertise in dysphagia care. In many facilities, problem-oriented rehabilitation team goals are supplanting discipline-specific goals to target improvement of specific abilities that pose barriers to discharge, creating a need for occupational therapists versed in dysphagia management. Early discharge from acute care and rehabilitation hospitals and minimized staffing in health care facilities create situations in which competence in dysphagia intervention has become a mandatory skill for occupational therapy practitioners. Occupational therapists, with their background in the many abilities and capacities that influence eating and swallowing, make logical primary swallowing therapists.

Procedures for Practice 43-2

Compensatory Swallowing Maneuvers: Their Purpose and Execution

The following techniques are ways to use volitional movement to improve the quality of the pharyngeal swallow. Most of them are complex and require a good attention span and the ability to follow complex directions on the part of the patient.

Maneuver	Purpose	Execution
Chin tuck	Moves base of tongue back; narrows opening to larynx, protecting airway; helps protect airway when larynx is low and swallow is delayed; improves quality of the swallow (Ertekin et al., 2001)	Tuck chin down toward chest while swallowing
Effortful	Helps to elevate base of tongue (Lazarus et al., 2002)	Squeeze hard with throat muscles while swallowing
Mendelsohn maneuver	Prolongs opening of upper esophageal sphincter (UES) when larynx is low (Lazarus et al., 2002)	Push tongue into roof of mouth; try to keep Adam's apple up while swallowing
Neck rotation	Closes weaker side of pharynx; uses stronger intact musculature in cases of unilateral weakness of pharynx and/or vocal folds; improves quality of the swallow (Ertekin et al., 2001)	Turn head to the weaker side while swallowing
Supraglottic swallow	Compensates for weak vocal cord closure, reduces penetration of food into larynx during swallow by closing vocal cords (Lazarus et al., 2002)	Swallow while holding breath; then cough. Volitional cough after swallow helps to ensure that anything in airway returns to pharynx to be reswallowed.
Super-supraglottic swallow	Reduces penetration of food into larynx during swallow by narrowing opening to airway (Lazarus et al., 2002)	Hold breath and bear down; maintain breath-hold, keep bearing down while swallowing; cough after swallowing

Definition 43-4

Instrumental Intervention

Surface electromyography provides patients with improved awareness of swallowing function, providing for better swallowing. This intervention has been shown to be useful in populations with stroke (Crary et al., 2004; Freed et al., 2001). One example of this is VitalStim Therapy®, which uses a specially designed electrical stimulation unit with surface electrodes placed on the neck (Fig. 43-9).

Figure 43-9 VitalStim, a specially developed neuromuscular stimulation unit that facilitates contraction of the muscles used in swallowing, in place on a dysphagic patient's neck. (©2005 Encore Medical, L.P. VitalStim is a registered trademark of VitalStim, LLC.)

Evidence Table 43-1	Best Evidence for Dysphagia Interventions Used in Occupational Therapy						
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Remedial	Effect of thermal-tactile stimulation as assessed pre- and poststimulation by videofluoroscopy	Thirteen patients with Parkinson's disease and dysphagia	Thermal tactile stimulation applied to faucial pillars in pharynx	Pre-post non-experimental design Level III C1a	Yes. Median pharyngeal transit time for swallowing both fluid and paste textures was improved. Oral transit time was unaffected with both textures.	Pharyngeal transit time for fluids: $p = 0.004$; for paste $p = 0.01$	Regan, Walshe, & Tobin (2010)
Compensatory	Comparison of three interventions for aspiration in patients with dementia and/or Parkinson's disease: chin down posture, nectar-thickened liquids, and honey-thickened liquids	Seven hundred eleven patients who aspirated on thin liquids assessed with videofluoroscopy	1. Chin-down posture 2. Nectar-thickened liquids 3. Honey-thickened liquids	Randomized controlled study Level IA1a	Yes. Honey-thickened fluids were more effective than nectar-thickened fluids to eliminate aspiration, and both were more effective than chin-down position with thin fluids.	1. Chin down versus nectar thickened $p < 0.001$ 2. Chin down versus honey thickened $p < 0.0001$ 3. Nectar thickened versus honey thickened $p < 0.0001$	Logemann et al. (2010)

case example

Mr. D.: Dysphagia Evaluation and Treatment for a Patient with Left Cerebrovascular Accident

	Clinical Reasoning Process	
Occupational Therapy Process	**Objective**	**Examples of Therapist's Internal Dialogue**
Patient Information Mr. D. is an 73-year-old man with a left hemispheric cerebrovascular accident (CVA). He was admitted to an acute-care hospital with aphasia and right upper extremity weakness, with a prior history of hypertension, transient ischemic attacks (TIAs) with aphasia, and chronic heart failure.	Understand the patient's diagnosis or condition	"According to my experience and the literature, patients with dysphagia caused by an acute single stroke eventually swallow safely without compensatory techniques. However, Mr. D. has had prior TIAs (possible permanent damage), which may limit his swallowing recovery. I expect that his symptoms will resolve, at least in part. He does have some control of his lips, cheek, and tongue, but reduced competence of his airway protection skills indicate that oral feeding should proceed cautiously."
	Know the person	"Although he is frail, Mr. D. is enthusiastic about advancing his diet and participates fully in his dysphagia intervention, and I believe that he will take responsibility for following through with his rehabilitation program. He enjoys meals at home and assists with meal preparation. He has a supportive spouse who will help to carry over mealtime recommendations and exercise programs. Because he is ambulatory, I believe that follow-up dysphagia therapy will occur on an outpatient basis."

Reason for Referral to Occupational Therapy

Mr. D. was referred to occupational therapy for dysphagia intervention, as well as to improve his upper extremity skills including self-feeding. The medical staff wants to be sure that he does not need alternative nutritional routes (nasogastric feedings or intravenous) to nourish and hydrate himself while in the hospital and wants assurance that he is not at risk for aspiration. The doctors also want to assure that he can maintain his nutritional requirements so that he can safely be discharged home.

Appreciate the context	"Mr. D. is being seen as a hospital inpatient. Although eating and mealtime in this setting is very different from being home, because of natural recovery, his level of function may improve quickly, and I should be alert to update goals on a daily basis. I'll be working together with the dietician to care for Mr. D.; she will monitor that he is eating and drinking enough and initiate any changes in diet that I recommend."
Develop the provisional hypotheses	"Because Mr. D.'s muscle tone is low, I may be working with him to reinforce muscle activity for both muscles involved in swallowing and his upper extremity muscles involved in self-feeding."

Assessment Process and Results

A dysphagia evaluation was done using the Dysphagia Evaluation Protocol (see Resources 43-1). The evaluation (Fig. 43-3) revealed that Mr. D. had hypotonicity and reduced control of his lips, cheek, and tongue on the right side. Decreased airway protection skills were evidenced by his inability to phonate because of vocal cord weakness, inability to cough volitionally, and reduced laryngeal elevation during swallowing. He was not aphasic. Mr. D. was able to swallow foods from the beginning level dysphagia diet, including foods with soft, moist textures, such as pudding and applesauce, with mild food spillage out of the mouth because of poor lip control, delayed formation and propulsion of the bolus, and delayed initiation of the swallow. He had difficulty grasping utensils and cups because of hypotonicity of his dominant right hand.

Consider evaluation approach and methods	"I have chosen a standardized evaluation of dysphagia skills that also examines self-feeding and includes all components of swallowing that I need to assess."
Interpret observations	"Given the evaluation results and observation over the course of several meals, Mr. D. should be able to nourish and hydrate himself with supplementary (not by mouth) nutrition or hydration."

Occupational Therapy Problem List

1. Hypotonicity of oral, pharyngeal, and laryngeal structures, resulting in
   - delay in and reduced coordination of bolus control both in the mouth and in propelling the bolus posteriorly to initiate the swallow
   - delayed initiation of the swallow
2. Reduced upper extremity control, making use of his dominant arm to self-feed awkward

Synthesize results	"Reduced muscle tone is evidenced with both his swallowing and self-feeding."

Occupational Therapy Goal List

(5 daily treatments prior to discharge)
1. Mr. D. will tolerate a more advanced dysphagia diet, adding soft chewables such as cooked fruit and soft pasta.
2. Mr. D. will tolerate these textures without clinical signs of aspiration (see Safety Note 43-2).
3. Mr. D. will be independent in vocal cord adduction exercises.
4. Mr. D. will support the right side of his lower lip and massage the right cheek during the oral preparatory stage to prevent food spillage and pocketing in his right cheek.
5. Mr. D. will feed himself with his right hand with built-up utensils and an adapted cup while weight bearing on his right elbow.

Develop intervention hypotheses	"I believe that focusing occupational therapy within a functional mealtime context can efficiently address both swallowing and self-feeding."
Select an intervention approach	"Because Mr. D.'s stroke is acute and has great potential for improvement, the initial approach will be remedial, although a compensatory dysphagia modification will be used to reduce any possible risk of aspiration or laryngeal penetration at meal or snack time."
Consider what will occur in therapy, how often, and for how long	"Because Mr. D. has had an acute stroke, the intervention plan should be intensive; exercises should be done once or twice daily, and mealtime techniques be employed each time he eats, for both safety and to facilitate improvement."

Intervention

Mr. D. was seen daily for occupational therapy during a week as a hospital inpatient. Constant supervision at mealtime was accomplished, and all meals and snacks took place with him seated upright in the chair. Occupational therapy intervention addressed exercises and positioning to enhance tone and control of oral motor skills, laryngeal exercises to strengthen his vocal cords and improve laryngeal elevation, and facilitation of tone and movement in his hypotonic right upper extremity to improve self-feeding skills. Mr. D. and his caregiver were educated and given handouts on the nature of his dysphagia, exercises, and mealtime procedures and precautions.

Assess the patient's comprehension	"Mr. D., with the help of his wife, was able to understand all instructions and followed through with the treatment plan. He was anxious to progress to his normal diet and eating habits. He understood that the supervision at mealtime and exercises would help him to improve and prevent complications such as aspiration. He demonstrated improvements daily, and although his appetite initially was limited, he showed definite improvement through the week in terms of his intake. His progress was on target with what I expected, given that he developed no further medical complications. Happily, he achieved his short-term goals within a week."
Understand what he is doing	
Compare actual to expected performance	
Know the person	

Next Steps

Mr. D. was discharged from the hospital to home in the company of his wife. He and his wife were taught to thicken fluids with commercial thickeners at home. As his vocal cord strength returned, his volitional cough became stronger, and he gradually became able to speak in a loud whisper; laryngeal strengthening exercises continued. Mr. D. was able to discontinue use of external lip control strategies as oral motor control returned. He continued use of built-up utensils and weight bearing at the elbow while self-feeding. He continued with outpatient occupational therapy for 4 more weeks. During that time, the following long-term goals were accomplished:

Anticipate present and future patient concerns	"I know that Mr. D. will likely be anxious to resume a normal diet and enjoy a normal range of food textures. I anticipate that he will also be concerned about being able to eat in a restaurant or with friends without his 'elbow on the table' weight-bearing strategy to improve his upper extremity control. For this reason and because of continued expected improvement, I'll continue to see him as an outpatient until the remedial long-term goals are accomplished. Once he has regained 'normal' function, I'll discharge him."
Decide whether the patient should continue or discontinue therapy and/or return in the future	

1. Mr. D. will tolerate a regular diet consisting of a variety of solid and liquid textures, dry cut-up chewable solids, and thin liquids without signs or symptoms of aspiration.
2. Mr. D. will eat independently with his right upper extremity without use of adaptive equipment and without compensatory movements.

Clinical Reasoning in Occupational Therapy Practice

Determining Treatment Approach Based on Past Response to Therapy

Mr. D., the patient encountered in the case study, successfully completed six outpatient dysphagia therapy visits with his occupational therapist. He was able to achieve a normal swallow as shown by a follow-up modified barium swallow (MBS), and eat with his right hand. A month later, Mr. D. was rehospitalized with an acute episode of chronic heart failure, pneumonia, and recurrence of his right-sided weakness. During his intensive care stay, his swallowing was reevaluated, and his evaluation results were similar to those on his prior admission. However, he did not demonstrate progress, and experienced low levels of aspiration and hypotonicity on the right side of his face and oral structures, making bolus containment and mobilization difficult, and a continued delay of his swallow. How would your treatment approach be different with this second course of intervention?

Summary Review Questions

1. What are the stages of swallowing, and what events occur during each stage? Which stage or stages are most amenable to therapeutic intervention, and why?
2. What is aspiration, and what are its warning signs and symptoms?
3. Outline the three types of dysphagia; compare the specific dysphagia symptoms of selected diagnoses with the typical manifestations of the appropriate category: paralytic, pseudobulbar, and mechanical dysphagia.
4. Which components of a thorough dysphagia evaluation are most accurately completed with a patient who can follow multistep commands? How would you alter bedside evaluation for patients with various cognitive and perceptual deficits?
5. What are the instrumental evaluations for dysphagia, and how does the information that each provides assist in dysphagia rehabilitation?
6. What recommendations should a dysphagia evaluation provide?
7. Define compensatory and remedial and direct and indirect dysphagia treatments and provide examples of each for specific diagnoses.

Glossary

Aspiration—Entrance of food or secretions into the larynx below the level of the vocal cords.

Bolus—Food or liquid in the mouth.

Deglutition—The act of swallowing.

Direct therapy—Therapeutic techniques involving ingestion of food or liquids.

Dysphagia—Difficulty with any stage of swallowing.

Eating—Ingestion of food and liquid, including the preoral, oral preparatory, oral, pharyngeal, and esophageal stages.

Feeding—Taking or giving nourishment.

Fiberoptic endoscopic evaluation of swallowing (FEES)—Direct visualization of the swallow using a small illuminated camera at the end of a flexible tube (endoscope), which is introduced into the pharynx through the nose

Indirect therapy—Therapy addressing the prerequisite capacities associated with swallowing without ingestion of food or liquid.

Instrumental evaluation—Use of technology to assess aspects of swallowing.

Laryngeal penetration—Entrance of food or secretions into the larynx above the level of the vocal cords.

NPO (nil per os)—Latin for "nothing by mouth": no food or medication to be administered orally.

Swallowing—Ingestion of nourishment, beginning with introduction of food into the mouth and ending with reception of food into the stomach; includes the preoral, oral preparatory, oral, pharyngeal, and esophageal stages.

Videofluoroscopy—Moving radiographic images of swallowing structure and physiology, also known as "modified barium swallow study," recorded on videotape or DVD.

Human Immunodeficiency Virus

Karin J. Opacich

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Convey the social and epidemiological history of HIV/AIDS in the United States, focusing on the populations most prevalently infected.
2. Summarize the natural history of HIV and its concomitant social trajectory.
3. Extrapolate the effect of HIV/AIDS at points along the disease trajectory on the occupations of people within different populations.
4. Select tools and assessment strategies to ascertain the specific occupational needs of individuals living with HIV/AIDS.
5. Describe interventions to preserve, restore, and adapt meaningful occupations of individuals living with HIV/AIDS.

Since the symptoms associated with human immunodeficiency virus (HIV) were first described in 1981 (Gottlieb et al., 1981; Masur et al., 1981; Siegal et al., 1981), over a million cases have been recorded in the United States alone. Acquired immunodeficiency syndrome (AIDS) was officially defined in 1993 and periodically updated (Centers for Disease Control and Prevention [CDC], 1993), and surveillance systems for both HIV and AIDS have been established and revised by the Centers for Disease Control and Prevention (CDC, 1999; Nakashima & Fleming, 2003). HIV/AIDS is regarded as a global pandemic because it has dramatically affected nations and populations throughout the world. Initially thought to be a fatal diagnosis, life expectancies have increased because of advances in medical management. HIV/AIDS is now considered a chronic disease. Although the science associated with HIV/AIDS has rapidly compounded, arresting the disease still depends largely on individual compliance with prevention strategies. Biological and physical aspects of HIV/AIDS have been systematically studied and documented, but the more variable social trajectory is shaped by the sociopolitical context in which individuals experience the disease. Consequently, quality of life after diagnosis is highly contingent on resources, support, and access to relevant treatment. Among the services that can impact the lives of people with HIV/AIDS, occupational therapy can be valuable.

EPIDEMIOLOGICAL HISTORY

Epidemiologists have now established that HIV and AIDS are the result of human exposure to a chimpanzee virus in Africa that mutated perhaps as early as the 1920s. It is conjectured that this mutant viral strain has spread in modern times because of increased slaughter and consumption of primate meat, widespread prostitution, and use of contaminated needles. After reexamination of stored specimens, it appears that HIV entered the United States sometime in the 1970s (Armstrong, Calabrese, & Taege, 2005; Vahlne, 2009). In the ensuing years, an increasing incidence of rare cancers and opportunistic infections precipitated curiosity among health scientists (Fan, Connor, & Villareal, 2004).

THE GLOBAL PICTURE

According to the World Health Organization (WHO), 34 million people were living with HIV/AIDS by 2010 (WHO & UNAIDS, 2011), a figure revised downward from earlier estimates. Of those living with HIV/AIDS in 2010, 3.4 million were women and children. In the 2011 joint report of global progress, *Global HIV/AIDS Response* (WHO, 2011), between 2.4 and 2.9 million people were newly infected with HIV in 2010. Estimates of the extent of the global HIV/AIDS pandemic are complicated by differences in surveillance methodology. Although new measurement techniques have added to a more nuanced understanding of the pandemic, these changes have made comparisons over time especially difficult (Brookmeyer, 2010). Nevertheless, it does appear that annual AIDS-related deaths peaked at around 2.2 million in 2005 as compared to 1.8 million world deaths in 2010. The decline in deaths has been attributed to increased access to antiretroviral therapy particularly in sub-Saharan Africa (WHO, 2011).

It is now understood that populations and subgroups most affected by HIV/AIDS vary greatly by country. Epidemiological histories are similarly unique. The most common routes of transmission continue to be unprotected sex and injection drug use, but behavior varies from population to population. These variations have in part been attributed to prevailing social, economic, and political influences and conditions. The *Global HIV/AIDS Response* report cites six indicators that have contributed to improvements in the overall world outlook. First and foremost is the decline in new infections. Although many people in middle and lower income brackets remain untested and unaware of their HIV status, access to testing and counseling has increased, especially for pregnant women. By 2011, reportedly 22,400 health facilities were able to provide access to antiretroviral therapy, reducing the number of deaths and new infections. Highly effective pharmaceutical interventions have continued to diminish maternal–child infection, and children infected with HIV have increased access to drug therapies (WHO, 2011).

Although there has been irrefutable progress in managing and arresting the progression of HIV/AIDS globally, the three United Nations Millennium Goals (United Nations, 2012) associated with HIV/AIDS and tailored to each participating country remain unmet by middle- and low-income countries, most notably sub-Saharan Africa, where the epidemic is largest and where adult women are infected 1.4 times more often than men. New infections are on the rise in the Middle East and North Africa. Europe and Central Asia have achieved goals related to reduction of infant and child mortality but still struggle with containing both HIV and tuberculosis as a coexisting opportunistic infection (Pontali et al., 2011). A consortium of global agencies reiterates the ongoing need for collaboration and continuing investment in science and health infrastructure (Stuckler, Basu, & McKee, 2010).

HIV/AIDS in the United States

Unlike the epidemiological history in Africa, HIV/AIDS in the United States first manifested among gay men. In the early years of the epidemic in the United States, those considered most at risk for infection were gay men, people requiring blood products, and users of injected drugs (Fan, Connor, & Villareal, 2004). Women and children initially represented a very small proportion of those infected.

Although predicted transmission has been contained, men who have sex with men of all races still comprise the largest cohort of people with HIV/AIDS in the United States (CDC, 2012b). Data accumulated through 2009 show that women now represent nearly 25% of all people with HIV/AIDS and 23% of the new cases in the United States. Black women are infected at 15 times the rate of white women and more than 3 times the rate of Latinas. Incidence among children rose until studies in the late 1990s demonstrated that drug therapies administered during the perinatal period could reduce transmission from mother to child. HIV infection among infants has been diminished, with only 13 new cases reported in children younger than age 13 years in 2009 (CDC, 2011). According to the CDC, nearly 619,400 people have died in the United States during the epidemic. The best line of defense remains to be prevention, and there are still approximately 50,000 people in the United States newly infected with HIV each year.

THE DISEASE MECHANISM

HIV is a retrovirus that results in a gradual deterioration of the immune system. Once the virus enters the human body, it overwhelms the CD4+ T cells that usually defend the body against viruses. HIV uses the cell machinery to convert its own RNA into a form that can be recognized and replicated using the DNA of the host, a process called transcription. Once emitted into the cytoplasm of the cell, this reconfigured virus translates itself prolifically, producing new copies and long chains of viral proteins that mature into new infectious particles that are emitted into other cells (National Institute of Allergy and Infectious Diseases [NIAID], 2009, 2012). The most efficient vehicle for transmission is blood and contact with delicate mucosal tissue susceptible to cuts and tears. Studies have shown that HIV is not spread through casual contact with saliva, sweat, tears, urine, or feces. HIV status is confirmed by blood tests such as enzyme-linked immunosorbent assay (ELISA), which detects exposure to the HIV virus via the presence of antibodies, or Western blot, which targets the presence of the virus itself. Home screening kits are now available as well. Despite the availability of laboratory tests, initial diagnosis is sometimes not made until a person is hospitalized for pneumonia, persistent diarrhea, or other AIDS-related illness.

Although it is rare for health care providers to contract HIV through patient contact or even accidental needlesticks (NIAID, 2012), precautions (Safety Note 44-1) are advised, particularly if the provider is handling blood and blood products. Surgeons performing extraordinarily bloody procedures (e.g., orthopedists) are at greatest risk. Special care should be taken to avoid exposing HIV-positive persons to infectious agents because their compromised immunity makes them more vulnerable to serious infections.

Safety Note 44-1

Standard Precautions

You must routinely use standard precautions to protect yourself from exposure to blood or body fluids from all patients, regardless of their diagnosis. Standard precautions consist of the use of protective barriers to prevent contamination of the skin, clothing, and mucous membranes (eyes, ears, and nose). Hepatitis B virus, hepatitis C virus, and HIV are communicated through blood-borne pathogens. Modes of transmission include sexual contact involving the sharing of body fluid, needlestick, contact with blood through mucous membranes or broken skin, childbirth, receiving blood or blood products, and organ transplantation. Proper use of protective barriers prevents exposure. Protect yourself by always following these recommendations:

- Wear and change gloves.
- Do not wash or decontaminate disposable (single-use) gloves.
- Wear a fluid- or moisture-resistant gown, apron, or lab coat when you anticipate contact with bodily fluids.
- Wear surgical cap and/or hood and shoe covers and/or boots when gross contamination is likely.
- Wear mask and eye protection with side shields and face shield when there is potential for splash, spray, or splattering of body fluids to the eyes, nose, or mouth.
- Wash your hands before and after contacting patients.
- Use a pocket mask or other ventilation guard device when doing cardiopulmonary resuscitation (CPR).

Needlestick or puncture is the most common mechanism for transmission for occupational therapists. To minimize risk, follow these precautions used by medical personnel:

- Use caution when handling all sharp objects.
- Do not bend, break, or manipulate items by hand.
- Place disposable sharp objects in a puncture-resistant container immediately after use.
- Do not recap or remove needles from syringe by hand unless no alternative exists.
- Use a device instead of your hand to pick up or remove contaminated needles or other sharp objects.
- Place reusable sharp objects in containers that are puncture resistant, leak proof on sides and bottom, and labeled.
- Use a mechanical device to clean up broken glassware.
- Promptly report all exposures to your supervisor and health care authorities.

SYMPTOMS

Within 2–4 weeks of initial exposure, most, although not all, people infected with HIV experience flulike symptoms, such as fever, headache, fatigue, and enlarged lymph nodes. Until the body's immune system is depleted

of resources to combat the virus, the infected person may not experience further symptoms. Symptoms reported before progression to full-blown AIDS include lack of energy, weight loss, fevers and sweats, yeast infections, skin rashes, pelvic inflammatory disease unresponsive to treatment, and short-term memory loss. In many people, progression to AIDS takes 10–12 years, although approximately 10% of those who are HIV positive will progress to AIDS within 2–3 years of infection (NIAID, 2009, 2012). According to the prevailing CDC (1993) definition, HIV-infected people with fewer than 200 CD4 + T cells per cubic millimeter of blood and manifesting at least one Category C opportunistic illness are considered to have AIDS. As the disease progresses and opportunistic illnesses accrue, people with HIV often experience cognitive, motor, and behavioral manifestations including memory impairment, poor concentration, incoordination, weakness, irritability, and depression. More severe neurological deterioration may occur, especially with high viral loads (NIAID, 2009, 2012).

MEDICAL INTERVENTIONS AND ADVANCES

Clearly, the best treatment for HIV is prevention. Prevention strategies entail raising public awareness, providing education, and promoting individual behaviors that avoid risk or minimize harm. Prevention strategies can have a dramatic effect as illustrated by the reduction in the rates of new infection among gay men in Thailand where safe-sex campaigns have been successful (Curran, 2003). Bailey et al. (2007) established that male circumcision is effective in reducing HIV transmission in sub-Saharan Africa, where heterosexual infection is highest. Scientists continue to focus on developing effective barriers to the virus and vaccinations that would protect people from sexual transmission (Armstrong, Calabrese, & Taege, 2005).

For those already infected with HIV, advances in pharmaceutical interventions have made notable effect upon survival and extended years of quality life. It is no longer unusual for people to experience 15 or more years of quality life from the time of diagnosis. The use of zidovudine during pregnancy (CDC, 1994) is among the most successful advances; it dramatically reduces transmission of the virus to infants born to HIV-positive mothers to a rate of about 1% (NIAID, 2009, 2012). Even though they may test positively for antibodies to HIV at birth, only a very small number of newborns now go on to develop the disease. Because women tend to underestimate their risk and because prenatal transmission to infants can be prevented, in 2001, the CDC recommended that all pregnant women be routinely tested for HIV.

For seropositive adults, three categories of drugs have evolved and are currently used to treat HIV. Reverse transcriptase inhibitors interrupt the viral cycle early in its proliferation, and protease inhibitors interrupt it later. The third class of drugs, fusion inhibitors, interferes with viral reproduction by blocking the cell membrane, preventing permeation of HIV. Combination therapies, called highly active antiretroviral therapy or HAART, are aimed at curtailing HIV at multiple points along its reproductive cycle. For those who tolerate and respond to HAART, the drugs can retard the progression of HIV and even restore some immune functions for those with AIDS (NIAID, 2009, 2012). Long-term use of HAART does seem to be associated with detrimental side effects including fat redistribution, insulin resistance, poor lipid profiles, and increased risk of myocardial infarction (Armstrong, Calabrese, & Taege, 2005; NIAID, 2009, 2012).

PROGNOSIS AND MITIGATING FACTORS

Numerous strains of HIV have been identified, and the virus tends to customize itself within the individual. Some people seem to be more resistant to rapid translation than others. Viral load and strength of the particular HIV strain also seem to be associated with the rate of progression of the disease. Concurrent diseases or poor health status before infection can increase vulnerability and complicate medical interventions. Early detection of infections and adherence to medication regimens can prevent or slow the virus from usurping the entire immune system. Unfortunately, not everyone has access to testing, and not everyone responds positively to the drugs. For many people infected with HIV, sociopolitical circumstances erect barriers to health.

The Sociopolitical Context of HIV/AIDS

HIV infection is most frequently attributed to unprotected sexual intercourse and behaviors that are generally not socially acceptable, such as illegal intravenous drug use and commercial sex. Globally, HIV manifested initially in the heterosexual population, and infections rates are highest among women who have sex with men. Based on 2012 data, sub-Saharan Africa represents 68% of global HIV infections, and 59% of those infected are women (WHO, 2012). Impoverished individuals in poor countries with few resources are more vulnerable to the spread of HIV. History demonstrates that people tend to underestimate their risk of exposure, and HIV infections are now permeating the mainstream heterosexual population in the United States. People with HIV often report being stigmatized or marginalized, and the potential for discrimination is very real. In the United States, HIV is still most prevalent among men who have sex with men. Minorities, especially poor women of color, are disproportionately infected and vulnerable to exclusion, stigmatization, and discrimination (Dean et al., 2005; Duffy, 2005). The distribution of HIV represents one

among many disconcerting health disparities globally and in the United States.

Gay Men

Although discrimination against gay men has long been an issue, the gay community has some attributes that yielded some positive preventive responses. Higher levels of education, access to resources, and community mobilization allowed the gay community to promote education and prevention strategies (Curran, 2003; Fan, Connor, & Villareal, 2004). Concerns about confidentiality and employer discrimination may deter access to appropriate health care. To be effective, occupational therapists providing treatment to gay and bisexual men must be culturally sensitive. Non-traditional life partners and families are likely to be involved in care, and the occupational therapist should be aware that the gay community has established many agencies, programs, and support networks that can enhance quality of life for people living with HIV/AIDS.

Women with HIV/AIDS

Poor women of color are disproportionately represented among those with HIV infection. According to the 2010 population data, African Americans and Hispanics together constitute approximately 30% of the total population but bear a disproportionate disease burden. For all U.S. HIV cases, 39.7% represent black women, and 11.8% represent Latina women in stark contrast to 2.6% among white women (CDC, 2011, 2012b, 2013; U.S. Census Bureau, 2010). Similar to their international counterparts, the women are generally socioeconomically disadvantaged and often disempowered. Their stories often reveal family violence, disrupted education, dependency on exploitive men, and engagement in high-risk behaviors such as drug and alcohol use and commercial sex (Gielen et al., 2007). General health literacy is poor, and health status even before infection may have been compromised. Therapists need to be particularly sensitive to the context in which these women live to avoid unreasonable expectations of them and exposure to increased harm from unempathic people. To attend to their own health, these women may need housing and transportation assistance, child care, and partner or family counseling.

People Who Abuse Drugs and Alcohol

For people who have been actively using drugs and/or alcohol, sobriety is critical to improving health. HIV infection often leads to an epiphany that provides a powerful incentive for getting clean and sober (Opacich, 2004). Because chemical dependency is a complex biopsychosocial phenomenon, it is important to collaborate closely with expert colleagues and to encourage participation in programs designed to support sobriety.

Effect on Scientific and Health Resources

Despite the tremendous social and economic effect of HIV/AIDS on nations worldwide, resources are still inadequate to meet needs. Over the years, programs have emerged that attend to the social complexities as well as the medical needs of people with HIV/AIDS. Many of these programs rely on grants and resources from international, state, federal, and private agencies. Treating HIV/AIDS successfully requires an array of health and human services and a culturally competent workforce to deliver those services. Labor statistics reveal shortages in many of those disciplines.

Using an accounting tool developed by UNAIDS (the Joint United Nations Programme on HIV/AIDS), data were collected from 28 countries to determine what proportion of total health care spending went to prevention and treatment of HIV/AIDS in sub-Saharan Africa where the infection rates are highest. The authors concluded that 19.4% of total health spending, reflecting billions of dollars, went to HIV prevention and treatment and translated to $9.34 to $118 spent per capita (Amico, Aran, & Avila, 2010). In the United States, the 2012 presidential budget request included $28.4 billion, a 34% increase over the 2007 budget request, for domestic and global HIV/AIDS-related activities, which represents less than 1% of the total federal budget. Of that total request, 53% ($14.9 billion) was allocated for treatment and 4% ($1 million) for prevention (Kaiser Family Foundation, 2011). In the United States, efforts toward the prevention of AIDS, along with other sexually transmitted diseases, have largely been funded by the CDC. According to CDC surveillance data from 2009, each new case of HIV is expected to accrue an average lifetime cost of $379,668 (in 2010 dollars) (CDC, 2012a). Savings from prevention efforts (cases averted) from 2001 to 2006 totaled $129.9 billion. The Ryan White Comprehensive AIDS Resources Emergency Act (CARE Act) (Government Accounting Office, 2005) provided over $2.3 billion in assistance including drug subsidies to individuals and families through state-administered programs in FY 2012 (Kaiser Family Foundation, 2013). However, poor health literacy, disempowerment, and stigmatization may still limit access to health resources.

CONTRIBUTION OF OCCUPATIONAL THERAPY IN THE TREATMENT OF HIV/AIDS

A growing body of professional literature attests to successful and potential occupational therapy contributions in addressing the needs of people with HIV/AIDS. Disease trends have stimulated research about the particular needs of women and the challenges people with HIV face in returning to work. To date, most of the literature has yielded program recommendations and educational strategies rather than evidence of effectiveness. Occupational therapy interventions for HIV/AIDS can be enhanced by

the use of instruments that address underlying abilities and capacities that lead to competency in occupational performance and that measure outcomes of therapy.

Neurobiological Changes That Affect Occupation

At times, it can be difficult to distinguish symptoms associated with HIV/AIDS and those related to the treatment of the virus. Nevertheless, these symptoms can impact quality of life. For many years, the Whalen Symptom Index (Whalen et al., 1994) has been used to indicate how frequent and troublesome the symptoms are. Since the 1990s, over 30 indices designed to capture both the severity and the individual's experience of symptoms have emerged. These indices include the Revised Sign and Symptom Checklist for HIV (Holzemer et al., 2001), the HIV/AIDS Stress Scale (Pakenham & Rinaldis, 2002), the World Health Organization QOL HIV Instrument (Fang, O'Connell, & WHO HIV/AIDS Quality of Life Group, 2002), the Body Image Scale (Martinez et al., 2005), and the Assessment of Body Change and Diarrhea Scale (Guaraldi et al., 2006). Combined with other data, a symptom index informs the occupational therapist and other health providers so they may help the person with HIV to manage symptoms.

Based on the outcome of these assessments, occupational therapists can recommend lifestyle modifications and compensatory strategies to cope with symptoms. O'Brien et al. (2010) compiled a summary review of instruments used to describe disability as experienced by people with HIV that occupational therapy practitioners may find useful in their work. Another group led by Worthington et al. (2012) reviewed instruments and evidence specific to workforce participation, some of which are reflective of occupation.

Psychosocial Manifestations

Awareness of the social trajectory is equally important in the treatment of people with HIV/AIDS. As with any serious illness, initial diagnosis is usually followed by a grief response. Depression is common both initially and intermittently throughout the disease process. Education is vitally important at this time because many misperceive HIV as a certain and imminent death sentence. Some programs link newly diagnosed people with a peer outreach worker who can comfort and inform them about HIV and helpful resources. If connected to relevant services, the person with HIV is less likely to become socially isolated or marginalized. As the disease progresses, neurological changes may predispose the person with HIV to mood swings, prolonged depression, and cognitive impairment. Occupational therapists should be prepared to employ psychosocial strategies to combat the psychomotor retardation that often accompanies depression and

to facilitate participation in family and community life (see Chapter 30).

Fatigue and Its Effect on Occupation

Among the most vexing symptoms of HIV is fatigue. Fatigue in contrast to tiredness is pervasive and persistent, contributing to a kind of occupational inertia. Although fatigue is associated with numerous diseases and disorders, it can affect people with HIV even when they are healthy and stable. There have been many attempts to discern the causes of fatigue in HIV (Jong et al., 2010). Most often, conclusions point to depression and anxiety in the absence of medical explanations. Some studies suggest that pharmacotherapies, for example, zidovudine or HAART, may themselves be responsible for fatigue. Stressful life events such as unemployment seem to contribute, as do poor sleep and coexisting medical conditions. Whatever the source, fatigue can be disabling and must be considered when addressing occupations (Stout & Finlayson, 2011).

It is suggested that practitioners use an assessment tool to measure the extent of fatigue that the client is experiencing to determine the effect on meaningful engagement. One such tool is the seven-item version of the Fatigue Severity Scale (Lerdal et al., 2011). Another assessment, the Energy Conservation Strategies Survey (Mallik et al., 2005) has been found to be useful in measuring changes in behaviors surrounding fatigue. Any number of qualitative and/or quantitative assessments in the occupational therapist's repertoire can enhance insight into the lived experience of a person with HIV that can lead to strategies to support participation and meaningful engagement (See additional discussion in Chapter 3).

With a clear understanding of the client's fatigue, the occupational therapy practitioner can assist in selecting appropriate strategies. Work simplification and energy conservation are long-standing tools. Habit training and lifestyle counseling may also be useful. Just being HIV positive entails rigorous adherence to medication regimens and frequent health care appointments that may exacerbate fatigue, and practitioners can assist clients to establish schedules and routines to maximize their energy. Some findings suggest that physical exertion is important in reducing feelings of fatigue, and therapists can help clients to select and to plan physical activities that benefit them.

Framing Occupational Problems and Developing Interventions

HIV insinuates itself into the human body and into every aspect of daily life. Although the diagnosis of HIV is devastating to some people, it becomes the vehicle to a more meaningful and productive life to others. An individual's

response to untoward events, including HIV infection, seems to depend on both internal and external resources and individual capacities. When establishing goals for occupational therapy treatment, it will help the therapist to think in terms of occupational role integrity, occupational competencies, and overall occupational coherence.

Because occupational functioning is the culmination of abilities and capacities that shape activities, tasks, and roles, multiple strategies may be needed to sort out occupational dysfunction. Although some problems in occupation may be directly attributable to AIDS-related illness, others may reflect contextual challenges or histories that prevented the development of occupational competency.

Integrity of Occupational Roles

In the initial interview, the occupational therapist working with a person with HIV/AIDS needs to develop a clear picture of the roles that characterize the person's life. Depending on the point along the disease trajectory at which the therapist encounters the recipient of services, evidence of role strain, role disruption, or role abandonment may be present. The therapist may find it useful to plot the person's role status on the Matrix of Occupational

Status (Table 44-1) to establish a baseline for decision making and intervention.

Role Strain. The occupational therapist should ascertain whether the HIV-positive person is responsible for the care of others. If there are children, life partners, elderly adults, or even pets in the household, the person with HIV may be experiencing the strain of taking care of others given the added burden of managing HIV. In addition, others in the family, however that family is constituted, may also have HIV.

Most people sustain multiple roles, and life is an exercise of juggling priorities and meeting obligations. Some individuals are very tenacious about their roles, even when their health is compromised. Because those with HIV frequently experience fatigue, it is important to designate time for rest and restoration throughout the day. The occupational therapist can help the person with HIV to establish role priorities, reserving time and energy to attend to personal health needs. This may entail negotiating and relinquishing some responsibilities and tasks to others or arranging for support (e.g., homemaker services).

Role Disruption. When immune system failure results in illness, the person with HIV might be confined to bed or

---

Table 44-1   **Matrix of Occupational Status for People with HIV/AIDS**

Occupational Domain	Occupational Role	Discontinued	Disrupted	Adapted	No Change	Expanded
Work	Parent/caregiver Homemaker (IADL) Employee Entrepreneur Vocational trainee Student					
Play/leisure	Participant/observer Spectator Hobbyist Athlete					
Self-care	Personal care (ADL) IADL Health-related care Self-advocacy Intimacy/sexual expression Spiritual/devotional expression					
Description of occupational context	Neighborhood/ community Home environment Health care setting Social network Employment setting					

By writing brief narratives regarding specific occupational roles in the box(es) corresponding to the domain/role status, the therapist can develop an occupational profile that can be used to generate therapeutic goals and priorities.
ADL, activities of daily living; IADL, instrumental activities of daily living.

hospitalized for brief or extended periods of time. This is not an unusual pattern and should be anticipated. The occupational therapist can help to plan strategies for dealing with health emergencies. Such strategies may include identifying babysitters, notifying family members, enlisting help from neighbors, calling health care providers, and arranging sick leave. When the individual with HIV is ready to resume a former role after a period of illness, the occupational therapist can assess, modify, and design rehabilitative strategies consistent with the person's state of health and abilities.

Role Abandonment. Many stories elicited from people with HIV reveal role abandonment. For those whose lives were dominated by chemical dependency, development may have been arrested and efforts diverted to the procurement of drugs or alcohol. For others who are HIV positive, depression or shame may have interrupted life plans. For still others, the symptoms and sequelae of HIV itself may have prevented full participation. Whatever the case, if reasonable health can be restored, then the occupational therapist may be the primary facilitator of role resumption or role exploration.

Occupational Competencies

At the start of therapy, the occupational therapist should generate a list of occupational competencies or skills relative to the roles the client fulfills. For example, if remunerative employment is relevant, the occupational therapist can help to delineate the skills the client has or needs to acquire to resume or pursue work. Some people with HIV/AIDS who had been unable to work have been restored to a level of health through HAART that makes employment feasible again (Kielhofner et al., 2004a). The therapist might advocate on behalf of the client to accommodate special needs (e.g., flexible work schedules, longer rest periods, or accommodations for adaptive equipment). The occupational therapist may need to assist clients to develop strategies to compensate for low vision or for poor coordination.

If the HIV-positive person is a homemaker, establishing routines to accomplish cleaning, shopping, laundry, and so on will be important. Safety in the kitchen, especially when handling sharp utensils, will prevent exposure of others to HIV-positive blood. If the person is living with family members or friends, the occupational therapist can help the individual to negotiate household responsibilities, rest and privacy needs, and accurate understanding of HIV/AIDS and healthy behaviors. Work simplification and energy conservation principles may be useful for coping with changes in strength, endurance, and sequencing tasks and activities. It is important to acknowledge that many people living with HIV/AIDS are impoverished and may be living in poor housing and unsafe environments, which pose additional challenges. For some, the social assistance surrounding HIV care may present new housing opportunities; the occupational therapist can guide the person through the establishment of a household, from obtaining utilities to paying bills to preparing meals.

Occupational Coherence

Occupational coherence speaks to the complementarity of roles, routines, habits, and behaviors that contribute to a life that, in totality, makes sense (Opacich, 2004). Coherence is a notion introduced by Antonovsky (1987), a sociologist, and later expanded by Nyamathi (1993). Coherence was first applied to occupations by Christiansen (1999) and Christiansen, Little, and Backman (1998) as an indicator for outcomes in the face of threats to health. Research on women with HIV/AIDS illustrated the construct by contrasting the lives of women living amidst chaos and uncertainty with those whose lives were more coherent (Opacich, 2004). If a person is ill with HIV, actively chemically dependent, and homeless, one would not describe that person as leading an occupationally coherent life. If that same person became sober, adhered to medical recommendations for arresting HIV, procured safe housing, and resumed remunerative employment, life would appear to be occupationally coherent and built on meaningful doing. The ultimate goal of occupational therapy with people with HIV might well be the achievement of occupational coherence.

Assessment

Occupational therapists use both qualitative and quantitative assessments to determine the occupational needs of persons with HIV/AIDS.

Qualitative Assessment Strategies

Each theoretical model of occupation is associated with instruments and strategies for framing occupation. An array of qualitative tools reflecting the naturalistic paradigm can be useful to reveal the nature of experience, in this case how an individual experiences HIV. Among these strategies, semistructured interviews can elicit narrative reflecting occupations. One of the published narrative tools, the *Occupational Performance History Interview II*, is reflective of the Model of Human Occupation (Kielhofner et al., 2004b). This particular template is used to probe how a given illness, condition, or untoward event shaped or altered the person's occupations. These narrative data can be analyzed by a number of ways and used to generate plans and strategies for reconstructing occupation. Based on the same model, two other instruments, the *Occupational Self-Assessment* (Baron et al., 2006) and the *Worker Role Interview* (Braveman et al., 2005) may be useful.

Quantitative Assessment Strategies

Quantitative strategies are useful when the phenomenon in question is well defined and the query is focused. An example of a quantitative criterion-referenced tool useful for people with AIDS is the *Assessment of Motor and Process Skills* (Fisher, 2012). This tool enables the therapist to observe the person with HIV engaging in familiar tasks, to quantify and compare the person's occupational performance, and to recommend strategies and levels of support necessary for safe living. The therapist might consider incorporating quality-of-life measures that reflect occupations and inform decision making (Robinson, 2004). Another developing occupational therapy tool for measuring the effects of neurocognitive impairment on task performance is the *PRPS (Perceive, Recall, and Perform System of task analysis)* (Ranka & Chapparo, 2010).

Intervention: Preserving, Restoring, and Adapting Meaningful Doing

The Occupational Functioning Model organizes roles and the definition of self into self-maintenance, self-advancement, and self-enhancement (see Chapter 1). Occupational therapy may address any or all of these aspects with the person with HIV/AIDS, depending on the occupational status of that person both before and after HIV infection. As previously noted, some cohorts of people with HIV have led marginal lives that are likely to have stymied their occupational potential.

Preservation

In the early stages of HIV infection, it is important that the individual resume or establish routines, habits, and behaviors that preserve healthfulness. Along with established roles, the newly diagnosed person must now incorporate medication regimens and attend appointments for regular lab tests and check-ups. For those whose lifestyles involved drug use or commercial sex, HIV treatment also entails intensive redirection, psychotherapy, and peer support. If pharmaceutical interventions or the virus itself results in symptoms, the person with HIV can face additional challenges in work, parenting, self-care, or other occupational pursuits. Whether the patient is a child or an adult, preserving and adapting occupational roles is critically important for both physical and mental health. For people whose lifestyles entailed maladaptive behaviors, occupational therapy may well require

role exploration that may have been derailed in childhood or adolescence or abandoned in adulthood. Strategies may include parenting classes, practicing independent living skills (e.g., laundry), and job training/retraining.

Restoration

As the disease progresses, it is common for people to experience periods of ill health and disruption of normal routines. Those with HIV/AIDS are immunocompromised and are therefore susceptible to illness and opportunistic infections. Improvement in health can occur when symptoms are addressed and HIV medication regimens bolster the immune system. Similar to cardiac rehabilitation, occupational therapy can be useful while the person is reconditioning and the illness is abating. During these times, therapy may entail work simplification or rebuilding endurance. Roles, routines, and habits related to work, self-care, and leisure may need to be negotiated and adjusted. When symptoms persist or abilities are permanently altered, the occupational therapist and the HIV-positive client should focus on adaptation.

Adaptation

As the immune system is overwhelmed, the person with HIV/AIDS is likely to lose abilities. Sensory deficits, weakness, incoordination, compromised memory, and other sequelae can compromise occupational roles and independent living. During this stage of illness, occupational therapy can facilitate adaptations that enable the person with HIV/AIDS to participate in daily life as fully as possible. This may entail environmental adjustments, adaptive strategies or assistive devices, personal assistance, or changes in living situation (see Chapters 18, 25, 27, and 28).

EVIDENCE OF EFFECTIVENESS OF OCCUPATIONAL THERAPY FOR PERSONS WITH HIV/AIDS

The literature pertaining to occupational therapy in HIV/AIDS is largely phenomenological. It reflects the experience of people with HIV/AIDS and informs the development of programs and services. A number of those studies have been mentioned in this chapter. Very few studies have been designed to examine particular interventions or to quantitatively measure effectiveness of occupational therapy interventions (see Evidence Table 44-1).

| Evidence Table 44-1 | Best Evidence for Occupational Therapy Practice Regarding HIV/AIDS |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Four-phase vocational program: (1) 8 weeks of self-assessment and preparation for work, (2) effort to reacquire productive roles through experiences, (3) support successful employment, and (4) support sustained employment	Model of Human Occupation (MOHO)–based program customized to individual needs to explore, develop skills, and seek employment	Convenience sample of 129 men and women with HIV/AIDS (106 males, 21 females, and 2 transgendered persons; mean age = 41 years); 30% attrition rate (39 of 129 participants)	Phase 1: 8 weeks, group session one time a week plus individual sessions; length of subsequent phases varied by individual.	Qualitative research Participatory action research to examine and improve the program as it unfolded Level: N	Yes, 50 participants achieved employment, 2 returned to school, and 8 participated in volunteer or internship programs from 6 to 24 months after the program. Persons with a history of mental illness were more likely to benefit.	Ninety participants completed program; 67% of those achieved successful outcome (achieved employment, returned to school, or started volunteering); effect size not reported.	Kielhofner et al. (2004b)
A program designed to increase productive participation; implemented in supported living environments	Experimental treatment based on MOHO and the Social Model of Disability: Enabling Self-Determination (ESD) aimed at achieving productive participation (employment, school or training, volunteering), consisted of group sessions focused on empowerment and the employment process, use of peer mentors; individual meetings with therapists on request. Control: standard care: education related to employment and productivity, written materials on community resources, option of individual meetings with therapists.	Sixty-five recruited; 38 (31 men; 7 women) received ESD and 27 (21 men; 6 women) received control treatment. Seventy percent African American. No significant differences between groups before or after attrition; 29.3% attrition	Both conditions overseen by occupational therapists. ESD: 2-hour initial evaluation session that focused the participant, eight 1-hour weekly group sessions, optional individual sessions for client-driven consultation, peer mentoring. Control: 1-hour peer week for 8 weeks group sessions, monthly presentations on employment & productivity for 9 months, written materials, optional meetings with therapist. Evaluation at 3, 6, and 9 months.	Nonrandomized two-group design Level: IIC2a	Yes. The ESD group achieved higher levels of participation than the control group at each interval of the study.	Intention-to-treat analysis indicated significantly more ESD participants were engaged productively: 3 months: $\chi^2_{(df = 1)} = 6.08$ ($p = 0.015$), odds ratio (OR) = 3.89; 6 months: $\chi^2_{(df = 1)} = 8.88$ ($p = 0.004$), OR = 5.44; 9 months: $\chi^2_{(df = 1)} = 5.75$ ($p = 0.018$), OR = 3.96. The ORs indicate large effects for the ESD program, with those participants twice as likely to be productively engaged at all three time points.	Kielhofner et al. (2008)

(continued)

Evidence Table 44-1 Best Evidence for Occupational Therapy Practice Regarding HIV/AIDS *(continued)*

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
A 2-year pilot program to improve balancing health, work, and daily life that combined job skills training with chronic disease self-management	The job skills training program entailed daily participation to which six biweekly sessions were added to address disease self-management, health, vocational performance, and quality of life.	Six groups of adults ($n = 53$) participated in the program over a 2-year period, 28 females and 25 males diagnosed with HIV 4+ years. Forty-two participants contacted 3–5 months postintervention. Twenty-one percent lost to follow-up.	For 6–7 weeks, 6 hours per day. Six 1.5-hour self-management focused sessions were integrated into an existing job skills training program to facilitate transition to work. Topics included balancing work and daily life, energy conservation, and nutrition.	Nonrandomized groups (6) received the same intervention over a 2-year period with pre- and postexamination of up to 42 individuals on key outcomes as measured by 11 scales, including the Canadian Occupational Performance Measure. Level: IIIB2b	Yes. Fifty-two percent of retained participants were working successfully, with another 41% actively seeking employment.	Outcome was determined using paired t tests and effect sizes. Three of the 11 scales indicated moderate to large effect sizes upon follow-up: perceived ability to balance health, work, and daily life ($r = 0.46$); health management and work ($r = 0.61$); and perceived ability to work ($r = 0.72$). However, only perceived ability to work showed significant ($p = 0.00$) improvement after treatment, which indicates that the outcome is probably not due to chance.	Bedell (2008)

case example
Ms. N.J.: Reestablishing Roles and Routines after HIV Infection

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information		The assessment process in general, including ascertaining personal background information, is described in Chapters 3–9.
Ms. N.J., a 49-year-old African American female with AIDS, participated in an outpatient occupational therapy assessment. The following problems were identified: (1) insufficient endurance for some activities of daily living (ADL) and instrumental activities of daily living (IADL), (2) mild memory impairment and confusion that interferes with self-care, (3) ambiguity of roles and routines, (4) intermittent loss of balance impacting environmental mobility, and (5) paresthesias that affect the execution of fine motor tasks.	Appreciate the context	"Ms. N.J.'s poor endurance is a direct result of her extended hospitalization and convalescence, during which she was bedridden and tube fed. Since her recovery, she has abandoned former dysfunctional pursuits, leaving her to redefine her roles, habits, and routines. Her remaining symptoms are natural sequelae of HIV/AIDS and/or drug interventions."
	Select an intervention approach	"The first order of therapy will be to identify critical ADL and IADL that support recovery, such as adherence to medication regimens, establishing intermittent rest periods, and planning for proper nutrition. Given the reported sensory and cognitive issues, precautions and compensatory strategies need to be implemented to assure the patient's safety. Finally and probably most importantly, the patient needs to be supported in her role exploration and resumption for maximal participation in family and community life."
	Reflect on competence	"Do I have adequate understanding of the relevant epidemiology, neurobiology, pharmacology, and psychodynamics? Am I sufficiently culturally competent, and can I be effective with this patient? I will need to collect tools and strategies for role exploration and practice any specific administration protocols."
Recommendations	Consider what will occur in therapy, how often, and for how long	"Since the initiation of the highly active antiretroviral therapy (HAART) protocol, Ms. N.J. has been slowly regaining her health and is more hopeful than she has been in years. She describes herself as having died and been reborn to a different life, and she says that she is actually grateful for HIV. She sees herself as having some special purpose. Because she once had many occupational competencies, she seems eager and able to reach her goals. Ms. N.J. is currently residing with her daughter and young grandchildren; they have agreed to support her in these goals and to be present for at least one in-home occupational therapy session each week."
The occupational therapist recommended home-based care two times a week initially for 4 weeks and one time a week for the next 2 months. In collaboration with Ms. N.J., goals for treatment were established as follows: (1) Ms. N.J. will identify which ADL and IADL tasks are indispensable to her management of HIV and will establish a daily schedule and record system for these, (2) Ms. N.J. will learn and implement home safety strategies relying on cue cards posted where most needed, and (3) Ms. N.J. will explore two roles or interests that will lead to safe and productive use of time.	Ascertain the patient's endorsement of plan	

Summary of Short-Term Goals and Progress

1. Ms. N.J. will identify which ADL and IADL tasks are indispensable to her management of HIV and will establish a daily schedule and a record system for these.

    Ms. N.J. and her therapist identified the following ADL and IADL tasks as indispensable: 15 minutes of morning meditation, showering once a day, preparing her own breakfast and lunch, eating her evening meal with the family, taking her medications at 6-hour intervals, and taking a nap for 1 hour in the afternoon. Ms. N.J. developed a schedule for herself that she kept next to her bed and checked off after completing each task. At each occupational therapy session, the therapist reviewed these with Ms. N.J. and addressed any problems.

2. Ms. N.J. will learn and implement home safety strategies relying on cue cards posted where most needed.

    Ms. N.J. and her therapist practiced safe methods of handling sharp objects in the kitchen and posted pictures of her using these procedures under the cabinets. With the assistance of the therapist, the family installed grab bars in the bathroom. The therapist also instructed Ms. N.J. in the use of a walker for those days when her balance felt precarious. Ms. N.J. also generated a list of emergency numbers that she programmed into her cell phone. The family also established a call system to check on her well-being.

3. Ms. N.J. will explore two roles or interests that will lead to safe and productive use of time.

    Through interviews with the therapist, Ms. N.J. will tell stories of things that she did in the past that she found enjoyable and fulfilling. Responding to the *Occupational Performance History Interview*, Ms. N.J. related that she loved to sing, and she began attending choir practice one evening a week and singing in the church choir on Sundays. She also decided that she would like to try working in her daughter's grocery store, and she began doing this for 2 hours two times a week in the early afternoon.

Next Steps

Revised short-term goals (1 month):

- Ms. N.J. will identify one household task for which she will take responsibility on a daily basis.
- Ms. N.J. will continue to adhere to established safety strategies and will report to the therapist any problems or other situations that seem to pose a threat to safety.
- Ms. N.J. will increase her hours at the grocery store to a maximum of 3 hours daily depending on the state of her health.

Understand what she is doing

"As Ms. N.J. began to feel better, she seemed genuinely happy to have a structure to her life. She would relate stories of how dysfunctional she had become before she got so sick. Even on the days when she was very tired or experienced a setback, she expressed gratitude for being here to help raise her grandchildren."

Assess the patient's comprehension

Know the person

Appreciate the context

"Ms. N.J. felt that she did not need the safety procedures most of the time, but she began to accept that it was better to be cautious than to have an unnecessary accident. Even her family members would remind her to do things 'like in the pictures.' Ms. N.J. took the walker with her when she left the house because it just made her feel a little safer if she got dizzy."

"Ms. N.J. really enjoyed singing in church, and joining the choir gave her the opportunity to make some new friends who were very supportive. Working in her daughter's grocery store was tiring at first, but Ms. N.J. felt like she was able to help out and even began to repair the strained relationship with her eldest child. Even though she shares a room with her grandchildren in her youngest daughter's apartment, she seems very happy to be there."

Anticipate present and future patient concerns

Analyze patient's comprehension

"Ms. N.J. seems much healthier in a short period of time. She is enthusiastic about the church choir, and a few of the ladies have even begun to visit her at home. She is acutely aware of how important it is for her to eat well, rest, and take her medication. She has a frank and wonderful rapport with her physician, and she trusts her advice. Ms. N.J. has a tendency to do a little too much, and she needs to be reminded to add things into her schedule gradually. Despite everything that has happened to her, she is not at all bitter and seems to have accepted her diagnosis and its implications in her life."

Clinical Reasoning in Occupational Therapy Practice

A Transition Plan for Returning to Work after a Period of Illness

You are assessing a new client today in an ambulatory clinic setting associated with a hospital that specializes in HIV/AIDS care. According to your phone intake, C.H. is a 32-year-old gay man who has been HIV positive for 6 years. C.H. was a meeting and event planner for an upscale hotel, and he really enjoyed the work. Although he was quite ill last year, his new highly active antiretroviral therapy (HAART) protocol has been very successful, and he would like to transition back to work. Having been a highly valued employee, he has been on leave of absence for the last year, but his employer does not know that he has HIV. His job entails attention to details, management of staff, coordination with vendors, and long hours. What will you need to further assess or explore with him to make a transition plan?

Summary Review Questions

1. How does the epidemiology of HIV differ in the United States compared with other countries?
2. By what mechanisms does HIV overwhelm the immune system?
3. What are the routes of transmission for HIV?
4. What are the precautions that an occupational therapist should observe when working with persons with HIV/AIDS or other blood-borne diseases?
5. Which populations are most vulnerable to HIV/AIDS and why?
6. What information is yielded from particular qualitative strategies and quantitative measures that is useful for developing interventions for people with HIV/AIDS?
7. How are occupational roles affected by HIV/AIDS?
8. How does the illness trajectory impact occupational therapy interventions?

Glossary

Disease trajectory—The expected biological and physiological manifestations of disease over time.

Global pandemic—An epidemic that affects many countries similarly.

HAART—An acronym for highly active antiretroviral therapy; combinations of pharmaceutical interventions configured to act on HIV at different points of reproduction of the virus.

Health disparities—Unintended differences in health status or health outcomes; seemingly associated with race/ethnicity, socioeconomic status, education, and access to health care.

Naturalistic paradigm—Research methodology that focuses on the lived experience, people in their natural environments; generally yields qualitative data, rather than quantitative data, from which themes or meanings are extracted.

Occupational coherence—Fluidity and complementarity of occupations that make outcomes predictable.

Occupational competencies—Skills and abilities associated with effective execution of occupations and occupational roles.

Occupational role integrity—Clusters of skills and abilities that support the tasks and activities associated with a given role; intactness of an occupational role.

Opportunistic illness—Infections and diseases that manifest because the normal protective responses of the immune system have been disabled.

Retrovirus—A virus that replicates itself using the mechanisms of host cells to convert RNA to DNA.

Social trajectory—The evolving social and behavioral responses that emerge as a disease progresses.

Cancer

Mary Vining Radomski, Mattie Anheluk, Kim Grabe,
Shayne E. Hopkins, and Joette Zola

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe general information regarding cancer incidence, cancer categories, and cancer care.
2. Appreciate the contribution of occupational therapy to cancer rehabilitation, survivorship, and palliative care.
3. Identify occupational therapy–specific assessment and intervention approaches with this population.
4. Address the psychosocial and communication needs of those affected by cancer.
5. Advocate for the provision of occupational therapy services for persons with cancer.

CANCER: BACKGROUND

The term "cancer" refers to a group of diseases that are characterized by growth of abnormal cells. Cells become abnormal because of a change in the cell's deoxyribonucleic acid (DNA) or genetic material. Abnormal DNA can be inherited; however, most changes occur during cell reproduction or as a result of exposure to something in the environment, and typically, the cause of cancer for a given individual cannot be determined. Unlike normal damaged cells, cancer cells do not die when damaged. They continue to reproduce and form new abnormal cells that are capable of invading normal tissue (National Cancer Institute, 2012c).

Cancer Classification

Oncologists and pathologists classify cancer in a number of ways. Doing so enables them to specify a diagnosis, plan treatment, consider patient eligibility for clinical trials, and determine a prognosis. One way cancers are classified is by the type of tissue from which the cancer originates (histological type). Histological classification includes six major categories: carcinoma, sarcoma, myeloma, leukemia, lymphoma, and mixed types (National Cancer Institute, n.d.[a]) (see Table 45-1). Carcinomas are the most common form of cancer and account for 80%–90% of all cases (National Cancer Institute, n.d.[a]). Cancer is also classified by the location in the body where the cancer first developed (primary site). Characterizing the spread of cancer is also used to classify the disease. Sometimes cancer cells get into the bloodstream or lymph vessels, travel to other parts of the body, and form new tumors; this is called metastasis. Cancers that have metastasized to different areas of the body are named for the location where it started (e.g., breast cancer with metastasis to the bones).

In addition to cell type and body location, cancers are often classified by grade and stage. Tumors are graded in terms of degree of differentiation, that is, the degree to which the cell resembles the source tissue (Hutson, 2004). Grading varies based on the type of cancer, but in general, the more abnormal the cell appears, the higher the grade, and conversely, the lower the grade, the better the prognosis (National Cancer Institute, n.d.[b]). Staging is the process of determining the severity of a person's cancer based on the degree to which a cancer has spread (National Cancer Institute, 2010a) (see Definition 45-1). Common elements in most staging systems consider the site of the primary tumor, tumor size and number, spread into lymph nodes, cell type and grade, and presence or absence of metastasis (National Cancer Institute, 2010a). The TNM staging system is the most common method and includes identification of tumor size (T), lymph node involvement (N), and the presence of metastasis, or distant spread of the cancer (M) (National Cancer Institute, 2010a). Staging helps physicians select the type of treatment that will be most appropriate for the patient, and it contributes to the estimate of prognosis.

Types of Cancer

As discussed earlier, cancers are labeled based on the location of the body in which the cancer starts. In this chapter, five types of cancer are described that reflect diagnostic groups often seen by occupational therapists in acute hospitals and rehabilitation settings (Table 45-2). Readers are referred to the Resources 45-1 for more websites and texts that offer additional information on an array of other cancer types and interventions.

Lung Cancer

The two major types of lung cancer are small-cell lung cancers, derived from neuroendocrine cells, and non–small-cell lung cancers, which arise from the epithelial types of tissues that line the lungs (American Cancer Society, 2012c). Cigarette smoking is the leading cause of lung cancer. Secondhand smoke, asbestos, radiation, air pollution, and exposure to toxic heavy metals have also been determined to increase lifetime risk of cancer.

Lung cancer is the deadliest form of cancer for both men and women (American Cancer Society, 2012b). Lung cancers tend to be diagnosed at later stages, when the cancer has metastasized to other sites and when other symptoms, such as weight loss, fatigue, pain, or osteoarthropathy (arthritis-like bone and joint pain), have become more prevalent and affect the individual's daily routines. Treatment of these cancers may entail surgery, chemotherapy, and/or radiation, which is determined by the type and stage of cancer and the goals of treatment (i.e., curative or palliative). People with lung cancer tend to be referred to occupational therapy to address quality-of-life issues related to maximizing performance in light of steady decline. However, new roles may be emerging for rehabilitation practitioners as

Table 45-1	Classification of Cancer Based on Tissue of Origination
Category	**Origination**
Carcinoma	Skin or lining of the internal organs
Sarcoma	Bone, cartilage, fat, muscle, blood vessels, or other connective or supportive tissue
Myeloma	Plasma cells of bone marrow
Leukemia	Blood-forming tissue such as the bone marrow
Lymphoma	Glands or nodes of the lymphatic system
Central nervous system	Tissues of the brain and spinal cord

From National Cancer Institute. (n.d.[a]). Surveillance, epidemiology and end result (SEER) training modules: Cancer classification. Retrieved September 20, 2012 from http://training.seer.cancer.gov/disease/categories/classification.html.

Definition 45-1

Grading and Staging Systems

In order to plan assessment and intervention, occupational therapists must understand terminology used in the medical record to characterize a patient's disease. Although criteria for stages vary based on type of cancer, for many cancers, TNM combinations correspond to one of five stages (National Cancer Institute, 2010a) as exemplified below.

Classification	TNM Interpretation	Stage (0–IV)
T1, N0, M0 breast cancer	T1: primary breast tumor is less than 2 cm across N0: no lymph node involvement M0: has not spread to distant parts of the body	Stage I
T3, N1, M1 breast cancer	T3: tumor more than 50 mm (2 inches) across N1: spread to nearby lymph nodes M1: cancer found in another part of the body	Stage IV

Staging Using the TNM System

T	Tumor size	T(X): tumor cannot be evaluated T(0): no evidence of primary tumor T(is): cancer in situ-abnormal cells that have not spread to surrounding tissue T(1–4): the greater the number, the larger and more invasive the tumor
N	Extent of spread to the lymph nodes	N(X): lymph nodes cannot be evaluated N(0): no lymph node involvement N(1–3): the greater the number, the greater the lymph node involvement
M	Presence of metastasis	M(X): metastasis cannot be evaluated M(0): no known distant metastasis M(1): distant metastasis is present

Stages of Cancer (0–IV)

Stage	Definition
0	Carcinoma in situ for most cancers. A very early stage in which cancer is present only in the layer of cells in which it began and has not spread. Note: not all cancers have a stage 0.
I	Cancer that is the next least advanced; patients often have good prognosis.
II–III	Cancer involving more extensive disease as indicated by greater tumor size and/or spread of the cancer to nearby lymph nodes and/or organs.
IV	Cancer that has spread to other organs.

Table 45-2 **Problems Relevant to Occupational Functioning for Five Types of Cancer by Location**

Location	Problems That May Interfere with Occupational Functioning
Breast cancer	Weakness, fatigue, body-image issues, pain, lymphedema, limited range of motion (ROM), brachial plexus injury, cognitive inefficiencies
Lung cancer	Fatigue, dyspnea, weakness, limited ROM, limited endurance
Brain cancer	Cognitive problems, impaired balance, decreased sensation, dysphasia, hemiparesis, impaired coordination, personality changes
Head and neck cancer	Limited cervical ROM, shoulder dysfunction, loss of scapular stability, difficulty swallowing, speech problems
Sarcoma	Possible amputation or issues associated with limb salvage, body-image issues

From Smith-Gabai, H. (Ed.). (2011). *Oncology*. Bethesda, MD: AOTA Press.

evidence suggests possible benefits of inpatient rehabilitation that addresses pulmonary function and exercise capacity (Spruit et al., 2006).

Breast Cancer

Breast cancer is the most common cancer among women and the second leading cause of death for women (Centers for Disease Control and Prevention, 2012), with over 250,000 Americans diagnosed each year (American Cancer Society, 2012a). Breast cancer death rates have been steadily declining since the 1990s because of progress with early detection, improved treatment, and possibly reduced incidence (American Cancer Society, 2012a). Risk factors for breast cancer include age, heredity, physical inactivity, weight gain, use of hormone replacement therapy, and race. African American women have the highest breast cancer death rates of all racial and ethnic groups, possibly because they often have cancers that grow faster and are harder to treat and may not have access to preventive and medical care (Centers for Disease Control and Prevention, 2012). Inherited gene mutations account for approximately 5%–10% of all breast cancer cases (American Cancer Society, 2012a). Individuals with a strong family history of breast cancer are often encouraged to seek genetic counseling to determine lifetime risk and whether preventive measures should be considered.

As with other types of cancer, treatment for breast cancer may contribute to decrements in occupational functioning. Treatment for breast cancer typically involves surgery to remove the tumor. Options include breast-conserving procedures (e.g., lumpectomy) or mastectomy (simple mastectomy in which the entire breast is removed,

modified radical mastectomy that also involves removal of axillary lymph nodes, or radical mastectomy in which pectoral muscles under the breast are removed as well) and sometimes reconstructive surgery (American Cancer Society, 2012f). Surgery may contribute to decreased shoulder range of motion (ROM). If axillary lymph nodes are removed, the patient is at risk for lymphedema, arm swelling caused by disruption in the lymphatic drainage system. Lymphedema causes the arm to become painful, swollen, and tight and may interfere with extremity use, performance of daily activities, and clothing options.

Some breast cancer survivors (and those with other types of cancer) report cognitive declines after chemotherapy, a condition that they call "chemobrain" or "brain fog." This may contribute to short-term occupational dysfunction for some and more permanent problems for others (Wefel & Schagen, 2012). The cause of this cognitive dysfunction is not clear, but some attribute the problem to chemotherapy-related neurobiological changes in the brain (Wefel & Schagen, 2012). Fatigue and pain, which often accompany cancer treatment, contribute to cognitive difficulties in and of themselves (Kahol et al., 2008; Seminowicz & Davis, 2007). Common cognitive deficits include attention, memory, processing speed, executive dysfunction, verbal ability, and visuospatial abilities (Biglia et al., 2012; Jim et al., 2012; Wefel & Schagen, 2012).

Brain Cancer

Each year, more than 22,000 adults in the United States are informed they have a brain tumor (National Cancer Institute, 2012a). Pathologists determine whether brain tumors are benign or malignant. Benign tumors do not contain cancer cells and usually do not grow back once removed. Malignant tumors contain cancer cells and are often considered more serious and life threatening. Tumors that originate in the brain are considered primary tumors, whereas those that result from cancers that have spread from other locations in the body are referred to as metastatic brain tumors (National Cancer Institute, 2012a). Metastatic brain tumors outnumber primary brain tumors by 10 to 1, occurring in 20%–40% of cancer patients (National Cancer Institute, 2012c). The most common types of primary brain tumors in adults are astrocytoma (which begin in glial cells called astrocytes), meningioma (which arise from the meninges), and oligodendroglioma (involving the protective covering of nerves) (National Cancer Institute, 2009). Glioblastoma multiforme, a type of astrocytoma, is the most common primary malignant brain tumor and the deadliest (Chandana et al., 2008).

Brain tumors of all kinds are capable of causing functional deficits, depending on their size and location on the brain (Smith-Gabai, 2011). Common deficits for which rehabilitation services are needed include impaired cognition, weakness, visual-perceptual deficits, sensory loss, and bowel–bladder dysfunction (Mukand et al., 2001).

These individuals may also need rehabilitation intervention to address fatigue, sleep issues, and role resumption (Vargo, 2011).

Head and Neck Cancers

Head and neck cancers begin in squamous cells that line the oral cavity, nasal cavities, thyroid gland, and pharynx (National Cancer Institute, 2012b); they are further categorized based on the specific area in which they begin.

Men are two times more likely to be diagnosed with head and neck cancers than women (American Cancer Society, 2012b). Most head and neck cancers are caused by tobacco and excessive alcohol use (National Cancer Institute, 2012b). While the general incidence rate of head and neck cancer has been declining, incidence of oropharynx cancer has been increasing over the last few years because of a rise in the human papillomavirus (HPV) (National Cancer Institute, 2012b). Symptoms of these cancers are often overlooked because they initially do not appear dangerous.

Treatment for head and neck cancers (which almost always involves surgery) may cause disfiguration, pain, and weakness and interfere with communication and swallowing (Goldstein, Genden, & Morrison, 2008). Furthermore, sometimes patients with head and neck cancer experience anxiety and guilt regarding the cause of cancer and implications for their loved ones (Goldstein, Genden, & Morrison, 2008).

Sarcoma

As a collection of diseases, sarcomas include both soft tissue sarcomas and primary bone tumors (American Cancer Society, n.d.). Soft tissue sarcomas include tumors that develop from fat, muscle, nerve, fibrous tissues surrounding joints, blood vessels, and deep skin tissues. Primary bone tumors arise from both bone and cartilage. Most sarcomas are found in the arms and legs, but they can arise in any part of the body (American Cancer Society, n.d.). Soft tumor sarcomas have no identified etiological factor, although some genetic conditions and previous treatment for cancer have been identified as predisposing factors (Yasko et al., 2001).

Surgery is the primary treatment for sarcoma, and in some cases of bone sarcoma, the affected limb has to be amputated. People who have either primary bone tumors or soft tissue sarcomas typically require the services of rehabilitation professionals during the course of treatment, particularly in the postoperative period. The needs and concerns of individuals with sarcoma may vary widely depending on the nature of the tumor and its location but may include peripheral neuropathy, fatigue, lymphedema, and inability to perform daily tasks and valued roles because of surgery to remove the tumor. Tumor growth may also impair circulatory function, resulting in edema, and can compress nerves and invade muscle or joint structures, causing pain or altered sensory perception and limiting ROM.

PHASES OF THE CANCER JOURNEY: IMPLICATIONS FOR OCCUPATIONAL THERAPY

Patients and providers often use metaphors to describe a person's experience with cancer (Harrington, 2012; Penson et al., 2004). Metaphors contribute to communication by using familiar experiences to represent unfamiliar medical concepts (Harrington, 2012); clinicians are advised to follow the patient's lead in this realm. The military metaphor, that of the fight against cancer, resonates with many patients and providers. However, many providers avoid this analogy because poor response to treatment may infer "failure" and the suggestion that the patient did not fight hard enough (Penson et al., 2004). Many patients and providers prefer to discuss the cancer journey, which emphasizes the illness experience as part of a larger narrative and supports each patient's path as unique (Harrington, 2012).

We now employ the journey metaphor to discuss phases of the cancer experience to provide context for occupational therapy assessment and intervention.

Diagnosis

At first you just can't believe it, surely they've got the wrong chart, surely this isn't mine. It can't be true. Then I hoped that the cancer was not very advanced. Hope keeps moving along. . . . (Penson et al., 2007, p. 1106)

Most people are shocked by a cancer diagnosis (Leigh, 2006; Penson et al., 2007). They must adjust their identity from one of health to that of illness; rapidly gather information to make decisions regarding the course of treatment; and alter plans, activities, and roles to accommodate. This potentially traumatic experience may be accompanied by clusters of stress-related symptoms ("I can't sleep" or "I can't stop thinking about it") and/or emotional avoidance and withdrawal ("I don't want to talk about it") (Penson et al., 2004).

Medical Treatment

Following my diagnosis, I underwent nine months of treatment—surgery, chemotherapy, radiotherapy, and brachytherapy. I felt as if I had a new full-time job on my hands, a project which took up all my time. It was structured around appointments and moved through defined stages to a clear end goal. (Ennis-O'Connor, n.d.)

Medical therapies for cancer typically involve surgical removal of the tumor, chemotherapy, and/or radiation. All of these interventions have potential consequences and side effects that may interfere with the patient's daily functioning (see Table 45-3). Surgery and medical treatment may impact patients' ability to perform activities of daily living (ADL), instrumental activities of daily living (IADL), and life roles, including driving and work (Campbell et al., 2012; Hoving, Broekhuizen, & Frings-Dresen, 2009; Yuen et al., 2007). In addition to the nature and extent of the patient's cancer, the ability to work during treatment is influenced by opportunities to work flexibly around appointments (and availability of paid time off), support of coworkers, and ability to manage fatigue (Pryce, Munir, & Haslam, 2007).

Cancer rehabilitation may begin after surgery and continue concurrent with chemotherapy and/or radiation and into the survivorship phase. These services are provided in acute medical settings, in inpatient rehabilitation units, or as outpatient services. In addition to occupational therapists, the cancer rehabilitation team includes physiatry, oncology nursing, psychosocial services, nutritional support services, pharmacy, pastoral care, physical therapy, speech language pathology, and comprehensive multidisciplinary lymphedema services (Committee on Cancer Survivorship: Improving Care and Quality of Life, 2006) (see Fig. 45-1). Patients may also be referred to

Table 45-3   **Types of Cancer Treatment and Possible Effects on Occupational Performance**

Type of Cancer Treatment	Description	Side Effects or Secondary Effects That May Interfere with Functioning
Surgery	Used to diagnose, treat, and prevent cancer	• Complications from surgery: blood transfusions, damage to internal organs, reaction to anesthesia • Pain (most common side effect) • Infection from wound site • Lymphedema
Chemotherapy	Medicines or drugs that are used to treat cancer; can be used to contain or slow tumor growth or kill cancer cells	• Fever and chills • Nausea and vomiting • Hair loss • Fatigue • Sores in the mouth or throat • Constipation or diarrhea • Itching or rash • Muscle or joint pain • Memory changes
Radiation	The use of high-energy particles or wavelengths to kill the cancerous cells and shrink tumors	• Fatigue • Skin irritation at radiation site • Fever/chills

From American Cancer Society. (2012d). Questions people ask about cancer. Retrieved November 25, 2012 from http://www.cancer.org/cancer/cancerbasics/questions-people-ask-about-cancer.

exercise and fitness programs during chemotherapy and/or radiation. There is evidence that moderate to vigorous exercise interventions are associated with reduced anxiety, depression, fatigue, and sleep disturbances and improved physical functioning (Mishra et al., 2012).

Survivorship

It was only when treatment ended and that structure fell apart, that the full impact of what had happened hit me. I felt cut adrift. There is an expectation that when you walk out of hospital on that final day of treatment, your cancer story has ended, but the reality is that in many ways your story is only just beginning. (Ennis-O'Connor, n.d.)

Figure 45-1   A patient with leukemia and her rehabilitation team.

When primary medical treatment concludes, the patient transitions from patienthood into survivorship (Thorne & Stajduhar, 2012). To the surprise of some patients and providers, the emotional relief associated with completing medical care may be accompanied by a sense of disequilibrium, fear of recurrence, and challenge in reorienting their lives (Thorne & Stajduhar, 2012). With the completion of their formal medical treatment, cancer survivors must figure out how to manage long-term health consequences of cancer treatments and lingering problems with physical functioning, fatigue, and cognition. Although increasing numbers of people are surviving cancer, more cancer survivors report poor mental and physical health-related quality of life than adults without cancer ($p < 0.0001$) (Weaver et al., 2012). Many survivors demonstrate resilience and even personal growth from their cancer experience, but others may experience psychological distress; young survivors are particularly at risk (Costanzo, Ryff, & Singer, 2009). In addition, cancer survivors may face roadblocks in returning to "normal" life. For example, cancer survivors have a higher risk of unemployment than healthy controls (Tamminga et al., 2010).

To address these concerns, the Institute of Medicine recommended the development of Survivorship Care Plans to summarize information about cancer type, treatments received and their potential consequences, timing and content of medical follow-up, recommendations regarding preventive and wellness practices, information about employment, and resources regarding psychosocial services in the community (Committee on Cancer Survivorship: Improving Care and Quality of Life, 2006).

However, the extent to which this recommendation has been implemented is unclear.

Palliative Care

. . . I want to live as usual but it's not possible. . . . I can't cook. . . . I can't go for a walk. . . . (Appelin & Berterö, 2004, p. 68; comments from a recipient of palliative care regarding fatigue)

Although most people who are diagnosed with cancer experience either a full recovery or live many years with cancer as a chronic condition (American Cancer Society, 2012d), some experience steady and significant decline from their disease. Many of those patients and their families choose to receive palliative care, an approach that aims to improve quality of life by addressing the emotional, physical, practical, and spiritual aspect of cancer for patients and their family who are facing life-threatening illness (National Cancer Institute, 2010b). An interdisciplinary team, including occupational therapists, provides relief from symptoms such as pain, fatigue, insomnia; addresses fear and depression; and assists in coordinating services that pertain to legal, financial, and employment concerns. Palliative care is available from the time of diagnosis through cancer treatment and beyond, including the transition to end-of-life care (National Cancer Institute, 2010b). During this phase of the cancer journey, occupational performance may continue to be limited by the disease process or medical treatment as described earlier (pain, fatigue, cognitive changes, strength and ROM, and home and community access and mobility). Intervention may emphasize supporting caregivers and making environmental changes as means of optimizing patient performance.

OCCUPATIONAL THERAPY ACROSS THE PHASES OF THE CANCER JOURNEY

Individuals with cancer have complex needs and priorities that can change, sometimes rapidly, depending on severity of illness, response to treatment, stage of cancer, and stage of treatment. The diversity of cancers and treatment regimens makes it challenging to establish definitive guidelines for practice. It is essential to continually reevaluate the patient's performance, adaptation, and plan of care, staying attuned to his or her goals and priorities. Therapy goals and activities must be relevant and understandable to the patient and family as the spector of a potentially life-threatening illness brings their priorities into focus.

It is fitting that this is the final chapter in this textbook because occupational therapy for persons with cancer draws on most if not all of the book's contents. Assessment, for example, may involve evaluating the patient's upper extremity strength, ROM, or swelling (Chapter 7); cognition (Chapter 6); performance of ADL or IADL roles (Chapter 4);

and/or environmental accessibility (Chapter 10). Similarly, intervention methods for patients with cancer will follow that which is described in the intervention sections of the book. Furthermore, patients with cancer may present much like those described in some of the diagnostic chapters, depending on the location of the tumor (and consequences of surgery). For example, individuals with spinal cord tumors may have issues that are similar to those with spinal cord injury (Chapter 38). Individuals with brain cancer may have sensory motor, visual, cognitive problems that resemble those of stroke (Chapter 33) or traumatic brain injury (Chapter 34). Therapists are advised to refer to Chapter 43 on dysphagia when treating patients with head and neck cancer and to Chapter 41 if caring for patients whose cancer has resulted in amputation.

In this section, we provide additional information about cancer-specific assessments and interventions, beginning with overarching considerations when serving this population.

Awareness of Psychosocial and Family Needs

Many people view their experience of cancer as life altering. Some use the diagnosis as a springboard for growth and development, regardless of outcome. Almost all the people that we have encountered in our practices have experienced psychosocial adjustment issues, and many of them note that intervention and support to help with the resolution of these issues is lacking among health care professionals. Occupational therapists are well equipped to address these issues throughout their involvement with a given patient and family.

Psychosocial Adjustment Issues

Effective patient–clinician communication is the foundation of any effort to address patients' psychosocial adjustment, and health care professionals who provide care for patients with cancer may benefit from communications skills training (Uitterhoeve et al., 2010). Communicating with individuals who have cancer is similar to communicating with those with other chronic conditions. There are, however, unique cancer-related factors that may affect communication. Experts suggest that "few other illnesses are both life-threatening and potentially curable; that care involves numerous clinicians and multiple treatment modalities (such as oral and intravenous medications, radiation, and surgery); that there is often a long period of uncertainty after treatment; and that the patient's health care team often changes over time" (Epstein & Street, 2007, p. 1). Epstein and Street (2007) developed a framework that describes the following six core functions of patient–clinician communication: nurturing healing relationships, sharing information, responding to emotions, managing uncertainty, making decisions, and facilitating patient self-management.

Occupational therapists contribute to psychosocial adjustment in many ways. As suggested above, it is essential that clinicians ask questions that begin the dialogue about adjustment and allow time during sessions to simply listen (also see Chapter 14 on Therapeutic Rapport). Clinicians may also encourage or recommend stress-relieving practices to patients and family, such as journaling, exercise, meditation, and yoga. Further, supporting leisure activities (both new and familiar) throughout the cancer journey may contribute to occupational engagement that is critical to socialization, health, and wellness.

Family Needs

Attending to the psychosocial needs of caregivers is also imperative for optimal occupational outcomes. Caregiver goals for the patient can at times differ from the patient's priorities, and it is critical that all areas be addressed. Caregivers may also need guidance in setting realistic expectations for functional recovery and training in strategies to promote patients' optimal participation in occupations.

Caregivers may be involved in supporting a person with cancer in many ways including eating, bathing, using the bathroom, medication management, shopping, cleaning, financial management, attending medical appointments, and coordinating care (American Cancer Society, 2012g). In addition to supporting their loved ones ADL/IADL, caregivers may have less time to care for their own needs. Amid these changes in their routines and roles, caregivers are often coping with the uncertainty and loss involved with their loved one's cancer diagnosis and occupational changes.

Occupational therapists help caregivers acquire the knowledge and skills required for supporting their loved ones with cancer. Clinicians support family members and caregivers by revisiting their need for information at various junctures in the illness trajectory (DuBenske et al., 2008). Therapists also incorporate caregiver skills training into their sessions and may refer caregivers to counseling, both of which have been demonstrated to decrease caregiver burden and improve coping and self-efficacy (Northouse et al., 2010). The rehabilitation team also collaborates with the patient to ensure that the informational and psychological needs of his or her young children are addressed as well.

Assessment

Occupational therapists establish rapport with a client by addressing immediate needs and by understanding who this person is, was, and wants to be through his or her narrative. The type of assessment chosen and the length of the evaluation process depend on the individual's medical and cognitive status. Information is obtained from significant others, team members, and chart review. The clinician needs to understand the client's medical history, previous responses to and side effects of treatments, prognosis,

and the current and potential impact of the disease and treatment on performance areas. In addition, precautions, such as immunosuppression, thrombocytopenia, isolation (to prevent exposure to vancomycin-resistant *Enterococcus*, *Clostridium difficile*, fungoides, etc.), and anemia should be noted, because these factors impact functioning and occupational therapy treatment (see Safety Note 45-1 for other precautions).

⊕ Safety Note 45-1

General Precautions in Treatment

If the patient is an inpatient:

- Before you enter a patient's room, read the chart and check with the patient's nurse to find out if any events or changes have occurred since your last visit.
- Monitor vital signs, because cancer treatments are capable of impacting cardiopulmonary and nervous system function.
- Practice universal precautions. You will protect the patient and prevent spread of infection to others.
- Be familiar with handling oncological emergencies and observe precautions as necessary. Categories of oncological emergencies include obstructive/compressive, hematological/immune, metabolic, those related to increased pressure or fluid accumulation, and pathological fractures (Garrett & Kirchner, 1995; Hockett, 2004; Tatu, 2005). Although some of these conditions/emergencies may not prevent you from working with individuals who have cancer, you should know how to respond should one occur.

Regarding the use of physical agent modalities:

- Follow all standard precautions regarding their use.
- Do NOT apply thermal or electrical modalities over areas of active or potential malignancies.
- Avoid areas with altered skin integrity (i.e., radiation sites, graft versus host disease, chemotherapy burns, etc.).
- Inappropriate use of modalities may exacerbate conditions, such as lymphedema.

Regarding the use of exercise:

- Consider the impairment or condition. Aggressive exercise may be contraindicated, as in the presence of spinal cord compression, lymphedema, or pathologic fracture.
- Manual muscle testing is contraindicated for patients with metastatic disease to the bones because it may lead to fracture.
- Verify use of stretching or resistive activity because of low platelet levels and risk of uncontrolled bleeding.
- When in doubt, consult with your clinical instructor or supervisor.

The Canadian Occupational Performance Measure (Law et al., 1998) and the Occupational Performance History Interview II (Kielhofner et al., 1998) are occupation-based assessments that facilitate identification of a client's sense of self-efficacy and self-esteem, as well as satisfaction with life roles in self-maintenance, self-advancement, and self-enhancement. Observing clients as they perform tasks and activities provides information about performance levels, abilities, and habits. Other assessments may be indicated to determine limiting factors and underlying reasons for diminished ability to meet activity demands.

Fatigue is the most common problem reported by individuals with cancer. The Brief Fatigue Inventory (Mendoza et al., 1999) provides a quick assessment of the severity of fatigue and its impact on daily function. Cleeland et al. (2000) also developed a global symptoms assessment, the M. D. Anderson Symptom Inventory, which measures the severity of many cancer-related symptoms and the degree to which they interfere with daily function. Either of these tools can be used routinely to monitor changes in the individual's status, side effects of treatment, and effectiveness of rehabilitation.

The Functional Assessment of Cancer Therapy (FACT) measures quality of life in persons undergoing cancer treatment (Cella et al., 1993). There are many versions of the original tool that are part of the FACIT measurement system, all of which are available for free online (FACIT.org, 2010). Several versions have been developed that are specific to different types of cancer (e.g., FACT-B for patients with breast cancer) and for various symptoms of cancer (e.g., FACT-Cog for patients with cognitive issues).

Occupational therapists have also recently developed cancer-specific measures. The Manual Ability Measure in Oncology-20 (MAM) is a self-report instrument composed of a list of commonly performed tasks requiring hand function (e.g., writing, clipping nails) that are rated using a four-point ordinal scale related to the patient's perceived level of difficulty (Hill & Chen, 2012). It may be particularly useful with patients who have had surgery for breast cancer or brain cancer. An earlier, 36-item version of the MAM was evaluated with patients who had hand dysfunction associated with neurological and musculoskeletal conditions (Chen & Bode, 2010). The MAM-36 demonstrated acceptable unidimensionality and psychometric properties. The Valued Activity Inventory for Adults with Cancer (VAI-AC) is a self-report instrument that measures activity limitations in tasks valued by individual patients undergoing chemotherapy (Lyons et al., 2012). Patients rate the importance and difficulty levels of various everyday tasks. The VAI-AC demonstrated moderate test–retest reliability, and evaluation of construct validity demonstrated that there was logical association with other related measures (Lyons et al., 2012).

Intervention Planning: Goal Setting across the Continuum of Care

The goal of therapy is to enable clients to optimize their quality of life by engaging in meaningful occupations and to facilitate living regardless of life expectancy. Many of the goals that are meaningful to the client who has cancer are the same as those encountered with persons who have other diagnoses. With cancer, however, distinct moderating variables may affect realistic goal setting. People with cancer experience rapid changes in medical and functional status across the continuum of care. It is sometimes difficult for the person and the therapist to determine how permanent these changes might be. The severity of the disease and the individual's expectations regarding function and recovery may be incongruous. The occupational therapist should continually monitor these changes and help the individual to modify valued goals and roles accordingly. At the same time, the therapist must walk a fine line to avoid dispelling hope.

The role of the occupational therapist varies according to the point at which he or she enters the patient's course of treatment. Duration of treatment depends on acuity of the condition and severity of the disease, along with the patient's wishes. Regardless, the treatment plan should be individualized and address the performance skills required to function at that point in the continuum of care. The patient's long-term goals should guide him or her toward resuming activities such as work, driving, leisure, social interaction, play, and education. Most patients are able to resume normal activities with few, if any, long-term restrictions.

The occupational therapy intervention plan will also be shaped by the composition of the broader medical and/or cancer rehabilitation team. All team members are advised to practice self-care strategies to optimize their own professional quality of life so that they may best serve their patients (Procedures for Practice 45-1).

Intervention

Occupational therapists rely on their general knowledge and expertise related to intervention for patients with physical dysfunction in treating patients with cancer. This section highlights areas of intervention that exemplify cancer-specific interventions that are within occupational therapists' scope of practice.

Arm Function

Occupational therapists address the consequences of cancer-related surgery on arm function, using exercise and activity to improve ROM, strength, and coordination (Campbell, Pergolotti, & Blaskowitz, 2009; Penfold, 1996). Occupational therapists with specialized training

Procedures for Practice 45-1

Maintaining Compassion Satisfaction and Preventing Compassion Fatigue

Professional quality of life is an important concept in health care today and its significance is gaining increased interest among researchers, health care administrators, and health care professionals. **Compassion satisfaction** is the positive feature of professional quality of life and involves the desirable effects of helping others (Stamm, 2010). Facilitating engagement in clients' occupations and roles at various stages and points of cancer recovery offers many opportunities for rewarding experiences that can lead to high compassion satisfaction (Prochnau, Liu, & Boman, 2003). The results of a qualitative study of occupational therapists working in palliative care suggested that clinicians derive high levels of satisfaction from their work and see it as a source of personal growth, in part because of rewarding relationships with patients and families (Prochnau, Liu, & Boman, 2003).

Occupational therapists are among health care professionals who are also at risk for compassion fatigue, which derives from the negative aspects involved in professional caregiving. The Professional Quality of Life Scale (ProQOL) is a measure often used to explore the positive and negative aspects of professional quality of life. The ProQOL is a free measure available on the internet to be used for research, to monitor the professional quality of life among workers in an

organization, and to monitor one's own status for personal use (Stamm, 2010).

It is important for occupational therapists to monitor and prevent compassion fatigue and to nurture a sense of compassion satisfaction. This can be accomplished through habitual use of prevention and self-care strategies. Costa (2005) recommends the following self-care skills for occupational therapy practitioners:

- Maintain your relationships with coworkers, family members, and friends.
- Practice healthy boundaries with your personal and work-related relationships.
- Develop self-awareness of activities that nurture and exhaust your energy.
- Seek life balance.
- Practice effective time management.
- Practice positive self-talk.
- Focus on your physical health.
- Learn from experiences when a client reminds you of a source of conflict.
- Make time for self-reflection of your values and strengths.
- Seek a mentor.
- Participate in educational and professional opportunities.
- Set measurable and timely goals surrounding your personal, professional, and work life.

---

in lymphedema management use techniques such as manual lymph drainage, wrapping, and garment fitting to treat lymphedema (Longpré, 2012). An occupational therapy program for women with cancer-related lymphedema that incorporated exercise and education was found to result in improvements in upper extremity swelling, arm flexibility, and mood (McClure et al., 2010) (see Evidence Table 45-1 for further discussion).

Fatigue

Occupational therapists often provide instruction in energy conservation and stress management techniques to patients with cancer who are experiencing fatigue (Longpré, 2012; Penfold, 1996; Vockins, 2004). A recent evidence review of 27 studies of psychosocial interventions to address cancer-related fatigue (including instruction in energy conservation, relaxation, and stress management) suggests that these interventions are effective in reducing fatigue, especially those programs that are specific to fatigue as compared to more general psychosocial interventions (Goedendorp et al., 2009). There is also increasing evidence to support the benefits of moderate-intensity exercise in modulating cancer-related fatigue and improving overall function (Anderson et al., 2012;

Brown et al., 2011), another important consideration in occupational therapy intervention for fatigue.

Cognition

Occupational therapists address problems with memory, concentration, and problem solving that may occur as a result of brain surgery (Campbell, Pergolotti, & Blaskowitz, 2009) or associated with patients' self-described "chemobrain." Many people with cancer, including those with breast cancer, experience mild cognitive impairment after chemotherapy in the areas of attention, learning, executive function, and information processing speed (Joly et al., 2011; Wefel et al., 2010). For some, these problems persist well past their completion of and recovery from chemotherapy (Wefel et al., 2004). Although there appears to be a linkage between chemotherapy and deficits on neuropsychological testing, the etiology and linkage to emotional factors and fatigue remain unclear (Poppelreuter et al., 2004). Cancer survivors who experience chemobrain indicate that it impacts their life economically, emotionally, and interpersonally (Boykoff, Moieni, & Subramanian, 2009). Despite the prevalence of this issue and its potential to disrupt everyday functioning, no specific interventions have been specified or recommended based on

Evidence Table 45-1 | Best Evidence for Occupational Therapy Intervention for Cancer

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Breast Cancer Recovery Program (BCRP) for lymphedema	BCRP consisted of education regarding lymphedema management and instruction in relaxation techniques (deep diaphragmatic breathing, progressive muscle relaxation). Controls received usual medical care.	Women with stage I or II unilateral breast cancer-related lymphedema (BCRL) with ≥10% increased affected arm size compared with unaffected arm (16 in each group)	Ten biweekly, 1-hour sessions for 5 weeks	Randomized controlled trial Level IC3b	Those receiving BCRP demonstrated significant treatment effects (extracellular fluid, arm flexibility, range of motion [ROM], and mood) compared to controls.	Extracellular fluid in affected arm (measured via bioimpedance): $p = 0.049, r = 0.43$ Total shoulder active ROM: $p = 0.034, r = 0.50$ Mood as measured by Beck Depression Inventory: $p = 0.03, r = 0.41$ Quality of life as measured by SF-36: $p = 0.03, r = 0.52$ (general health)	McClure et al. (2010)
Exercise to address cancer-related fatigue (CRF)	Various exercise interventions (24 studies of aerobic exercise, 6 studies of resistance exercise, 11 studies of a combination, 6 with other types like yoga and Tai Chi).	3,254 participants with various types and stages of cancer	Average length of intervention was 11.5 weeks. Mean level of exercise was 3.5 days per week for an average of 48.5 minutes per session.	Meta-analysis involving 44 studies Level IA1a	Statistically significant improvements in CRF (all cancers)	$d = 0.31$ (95% confidence interval 0.22–0.40)	Brown et al. (2011)
Problem Solving Occupational Therapy (PST-OT)	PST to help subjects identify and analyze problematic activities and design compensatory approaches. Control group received usual care.	Rural patients with breast cancer (stages I–III) who were undergoing chemotherapy PST-OT ($n=15$), Control ($n = 16$)	Six weekly sessions via telephone	Feasibility study of PST-OT	Established feasibility of intervention	Ninety-seven percent of all planned sessions were completed; 92% of participants reported PST-OT to be helpful in overcoming performance restrictions; 81% study retention rate	Hegel et al. (2011)

scientific research (Joly et al., 2011). Occupational therapy intervention largely focuses on teaching patients to modify their approach or the environment to minimize cognitive load and implementing compensatory cognitive strategies (see Chapter 24), but there is little scientific literature at present to support this approach.

Intervention to Address Activity Limitations

Occupational therapists provide intervention to reduce activity limitations by providing ADL, IADL, and transfer training to persons with cancer (Campbell, Pergolotti, & Blaskowitz, 2009; Penfold, 1996; Vockins, 2004). This may involve providing equipment and optimizing access within the home, particularly for individuals receiving palliative care (Kealey & McIntyre, 2005; Keesing & Rosenwax, 2011). It is noteworthy that even though patients with cancer appear to have driving-related concerns (Yuen et al., 2007), this aspect of IADL intervention is not currently described in the literature.

Intervention to Address Role Resumption and Prevent Occupational Disengagement

Ultimately, all occupational therapy intervention for persons with cancer should contribute to role resumption and engagement in valued occupations. This emphasis is aligned with what many cancer survivors want and need, as underscored by a qualitative study of people participating in a hospice day program (Lyons et al., 2002). These individuals described the importance of remaining socially engaged, doing for themselves, and trying new things, even with life-threatening illness (Lyons et al., 2002). Unfortunately, in many cases, these participation-related needs go unmet (Taylor & Currow, 2003). In a survey of patients receiving cancer or palliative services over a 1-year period at a cancer center, over 30% reported that they had unmet needs—work, leisure, and driving needs were most frequently reported (Taylor & Currow, 2003). Of note, 19% of patients at this center were referred to occupational therapy, and 31% of that subgroup also reported unmet needs.

New programs such as Problem Solving and Occupational Therapy (PST-OT) demonstrate the potential contributions of occupational therapists in reducing participation restrictions (Hegel et al., 2011). PST-OT was a telephone-delivered 6-week, six-session intervention for women with breast cancer who were undergoing chemotherapy. Each session focused on a patient-established goal, using the person-environment-occupation model (Law et al., 1996) as the foundation for problem solving. Common patient-identified problems included maintaining aerobic exercise, IADL (housecleaning, shopping, and childcare), and work. Researchers found high levels of satisfaction and use of therapy-related action plans among participants (Hegel et al., 2011).

Finally, successful return to work is increasingly recognized as a problem for many cancer survivors (Pryce, Munir, & Haslam, 2007). A work-directed intervention that involves early contact with vocational specialists and development of a return-to-work plan is described in the literature (Tamminga et al., 2010), but no outcomes of this program have been reported as yet. Occupational therapists have the education and expertise to address this important aspect of functioning.

ADVOCACY

As more people continue to survive cancer (American Cancer Society, 2012b), cancer rehabilitation services, including that provided by occupational therapists, will be increasingly important in remediating disease and treatment-related sequelae and helping people return to personally valued roles and activities. There is evidence, however, to suggest that we could be doing more, because many cancer survivors report unmet rehabilitation needs (Taylor & Currow, 2003; Thorsen et al., 2011). As we better articulate the breadth of our potential contributions to cancer care and conduct research to provide evidence of the impact of our services, occupational therapists are well positioned to substantively contribute to the cancer rehabilitation field.

case example
Ms. S.: Evaluation and Treatment for a Patient with Breast Cancer

Occupational Therapy Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information	Understand the patient's diagnosis or condition	"I would be so overwhelmed if I were her. She is used to being so healthy and able to manage so many life roles."
Medical		
Ms. S. (Sarah) is a 32-year-old woman who was diagnosed with stage II breast cancer. She has a family history of breast cancer. She underwent bilateral mastectomy and is preparing for reconstructive surgery. She currently has expanders in place on her chest wall and hopes to complete the procedure in 6 weeks. She reports discomfort on both chest walls that is interfering with her sleep. She is currently receiving chemotherapy and has two of four cycles left to complete. She receives the medication on a 1 week on, 2 weeks off regimen.	Know the person	"I wonder how much effect the pain and lack of sleep are having on her function. I wonder how she is tolerating the chemotherapy. I wonder what coping strategies she is using."
		"I need to contact her physical therapist. She has so many life demands and appointments. We need to see which one of us will address the positioning concerns related to her disrupted sleep as well as her walking program."
Social		
Sarah has been married for 12 years and has a 6-year-old daughter and 18-month-old son. Another son died from an undiagnosed heart condition when he was age 3 years. This occurred 6 months before her cancer diagnosis. Her sister lives in town, but the rest of her family is out of state. She reports that her husband is supportive but travels a lot with his job. She is primarily responsible for the household management tasks and care of her children. She is active in her church and teaches religion classes.		"She has had to manage so much loss this past year: her son, her health, and temporarily her role as a full time worker. I hope she is working with a counselor."
		"She appears to be a type A personality. I cannot believe she is still volunteering and managing her home and children throughout her chemo treatments. It may be difficult for her to incorporate fatigue management strategies."
Vocational		
Sarah works in human resources at a local hospital. She has always worked full time and hopes to return to her position as soon as she has medical clearance from her doctor. She has been off of work for 12 weeks and has used up her Family Medical Leave. She reports that her manager is supportive. She plans to return to work in 1 month. Sarah drove herself to the appointment and reports no community mobility concerns.		"I am concerned about her returning to work in 1 month. She will still be getting chemotherapy treatments and needs to finish up her reconstructive surgery. I wonder if that start date is a work requirement or if that is more of a personal requirement?"
		"I need to make sure she is confident in her driving skills, especially when she is tired."
Reason for the Referral to Occupational Therapy	Appreciate the context	"She is demonstrating the common symptoms of mild cognitive impairment related to cancer treatments. She sounds resistant to using strategies typical of someone who prided herself on good memory. I am going to need some quick wins to get her to embrace changes. I really need to listen to her story when I meet her and focus on the area she cares most about."
Sarah had an appointment with her physiatrist and reported concerns related to excessive fatigue, memory errors, and frustrating incidents in which she lost items and track of what she was doing. She is afraid this will affect her job performance. She has recently started to use the calendar on her cell phone, but it frustrates her because she never had to do so before. She is starting to make lists but usually forgets them at home.		
She recently had diagnostic brain imaging and does not have any metastases.		"I am so relieved that she does not have metastases to the brain. We can really focus on showing her ways she can regain some control with good strategy use."

She reports that she is managing all of her medical needs; she is caring for her children and resumed her volunteer teaching role last week. She has more difficulty completing all of her roles during chemotherapy weeks, but she is determined and has been able to get it all done. Despite feeling very tired, she is having difficulty sleeping because of her expanders. She does not want to take any sleep medications; she feels that the chemotherapy is too many toxins already. She told her doctor she is not sure she needs occupational therapy (OT) and is worried about her return-to-work schedule.	Develop provisional hypotheses	"I will need to address fatigue management fairly quickly in her treatment. She seems like someone that has worked hard all her life and will need some tips and support to work smarter and take care of her own needs." "I think she will have a good outcome. I will likely need to see her weekly for 1 month and then have a follow up visit when she returns to work. I will talk with her about possibly postponing work until she has finished chemotherapy and then with a gradual increase in hours."
Assessment Process and Results *FACT-Cog*: score of 44.83 (top score is 131.78) Higher scores indicate better quality of life. Goals identified by the Canadian Occupational Performance Measure	Consider evaluation approach and methods	"I think it would be counterproductive to administer cognitive tests that highlight her cognitive inefficiencies. I am going to need to identify what roles she values, figure out what is frustrating her, and give her some tools to cope better."
1. Consistently effective parenting 2. Consistently effective household management 3. Effective/accurate worker 4. Consistent with care of self 5. Continue volunteer commitments to a lesser extent	Interpret observations	"Her score on the FACT-Cog indicates that she is experiencing stress related to her cognitive changes. She is really focused on what she is not doing well or accurately. I am really going to need her to be part of the strategy selection if she is going to accept the need to use these." "She really puts others first; I will need to make sure she talks with her counselor about the importance of taking care of herself first." "If I start with concepts to give her some control and strategies to help with parenting, I may get her to invest energy into the solutions."
Occupational Therapy Problem List 1. Disrupted sleep and ongoing fatigue 2. Difficulty with information management 3. Disrupted routines/habits 4. Difficulty with consistency of care of others 5. Decreased participation in community including volunteer work and vocational pursuits 6. Difficulty with time management within her activity tolerance capabilities	Synthesize the results	"She is not consistently managing her own needs first, and this results in fatigue and inefficiencies that affect the quality of her life roles. She will continue to spiral down if I cannot get her to be aware of the effects of her choices." "I think I need to start by addressing the areas of her life that need to be managed for best function: sleep, nutrition, physical exercise, and stress reduction."
Occupational Therapy Goal List 1. Patient will consistently employ bedtime routines for her children and herself evidenced by going to bed and getting up at the same time 5 out of 7 days, 4 out of 4 weeks. 2. Patient will independently and consistently use the calendar on her cell phone, including the alarm options, evidenced by no missed appointments. 3. Patient will effectively manage her fatigue throughout the day/week by prioritizing her tasks and initiating breaks with cues from the alarms on her cell phone.	Develop intervention hypotheses	"I suspect that as Sarah gets a handle on her fatigue and puts in place some new cognitive strategies, she will realize improved cognitive function. If I can also give her a few strategies that help decrease her errors and/or frustration, she will likely start to develop her own strategies and need less occupational therapy."
	Select an intervention approach	"I know she values taking care of her children and feels badly when she is too tired to engage with them. I think changing bedtime routines could be a quick win for everyone. I will suggest she focus on moving bedtime up by 45 minutes for the children and herself. I will help her think through the cues or changes she may need in her day to make this happen. I wonder if she would try using a timer. I will send one home if she is willing."

4. Patient will spontaneously manage the distracters in her environment evidenced by accurately completing high-consequence tasks such as paying bills in a quiet environment with limited interruptions.	Consider what will occur in therapy, how often, and for how long	"I will start therapy one time per week for five sessions after initial assessment. She will likely need a 1 month follow-up as she returns to work."

Interventions

1. Education on importance of routines/habits
   a. Develop routines/checklists for different activities of daily living (ADL) tasks: getting ready for bed, leaving the house, daily planning
   b. Create a weekly activity template
2. Education on fatigue management strategies
   a. Develop/employ strategies that assist in effective use of her energy: pacing, planning, prioritizing, and taking breaks
   b. Pedometer use/walking program to increase her energy level
   c. Education on good nutrition
   d. Education on sleep hygiene, options for positioning to decrease discomfort from the expanders when sleeping
3. Education on information processing
   a. Develop/employ strategies related to calendar/alarm use on her cell phone
   b. Develop/employ use of strategies to manage information from meetings when she resumes her job; explore technology that could be useful
4. Education on time-management skills
   a. Develop/employ strategies to help her manage ADL roles
   b. Develop/employ strategies to manage home-management roles
   c. Develop/employ strategies to manage her vocational roles

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

"I have to make sure she summarizes what she learned and what she will focus on the next week at the end of each session. She could easily get overwhelmed and do nothing. I do not want her to feel like she failed at treatment."

"I will issue a grid so she can check off if she used the strategy each day or not. I need to make sure she understands that she can change the strategy to meet her needs or decide not to use it if it is not helpful. Each week she comes back I will review the use of her strategies by looking at the grid, and she can decide if the strategies are ones she will continue to use or discard."

"I need to make sure that as she understands the concepts and her confidence is growing, I let her really find her strategies or solutions more independently."

"I need to make sure that the concepts and strategies do not add stress to her life but help decrease it as she uses her energy more wisely."

"I will use motivational interviewing techniques to help her come up with her own strategies or modifications."

Next Steps

1. Sarah has decided not to return to work until 2 weeks after she has finished her chemotherapy to ensure she has adequate activity tolerance. Occupational therapy can assist in crafting work accommodations.
2. Follow-up at 1 month to ensure that she is habitually employing her strategies and effectively managing her life roles.
3. She may need a few additional sessions once she has returned to work to develop any new strategies she may need to be successful at work.

Anticipate present and future patient concerns

Decide whether the patient should continue or discontinue therapy and/or return in the future

"She will very likely learn how to use her energy well enough to consistently care for her children and her home. I need to make sure that she understands that she may notice more cognitive difficulties when she first returns to work. The increased demands may lead to fatigue again. She will need to plan for that and either delegate more at home or return part time with a gradual increase in hours."

"I am going to schedule a follow-up session 1 week prior to return to work to assist her in thinking through the challenges and having some strategies she can use to minimize errors. At that session we can determine whether she needs an additional 1 month follow-up or whether she is ready for discharge."

 # Clinical Reasoning in Occupational Therapy Practice

Building a Therapeutic Alliance

What can the therapist do to establish rapport and a therapeutic alliance with Sarah early on in their work together?

case example
Mrs. K.: Assessing One's Clinical Competence

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Mrs. K. is a 50-year-old woman with a diagnosis of left postmastectomy lymphedema with multiple infections and fibrosis. Mrs. K. underwent mastectomy for left breast cancer 15 months ago and had 20 of her lymph nodes removed on the left side. She had chemotherapy and radiation therapy and now shows no evidence of disease. She recently saw her oncologist with complaints of left upper extremity swelling and aching heaviness in the arm and across her chest and back. She reported difficulty with fit of clothing on the left, which causes her increasing embarrassment at work. Her sleep is also disturbed because of left arm discomfort. She is referred to outpatient occupational therapy for evaluation and treatment of lymphedema, including manual lymph drainage, compressive bandaging, fitting of custom compressive garments, and instruction in home exercises and skin care.

Although the occupational therapist had previous experience treating cancer patients and instructing in self-care, home management, and work-simplification strategies, she had no specific or specialized training in the area of lymphedema management. Because this new area of practice interested her, she searched the Internet for information. She readily found information on lymphedema and its treatment (www.cancer.org) and guidelines for contacting a lymphedema treatment center, information about training programs, and names of clinicians with specialized training (www.lymphnet.org). She searched the National Library of Medicine (www.nlm.nih.gov) for abstracts of research regarding treatment of lymphedema.

Objectives

Appreciate the context

Develop intervention hypotheses

Reflect on competence

Examples of Therapist's Internal Dialogue

"I wonder how much Mrs. K. knows about lymphedema and how to manage it. I wonder what kind of work she does along with other kinds of activities. Do any of these need to be modified in order to prevent recurrence of lymphedema once it is under control? Does Mrs. K. have a support system in place to which she can delegate tasks to prevent further exacerbation of the lymphedema?"

"It appears that Mrs. K. needs a specialized form of intervention."

"I am an occupational therapist working in a small physical disabilities setting at a suburban hospital in the Midwest. I have 5 years of experience, working in long-term care for 1 year and for 4 years in my present position. I typically work with both inpatients and outpatients, primarily with orthopedic or neurological problems. I am concerned that I do not have the expertise that is required to perform the manual lymph drainage or the fitting for a compression garment in this case."

Recommendations

Having some preliminary information, the occupational therapist used American Occupational Therapy Association Standards of Continuing Competence (American Occupational Therapy Association, n.d.) to assess her competence to treat Mrs. K. She concluded that she did not have the knowledge, critical reasoning, or performance skills necessary to assess and treat Mrs. K. She used information from her Internet search to provide Mrs. K. with suggestions to help minimize the impact of lymphedema in her daily life and to refer Mrs. K. to another facility with specially trained therapists. She also decided to pursue training herself to make these services available to patients at her hospital.

Summary Review Questions

1. Define two methods of classifying cancer and how an occupational therapist might use this information.
2. Describe common medical treatments for breast cancer.
3. List potential side effects of cancer treatments that may interfere with occupational performance.
4. Summarize clinician practices that may help prevent compassion fatigue. Propose the unique circumstances that make use of self-care strategies particularly important for occupational therapists involved in cancer care.
5. Explain why it is important to address the needs of caregivers for persons with cancer.
6. Discuss three strategies you could employ to meet the needs of caregivers.
7. Describe potential occupational needs a client with cancer may have throughout the cancer journey.
8. Summarize occupational therapy interventions for fatigue and cognition. How might those interventions be different for patients in medical treatment or survivorship phases as compared to those receiving palliative care?

Glossary

Compassion satisfaction—The positive feature of professional quality of life that involves the desirable effects of helping others (Stamm, 2010). Its opposite is compassion fatigue.

Lymphedema—A buildup of lymph fluid in the fatty tissues under the skin that causes swelling. It is often a sequela to surgery and/or radiation that involves one or more lymph nodes and remains a lifetime risk for cancer survivors (American Cancer Society, 2011).

Metastasis—The term to describe the situation in which cancer cells get into the bloodstream or lymph system, travel to other parts of the body, and form new tumors

Palliative care—An approach that aims to improve quality of life for patients who are facing life-threatening illness and for their families. It provides relief from pain and other distressing symptoms and provides support to help patients live as actively as possible as well as for coping and bereavement (World Health Organization, 2012).

Peripheral neuropathy—Numbness, tingling, and/or pain caused by nerve damage.

Survivorship—The phase of the cancer journey beginning as the patient completes medical treatment and continuing throughout his or her life.
