NOTICE TO READER: This publication contains information relating to general principles of medical care that should not be construed as specific instructions for individual patients. Manufacturers' product information and package inserts should be reviewed for current information, including contraindications, dosages, and precautions. It remains the responsibility of the practitioner to evaluate the appropriateness of a particular opinion or therapy in the context of the actual clinical situation and with due consideration of any new developments in the field and current drug information.

9 8 7 6 5 4 3 2 1

DISCLAIMER

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

Dedication

To the profession's authors—past, present, and future.

Preface

The seventh edition of *Occupational Therapy for Physical Dysfunction* emphasizes four key themes that are essential to the best possible occupational therapy for adults with physical disabilities and to the future of the profession:

- Reliance on evidence/research to inform occupational therapy assessment and intervention
- Occupation as the central intervention and outcome of occupational therapy services
- Importance of expert activity analysis that synthesizes theoretical knowledge, clinical skills, and awareness of person and contextual factors to occupational therapy practice
- Appreciation for the individuality, unique circumstances, and priorities of each patient/client.

These themes are evident in the book's organization, features, ancillaries, terminology, and authorship.

ORGANIZATION

Similar to the previous edition, the seventh edition is composed of six sections with 45 chapters.

Section I lays the foundation for the rest of the textbook. Chapter 1 addresses theoretical foundations (with emphasis on the Model of Occupational Functioning), and Chapter 2 addresses practical foundations of occupational therapy for adults with physical dysfunction.

Section II presents the areas of assessment in which an occupational therapist working in acute medical, inpatient/outpatient rehabilitation, and community-based rehabilitation settings should be competent. The chapter sequence generally represents the order in which occupational therapists might conduct assessment, beginning with appraisal of the specific context and evaluating the person's occupational roles and competence, followed by assessment of the person's abilities and capacities that support role performance and finally assessment of the relevant environmental constraints and enablers of performance.

Section III presents three mechanisms of therapeutic change: occupation and occupation as therapy, learning, and therapeutic rapport.

Section IV presents therapeutic technologies that enable and support occupational functioning: splinting, wheelchairs, adapted or assistive devices, and physical agent modalities.

Section V elucidates intervention principles and practices for persons with physical dysfunction. As in earlier editions, this section does not provide recipes for the treatment of people with particular diagnoses but rather descriptions of best practice. The professional occupational therapist can choose from these for a particular patient who has his or her own particular goals and manifestation of a diagnosis.

Section VI includes discussions of the practice of occupational therapy for particular major diagnostic categories, each written by a specialist in that area. These experts alert therapists who are beginning to practice with one of these populations to various commonly encountered impairments that affect occupational functioning and to the specialized assessments and treatments that have been developed for persons carrying the diagnosis.

In addition to the textbook, the following three chapters from the sixth edition are now available to readers on thePoint, the book's website (thepoint.lww.com): Optimizing Motor Behavior Using the Bobath Approach, Optimizing Motor Behavior Using the Brunnstrom Movement Therapy Approach, and Managing Deficit of First-Level Motor Control Capacities Using Rood and Proprioceptive Neuromuscular Facilitation Techniques. The intervention techniques described in these chapters are not adequately supported by current evidence, and to remain consistent with the key themes described above, we did not include them in the book. However, because many practitioners continue to refer to these approaches and related concepts, these chapters are preserved to serve as important resources.

FEATURES

This edition also has a number of features that emphasize the scientific and reflective foundations of clinical practice.

The chapters in Section II (Assessment of Occupational Function) include **Assessment Tables** that summarize the psychometric properties, strengths, and weaknesses of the assessment methods described in the chapter.

Evidence Tables (where evidence exists) are included in chapters in Section III (Therapeutic Mechanisms), Section IV (Therapeutic Technologies), Section V (Intervention for Occupational Function), and Section VI (Rehabilitation to Promote Occupational Function for Selected

Diagnostic Categories). These tables summarize research studies that address the interventions mentioned in the chapters and/or Case Examples. They are not exhaustive compendia of all research but represent the current best evidence for the effectiveness of the interventions and serve as examples of culling critical information from research articles. Readers will find information pertaining to these tables and other features in this volume's **User's Guide**.

The **Case Examples** in this edition continue to highlight the "whys" of the assessment and intervention process. In general, Case Examples are designed to help students appreciate how various topics described in the chapter relate to and inform occupational therapy practice. Readers will find that the Case Example format in this edition describes the actions of therapy ("Occupational Therapy Process") along with the therapist's internal dialogue to explain why he or she approached occupational therapy assessment and/or intervention as he or she did ("Clinical Reasoning Process").

New to this edition are three **Activity Analysis Case Examples**, the goal of which is to explicate the clinical reasoning that occupational therapists use in selecting and modifying activities to meet patients' therapeutic goals. Three types of activity analyses are introduced in Chapter 12 by Catherine Verrier Piersol, PhD, OTR/L, and modeled in later chapters by other authors. In Chapter 27 (Restoring Competence for Homemaker and Parent Roles), Susan Fasoli, ScD, OTR/L, developed an **Activity-Focused Analysis Case Example**. This is a deconstruction of the activity itself outside of the client-specific application or context. This type of activity analysis is intended to provide a schema that readers may use to build a repertoire of therapeutic occupations and emphasizes occupation-as-means. In Chapter 37 (Hand Impairments), Cynthia Cooper, MFA, MA, OTR/L, CHT, developed a **Client-Focused Activity Analysis Case Example**. This is a description of the reasoning involved in the therapeutic use of occupation-as-means for a particular therapeutic goal for a specific person. In Chapter 25 (Restoring the Role of Independent Person), Anne Birge James, PhD, OTR/L, developed an **Environment-Client Focused Activity Analysis Case Example**. This is a deconstruction of the specific activity-environment-person fit to determine and/or optimize the likelihood of successful performance of occupation-as-end. Activity Analysis Case Example templates are also available on thePoint (thepoint.lww.com) should readers choose to use them to develop activity analyses on their own.

As in the previous edition, a **Glossary** and boxes highlighting **Clinical Reasoning** (opportunities to develop clinical reasoning skills that go beyond the material that can be looked up in the chapter), **Procedures for Practice** (how to do a particular assessment or treatment), **Definitions, Research Notes** (examples of application of research, including that from other disciplines, to practice), **Safety Notes** (precautions to be observed), and **Resources** (where to find information and equipment) are included throughout the chapters to showcase and emphasize key concepts.

ANCILLARIES

As indicated above, a website is available at thepoint.lww.com. Students can go to the site to see how an expert would answer the questions posed in Clinical Reasoning Boxes throughout the text. Clinical Reasoning Boxes (questions and answers) from the sixth edition are also available on the site. Instructors' Resources have been posted, including PowerPoint slides that provide lecture outlines for each chapter and an image bank containing all images and tables from the book.

Also at thePoint, students can access audiovisual content in which core techniques are demonstrated. Brief video clips help learners visualize and review key aspects of practice, including the measurement of upper extremity range of motion and hand strength, upper and lower extremity dressing techniques for individuals with hemiplegia and paraplegia (new to this edition), how to fabricate a splint, and how to assist clients as they transfer into and out of a wheelchair.

TERMINOLOGY

Throughout this book, readers will note an amalgam of occupational therapy terminology, derived from the *Occupational Therapy Practice Framework: Domain & Process, Second Edition* (American Occupational Therapy Association, 2008), *International Classification of Functioning* (World Health Organization, 2001), *Occupational Functioning Model*, and generic "OT speak." This supports our aim to develop multilingual practitioners. The use of various terms and frameworks in the textbook reflects the different ways in which practicing occupational therapists and occupational therapy scholars talk about the work we do each day. If you find yourself needing to think twice to do some translation, get used to it. In practice, we must be proficient at adapting our language based on the needs of those with whom we communicate, understanding that most of us spend our day with people who have never heard of occupational therapy, much less our professional vocabulary. Similarly, some authors elected to refer to recipients of occupational therapy services as clients, others as patients. This too reflects ways in which appropriate terminology varies based on the context of the situation. In general, the term "patient" is most often used in acute medical and inpatient rehabilitation settings; it reflects a more passive role of the person receiving care and is the term used by other professionals on the health care team. The term "client" is

used in reference to a person living in the community who is receiving outpatient, home-based, or community-based services. It reflects the assumption that the person receiving services is ready to assume a more directive role in organizing his or her care.

AUTHORS

Sixty-eight outstanding clinical and academic occupational therapists and experienced lay persons contributed to this edition. They each did so with the desire to contribute to the profession of occupational therapy by sharing their knowledge and skills with occupational therapists preparing to enter the field.

Mary Vining Radomski
Catherine A. Trombly Latham

About the Cover Artist

Cover and Interior Art: **Transition**
Artist: **Elizabeth Plummer**

The cover and thematic image for this volume, "Transition," is a photograph taken by Elizabeth Plummer (St. Paul, MN), so named by the artist because the flower is blossoming rather than fading as it may appear at first glance. Elizabeth was struck by a car in 1994, resulting in a traumatic brain injury. Because of her physical limitations, she finds that shooting photography helps her express her creative self, and she endorses the helpfulness of long lenses!

This User's Guide introduces you to the many features of *Occupational Therapy for Physical Dysfunction*, Seventh Edition. By taking full advantage of these features as well as the text, you will develop the ability to practice using sound measurement, theoretically based interventions, and reflective reasoning.

Each chapter includes features that help you focus on the key points, deepen your knowledge, and guide you to select correct assessment and intervention tools.

LEARNING OBJECTIVES AND DIAGRAMS set forth each chapter's learning goals and how the information in the chapter fits within the Occupational Functioning Model.

CASE EXAMPLES stress the underlying rationales for assessments, interventions, and activity analyses and help students apply what they learn in practice.

case example

Able: Optimizing occupational performance after SCI.

	Clinical Reasoning Process	
Occupational Therapy Process Internal Dialogue	**Objectives**	**Examples of Therapist's**
Obtain Information About the Patient	Understand the patient's diagnosis or condition	"If Able has a functional level of C6 he may be able to achieve independence in many areas. Unfortunately, because he has an AIS A (complete) injury, his muscle and sensory return will most likely be only in the Zone of Partial Preservation (ZPP)."
Able is a 19-year-old man with C6AISA (complete) tetraplegia resulting from an ocean diving accident 3 months ago. Able is a sophomore at a community college. He came to the United States from Samoa to attend college on a football scholarship. Able is single and lives with fellow students in a rented house near campus. He has a large and supportive family in Samoa. After his injury, Able's mother, aunt, and two of his sisters came to be with him for a month. Able is fluent in English. He was hoping to stay in California and resume his studies. He did not have a discharge destination.		
Following his injury, Able was sent to a trauma center, where he underwent posterior fusion surgery to stabilize C4 to C7 vertebrae and was placed in a Philadelphia collar, a rigid collar that limits neck motion. Following surgery, Able was prescribed spine restrictions in order to protect the surgical site. Precautions allowed Able to perform shoulder bilateral/symmetrical activities with minimal resistance (no greater than 3+/5) and unilateral, active only activities with no resistance.	Know the person	"Able is passive and quiet and seems quite depressed. Knowing that the best predictor of future behaviors and disposition is pre-morbid personality and behaviors, I am very hopeful that he soon will feel better, as he sees his renewed abilities. It is excellent that he has such a supportive, loving family; however, we will most likely request that they limit their visits somewhat, in order to enable Able to see that he can manage without them, to allow him to become more active in his rehabilitation, and to encourage him to begin directing his own care. Prompt identification of discharge destination and potential caregivers is crucial for goal setting. Therefore, the social worker must address these important issues as soon as possible."
During the post-operative hospital stay, Able was on a rotating bed to prevent pressure sores. The occupational therapist performed daily upper limb range-of-motion exercises. She established a shoulder-positioning program and fitted Able with prefabricated resting hand splints. In conversations with the patient and family, the therapist began to explain the process of rehabilitation. The occupational therapist documented that the family was engaged and supportive and that the patient appeared passive and quiet. Able was transferred to a rehabilitation center 3 weeks post injury.		
Reason for Referral to Occupational Therapy	Appreciate the context	hypotheses
Able was referred to occupational therapy to address limitation in performance skills and patterns.		
	Develop provisional	
"Able's past accomplishments and tough school/sports schedule required him to be disciplined and structure his time efficiently. I think this will help him in the acute rehabilitation setting, a place that requires hard work. More importantly, his past level of engagement is an indicator that he will be able to continue a life full of participation in meaningful occupations."	**Assessment Process and Results** **Occupational profile:** Interviews included	establishing rapport; in-depth interviews about Able's typical day, interests, routines, habits and roles; and administering of the Canadian Occupational Performance Measure. Initially, because of Able's withdrawn mood, the therapist secured Able's permission and interviewed his family about his life and about family goals.

DYNAMIC VIDEO CLIPS on thePoint demonstrate range of motion, manual muscle testing, construction of hand splints, adapted dressing techniques, and transferring patients.

FEATURES TO HELP YOU BE A SUCCESSFUL OCCUPATIONAL THERAPIST

Occupational therapists who practice competently and ethically do so from a background of evidence that assessments are valid and reliable and treatments are efficacious. Two table features of *Occupational Therapy for Physical Dysfunction* support evidence-based practice.

ASSESSMENT TABLES, located at the end of each assessment chapter, help the therapist select an appropriate measure and interpret the results. Terms used in these tables include the following:

- **Reliability** is a measure of an instrument's stability. Interobserver or interrater reliability refers to the outcome when two different individuals administer the instrument to a particular person and achieve similar results. Test–retest reliability, or intrarater reliability, refers to the constancy of results over repeated use of the instrument by the same tester in the absence of change in the person being tested. This type of reliability applies most directly to practice in which the same therapist measures the patient's abilities before and after treatment.
- **Sensitivity** is the ability of an instrument to detect clinically important changes. The more sensitive the instrument, the greater likelihood that small changes will be detected.
- **Validity** is the ability of an instrument to measure what it is intended or presumed to measure. Criterion validity is determined by comparing the examined test to an agreed-on *gold standard* (accepted test). Predictive validity is its ability to predict future outcomes.

Assessment Table 38-1		Comparing interventions and their outcomes					
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability**	**Reference**
Intervention to improve voluntary hand function in incomplete individuals with C4-C7 spinal cord injury	Comparison of 2 treatment groups: Conventional occupational therapy and functional electrical stimulation therapy	22 individuals with incomplete C4-C7 tetraplegia. Single-site.	1 dose defined as 60 min per day, 5 days per week for 8 weeks). Conventional OT group: 2 units of conventional OT FES group: 1 unit of conventional OT and 1 unit of FES	Randomized control; small groups (10 and 12) No control who did not receive treatment. Level: IIB	Group that received FES and conventional OT showed greater improvement than group that had 2 hours of conventional OT.	FIM P=0.015; SCIM UE sub-scale < 0.0001; Hand test TRI-HFT: 10 objects=0.054; Rectangular blocks= 0.124; Able to hold wooden bar= 0.065	Kapadia, Zivanovic, Furlan, Craven, McGillivray, & Popovic, 2011
Intervention to improve self-efficacy, ability to set/achieve goals, and perceived independent-living status	Occupational therapists and other health care providers conducted health promotional seminars, group discussions, physical and recreational activities.	SCI=16 MS=12	10 full day sessions, twice a month for 5 months.	Small group, quasi-experimental repeated-measures; non-randomized Level: IIIC	Yes. Self-efficacy and ability to formulate and achieve goals in the areas of independent-living skills improved for intervention participants.	Statistically significant difference in the change in self-efficacy scores t(38)=2.855 p=0.007	Block, Vanner, Keys, Rimmer, & Skeels, 2010

EVIDENCE TABLES, located at the end of each chapter which is devoted to a treatment or a diagnosis, list some of the best evidence concerning the treatments mentioned in the chapter. Terms used in the evidence tables include the following:

- **Effect size** is a unitless indication of the strength of the relationship between the treatment and the outcome (Rosenthal, 1984). There are several representations of effect size, including r, Hedges's g, Cohen's d, and η^2 (eta squared). Effect size, "r," is interpreted like a correlation coefficient: 1.0 equals a perfect, strong, relationship, and 0 equals no relationship (Rosenthal, 1984). An effect size of $r = 0.10$ is considered small; of 0.30, medium; and of 0.50, large (Cohen, 1988) (η^2, eta squared, is interpreted similarly to "r").
- **Level of evidence** rating scale used in this textbook is the American Occupational Therapy Association's Evidence-Based Project Scale (Trombly & Ma, 2002): Level I (highest) to Level IV (lowest). The higher the level, the better the evidence that the intervention was the cause of the change reported. The scale also presents grades relating to sample size, internal validity (how well the study controlled for alternate explanations of outcome), and external validity (how well the study generalizes to persons other than the study participants or to settings other than the study setting). For example, a rating of IC2c means that the study was a randomized controlled trial (I), with 20 or fewer participants in each group (C), that had no strong alternative explanation for outcome but had one or two threats to validity (2), and that the participants do not necessarily represent the population of patients of that diagnosis AND the treatment does not represent current practice OR it was carried out in an unnatural (laboratory) setting (c).
- **Statistical probability** indicates the likelihood that the outcome was due to chance. A probability level of 0.05 indicates that there are only five chances out of a hundred that the outcome occurred by chance (Rosenthal & Rosnow, 1991).

Evidence Table 38-1   Comparing interventions and their outcomes

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Intervention to improve voluntary hand function in incomplete individuals with C4-C7 spinal cord injury	Comparison of 2 treatment groups: Conventional occupational therapy and functional electrical stimulation therapy	22 individuals with incomplete C4-C7 tetraplegia. Single-site.	1 dose defined as 60 min per day, 5 days per week for 8 weeks). Conventional OT group: 2 units of conventional OT FES group: 1 unit of conventional OT and 1 unit of FES	Randomized control; small groups (10 and 12) No control who did not receive treatment. Level: IIB	Group that received FES and conventional OT showed greater improvement than group that had 2 hours of conventional OT.	FIM P=0.015; SCIM UE sub-scale < 0.0001; Hand test TRI-HFT: 10 objects=0.054; Rectangular blocks= 0.124; Able to hold wooden bar= 0.065	Kapadia, Zivanovic, Furlan, Craven, McGillivray, & Popovic, 2011

SUMMARY REVIEW QUESTIONS let you assess your ability to recall the information presented in each chapter. The answers are found in the chapter.

Summary Review Questions

1. List three key epidemiological factors of the SCI population and describe how these factors influence evaluation and treatment.
2. List three precautions the therapist must consider in planning for an outing with a patient with C5 injury.
3. What is a tenodesis grasp? Why is it important, and how can the occupational therapist facilitate it?
4. List five parts of the initial occupational therapy evaluation of a patient with SCI.
5. Describe a typical feeding setup for person with C5 tetraplegia.
6. What are the functional expectations for the patient with a C7 injury?
7. You read in the medical chart that a patient lost consciousness at the time of injury. How do you modify your evaluation? Describe how concomitant brain injury may alter your treatment goals and interventions.
8. What are the roles of the occupational therapist in the transition phase?

Nurses are the primary trainers of bowel and bladder routines, and occupational therapists have a vital role in supporting the acquisition of these new skills and habits. A typical bowel program for a person with paraplegia includes taking oral medications to allow for optimal feces consistency and establishing a daily routine of transferring to the toilet, managing clothing, inserting a suppository, and, after waiting for some time, inserting a finger to the anus (called digital stimulation), which causes reflexive defecation. The occupational therapist may assist in facilitating skill acquisition in a person with poor vision and/or cognitive deficits. A magnifying mirror and a lamp may be placed on the floor to help the person see and further break down the activity to better reinforce each step. Persons with low tetraplegia have added challenges in becoming independent in bowel care. They may achieve independence or assist in managing their bowel care only after much practice. To compensate for poor trunk control, individuals perform the bowel program on a commode; to compensate for finger paralysis, they require a tool called the dill stick to stimulate the anal reflex to defecate (Figure 38-4); and to compensate for lack of sensation in the anus and/or parts of the hand, they require a mirror. For safe task performance, occupational therapists may practice commode mobility and dill stick insertion focusing on effective visual compensation. When patients become skillful at bowel evacuation practices, they decrease the risk of complications. Most individuals, after discharge, opt to carry out their bowel program in the morning every other day and can complete the procedure within 45 minutes (Kirshblum, Gulati, O'Conner, & Voorman, 1998).

As with the bowel program, the goal of the bladder program is to achieve a simple routine with minimal risk of complications. Recurring urinary tract infection is a frequent complication and the most frequent cause of rehospitalization after spinal cord injury (Cardenas, Hoffman, Kirshblum, & McKinley, 2004). To avoid complications, patients must empty their bladder routinely.

An indwelling catheter, which is a catheter that stays in the urethra and is changed only periodically, is commonly inserted soon after the person is admitted to the acute care hospital (Consortium for Spinal Cord Injury, 2008 [Early Acute Management]).Although some patients continue to use an indwelling catheter, an effort is made

Clinical Reasoning in Occupational Therapy

Helping the Client Hire a Caregiver

Able is hiring his first caregiver. A. What activities will the caregiver need to perform? B. What important precautions does the caregiver need to exercise? C. As Able's therapist how would you facilitate the caregiver's learning?

CLINICAL REASONING BOXES give opportunities to solve clinical problems by applying the knowledge gained in each chapter to real-life situations. The answers supplied by experienced therapists are located on the website, thePoint (thepoint.lww.com).

concentrate on learning to know patients' factors, their unique life contexts, and their individual reactions to their trauma or illness.

- Provide psychological support. At times when the patient is overwhelmed with sadness, it is okay just to be present and available to the person. It is okay to stop an

to rest between sessions?").

- Facilitate solving problems ("What do you think is the best way for you to hold your pen?" "What do you think will make you sleep better at night?")
- Engage the person in activities that are personally relevant and meaningful.

Later in the continuum of care, therapists can facilitate positive coping by helping the patient identify optimal transportation, reduce environmental barriers and facilitate the return to gainful employment.

To understand the complexity of the psychosocial adjustment to SCI, we must also examine the reactions of the patient's relevant others. Family members and friends may also experience distress, sadness, anger or a myriad of other emotions. Concurrently, they may have to reassess their future commitment to the injured person. A mother, for example, may grieve and be sad while having to decide whether to take her fully dependent son home after a turbulent adolescence.

We must also examine our own emotional reactions and the influence of these emotions on the patient and therapeutic process. For example, sometimes upon interviewing a newly injured person, I become especially sad as I strongly identify with something in the patient's life narrative (e.g., the struggles of a mother with two young children). I am reminded of my projection, as the patient may be more accepting and positive. As occupational therapists, we contribute to psychosocial adaptation after SCI by incorporating the following considerations into evaluation and treatment.

- Set aside all preconceived biases about who the patient is and how he or she should feel or behave. Instead,

PROCEDURES FOR PRACTICE BOXES provide step-by-step directions for carrying out particular assessment or intervention practices.

Procedures for Practice 38-1

Linking Long- and Short-Term Goals to Anticipated Rehabilitation Outcomes

P.B. is a 20-year-old man with C8 tetraplegia beginning multidisciplinary inpatient rehabilitation. The following examples of outcome and long- and short-term goals are not meant to be exhaustive lists of intervention plans but rather to illustrate the linkage between global outcome projections and therapy plans.

- Projected outcome of rehabilitation stay: In 8 weeks, P.B. will resume self-maintenance roles, requiring no more than occasional physical assistance from family members to manage in the home environment.
- Examples of long-term occupational therapy goals (to be achieved in 8 weeks):
  1. P.B. will perform upper body dressing independently and require no more than moderate assistance for lower body dressing.
  2. P.B. will use adaptive equipment to feed himself independently.
- Examples of short-term occupational therapy goals (to be achieved in 2 weeks):
  1. P.B. will don a pullover shirt with no more than general verbal cues.
  2. P.B. will participate in the evaluation of various types of adaptive equipment for self-feeding and use selected aids to feed himself independently after set up by therapist.

thePoint, the website associated with this textbook, has, in addition to the answers to the Clinical Reasoning Boxes, the clinical reasoning boxes with answers from the sixth edition as well as an image bank and learning objectives. To access and log onto thePoint, go to www. thepoint.lww.com and register.

Contents

thePoint

Our website provides a **consolidated set of easy-to-use resources** to help you excel in your coursework, ace your exam, and launch your professional career. Whether you want to **access Student Resources** or **search online content**, thePoint gives you the edge by helping you find the right tools for your learning needs.

Step 1: Get the Resources for Your Title

Your VitalBook comes with immediate access to the companion resources on thePoint.

No need to enter an access code! Simply click the link below, and you will be taken to the product page at thePoint, with live links to all the student resources*.

http://thepoint.lww.com/VitalSource/EBook/9781451127461

Step 2: Accessing Student Resources

Follow the instructions on the screen to login to thePoint. (First time users of thePoint will have to register an account.) Once you have signed in you will not need to do so again**.

Click the link above to go to the product page on thePoint, then click on the **Student Resources** tab for that title.

After clicking on **Student Resources**, you'll see an extensive list of available materials associated with that title. Certain resources (such as videos and image banks) should be viewed on screen, while other resources (such as Microsoft Word and PowerPoint files) may be downloaded to your computer. The drop-down menu on each title's product information page makes it simple and intuitive for you to locate and access the resources you want.

Instructors, these instructions are for the **student resources only. To gain access to the instructor's resources, you will need to use an access code, which you can request by clicking the "Request Access to Online Resources" link for this title on thePoint, or through your local sales representative.*

**Users will only need to register once, but if you delete the cookies on your computer or terminate your session on thePoint, you will have to login again.

Need More Help?

We'll make sure you get the answers you need fast.

We're here to help, so be sure to select the **Help** tab in the upper right corner of every page any time you have questions or need assistance during your experience at thePoint.

You can also contact **thePoint Online Support at 1-800-468-1128** or **by email at** <u>techsupp@lww.com</u> if you're experiencing technical problems with the site.

Thank you for choosing Lippincott Williams & Wilkins and thePoint, your partners in education and practice.

Conceptual Foundations for Practice

Catherine A. Trombly Latham

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the Occupational Functioning Model (OFM).
2. Relate the American Occupational Therapy Association's Occupational Therapy Practice Framework (OTPF) to the OFM.
3. Use the language of the Occupational Functioning Model, the American Occupational Therapy Association's OTPF, and the World Health Organization's International Classification of Functioning (ICF) interchangeably.
4. Organize assessment and treatment planning according to the Occupational Functioning Model.

Sense of self-efficacy
and self-esteem

Satisfaction with
life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

Competence in tasks
of life roles

Activities and habits

Abilities and skills

Developed

Organic
substrate
How do occupational therapists know what to do when a person with occupational dysfunction secondary to a disease or injury that results in physical impairment is referred to them? First, they have *specific knowledge* about what the diagnosis means in terms of limitations of bodily structure or function and subsequent probable limitation of occupational performance, and they know the outcome of research on the effectiveness of interventions available—the evidence base of practice. Second, they have *specific skills* for assessing and treating persons with occupational dysfunction secondary to physical impairment. Third, they know *how therapy is organized*—the conceptual foundation for practice. The organization or process of occupational therapy is found in various conceptual models of practice. A conceptual model is a representation of an object or process that indicates how various parts fit into a whole or work together for a particular purpose.

Conceptual models of practice are meant to be used in conjunction with the American Occupational Therapy Association's Occupational Therapy Practice Framework (OTPF). That framework describes the domain and process of the entire practice of occupational therapy (American Occupational Therapy Association [AOTA], 2008). The framework aims to standardize the language of the domain and process of occupational therapy. Because the framework is not a conceptual model (AOTA, 2008), it is expected that occupational therapists will apply pertinent aspects of the framework through the particular conceptual model they choose to guide their practice. Therapists may choose from among many different conceptual models of practice in order to put the framework into practice. An occupational therapy model of practice is a way of conceptualizing the interrelatedness of the person's characteristics and his or her environment, occupation, and quality of life to guide assessment and intervention. This textbook has chosen the Occupational Functioning Model (OFM) to conceptualize the process of occupational therapy for persons with physical dysfunction. How, then, do the Occupational Therapy Practice Framework and the OFM relate? What are their similarities and differences? The language and process of the two are comparable (Tables 1-1 and 1-2). They share some ideas and differ on others (Table 1-3).

The OFM also shares some language and ideas with the World Health Organization's International Classification of Functioning (ICF) (World Health Organization [WHO], 2001). The ICF is a classification tool for universal (transcultural) description of functioning and disability in everyday activities and social involvement of individuals with medical conditions (Bilbao et al., 2003). Occupational therapists were involved in the development of this classification; therefore it reflects the philosophy of occupational therapy regarding health being a state enabling full participation in life's activities (Mahaffey &

Colaianni, 2012). Both occupational therapy (here represented by the OFM) and the ICF believe that recovery goes beyond remediating impairments, and both focus on the interaction between the person and the environment (Mahaffey & Colaianni, 2012). However, the ICF is neither detailed nor focused enough to guide occupational therapy practice. The ICF is used frequently in epidemiological research and public policy making because its language is discipline free and because it has been adopted internationally. See Table 1-4, which relates the ICF language to that of the OFM.

THE OCCUPATIONAL FUNCTIONING MODEL

The OFM guides assessment and treatment of persons with physical dysfunction leading to competence in occupational performance and subsequent feelings of self-empowerment. In this textbook, the diagrams on the title pages of each of the chapters (except chapter 2 and chapters on diagnostic categories) indicate how the pieces of the various aspects of the OFM fit together and where the contents of each chapter fits in the overall model.

The OFM was derived from clinical practice with persons with physical impairments. The primary belief is that people who are competent in their life roles experience a sense of self-efficacy, self-esteem, and life satisfaction. Research indirectly supports the idea that competency is related to satisfaction or a positive quality of life (Elavsky et al., 2005; Eriksson et al., 2009; Korpershoek, van der Bijl, & Hafsteinsdóttir, 2011; Robinson-Smith, Johnston, & Allen, 2000). Successful performance strengthens personal efficacy beliefs (Bandura, 1977, 1997, 2001; Brock et al., 2009; Resnick, 1998). The goal of treatment, according to the OFM, is to enable competent engagement in valued roles whether by restored self-performance (personal agency) or by directing others (proxy agency) (Bandura, 2001).

Another assumption of the OFM is that the ability to carry out one's roles, tasks, and activities of life depends on basic abilities and capacities (e.g., strength, perception, and ability to sequence information). As do other systems (WHO, 2001), this hierarchical organization assumes that lower level capacities and abilities are related to higher level performance of everyday tasks and activities. This organization has been tangentially supported by research (Dijkers, 1997, 1999; Geertzen et al., 1998; Michielsen et al., 2009; Pollard, Johnston, & Dieppe, 2011; Sveen et al., 1999). However, the relationship is not linear (Michielsen et al., 2009). Only part of the variance associated with function is accounted for by any one ability. For example, Lynch and Bridle (1989) found a moderately strong ($r = -0.65$; $p < 0.01$) negative relationship between the scores of the Jebsen-Taylor Hand Function Test (Jebsen et al., 1969) and the scores of the Klein-Bell Activities of Daily Living (ADL) Scale (Klein & Bell, 1982).

Table 1-1 The Domains of the Occupational Functioning Model and the Occupational Therapy Practice Framework

Occupational Functioning Model	Occupational Therapy Practice Framework (AOTA, 2008)
Competence and Satisfaction with Life Roles and Competence in the Performance of Tasks of Life Roles	*Areas of Occupation*
Life roles and the tasks that comprise them are defined by the patient or client. Generally, roles fall into one of the following three categories: *Self-maintenance roles*—These roles maintain self, family, pets, and home, including all basic activities of daily living (BADL) and instrumental activities of daily living (IADL) associated with self-care; all IADL associated with care of family; and all IADL associated with care of home, and other possessions. *Self-advancement roles*—These roles add to the person's skills, possessions, or other betterment. *Self-enhancement roles*—These roles contribute to personal accomplishment and enjoyment or sense of well-being and happiness.	*ADL*—Care of one's body including bathing and showering, bowel and bladder management, dressing, eating, self-feeding, functional mobility, personal device care, personal hygiene and grooming, sexual activity, and toilet hygiene *IADL*—Activities to support daily life in the home and community including, care of others, child rearing, care of pets, communication management, community mobility, financial management, health management and maintenance, home establishment and management, meal preparation and cleanup, religious observance, safety and emergency maintenance, and shopping *Rest and sleep*—Rest, sleep, sleep preparation, and sleep participation *Education*—Participation in formal or informal education; exploration of informal educational needs or interests *Work*—Employment interests and pursuits, employment seeking and acquisition, job performance, retirement preparation and adjustment, and volunteer exploration and participation *Play*—Play exploration and participation *Leisure*—Leisure exploration and participation *Social participation*—Engaging in activities that result in successful interaction at the community, family or peer/friend levels
Competence in the Performance of Activities and Habits of the Tasks of Life Roles	*Performance Patterns—Person*
Activities—Smaller units of goal-directed behavior that comprise tasks *Habits*—Chains of action sequences acquired by frequent repetition that can be carried out with minimal attention. Therapy aims to sustain useful habits, release useless habits, and develop new habits.	*Habits*—Automatic behavior integrated into more complex patterns of daily behavior; can be useful, dominating, or impoverished and either support or interfere with performance in areas of occupation *Routines*—Patterns of behavior that provide structure for daily life *Rituals*—Symbolic actions that contribute to the client's identity and reinforce values and beliefs *Roles*—A set of behaviors expected by society, shaped by culture, and defined by the client
Abilities and Skills	*Performance Skills*
Abilities and skills that are basic to interaction with objects and physical and social environments include: *Motor*—Adequate strength, coordination, range of motion, dexterity, and muscular endurance *Sensory*—Abilities to adequately receive and interpret sensory stimuli to enable occupational performance *Cardiorespiratory*—Adequate cardiac and pulmonary function to sustain performance *Visual-perception*—Adequate visual acuity and ability to perceive and interpret sensory stimuli and to perceive self and objects in space to enable occupational performance *Cognitive*—Abilities and skills that are basic to interaction with the environment, to organizing life tasks, and to solving occupational problems; abilities include attention, memory, problem solving *Socioemotional*—Abilities and skills that enable occupational performance in a social context or environment	Abilities that clients demonstrate in the actions they perform. *Motor and praxis skills*—Actions or behaviors used to move and physically interact with tasks, objects, contexts, and environments; includes planning, sequencing, and executing novel movements *Sensory-perceptual skills*—Actions or behaviors used to locate, identify, respond and interpret sensory events *Emotional regulation skills*—Actions or behaviors used to identify, manage, or express feelings while engaging in activities alone or with others *Cognitive skills*—Actions or behaviors used to plan and manage the performance of an activity *Communication and social skills*—Actions or behaviors used to communicate and interact with others in an interactive environment

(continued)

Table 1-1   **The Domains of the Occupational Functioning Model and the Occupational Therapy Practice Framework** *(continued)*

Occupational Functioning Model	Occupational Therapy Practice Framework (AOTA, 2008)
Developed Capacities	*Client Factors*
Voluntary responses that have developed from first-level capacities	Values, beliefs, and spirituality. Body functions, including mental functions; sensory functions and pain; neuromusculoskeletal and movement-related functions; cardiovascular, hematological, immunological, and respiratory functions; voice and speech functions; digestive, metabolic, and endocrine functions; genitourinary and reproductive functions; and skin and related structure functions
First-Level Capacities	*Client Factors*
The reflexive subroutines of voluntary movement and behavior. These functional foundations for movement and behavior include sensorimotor, cognitive-perceptual, and socioemotional capacities.	(as above)
Organic Substrate	*Body Structures*
Structural and physiological foundation for movement, cognition, perception and emotions. The substrate includes central nervous system organization and the integrity of skeleton, muscles, peripheral nerves, heart, lungs, and skin.	Those anatomical parts of the body that correspond to the functions mentioned above.
Environment and Context	*Contexts and Environments*
Physical—Including the natural and built environments, objects and utensils, and the requirements that tools and utensils pose for use *Personal*—Including age, gender, activity history, sense of competency, and spirituality *Cultural*—Including norms, values, beliefs, and routines or rituals of the family, ethnic group, community, or religious group *Social*—Including therapeutic interaction and relationships with family members, peers and friends, and community *Temporal*—Including temporal demands of role tasks, activities and habits; balance of activity types; and balance of activity and rest *Situational*—Including circumstances related to the setting or surroundings at a given moment	*Cultural*—Including ethnicity, beliefs, activity patterns, and behavior standards *Personal*—Including age, gender, socioeconomic status, and educational status *Temporal*—Including stage of life, time of year or day, duration, rhythm of activity, and history *Virtual*—Defined as the communication that occurs via air waves or computers with an absence of physical contact *Physical*—Including built and natural nonhuman environments and objects in them *Social*—including relationships with individuals, groups, organizations, and systems
	Activity Demands
The OFM has no comparable concept within the hierarchical model. Activity analysis is, however, a basic therapeutic process within the OFM. Three analyses are described in Chapter 12. 1. Task-focused activity analysis—Deconstruction of activity itself outside of the client-specific application to build student's or clinician's repertoire of therapeutic occupations 2. Client-focused activity analysis—Description of the reasoning used in the therapeutic use of occupation-as-means for a particular therapeutic goal for a particular person 3. Client-environment fit analysis—Deconstruction of the specific activity-environment-person fit to determine and/or optimize the likelihood of successful performance of occupation-as-end	*Objects used and their properties*—Tools, materials, equipment *Space demands*—Size, arrangement, temperature, etc. *Social demands*—Social environment and cultural contexts *Sequence and timing*—Rules, sequences *Required actions and performance skills*—Sensory, perceptual, motor, praxis, emotional, cognitive, communication and social performance skills *Required body functions*—Those physiological functions required to support the actions required of the activity *Required body structures*—Anatomical parts of the body that are required to perform the activity

Table 1-2 **The Process of Occupational Therapy**

Process	Occupational Functioning Model	Occupational Therapy Practice Framework (AOTA, 2008)
Goal of therapy	Satisfactorily engage in self-identified, important life roles through which the person gains a sense of self-efficacy and self-esteem	Support health and participation in life through engagement in occupation
Evaluate to identify the problem(s)	• Identify roles, tasks, and activities the person wants to do or needs to do • Observe and analyze the person's performance, preferably within usual context • Identify inadequate performance • Identify impaired abilities or capacities that contribute to inadequate performance and assess level of impairment using valid, reliable assessment tools administered according to the standardized protocol • Identify environmental or contextual enablers or hindrances • Interpret assessment data to the patient and family and document in the patient's record	• Develop an occupational profile to understand the client's occupational history, patterns of daily living, interests, values, needs, problems with performance, and priorities • Do an analysis of occupational performance by observation within personally relevant context to specifically identify effectiveness of client's performance skills • Measure performance skills • Interpret assessment data to identify facilitators and barriers to performance • Develop hypotheses about what strengths and weaknesses the client brings to occupation
Plan intervention	• Plan in collaboration with the person or family, after presenting the current evidence, to determine whether the person wants to engage in either remediation of impaired abilities or capacities to enhance overall performance or restoration of occupational performance through relearning and/or adaptation of method or environment • With the patient, establish short-term goals that directly relate to the long-term goal of successful role functioning identified by the patient and that can be objectively and reliably measured • Select interventions that have evidence for effectiveness for the immediate goal	• With the client, develop a plan with objective, measurable goals and a time frame to guide action • Plan occupational therapy intervention based on theory and evidence • Consider discharge needs and plan • Select outcome measures • Refer to other professionals as needed
Implement the intervention	Use therapeutic mechanisms, as appropriate: *Occupation* • Occupation-as-end to restore occupational functioning • Occupation-as-means to optimize abilities or capacities *Therapeutic rapport* *Education*—Learning or relearning *Adjunctive therapies*—Therapies such as orthoses, technological aids, physical agent modalities, mobility aids used to facilitate performance *Contextual and environmental modification*—To facilitate performance	Determine the types of occupational therapy interventions to be used and carry them out • Therapeutic use of self • Occupation-based intervention • Purposeful activity • Preparatory methods • Consultation • Education • Advocacy Monitor and document client's response
Evaluate the result	• Assess patient outcomes • Determine whether the short-term goals were achieved • Determine whether achievement of the short-term goals resulted in desired occupational performance • If not, reevaluate and modify the plan relative to achieving targeted outcomes • If yes, determine whether the person was satisfied with his or her achievement • Plan for the next level of therapy or plan for discharge and referral as appropriate	• Determine success in achieving targeted outcomes • Modify the plan as needed • Determine need for continuation, discontinuation or referral
Types of outcomes	• Satisfactory occupational performance to allow expected discharge success • Voiced, or otherwise indicated, sense of self-efficacy and self-esteem • Prevention of further disability through education and follow-up, if necessary	• Occupational performance • Adaptation • Health and wellness • Participation • Prevention • Quality of life • Role competence • Self-advocacy • Occupational justice

Table 1-3 **The Similarities and Differences between the Occupational Functioning Model and the AOTA Occupational Therapy Practice Framework**

	Occupational Therapy Practice Framework (AOTA, 2008)	Occupational Functioning Model
Central focus	Occupation to achieve health (Gutman et al., 2007)	Self-fulfillment through role competence
A conceptual model	No	Yes
Describes the relationships (dynamic interaction) among the terms and categories in the classification system	No (Nelson, 2006)	Yes
Domain	Incorporates all aspects of occupational therapy practice	Limited to practice for those with physical dysfunction
Hierarchical	No (Smith Roley & Delany, 2009)	Yes; successful performance of higher occupations depends on lower abilities, skills, and capacities
Clients include person, organization, society	Yes	No; limited to practice with individuals
End goal	Support health and participation in life through engagement in occupation	Satisfactorily engage in self-identified, important life roles through which the person gains a sense of self-efficacy and self-esteem
Process	Evaluation, planning, intervention, outcome monitoring	Evaluation, planning, treatment, reevaluation
Evaluation	Occupational profile and occupational performance; factors that influence performance skills and patterns	Role performance; task and activity performance; skills, abilities; developed capacities; first-level capacities; and organic substrate, as needed Environmental and contextual influences on performance
Top-down evaluation process	Yes	Yes
Process of evaluating, planning, treating, and monitoring outcome is iterative, not sequenced	Yes	Yes
Process is collaborative, i.e., client centered	Yes (Gutman et al., 2007)	Yes
Key skill of occupational therapist	Analysis of occupational performance: observe, analyze, and interpret performance and detect the client, contextual, or environmental factors that enable successful performance or that impede that performance	Activity analysis: observe, analyze, and interpret performance and detect the clinically relevant impairment and/or the contextual-environmental enablers or barriers to performance
Interventions	Therapeutic use of self Therapeutic use of occupation and purposeful activities Preparatory methods Education Consultation Advocacy	Therapeutic rapport Therapeutic use of occupation as occupation-as-means and/or occupation-as-end Learning (education) Therapeutic technologies

Table 1-3   **The Similarities and Differences between the Occupational Functioning Model and the AOTA Occupational Therapy Practice Framework** *(continued)*

	Occupational Therapy Practice Framework (AOTA, 2008)	**Occupational Functioning Model**
Occupational therapy intervention approaches	Create, promote (health promotion) Establish, restore (remediation, restoration) Maintain Modify (compensation, adaptation) Prevent (disability prevention)	Collaborate Remediate skills and abilities Restore activities, tasks, and role performance by relearning or adaptation
Evidential support	None offered (Smith et al., 2009)	Tangential supporting evidence, that is, incidental evidence of the various assumptions, but not direct evidence for the model
Practical usefulness (usable and clinically relevant; use of everyday language)	No (Gutman et al., 2007; Nelson, 2006)	Yes

The correlation is negative because better performance on the Jebsen-Taylor is indicated by less time (lower score), whereas better performance on the Klein-Bell is indicated by a higher score. Filiatrault et al. (1991) found a similar relationship ($r = 0.6$) between the Fugl-Meyer Motor Function Test (upper extremity subtest) (Fugl-Meyer et al., 1975) and the Barthel Index (ADL) (Mahoney & Barthel, 1965).

Rudhe and van Hedel (2009) found relationships within a similar range between manual muscle testing and self-care activities, although they found higher relationships ($r > .82$; $R2 > .67$) between finger and thumb strength and grooming. These outcomes do indicate that sensorimotor control of the upper extremities is related to self-care, but because the variance (r^2) is only approximately 40%

Table 1-4   **Occupational Functioning Model Related to the World Health Organization International Classification of Functioning**

Occupational Functioning Model	**World Health Organization International Classification of Functioning Classification (WHO, 2001)**
Self-efficacy and self-esteem as a by-product of successful role performance	No corresponding concept
Satisfaction with life roles • Self-maintenance • Self-advancement • Self-enhancement	**Participation:** involvement in a life situation; the nature and extent of a person's societal functioning; the interaction between the person having a disability and/or impairment with contextual factors
Competence in **tasks of life roles** Mastery of **activities and habits** Having **abilities and skills** that underlie mastery and competence	**Activity:** the execution of a task or action by an individual; the nature and extent of functioning at the level of the individual; all that a person does at any level of complexity
Developed capacities **First-level capacities** **Organic substrate**	Bodily **structures** and psychological and physiological **functions**
Environment and context: the milieu in which occupation occurs, including natural and built physical environments, tools and utensils, social relationships, cultural situations, and time	**Contextual factors:** the complete background to a person's life and living, including both external environmental factors[a] and internal personal factors.[b] Environmental factors include all aspects of the physical, social, and attitudinal world.

[a]Natural environment (weather or terrain), human-made environment (tools, furnishings, and the built environment), social attitudes, customs, rules, practices and institutions, and other individuals.
[b]Age, race, gender, educational background, experiences, personality and character style, aptitudes, fitness, lifestyle, habits, upbringing, coping styles, social background, profession, and experience.

(0.65² or 0.60²), other unidentified variables must account for the remaining approximately 60% variance associated with ADL. This makes sense because, in addition to upper extremity function, ADL independence requires such skills as sitting and standing balance, perception of positions of objects in space, ability to sequence steps of a procedure, environmental support, and so forth.

It appears that the relationship between two adjacent levels of performance (e.g., capacities and abilities) is stronger than between two nonadjacent levels (e.g., capacities and roles) (Dijkers, 1999; Pollard, Johnston, & Dieppe, 2011). The relationship between levels is strong both at the low end of the model (Pendlebury et al., 1999; Pollard, Johnston, & Dieppe, 2011) and at the high end (Dijkers, 1997, 1999; Pollard, Johnston, & Dieppe, 2011). Pendlebury et al. (1999) found a strong ($r = 0.90$) relationship between deficits in organic substrate and deficits of motor capacities and abilities. In a large sample of persons with spinal cord injury, Dijkers (1999) found a moderately strong relationship ($r = 0.24–0.42$) between life satisfaction and roles related to social integration and occupation (work) but not between impairments and life satisfaction ($r = 0.04–0.07$). He concluded that "these relationships suggest a causal chain [i.e., one link leading to the next]. . . . The impact of impairment on quality of life is almost entirely through its impact on disability, and the effect of disability is largely through its impact on handicap" (Dijkers, 1999, p. 874). This suggests that the relationship between low-level capacities and abilities and higher level tasks and roles is not direct. That is, having a particular ability, such as strength, does not ensure that a person can accomplish a given activity or task (Dagfinrud et al., 2005). Likewise, the ability to accomplish a single activity does not account for role performance. Many capacities contribute to the development of one ability, and many abilities are needed to engage successfully in an activity. When one capacity or ability is impaired, occupational dysfunction does not automatically occur. A person may adaptively use other capacities and abilities to allow accomplishment of the activity (Foroud & Whislaw, 2010).

Research is needed to clarify the multivariate relationships among lower level abilities and capacities and higher level activities, tasks, and roles. Researchers also must verify whether remediation of impaired capacities and abilities results in more complete and more versatile participation in the activities and tasks of importance in people's lives than would learning specific routines of activities in an adapted way. This is a key question for the practice of occupational therapy with persons having physical dysfunction.

Another assumption of the OFM is that satisfactory occupational functioning occurs only within enabling environments and contexts particular to the individual. True occupational functioning does not occur in a vacuum nor in a controlled situation such as the clinic;

occupational functioning is the successful interaction of the person with the objects, situations, and surroundings of his or her home, family, and community. Although the contexts of particular actions and occupations used to regain lost abilities and capacities may be controlled at first, therapy is not complete until generalization to the person's particular environment has occurred (Raina, Rogers, & Holm, 2007).

Achievement of occupational functioning after injury or disease is accomplished through occupation as well as adjunctive therapies described in this textbook. In the OFM, occupation has two natures: occupation-as-end and occupation-as-means (Trombly, 1995). Occupation-as-end equates to the higher levels of the OFM, at which the person tries to accomplish a functional goal (an activity or task) by using whatever skills, abilities, habits, and capacities he or she has. Occupation-as-means, on the other hand, is *the therapy* used to bring about changes in impaired capacities and performance skills. Occupation-as-means is therapeutic because the goal presents challenges to impaired capacities and abilities, and the successful achievement of that goal results in improved organic or behavioral impairments. Both occupation-as-end and occupation-as-means derive their therapeutic impact from the qualities of purposefulness and meaningfulness (see Chapter 11 for discussion of these concepts).

The constructs of the occupational functioning model shown in the diagram on the title page are described next.

Sense of Self-Efficacy and Self-Esteem

The goal of occupational therapy is the development of competence in the activities and tasks of one's cherished roles, which promotes a sense of self-efficacy and self-esteem. *Competence* refers to effective interaction with the physical and social environments (Fig. 1-1). To be competent means to have the skills that are sufficient or adequate to meet the demands of a situation or task (Gage et al., 1994; White, 1959). It does not equate to excellence, normality, or the ability to do everything, and it recognizes that there are degrees of sufficiency and adequacy in people (Gage et al., 1994; Mocellin, 1992; White, 1971).

Competence develops by enabling a person to engage in graduated, goal-directed activity that is accomplishable by that person and that produces a feeling of satisfaction (White, 1959). Occupational therapists help people achieve competence through graded engagement in occupation, vicarious engagement in occupation (watching others), virtual engagement in occupation, developmental and instrumental learning with immediate and precise feedback, and therapeutic interaction with the therapist (Radomski, 2000; Robinson-Smith, Johnston, & Allen, 2000).

When people feel competent, they have a sense of self-efficacy. The most powerful source of personal efficacy expectations is past accomplishments in similar situations

Figure 1-1 Competency in self-advancement role of contractor's helper.

(Fig. 1-2). They have perceived their capability to perform a behavior (Williams, 2010). Self-efficacy is concerned not with the skills one possesses but with the judgments of what one can do with those skills. Perceived self-efficacy is influenced through an ongoing evaluation of success

Figure 1-2 For this accomplished artist, painting a picture is a task of one of her self-advancement roles (worker). For another person for whom painting is a hobby, it would be classified as a task of a self-enhancement role (hobbyist).

and failure with each task people participate in over the course of their lives (Gage & Polatajko, 1994). Self-efficacy is likely to lead people to esteem themselves (Hughes, Galbraith, & White, 2011).

Satisfaction with Life Roles [Areas of Occupation][1]

Being in control of one's life means being able to engage satisfyingly in one's life roles or to voluntarily reassign a role to another. Role performance is a vital component of productive, independent living (Hallett et al., 1994). Various occupational therapy scholars have proposed taxonomies of roles. The OTPF categorizes a role as a subunit of the performance patterns of the person (see Table 1-1). The framework's equivalent to the OFM's category of role performance is called "areas of occupation," which includes activities of daily living (ADL), instrumental activities of daily living (IADL), rest and sleep, education, work, play, leisure, and social participation.

The OFM sorts roles into three domains related to aspects of self-definition: self-maintenance, self-advancement, and self-enhancement (Rogers, 1984; Trombly, 1993, 1995), but recognizes that the assignment of roles to a particular category is not absolute. Some roles may be classified in one domain by one person but in another domain by another person, depending on the motivation or context. For example, volunteering may be classified by one person as a self-advancement role because volunteering promotes skills that will be useful in a worker role. Another person may classify volunteering as self-enhancement because it promotes a sense of satisfaction without expectation of gain. The individuality of motivation underscores the importance of assessing each person from his or her own point of view, letting each define his or her roles and their meaning. That is a major aspect of client-centered therapy.

Self-Maintenance Roles [Activities of Daily Living and Instrumental Activities of Daily Living]

Self-maintenance roles are associated with maintenance of the self and care of the family, pets, and home. Examples of roles in this domain are independent person, grandparent, parent, son, daughter, homemaker (Fig. 1-3), home maintainer (Fig. 1-4), exerciser, cat owner, and caregiver.

Self-Advancement Roles [Work and Education]

Self-advancement roles are those that draw the person into productive activities that add to the person's skills, possessions, or other betterment. Self-advancement roles

---

[1]The comparable Occupational Therapy Practice Framework language is added in brackets to assist the student in using the language interchangeably.
Figure 1-3 Self-maintenance role: homemaker; task: meal preparation; activity: grilling fish.

Figure 1-4 Self-maintenance role: home maintainer; task: painting the walls; activity: preparing the paint.

correspond to the participation category of the ICF (Table 1-4). Examples of roles in the self-advancement role domain include worker (Figs. 1-1 and 1-5), student, intern, commuter, shopper, investor, manager, and voter.

Self-Enhancement Roles [Play, Leisure, Social Participation]

Self-enhancement roles contribute to the person's sense of accomplishment and enjoyment or sense of well-being and happiness (Figs. 1-2 and 1-6). Examples of roles in this domain include hobbyist, friend, club member, religious participant, vacationer, golfer, moviegoer, and violinist.

Competency in Tasks of Life Roles [Areas of Occupation]

Roles consist of constellations of tasks. For example, the role of homemaker may include the tasks of food preparation (Fig. 1-3) and service, housecleaning, laundry, and decorating (Fig. 1-4). The tasks identified for the same role by different people may be different (Nelson & Payton, 1991; Trombly, 1993, 1995). The value ascribed to tasks varies among people of similar situations and may vary from what therapists consider important for patients. Because people have different values, each person must

define his or her role by identifying the tasks that he or she believes are crucial to satisfactory engagement in that particular role. The therapist cannot assume that particular tasks are or are not important to a person's interpretation of a role.

Tasks consist of constellations of related activities and are therapeutically developed using occupation-as-end, that is, practicing the activities constituting the task in normal temporal order and environmental demand, with or without assistive technology as required.

Activities and Habits [Performance Patterns]

Activities, in the OFM, are smaller units of goal-directed behavior that, taken together, comprise tasks (Figs. 1-1 to 1-6). Activities bring together abilities and skills within a functional context. For example, one task of the gardener is pest control. Activities that make up this task may include hanging lures, spreading granular insect killer, mixing and spraying liquids, and picking insects off plants. Furthermore, each of these activities consists of even smaller units of behavior, such as opening the package and pouring granular insect killer into a garden spreader. Some activities, such as picking insects off plants, require full attention. Others, called habits, do not. Habits are chains of action sequences that are so well learned that the person does not have to pay attention to do them under ordinary circumstances

Figure 1-5 Self-advancement role: contractor; task: installing floor; activity: moving the wood into place.

and in familiar contexts. Physical dysfunction disrupts habits, requiring attention to be paid to the simplest of ADL. This adds to the fatigue experienced by many persons (Wallenbert & Jonsson, 2005). Using the OFM, occupational therapists seek to help the person sustain or relearn adaptive habits, let go of habits that are no longer adaptive, and develop new habits, given the person's changed abilities and capacities.

Activities and habits are learned using occupation-as-end, that is, "task-specific training." In task-specific training, functional and meaningful activities are practiced over and over using assistive technology, adaptive methods, or adapted environment to enable performance, if necessary. See Chapter 11 for a more complete discussion of the therapeutic use of occupation-as-end.

Abilities and Skills [Performance Skills]

Activities depend on more basic abilities (Clark, Czaja, & Weber, 1990; Fleishman, 1972; Fleishman & Quaintance, 1984; Kielhofner, 2008). A person with a great number

of highly developed abilities can become proficient at a greater variety of activities. An ability is a general trait, such as muscle strength or memory, that individuals bring with them to a new task (Fleishman, 1972). In the OFM, abilities are seen as a combination of endowed talents and acquired skills. A skill is the ability to use one's knowledge to effectively and readily execute performance (Merriam-Webster Online, 2011). Skill enables goal achievement under a wide variety of conditions with a degree of consistency and economy. Abilities and skills develop from one or more developed capacities. They are more voluntary and organized and evidence smoother execution than do developed capacities. The OFM identifies six categories of abilities and skills: motor, sensory, cognitive, perceptual, socioemotional, and cardiorespiratory.

To accomplish the activity of hanging lures in the previous example of the gardener, the person needs certain abilities, such as coordination, dexterity, and ability to follow directions. The person also needs to be able to translate these endowed talents into the skilled actions required to hang the lures. Carefully analyzed occupation-as-means is used to develop deficient abilities and skills. In the process of repeatedly accomplishing occupations that demand greater levels of the deficient ability or skill, in varying contexts, the patient gains greater levels of that ability or skill. By varying the context, the therapist encourages more robust learning. See Chapter 11 for a more complete discussion of the therapeutic use of occupation-as-means.

Developed Capacities [Client Factors]

Developed capacities reflect the organization of first-level capacities into more mature, less reflexive, and more voluntary responses. For example, to support dexterity, an ability, a person needs independent use of fingers, graded release, and pinch, which are developed capacities that derive from reflexive grasp and automatic release (first-level capacities). This organization is normally acquired through maturation. In therapy, occupation-as-means is used to develop these capacities. Therapeutic demands for gradually more mature and varied responses are made through repeated opportunities to engage in selected occupations.

First-Level Capacities [Client Factors]

First-level capacities are the functional foundation for movement, cognition, perception, and emotional life based on the integrity of the organic substrate. In the motor domain, first-level capacities are reflex-based motor responses that reflect the organization of primary visual, sensory, and motor systems. Examples include reflexive grasp, reflexive release, primitive

Figure 1-6 **A.** Self-enhancement role: pet owner; task: exercise dog; activity: throw the stick. **B.** Molly with stick.

Clinical Reasoning in Occupational Therapy Practice

Occupational Self-Analysis

Occupational therapists evaluate a patient's occupational profile. Practice this skill by analyzing your own occupational profile. The following directions are one way to determine the profile.

1. Make an occupational diary by listing awake hours along the left side of a piece of 11 × 8.5-inch paper and listing the days of the week across the top.
2. Fill in activities or tasks you do hour by hour in a typical week.
3. Classify these into role categories: self-maintenance, self-advancement, or self-enhancement.
4. Calculate what percentage of time you engaged in these role categories (hours spent in one role category/total awake hours × 100%).
5. Do these percentages align with your values and goals? To what extent does performance of these roles contribute to your self-esteem or role satisfaction?

6. Do you feel occupationally balanced, that is, physically, mentally, socially, emotionally, and spiritually healthy? Or are you stressed because of occupational imbalance? How have you gauged your balance—using time distribution, degree of challenge of the occupations in your life, type of occupations (physical, mental, etc.), or degree of self- or other-centeredness?
7. Make another chart. Choose a favorite role. What tasks make up this role for you? Are the tasks the same as those of your classmates who chose the same role?
8. Choose the key task from your answer to Question 7. What activities comprise this task?
9. Choose one activity from your answer to Question 8. What abilities are needed to do this activity?
10. What type of impairments would prevent you from doing the activity as you usually do it?
11. What type of environmental or contextual barriers would prevent or hamper you from doing the activity? Enable or facilitate your performance?

reaching, kicking, and stepping. They are the subroutines that Bruner (1973) described as underlying the development of all voluntary movement. The ability to recognize a connection between an instrumental, non-reflexive response given consistently within a particular perceptual situation is a first-level capacity of cognition and perception. The fascination of babies with human faces is a first-level capacity of the socioemotional domain.

Organic Substrate [Client Factors]

Organic substrate is the structural and physiological foundation for movement, cognition, perception, and emotions, including the primordial central nervous system (CNS) organization in the neonate; the CNS organization that is spared or recovers spontaneously after injury or illness; and the integrity of the skeleton, muscles, sensory and motor nerves, heart, lungs, and skin. If the organic substrate is not present, therapy cannot generate it. If it exists at all, therapy attempts to develop it into first-level capacities through techniques classified as augmented maturation (see Web Chapters A through C).

Environment and Context [Contexts and Environments]

The words *environment* and *context* are often used interchangeably. In current health care literature, the term *context* is used to encompass all that influences any aspect of human functioning, including physical, social, personal, temporal, and situational influences, as well as familial and cultural beliefs and practices that influence the life of an individual. Context is the interpretive dimension of the circumstances surrounding occupational engagement. Seemingly similar circumstances may result in different occupational behavior depending on the person's interpretation of the circumstances. It is this interpretive dimension of context that is important to the occupational therapist.

Environment is defined as the complex of external factors, circumstances, objects, structures, and social surround that inhibit or facilitate occupational functioning. Research has shown that familiarity of environment positively affects daily functioning (Geusgens et al., 2010). Successful and satisfactory performance of complex, cognitive IADL, which involve equipment and planning, has been found to be more affected by the environment than physical ADL, such as basic self-care (Raina, Rogers, & Holm, 2007).

Context in the OTPF refers to cultural, physical, social, personal, temporal, and virtual aspects of living. Similar to the OTPF, the OFM assumes that context and environment surround and permeate all levels of the occupational functioning hierarchy. However, the OFM distinguishes between the greater influence of context and environment at the higher levels of the hierarchy and the lesser influence at the lower levels. At the lower levels, the immediate physical and personal context and environment influence the actions. For example, organization of a reaching movement was shown to differ when actual, natural objects and utensils were used versus when simulated objects were used (Ma, Trombly, & Robinson-Podolski, 1999; Wu et al., 1998). Cultural and social contexts pertain less to this level. At the higher levels of activities, tasks, and roles, however, all aspects of context and environment—personal, social, cultural, temporal, situational, and physical—interact with the person's abilities to yield occupational functioning for the particular person. The diagram of the OFM on the title page depicts these ideas about context and environment within the limitations of two-dimensional representation. Chapters 3 and 30 discuss the influence of personal, social, cultural and situational contexts on occupational functioning, and Chapters 10 and 31 discuss the influence of physical context.

When the challenges of the environment exceed the capabilities of a person, that person is said to be disabled (Bilbao et al., 2003; Institute of Medicine, 2007). A person with impaired abilities and capacities, however, may be able to accomplish activities and tasks of his or her roles if the environment is adapted to enable that (Geusgens et al., 2010). Therefore, occupational therapy treatment may focus on changing the environment or context rather than on remediating the person's impaired abilities or capacities.

THE PROCESS OF OCCUPATIONAL THERAPY FOR PERSONS WITH PHYSICAL DYSFUNCTION

The process of occupational therapy follows the universal plan for problem solving: identify the problem, determine possible solutions, intervene, and evaluate the result. The occupational therapist, however, focuses only on problems related to the person's occupational life, including occupational balance. What a person needs to do, wants to do, and can do are identified. Discrepancy between what the person needs or wants to do and what he or she can do identifies the problem. The occupational therapist then uses various occupational, adaptive, and adjunctive therapies to intervene, or the occupational therapist may detect the person's dissatisfaction or stress caused by an occupational imbalance and intervene using educational therapies. The processes of the OFM and the OTPF are similar (Table 1-2). A discussion of the OFM process follows.

Assessment [Evaluation]

The hierarchical organization of the OFM indicates that higher level occupational functioning is established on a foundation of abilities and capacities. Assessment *always* follows a top-down approach. That is, the therapist determines what roles and tasks the person was responsible for in life before the accident or disease and what the person is expected to be, and wants to be, responsible for in post-rehabilitation life, including the context and environment in which the person typically engaged in these valued roles and tasks (Mathiowetz, 1993; Mayer, Keating, & Rapp, 1986; Trombly, 1993, 1995). The Role Checklist (Barris, Oakley, & Kielhofner, 1988; Colon & Haertlein, 2002; Cordeiro et al., 2007; Oakley et al., 1986), the Canadian Occupational Performance Measure (COPM) (Carswell et al., 2004; Eyssen et al., 2011; Law et al., 2005), and the Client-Oriented Role Evaluation (Toal-Sullivan & Henderson, 2004) are examples of assessments the therapist may use to gather this information. The therapist may also measure the patient's sense of self-efficacy concerning the ability to do the tasks required to fulfill particular roles by having the patient assign a number on a visual analog scale that ranges from 0 (not at all confident) to 10 (absolutely certain) for each major task that defines a specific role (Gill et al., 1994). For example, "on this scale from 0 to 10, how confident are you that you can prepare your own lunch without help?" Other assessments of self-efficacy are the Self-Efficacy for Functional Activities Scale (Resnick, 1999) and the Self-Efficacy Gauge designed especially for occupational therapists to measure the patient's current level of perceived self-efficacy and the change in perceived self-efficacy over time (Gage et al., 1994).

Wilcock et al. (1997), focusing on the importance of occupational balance, developed an assessment that can be used to gauge balance. It asks subjects to rate their current and ideal involvement in physical, mental, social, and rest occupations. A therapist can also determine whether the person feels that his or her life is in balance, and what the imbalance may be, through careful interviewing or the use of the Life Balance Inventory, which determines a person's satisfaction with time use in four dimensions: health (self-care), relationships, identity (e. g. vocational or social activities) and challenge (e. g. hobbies) (Matuska, 2012).

When evaluating a patient's competence to accomplish the roles he or she identifies as important, the therapist observes the patient attempting to do the tasks and activities, also identified by the person, of those roles in the most familiar context. The Assessment of Motor and Process Skills (AMPS) (Fisher, 2003), the Klein-Bell ADL Scale (Klein & Bell, 1982), the Barthel Index (Della Pietra et al., 2011; Mahoney & Barthel, 1965; Tennant, Geddes, & Chamberlain, 1996), and the Performance Assessment of Self-Care Skills (PASS) (Holm & Rogers, 1999; Skidmore et al., 2006) are examples of observational assessments

of tasks and activities. Using an assessment that structures observation of performance and having knowledge of the probabilities established by the diagnosis and age of the person, the therapist detects which of the myriad abilities and capacities assumed to be related to accomplishment of these activities are impaired (the process of activity analysis applied to assessment; see Chapter 12 for client-centered activity analysis procedure and example). The therapist then assesses these abilities and capacities more directly using assessments that have been validated and found reliable for the type of patient being evaluated. For example, if the patient's goal is to shave with an electric razor, but he appears to lack the grasp strength and endurance to do so, strength and endurance are assessed according to the procedures described in Chapter 7. A person whose abilities and capacities are found deficient may be treated to optimize them, allowing not only shaving but other occupations.

Some therapists prefer to use a bottom-up evaluation procedure in which capacities, abilities, and skills are assessed before occupational performance (Gutman et al., 2007; Weinstock-Zlotnick & Hinojosa, 2004). However, this practice often results in emphasizing these lower level factors without translation of the regained abilities to occupational performance. Furthermore, when this approach is used, the patient often fails to see the connection between therapy to optimize skills and abilities and achievement of his or her occupational goals.

The environment in which the patient will live, work, or play is assessed to determine whether it enables or hinders occupational functioning. Assessments of the home environment have been developed (e.g., Safety Assessment of Function and the Environment for Rehabilitation [SAFER] [Chui et al., 2002] and Home Occupational-Environmental Assessment [Baum & Edwards, 1998]), but assessments of other environments have not yet been developed (Letts, Baum, & Perlmutter, 2003). To assess the effects on occupational performance of other physical and social environments typical for the patient, the occupational therapist needs to observe performance under those conditions, using the process of client-environment fit activity analysis (see Chapter 12). In practice, this assessment usually occurs immediately before or after discharge from an inpatient rehabilitation setting.

Treatment [Intervention]

Treatment may focus on changing the environment (Raina, Rogers, & Holm, 2007), changing the impaired skills and abilities of the person (Lum et al., 2009), teaching specific tasks or activities using goal-directed training (Mastos et al., 2007), or teaching compensatory ways to accomplish activities and tasks. Treatment to improve occupational functioning, then, may start toward the bottom of the OFM hierarchy, focusing on optimizing abilities

and capacities; or it may start higher, at the activity level of the hierarchy, focusing on restoring competence in doing the activities and tasks of valued roles that the patient has identified as concerns; or it may start peripheral to the person, focusing on modifying the context or environment. The starting point should acknowledge the problem that the patient has identified as an immediate concern, although treatment may not actually start there. For example, if the patient identified resuming fishing as the goal, the therapist may choose to teach adaptive methods to enable that. If, however, the evidence and the experience of the therapist indicated that it would be more effective to start treatment by regaining finger dexterity to enable various activities related to fishing (e.g., baiting the hook and removing the fish from the line), the therapist must help the patient understand how treatment of this lower level ability addresses the stated concern at the task level. In addition, the therapist must ensure carryover of any gained dexterity to the fishing task. Optimizing impaired abilities and capacities is accomplished through remedial therapy in which a change in physiological structure, function, or organization is sought through occupation-as-means. If remediation of deficit abilities or capacities does not restore occupational functioning, if economic constraints prevent such thorough treatment, or if the patient is not committed to the extensive work required to recover abilities and capacities, a degree of competence can be restored using goal-specific training and/or adaptive therapy. Adaptive therapy seeks to find and promote a balance among the person's goals and environmental demands and his or her current capacities and abilities (Thoren-Jonsson, Moller, & Grimby, 1999). In this type of therapy, the method of doing an activity may be modified, assistive technology may be used to enable completion of the activity, and/or the physical or social environments may be modified. The person may be counseled to reassess the need to accomplish a particularly difficult activity alone and opt to employ another to do it.

Optimizing Abilities and Capacities [Intervention]

It is believed that remediating impaired sensorimotor, cognitive, perceptual, and emotional capacities and abilities to as high a level as a person's organic substrate allows will enable versatile performance of activities. Versatile performance allows the person to adjust to changes in the social and physical environments, whereas if a person learns only one compensatory response, adaptation to new situations is less likely. As in the typical development of these capacities and abilities, therapy engages the patient in circumscribed encounters with the environment using occupation-as-means. Using the example of the man who wanted to shave, the therapist might start treatment by providing a cuff to hold the razor to eliminate the need for grasp (adaptive therapy) and let the patient shave as

much as he could. Then the occupational therapist would finish the activity. Day by day, the patient's endurance for shaving would increase, and he would do more of the task on his own (occupation used as a means of remediation). Concurrently, the therapist would engage the patient in other activities that require grasp strength until the patient was able to hold the razor.

Occupation-as-means, that is, activities that provide stretch of soft tissues, active or passive movement to preserve and restore full range of motion, resistance and other stress to strengthen weak muscles, or graduated, increasing levels of aerobic exercise to improve endurance, is used to optimize motor abilities and capacities. The intervention techniques for optimizing abilities and capacities are described in Chapter 20; adjunctive therapies that support this approach are discussed in Chapters 15, 18, and 19; and the application of the approach, in combination with complementary approaches, is illustrated in Chapters 36–42.

When impairment of the CNS results in the inability to move voluntarily to effect a desired change in the environment, a therapist may use occupation-as-means in conjunction with controlled sensory input and ontogenetic or recovery-based developmental postures or patterns (augmented maturation) to facilitate change in first-level and developed capacities of sensorimotor organization. Whereas some therapists have anecdotally reported success using controlled sensory stimulation and developmental movements or postures to develop motor control, as described in the Bobath (1990), Brunnstrom (1970), Rood (1956), and proprioceptive neuromuscular facilitation (PNF) (Knott & Voss, 1968) approaches, there is little to no evidence in the literature to support these approaches. However, because some therapists do find aspects of these approaches clinically helpful, especially when there is a need to optimize first-level capacities, chapters describing these approaches have been preserved online (see pages 675, 677, 679 for access), but they have been removed from this textbook because we subscribe to the AOTA Centennial Vision: We envision that occupational therapy is a . . . science-driven and evidence-based profession. . . . (AOTA, 2008).

Alternatively, because of the preponderance of research that documents that neural reorganization occurs secondary to practice of goal-directed movements, the therapist may use motor learning principles in conjunction with occupation-as-end to bring about change in voluntary movement behavior (Mastos et al., 2007). The application of motor learning principles and methods of treatment for persons with CNS impairment is described in Chapters 13 and 21. This approach emphasizes motor performance using functional tasks, includes modification of the environment to improve task performance, and stresses practice that fits the nature of the task. The approach further heeds the research findings on the effect

of context on the organization of movement, which indicates that practicing a skill under simplified, non–context-specific conditions is different from practicing with an actual object in a context-specific situation (Mathiowetz & Wade, 1995; Trombly & Wu, 1999; Wu et al., 1998).

Restoring Competence [Intervention]

Restoration of occupational functioning depends on developing competence in the valued tasks and activities of the patient's life roles. Competence in tasks and activities is synthesized through successful engagement with the environment. Occupational therapists are skilled in developing graduated encounters with objects and the surrounding physical and social environments to promote successful performance. They are also expert in teaching compensatory methods to accomplish activities. Some therapists use this approach exclusively (Mayer, Keating, & Rapp, 1986). Others believe that first optimizing the impaired abilities and capacities requires less compensation and produces more versatility of performance. There is no research to support one point of view over the other.

When activity, task, and role levels of the OFM are dysfunctional, treatment may aim at making people as independent as possible in spite of any residual impairment. The occupational therapist will concentrate on helping a person find ways to compensate by reorganizing activity patterns or adapting techniques, equipment, or the environment. The goal is independence. People are considered independent when they perform tasks for themselves using assistive equipment, alternative methods, or adapted environments, as required, or when they appropriately oversee completion of activities by others

on their own behalf (Moyers & Dale, 2007). The therapist teaches the patient to recognize and use remaining abilities in adapted ways and teaches the principles and concepts of adapted methods so that the person can become an independent problem solver. For example, Chapter 24 explains how to help develop habits as a means of addressing cognitive-related performance problems that interfere with previously automated tasks. Therapeutic mechanisms of change include occupation-as-end, teaching-learning, and therapeutic rapport. The treatment procedures for restoring or preventing loss of role performance are described in Chapters 25–32.

SUMMARY

This chapter describes one model, the OFM, to guide the process of occupational therapy for persons with occupational dysfunction secondary to physical impairments and relates that model to the Occupational Therapy Practice Framework, which is an official document of the American Occupational Therapy Association concerning domain and process of the entire practice of occupational therapy. The framework needs an organizational model to guide assessment and intervention. That model can be the OFM, the Model for Human Occupation (MOHO) (Kielhofner, 2008), the Occupational Adaptation Model (Jack & Estes, 2010) or any number of other models (see Table 3-1) that complement your way of thinking and analyzing problems and that facilitate clinical reasoning. Furthermore, this chapter relates the OFM to the WHO ICF, an international classification of the effects of impairment and the process of rehabilitation.

case example

Mr. J.: Application of the Occupational Functioning Method to a Patient with Spinal Cord Injury

Occupational Therapy Process		Clinical Reasoning—Examples of Therapist's Internal Dialogue
Obtain Information About the Patient	Mr. J. is a patient with a spinal cord injury (SCI) (see Chapter 38 for a description of this condition, including special circumstances such as tenodesis grasp).	He can become independent in self-care and other tasks and activities important to him if he is willing to work hard. Even though he may choose, in the future, to employ a personal care attendant to help with dressing and personal care to conserve his energy, as many others with his level of SCI do, he needs to learn the adapted techniques so he can be independent if he needs to be.
	Diagnosis: fracture/dislocation of C6–7 of his spine in a diving accident. Status: post cervical laminectomy and fusion; medically stable. He exhibits C6 functional level.	
	Interview: Mr. J. is 24 years old, a college graduate, who lives with his parents in a second-floor apartment in a small city. He has four older siblings who are all married. He has many friends.	He will have to relocate to a first-floor apartment or to a building with an elevator. This needs to be discussed soon and a referral made to Social Services.
		His sociability should make developing rapport with him easy.
Evaluate to Identify Problem(s)	Interview: In addition to his role as independent person, Mr. J. identified self-advancement and self-enhancement roles of worker and sportsman.	Mr. J. values his roles as independent person, worker, friend, and sportsman. He appears ready to work to regain those roles.
	Mr. J's worker role was that of computer programmer. The company is holding his job for him. He identifies keyboarding as a major physical task of this role.	Although he cannot do keyboarding now because of paralysis of his fingers, he should be able to resume his job with adaptations and reasonable accommodations. However, he also needs to regain activities of daily living (ADL) independence, functional mobility, and commuter activities and skills in order to do so.
	Swimmer, basketball player, camper, and friend are his major self-enhancement roles.	
	The family is supportive, but they expect Mr. J. to be independent in self-care, with the prospect of resuming work, at discharge.	Because of the paralysis, he will need to learn adaptive methods of resuming his sports interests.
	Assessment: *Observation*: Mr. J. was unable to accomplish any tasks or activities associated with the independent person role; he is dependent in all basic self care.	There is no need to evaluate any other activities until he can do basic self-care activities. It will be frustrating for him.
	He is unable to move his lower limbs; movements of the upper limbs are weak and incomplete; unable to grasp. His sitting balance is poor.	I am going to introduce him to Mr. L. who has a similar disability and who is nearing discharge after gaining many skills and resuming several of his roles. It will let Mr. J. see the possibilities for recovery of his own roles.
	Measurement: Manual muscle testing revealed that Mr. J.'s proximal upper extremity musculature rated 4 to 5, with the exception of the triceps, which graded 2 (see Table 7-1, which describes muscle strength grading). Wrist extensors graded 3+ on the left and 4− on the right; wrist flexors and finger and thumb muscles graded 0 bilaterally.	He will need to learn adaptive ischial pressure relief methods and how to use tenodesis grasp.
Plan Intervention	During our planning conversation, Mr. J. agreed that treatment to increase the strength of his arms and to promote sitting balance would enable him to do the activities and tasks that he needs and wants to do. Again, he mentioned sports activities being important to him.	Weakness of the proximal upper extremity musculature, wrist extensors, and sitting balance can be improved through occupation-as-means that uses activities that provide Mr. J.'s current strength with a just-right challenge, one that is within his capability but also requires effort. The activity needs to be repetitious enough to build muscular endurance. Strength and endurance training will be done in tandem.

Implement Intervention	During occupational therapy, Mr. J. engaged in *occupation-as-means* to remediate the weakness of his upper arms and wrists and to improve his balance. He also engaged in *occupation-as-end* to learn adapted ways to accomplish important tasks and activities of his independent person and worker roles and to overcome environmental barriers.	I used simulated basketball shooting games (bean bag shoot, etc.) among other activities, and he enjoyed them enough to work hard while in the clinic. His enthusiasm is spurring on others and making his family less stressed.
	Because of paralysis of his trunk and lower extremities, Mr. J. is required to use a wheelchair, which needs to be adapted to allow propulsion without requiring grasp.	Because of his returning strength, he is able to accomplish more ADL each day. I determined his openness to using adaptive devices, and he was willing as long as the devices increased abilities. I must continue to organize those practice sessions to keep the physical and emotional demands within his capabilities.
	The physical therapist and I collaborated on developing his permanent wheelchair order, teaching him to use it and teaching and supervising his ischial pressure relief maneuvers.	Relearning basic ADL can be distressing; I am paying close attention to his emotional responses and make the opportunity to discuss these with him.
	Mr. J. and I enjoyed a beneficial *therapeutic relationship* in which he knew that I would not make demands for action that were beyond his capabilities and that I was available to help him work through his feelings of loss.	Mr. J has "down" periods but seems able to work through them with the help of the other group members and his own optimistic life outlook. He enjoys sharing new ideas and "tricks" with the others, as well as learning "tricks" of wheelchair usage from them.
	He participated in group *educational sessions* for social, emotional, and practical problem solving; members are other persons with similar activity limitations.	
Evaluate the Result	Mr. J. is able to wheel himself 50 feet on flat carpeting and is able to mount one step or curb with the wheelchair. He is happy with his progress and expects to develop more advanced wheelchair skills on his own.	The people he will be playing wheelchair basketball with after discharge are expert wheelchair users and will teach him their "tricks." He has the initiative and desire to become expert.
	Mr. J. uses gravity, momentum, and leverage to move his body in the wheelchair and bed.	The problem-solving skills he probably developed while camping and playing sports, and those he learned in therapy, have served him well in learning adapted techniques for self-care so he should be able to solve any new activity problem that presents itself after discharge.
	His proximal upper extremity musculature recovered to normal strength, but because the triceps remained at less than functional strength, he cannot elevate himself off the wheelchair cushion. Therefore, he learned an adaptive method of relieving ischial pressure to maintain skin integrity. Mr. J. was glad to take control and responsibility for regular pressure relief so I expect that he will be faithful to this procedure to prevent decubiti.	Ischial pressure relief is so important, I am sending a work sheet reminder and a programmed reminder alarm home with him to help him remember during the exciting transition time from hospital to home.
	Mr. J.'s wrist extensor strength improved to 4+ bilaterally, which allowed a functional tenodesis grasp. This enabled showering, dressing, and bowel and bladder management. He showers using a bath bench and handheld showerhead, and he dresses independently using adaptive methods and devices.	His time to do self-care will improve with practice, but I will remind him that for purposes of energy conservation, he may prefer to receive assistance with these activities.
	He keyboards using universal cuffs with typing sticks tipped with rubber ends. His computer is adapted to allow one-key depression for all operations. He feels ready to return to work; he plans on resuming work part time (noon to 4 pm).	His speed will increase with practice, but at some point he may be interested in returning to occupational therapy to evaluate strategies to boost his speed, such as speech recognition software.

This schedule will allow enough time for morning care. |
| | He plans on joining the local wheelchair basketball team. | Go, Mr. J.! |
| | Acknowledging his loss caused by the accident, he has worked hard in therapy and feels ready to resume his previous roles. | Mr. J. successfully completed this first phase of his rehabilitation. He will likely need intermittent rehabilitation "tune-ups" for many years as his interests, needs, and capacities change. For example, he may soon want to return to outpatient therapy to review technologies to assist him with his job and to resume driving. |

Clinical Reasoning in Occupational Therapy Practice

Treatment Planning for Mr. J.

When Mr. J. began occupational therapy, he had extensive impairments that prevented him from engaging in the activities and tasks of his valued roles. The occupational therapist, in collaboration with Mr. J., must decide what approach to take in treatment. What are the pros and cons of concentrating therapeutic intervention on restoration of activities, tasks, and roles (occupation-as-end) versus remediation of capacities and abilities using occupation-as-means?

Summary Review Questions

1. Describe the OFM.
2. In what ways are the OFM and the OTPF similar? Dissimilar?
3. What is the overall goal of occupational therapy for persons with occupational dysfunction caused by physical impairments according to the OFM? According to the OTPF?
4. Using the OFM as your model of practice, what would you assess first in a patient with stroke: level of spasticity of the upper extremity, ADL, or role history and expectations?
5. Define *ability* and *developed capacity*. Give an example of each. To what levels of the OTPF and the ICF do these terms correspond?
6. Define *task* and *activity*. Give an example of each. To what levels of the OTPF and the ICF do these terms correspond?
7. What distinguishes occupation-as-means from occupation-as-end?

Glossary

Ability—Competence in doing; natural aptitude or acquired proficiency (Merriam-Webster Online, 2011). A general trait an individual brings to learning a new task (Fleishman, 1972).

Activity, activities—In the Occupational Functioning Model (OFM), activities are considered small units of goal-directed behavior that make up tasks. The Occupational Therapy Practice Framework defines activity as a class of human actions that are goal directed; the term *occupation* encompasses activity (AOTA, 2008, pp. 629, 669). In the International Classification of Functioning (ICF), activity is defined as the "execution of a task or action by an individual" and includes everything a person does at any level of complexity from basic physical and mental functions of the person as a whole (e.g., acquisition of knowledge or grasp) to complex skills and behavior (e.g., driving a car or interacting with persons in formal settings) (WHO, 2001).

Activity analysis—A process used to identify the properties inherent in a given occupation, task, or activity, as well as the skills, abilities, and capacities required to complete it. Activity analysis is used to analyze and assess performance, to select occupations to remediate deficient capacities and abilities, or, knowing the person's skills, abilities, and capacities, to modify an activity or environment to ensure successful completion of the activity.

Adaptive therapy—Therapy that promotes a balance among a person's goals, capabilities, and environmental demands by use of assistive technology, adaptation of the environment or methods of accomplishing an activity, and/or redefinition of goals.

Augmented maturation—Therapeutic techniques that challenge further development of first-level capacities or developed capacities, such as controlled sensory stimulation and activities that promote responses in developmental postures or patterns.

Capacities—Potential attributes that, once developed into abilities and skills, will contribute to occupational functioning. Capacities are the basis of performance.

Context—Interrelated conditions in which something exists or occurs (Merriam-Webster Online, 2011). In health care, context has personal, social, cultural, physical, temporal, and situational dimensions, which together qualify a person's experience. In the OFM, context is considered the circumstantial milieu in which occupation occurs and may be fully understood.

Environment—The tangible objects, structures, or conditions by which one is surrounded and in which one's daily occupations occur. The aggregate of physical, social, and cultural conditions that influence the life of an individual (Merriam-Webster Online, 2011). In the OFM, environment is considered the encompassing surround in which the person accomplishes the activities and tasks of his or her life.

Functioning—An umbrella term encompassing all body functions, activities, and participation (WHO, 2001).

Impairment—Any significant deviation or loss of body structure or physiological or psychological function (WHO, 2001).

Occupation—The breadth and meaning of everyday activity (AOTA, 2008, p. 628).

Occupation-as-end—Occupation is the functional goal (activity, task) to be learned or accomplished. Its therapeutic impact comes from its characteristics of purpose and meaning (Trombly, 1995). Through repeated carrying out of an occupation ("task-specific training"), the patient will relearn the actions and routine of an activity, or through adaptation, the activity will be made possible for the person, given his or her current capacities and abilities.

Occupation-as-means—Occupation that is used as the therapeutic change agent to remediate impaired abilities or capacities. Its therapeutic effect derives from characteristics of purpose and meaning (Trombly, 1995).

Occupational balance—The distribution of occupations within a person's life. When the occupations are balanced, the person perceives him- or herself to be healthy or stress free; too much or too little of an occupation or type of occupation is unhealthy. The dimension through which satisfactory balance may be achieved differs for different people and at different times in one person's life. Dimensions identified to date are time (hours spent in self-care, play, work, and rest for example), degree of difficulty (challenging occupation versus relaxing occupation),

degree of self-focus (occupation is meaningful for the person versus being meaningful for others; care of one's self versus care of others) (Rogers, 1984; Stamm et al., 2009; Wilcock et al., 1997).

Occupational dysfunction—Inability to accomplish a necessary or desired occupational goal, for example, maintain one's self (i.e., care for self, dependents, and home); advance oneself through work, learning, and financial management; or enhance the self by engaging in self-actualizing activities that add enjoyment to life, because of either impairment of abilities and skills or environmental barriers. Occupational dysfunction is the focus of occupational therapy (Rogers, 1984).

Occupational Functioning Model—A conceptual model that guides occupational therapy evaluation and treatment of persons with occupational dysfunction secondary to physical dysfunction. The particulars of the model are as follows: (1) To engage satisfactorily in a life role, a person must be able to do the tasks that, in his or her opinion, make up that role. (2) Tasks are composed of activities, which are small units of behavior. (3) To be able to do a given activity, one must have certain sensorimotor, cognitive, perceptual, emotional, and social abilities. (4) Abilities are developed from capacities that the person has gained through learning or maturation. (5) These developed capacities depend on first-level capacities that derive from a person's genetic endowment or spared organic substrate (Trombly, 1993, 1995).

Participation—Ability to engage in all areas or aspects of human life, including the full experience of being involved in a practice, custom, or social behavior (WHO, 2001); involvement in a life situation (AOTA, 2008, p. 673).

Performance patterns—Patterns of behavior related to daily life activities that are habitual or routine, including habits, routines, rituals, and roles (AOTA, 2008, p. 673).

Performance skills—The abilities clients demonstrate in actions they perform, including motor and praxis, sensory-perceptual, emotional regulation, cognitive, and communication and social skills (AOTA, 2008, pp. 639, 673).

Self-efficacy—Perceived capability to perform a behavior (Williams, 2010). Belief in personal competence (Brock et al., 2009).

Skill—Competence in doing (Merriam-Webster Online, 2011).

Practical Foundations for Practice: Planning, Guiding, Documenting, and Reflecting

Mary Egan and Claire-Jehanne Dubouloz

Learning Objectives

After studying this chapter, the reader will begin to be able to do the following:

1. Describe aspects of clinical reasoning that shape provision of occupational therapy services.
2. Identify how different types of research and expert and patient evidence can inform practice.
3. Discuss issues related to determining the objective of therapy and identifying long- and short-term goals.
4. Describe the purpose of documentation and documentation requirements for occupational therapy services.
5. Commit to professional development plans based on continuous reflection on practice.

Occupational therapists, like all health professionals, use a process to plan, guide, document, and learn from their work with each patient. Throughout this process, there are many decisions to make. This process can seem overwhelming at first, but it does get easier over time. In some ways, implementing this process is like planning a trip.

To plan a trip, you need to decide where you want to go and the best way to get there. You also have to consider your resources, particularly how much time and money you have. Most importantly, if you are traveling with a partner, you have to be in agreement about where you are heading and how you are going to get there.

To help with your planning, you consult with maps, guidebooks, websites, and friends and family who have taken similar trips. You determine what information is the most trustworthy. For example, you are likely to be more confident about a glowing hotel recommendation from a trusted guidebook than about one from the website of that hotel.

Clinical reasoning in occupational therapy is a lot like going on a trip with a partner. First, you must determine whether you should be "traveling" together. This is *screening* to determine whether there are good reasons to enter into a therapeutic relationship with the patient. Next, you have to be sure that you are both in agreement about where you are going. This is the *overall objective of therapy*. You need to know how much time, money, and other means you have for the trip. These are the *resources* that you and the patient have at hand. You also must have a map to your destination. This is your *practice model*. You look for travel tips from people who have been there before. This is *research* and *expert clinical and patient evidence*.

Next, you sketch out your itinerary, including stops along the way, as best you can by combining all this evidence. These are your *intervention plan* and *short-term goals*. As you travel, you and your partner may change your plans a bit to respond to new challenges or opportunities. This is your *intervention implementation*. Often, at the end of the trip, you adjust plans toward a new travel goal. This is your *discharge plan*. An additional feature of occupational therapy is the creation of an official record of the trip. This is your *documentation*. Finally, because travel is such a big part of your life, you consider your experience and put plans in place to ensure that you continue to develop as a traveler. This is your *reflection and development plan*.

This chapter is structured around these basic considerations for practice. Note that these considerations inform the reflection involved in the major decision points regarding a particular patient's care and are summarized in Table 2-1. This table provides the outline for the case example format used throughout the textbook. Table 2-2 outlines the various ways in which this journey is documented. The chapter concludes with a discussion of the ways therapists reflect to improve their clinical competence.

SCREENING: SHOULD WE TAKE THIS TRIP?

Screening is defined as reviewing information relevant to a prospective patient to determine the need for further evaluation and intervention (Moyers, 1999). Therapists gather this information through chart review and a brief interview.

Occupational therapists review relevant documents in the patient's medical record before beginning assessment or treatment. Other team members' assessments (e.g., the physician's history and physical, social service or psychology intake notes, and nursing assessments) help the therapist create a preliminary clinical image related to disease, severity of illness or disorder, comorbidities, age, sex, and personal and social background (Rogers & Holm, 1991). After the chart review, the occupational therapist typically introduces him- or herself to the patient and/or significant other, informs them of the referral, and briefly describes the nature of occupational therapy and the anticipated services. The purpose of this conversation is to ensure the appropriateness of the referral and obtain preliminary consent for occupational therapy intervention. The conversation may take place during the first few minutes of the initial assessment session, such as with outpatients or patients receiving home care, or as a brief encounter in the patient's hospital room, with the assessment scheduled to take place later.

Required Documentation: Screening Note

If the screening suggests that the referral to occupational therapy is inappropriate or the patient does not wish to have occupational therapy, the therapist records that orders were received and a screen was performed and explains why further assessment and treatment appear unwarranted. If the screening suggests that occupational therapy is appropriate and the patient wishes to receive this service, the therapist documents this and, with the patient's input, proceeds to determine the overall objective of therapy. Table 2-2 shows the purpose of typical documentation throughout the occupational therapy process and what must be included.

OVERALL OBJECTIVE: WHERE ARE WE HEADED?

All health care intervention is focused on arriving at a particular goal. A key component of our profession is the ability and commitment of occupational therapists to consider the unique experiences and desires of each patient in determining the goal of our work. Using a structured interview, the clinician identifies the client's needs and goals in the context of his or her life (Fisher, 1998). Fisher extolled the value of this aspect of the assessment process: "This step is critical, and it must occur, even under the pressures of cost containment, reduced duration of care, staff cuts, and increased accountability. In fact,

Table 2-1   **Clinical Reasoning Underlying the Process of Delivering Occupational Therapy Services**

| Service Delivery | Clinical Reasoning Objectives | What the Therapist . . . | | Documents |
		Does	Thinks (Examples of Internal Questions and Self-reflections)	
Screen	Understand the patient's diagnosis or condition	Obtain and review background information	What do I know about the patient's medical diagnosis? What impairments, activity limitations, and participation restrictions are typical for individuals with this diagnosis or condition? Do the patient's records and information from referral sources suggest that occupational therapy services would be appropriate for this patient at this time?	Informal note-taking and record keeping
Assess occupational functioning	Know the person	Interview, listen, write	What do I need to know about this patient's current and past occupational functioning? What does the patient's past tell me about his or her priorities, strategies, and resources under the present circumstances? Which of the patient's current concerns relate to his or her occupational functioning? What seem to be the patient's main priorities regarding his or her occupational functioning?	Daily contact notes
	Appreciate the context		Are there social, cultural, personal contextual factors that may affect the evaluation or intervention process? Who should I talk with to better understand the patient's situation, occupational functioning, and/or needs? Where is the patient in his or her recovery relative to onset of the condition? What is the projected duration of this episode of care? What sorts of resources are available to support the occupational therapy process? What other medical, rehabilitation, and therapy services have been or are involved in the patient's care? What have been the outcomes of past or current services?	
	Reflect on competence	Consult others (as needed)	Do I have adequate experience, education, and training to provide occupational therapy services to this patient? If not, should I share responsibility with someone who can provide coaching or assistance? Should this patient be referred elsewhere for services?	
	Develop provisional hypotheses		What physical, cognitive, or contextual barriers may be interfering with the patient's occupational function?	
	Consider the evaluation approach	Select evaluation tools and methods	Do I want to observe function to make inferences about impairment? Do I want to assess specific impairments to make inferences about function? How can I use existing information from other disciplines to inform questions about barriers to occupational functioning?	Evaluation note

Table 2-1   **Clinical Reasoning Underlying the Process of Delivering Occupational Therapy Services** *(continued)*

Service Delivery	Clinical Reasoning Objectives	What the Therapist . . .		Documents
		Does	**Thinks (Examples of Internal Questions and Self-reflections)**	
	Consider the evaluation tools		Are there standardized assessments that will help specify the nature of the barriers to occupational functioning? What are the psychometric properties of these assessments (e.g., reliability and validity)? On what diagnostic groups have this assessment been tested?	
			What forms of evaluation or specific tools will put the patient most at ease, given what I know about his or her background?	
	Interpret observations	Administer evaluation; observe; take notes on performance	How closely am I adhering to administration instructions for standardized assessments?	
			Does the patient seem to understand the instructions?	
			What physical, cognitive, sensory processing capacities are challenged by this assessment?	
			What strategies or approaches does the patient use to perform the assessment?	
	Synthesize results	Write up evaluation findings	How does the patient's performance compare to that of others?	
			To what extent could the patient's performance have been affected by unrelated factors (e.g., fatigue, medication, pain, distraction, etc.)?	
			Do patterns emerge in the patient's performance across task or assessment?	
Plan intervention	Develop intervention hypotheses		What seem to be the most salient barriers (i.e., physical, cognitive, emotional, or contextual) to the patient's occupational functioning?	Intervention plan
	Consider the evidence		What type of intervention is supported by the best scientific evidence?	
			If limited evidence is available, what type of intervention approach do experts recommend? What kind of outcomes have I observed with past patients?	
	Select an intervention approach or model		What intervention approach or model has the strongest evidence of effectiveness in the rehabilitation research literature for patients similar to my current patient?	
	Reflect on competence	Consult others (as needed)	Do I have adequate experience, education, and training to provide occupational therapy services to this patient?	
			If not, should I share responsibility with someone who can provide coaching or assistance?	
			Should this patient be referred elsewhere for services?	
	Consider the patient's appraisal of performance	Discuss evaluation impressions and findings with patient and possible course of intervention	To what extent does the patient understand and/or agree with my hypotheses regarding barriers to his or her occupational functioning?	
			Given what I suspect are underlying barriers to occupational functioning, what does the patient seem to want to achieve in therapy at this time?	
			Are there any constraints on the length of time that I am able to provide services to this patient?	

(continued)

Table 2-1   **Clinical Reasoning Underlying the Process of Delivering Occupational Therapy Services** *(continued)*

| Service Delivery | Clinical Reasoning Objectives | What the Therapist . . . | | Documents |
		Does	**Thinks (Examples of Internal Questions and Self-reflections)**	**Documents**
	Consider what will occur in therapy, how often, and for how long	Specify treatment activities, time frame, and intensity	What specific techniques or activities should be used in therapy, given the approach I have selected and what I know about the person? What does the literature suggest about the optimal time frame, intensity, and duration of therapy needed to achieve results? If there is no scientific evidence in this area, what do experienced clinicians recommend about time frame, intensity, and duration?	
	Ascertain patient's endorsement of intervention plan	Discuss with patient and modify as necessary	What are the indicators that this patient understands the intervention plan that I've proposed? What are the indicators that this patient (and/or significant others) endorse the plan as proposed?	
Provide intervention and monitor progress	Assess the patient's comprehension	Provide instructions for therapy exercises, tasks, and activities	Does the patient seem to understand what I am saying? Am I using language or expressions that likely make sense to this person?	Daily contact notes
	Understand what the patient is doing	Observe patient's performance	What specific actions is the patient taking? What do the actions infer about how the patient is thinking or processing? Why does the patient appear to be performing in this manner?	Weekly and/or monthly progress notes Home programs
	Compare actual performance to expected performance	Discuss with patient; readminister selected assessments; modify the treatment plan as needed	To what extent does this patient's performance support my hypotheses regarding the nature of his or her barriers to occupational functioning? Is the patient's performance improving at the rate I anticipated? If not, why? To what extent is the patient adhering to home recommendations, exercises, and activities?	
	Know the person		What does the patient's performance tell me about who this patient is? How should these insights further shape the intervention plan?	
	Appreciate the context		Are there other possible factors that are interfering with his or her occupational functioning? If so, what might they be? Does the patient seem to understand what I am saying? Am I using language or expressions that likely make sense to this person?	
	Consider alternatives to current services		Is the patient making enough progress toward his or her occupational therapy goals to warrant continuation? Are the goals still appropriate? Would services from other providers be beneficial?	

Table 2-1 **Clinical Reasoning Underlying the Process of Delivering Occupational Therapy Services** *(continued)*

| Service Delivery | Clinical Reasoning Objectives | What the Therapist . . . | | Documents |
		Does	Thinks (Examples of Internal Questions and Self-reflections)	
Discontinue occupational therapy services	Anticipate present and future patient concerns	Write and discuss recommendations; together, develop an adherence plan	Given what I know about the diagnosis or condition, who he or she is, and his or her progress to date, what should this patient continue to do (or discontinue) to optimize his or her occupational functioning? What does the patient think needs to be in place to help him/her to adhere to the discharge recommendations?	Home program
	Analyze the patient's comprehension		Does the patient seem to understand what I am saying? Am I using language or expressions that likely make sense to this person? What other people in the patient's life also need to understand this information?	Referral
	Decide whether or when the patient should return for therapy	Plan for follow-up	Do I expect the patient's occupational functioning to change at some point in such a way that therapy should then be resumed? If so, when would it make sense to reevaluate the patient's need for occupational therapy services? Are there resources to pay for follow-up occupational therapy services? Does the patient seem to understand under what circumstances to contact me again, or should we schedule a time at which he or she will return? Are there other services in the community that this patient should be accessing at this point?	Discharge summary

there is some evidence that taking more time, initially, to establish client-centered performance will result in over-all outcomes being enhanced and overall costs reduced" (Fisher, 1998, pp. 515–516).

Many patients value the possibility of helping inform the goals of therapy (Holliday, Ballinger, & Playford, 2007). In fact, evidence supports the idea that intervention that considers patients' goals is more effective and efficient (Jack & Estes, 2010). Getting to know patients and their hopes for therapy is an important part of beginning the process (Holliday, Ballinger, & Playford, 2007). Learning about their preferences and needs regarding goal setting (for example, what information they might need to be able to participate in goal setting) is also important (Levinson et al., 2005).

There will be times when patients are not able to express their goals for therapy. For example, they may be overwhelmed by their personal situation, too ill, or simply unaware of what occupational therapy can offer. When working with such individuals, we have a responsibility to provide the support they need to participate as much as they can and to actively listen for their valued goals

(Hobson, 1996), rather than substituting them with ideas about what we think is best (Levack et al., 2011).

Once the overall goal is set, we can begin to use clinical reasoning to move toward achieving these goals.

CLINICAL REASONING: HOW ARE WE GOING TO GET THERE?

Clinical reasoning is the thinking process by which therapists collect and use information to make decisions about the care of an individual client (Rogers, 1983). Clinical reasoning is ongoing. It begins as the therapist first reads a patient's referral; extends through assessment, intervention, and discharge; and continues as the clinician reflects on the process and results of intervention with a patient as he or she plans therapy for another patient. Clinical reasoning in practice typically does not occur as a tidy progression of thoughts. It may appear cyclic or even chaotic as therapists dance back and forth between hypothesis testing and storytelling throughout each patient's care (Hagedorn, 1996). Note how the same internal questions and self-reflections in Table 2-1 are repeated at various junctures in the delivery of services.

Table 2-2 **Overview: Types of Occupational Therapy Documentation**

Documentation	Purpose	Typical Formats	Contents	When to Document
Contact, treatment or visit note	Brief account of an individual session	Short narrative note, checklist, or flow sheet	• Amount of time spent evaluating or treating the client • Brief characterization of intervention (e.g., activities of daily living instruction, strengthening, compensatory strategy training) • Description of client response relative to short-term goals	After each evaluation or treatment session
Evaluation report	Detailing of assessment findings, interpretation of results, estimated outcomes of intervention, goals, time frame, and treatment plan	• Therapist's observations and findings written or typed into a fill-in-the-blank form or template (as in an electronic medical record) • Handwritten or dictated and typed report	• Background information on the client (age, sex, and diagnosis); summary of medical history, secondary problems, and comorbidities; and precautions and contraindications • Referral source, services requested, date of referral • Date(s) of evaluation sessions and amount of time • Premorbid or prior level of functioning in occupational function; self-report of problems and priorities (Occupational Profile [AOTA 2002]) • Assessment results: scores, observations, summary, and analysis of assessment findings (Analysis of Occupational Performance [AOTA, 2002]) • Intervention plan: projected outcomes of therapy, goals, and time frame; statement of client participation in goal setting for therapy; general description of treatment plan (including treatment approach and recommended frequency of treatment sessions)	After completing the assessment, synthesizing the results, and collaborating with client about therapy goals
Progress report	Summary of progress toward functional goals, interventions employed, updated goals, and treatment plan	• Fill-in-the-blank form or template or checklist with section for handwritten comments • Flow sheet (as used with clinical pathways) • Handwritten or dictated and typed report	• Dates of service and dates of progress period • Number of treatment sessions during progress period • Overview of activities, techniques, and modalities used • Summary of instruction provided to client or family • Description of adaptive equipment issued or recommended • Client's response to intervention specific to therapy goals • Recommendations regarding continuation of therapy • Revised goals and time frame for achievement • Revised treatment plan (treatment approach and recommended frequency of sessions) • Statement of client participation in goal setting for therapy	Daily, weekly, or monthly, depending on setting
Discharge report	Review of occupational therapy assessment, intervention, and outcome	• Fill-in-the-blank form or template or checklist with section for handwritten comments • Flow sheet (as used with critical pathways) • Handwritten or dictated and typed report	• Dates of referral, service initiation, and discontinuation • Total number of evaluation and treatment sessions • Summary of client's progress toward each therapy goal • Overview of interventions employed specific to each goal • Description of maintenance program and discharge instructions • Recommendations for follow-up, maintenance programs, referrals to other services or agencies	After the last session in an episode of care

Wilson, D. (1997). Clinical reasoning for documentation. In J. D. Acquaviva (Ed.), *Effective documentation for occupational therapy* (2nd ed., pp. 1–3). Bethesda, MD: American Occupational Therapy Association.

The Three-Track Mind

In their classic study of clinical reasoning among American occupational therapists, Mattingly and Fleming (1994) observed that therapists reasoned with a "three-track mind," using procedural, narrative, and conditional forms of reasoning.

- *Procedural reasoning* refers to rational, linear thinking about the nature of the client's problems and the optimal course of action in treatment (Mattingly, 1991; Rogers, 1983). This thinking is generally based on logical ideas of "if, then" that therapists have learned in their courses and clinical training (Unsworth, 2004). For example, a therapist may think, "If my activities of daily living (ADL) assessment shows that the patient has trouble rising from the bath, then he needs some type of tub seat."
- *Narrative reasoning* refers to thinking in story form to place the client's functioning in the context of his or her background and broader experience (Schell & Cervero, 1993). Therapists employ narrative reasoning when they try to understand the meaning of disability in the patient's life in order to link the patient's goals and values to the therapy process (Mattingly, 1991). For example, a therapist may think, "This patient prides herself on her beautiful home. I should ask how she would feel about installing tub equipment, and if she has any ideas that could help minimize the impact of environmental adaptations on the appearance of her bathroom." Unsworth (2004) refers to this type of reasoning as "interactive" because it "is concerned with understanding the client as a person and his or her perception of events that have led him or her to see the therapist" (p. 11).
- *Conditional reasoning* uses therapist's understanding of the unique patient and his or her specific condition and life situation to predict what might happen if different therapeutic plans are carried out. For example, a therapist may think, "This patient will likely eventually need a roll-in shower. It may be distressing to think about disease progression. However, she has raised this issue of disease progression with me once. She would probably appreciate planning for the long term when considering any home adaptations right now."

Two Additional Tracks of Reasoning: Pragmatic Reasoning and Generalization Reasoning

Schell and Cervero (1993) added *pragmatic reasoning* to this classic list of types of occupational therapy reasoning. Pragmatic, or management, reasoning (Lyons & Crepeau, 2001) considers the logistics and practical aspects of delivering services to clients within a given setting or organization. Therapists employ pragmatic reasoning when they consider norms of the department or expectations related to accreditation, personnel, or reimbursement factors as they provide occupational therapy services (Schell & Cervero, 1993). In many ways, pragmatic reasoning places limits around what can currently be offered by the therapist. For example, a therapist might reason, "I think I understand the layout of this patient's bathroom, but I know that in a small space like this you really need to see and measure to determine the best equipment to recommend. Therapists do not normally do home visits from my facility. I need to ask if there are rules against this or whether I might be allowed to go. If I cannot see the patient's bathroom, I need to find a way to get more precise information."

Generalization reasoning is a subcategory in which a therapist's previous experience with patients judged to be similar to the specific patient whom they are treating adds to their knowledge about the situation (Unsworth, 2004). For example, a therapist might think, "I have had a lot of patients who never used bath seats that were recommended for them. I wonder what might keep this patient from using a bath seat, and whether there's anything we can do about this, or whether we need to find another plan?"

The Lenses through Which We See: Worldview

Overarching all these forms of reasoning are the therapist's preferences and skills and his or her worldview (Hooper, 1997). Worldview includes the therapist's values, beliefs, ethics, faith/spirituality, personal style, and motivation (Unsworth, 2004). Our worldviews serve as the lenses through which we see the world. These lenses affect *all* of our reasoning but are incredibly difficult to reflect on because we tend to take for granted that everyone sees things through similar invisible lenses. (Chapter 3 expands upon this topic in the discussion regarding personal context.)

Reflecting on one's worldview is an essential concurrent subprocess of reflection during the clinical reasoning process. Such reflection is particularly important when patients seem hesitant or even hostile regarding our recommendations. In these situations we must identify our own preconceived ideas regarding the patient's situation through critical reflection (Kinsella, 2000). For example, a therapist might think, "This patient gets help from her husband to take a bath. I think she could bathe alone if she had a bath seat. When I suggest this, she keeps telling me it will not work. Why is it so important for me that she be independent in this activity? Maybe there are other aspects of the situation, such as maintaining autonomy (that is, being able to carry out the activity in the way she wishes) or enjoying the intimacy that this shared activity involves, that are more important to her than my professional idea of independence."

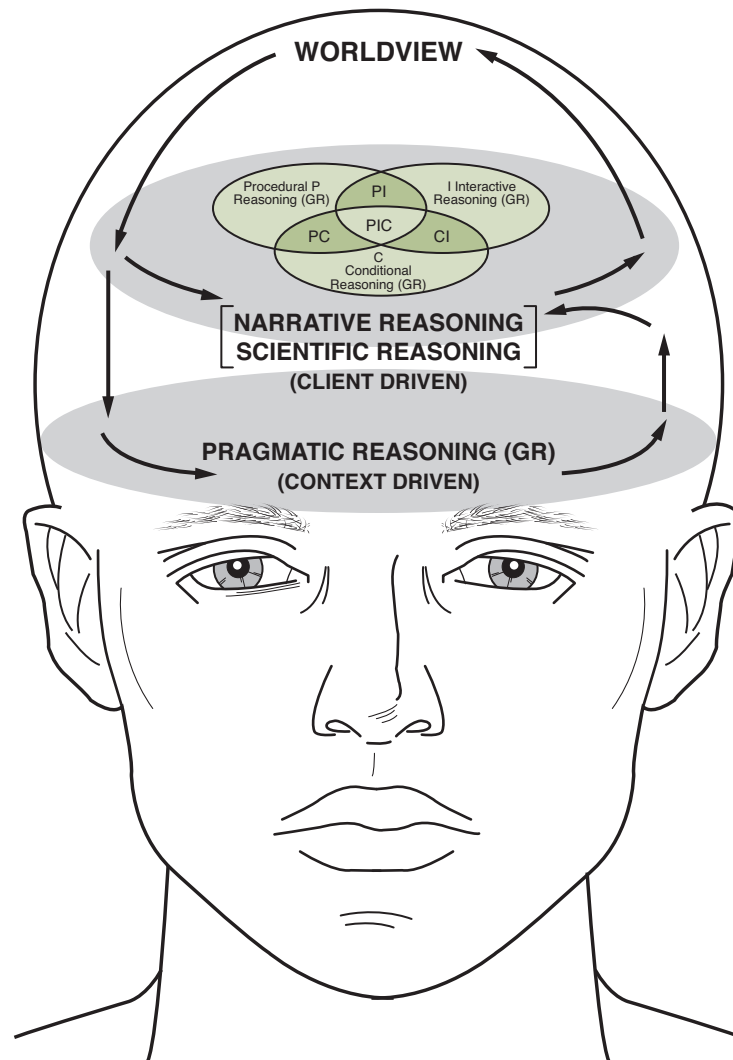
The interactive nature of the different forms of reasoning is illustrated in Figure 2-1. The reasoning of novice


Figure 2-1 Clinical reasoning in client-centered occupational therapy. (Reprinted with permission from Unsworth, C. A. [2004]. Clinical reasoning: How do pragmatic reasoning, worldview and client-centeredness fit? *British Journal of Occupational Therapy, 67*, 17. Note: Generalization reasoning (GR) is a subcategory of each type of reasoning in the model.

therapists tends to be dominated by procedural reasoning, a tendency to rely on formulas for practice and a reluctance to discuss potentially painful issues with patients (Mitchell & Unsworth, 2005). This seems to be part of beginning to practice. With experience, therapists more easily move between different forms of reasoning (i.e., procedural, interactive, conditional, and pragmatic forms of reasoning). Their thinking also flows more fluidly between the steps of assessment and decision making, and they more easily find ways to address difficult issues with patients (Mitchell & Unsworth, 2005).

Recently, Unsworth (2011) added another related consideration in clinical reasoning: the patient's reasoning. Patients have both theoretical information about their health and functioning (Krefting, 1991) and practical knowledge about living in their own bodies and in their own communities, particularly after many years with a particular condition. This information is a valuable resource for clinical reasoning.

Evidence-Based Practice: Adding Knowledge from Research

We have just discussed five aspects or tracks of thinking that run through an occupational therapist's mind as he or she reasons about what to do. We have also considered how these tracks of reasoning may interact with the patient's reasoning to influence the intervention plan. There is one additional important track: the evidence-based practice (EBP) track. In this track, the therapist considers evidence from research literature, the patient, and clinical experts regarding the potential benefits of specific therapy decisions.

In everyday life, we rarely make a decision without consulting some form of evidence. Should we take the bus, plane, or train to visit family at Thanksgiving? Any form of transportation that will not get us there should be ruled out immediately. Our final decision will likely rest on the relative cost (in dollars) and benefit (in time) of each of the remaining transportation methods. In occupational therapy, evidence helps us rule out ineffective actions and make the best choices from among the remaining options.

Evidence-based medicine has provided the starting point for evidence-based occupational therapy. In evidence-based medicine, intervention decisions are based on the "integration of best research evidence with clinical expertise and patient values" (Sackett et al., 1997, p. 1).

Which evaluations and which treatments to use are two of these important decisions. Information in Section II of this textbook will help you make evidence-based evaluation choices. An understanding of the different levels of evidence for the effectiveness of treatment, provided below, will help you make evidence-based intervention choices, which are further discussed in Sections V and VI. In this chapter, we examine how occupational therapists use experimental research, clinical practice guidelines, and qualitative research to guide intervention planning.

Guidance from Experimental Research

When properly designed and interpreted, intervention studies answer the question, "What is the benefit of this intervention?" This benefit is called the "treatment effect." Well implemented randomized controlled trials (RCTs) are the most trustworthy of intervention studies. To understand this, imagine a researcher trying to determine the level of effectiveness of an ADL retraining program for patients after a stroke. Using a pretest/posttest study design, the researcher measures ADL before the treatment starts, using the 100-point Barthel Index. After the intervention, the researcher reassesses the patients using the same test. She finds that the patients have improved, on average, by 15 points, which is judged an important difference. Can the researcher conclude that this occupational therapy intervention was effective? Unfortunately not. It is possible that these patients developed better skills on their own or with the help of other interventions they received in rehabilitation.

To control for these possibilities, the researcher carries out another study. Here she examines the average change in ADL for a group who receives the intervention (intervention group) and a group who does not receive the intervention (control group). She subtracts the change in the control group (which provides an idea of how much patients change over time without occupational therapy) from the change in the intervention group to determine the treatment effect of occupational therapy. She finds a treatment effect of 12 points, which is still considered an important change.

Although this is clearly a better estimate of the effect of occupational therapy on ADL, one serious problem remains. That is, were the patients who were put into the intervention group simply the patients in the study who were more likely to get better on their own? To control for this possibility, the researcher conducts a third study in which patients are randomly assigned to either the intervention group or the control group. This study is an RCT.

As stated previously, the treatment effect is calculated by subtracting the change in the control group from the change in the treatment group. The treatment effect represents an estimate of the average benefit of treatment experienced by the patients in the study. Researchers also generally provide an estimate of the confidence interval (CI) around this estimate. The CI provides an estimate of the average benefit of treatment that would likely be observed had the study been done repeatedly with different samples. In our example RCT, the researcher found a treatment effect of 10 with a 95% CI of 7–13, meaning that through statistical calculations, she estimates an average change somewhere between 7 and 13 in 95 out of 100 such studies of the intervention.

This estimate of effect is often presented as a standardized effect size. A standardized effect size is calculated by dividing the treatment effect by the standard deviation of the outcome variable in the population from which the study sample originated. Because this information is usually not available, it is estimated by the standard deviation of the control group or both groups (Coe, 2002).

For example, the researcher who carried out the RCT of interventions to improve ADL post stroke might calculate a standardized effect size so that she could compare her findings with those of another RCT in which a different test with a different scale was used. To do this, she divides the effect size she found (10 points) by the standard deviation in Barthel Index scores at baseline (15 points), giving her a standardized effect size of 0.67.

Some evaluations come with indications of what an important or clinically significant difference in the measure is. In other situations, the therapist estimates this number by looking at the scale and determining how much change would represent an important difference for a patient. Of course, this is something that can be done in consultation with the patient. For example, a 10° increase in fifth digit distal interphalangeal joint finger flexion for a violinist may be enormously important, whereas the same change for a professor may be virtually unnoticeable.

Although RCTs provide very strong evidence of the effectiveness of an intervention, systematic reviews provide even more robust evidence. In a systematic review, the researcher uses an established process to locate as many studies as possible regarding a particular intervention with a particular type of patient. This provides an overview of the results of many related studies. If these RCTs

examined similar outcomes, a meta-analysis can be performed by statistically combining the results. The result is a more precise estimate of the treatment effect.

Guidance from Clinical Practice Guidelines

Although a systematic review will provide a comprehensive summary of the anticipated effects of a particular treatment, clinical practice guidelines (CPGs), "statements used to assist practitioners to make decisions about appropriate health care for specific clinical circumstances" (Field & Lohr, 1990), generally focus on which types of care are most helpful for a particular condition. Therefore, they are generally broader in nature and particularly helpful to the practitioner.

A search for broad CPGs specific to a health problem of interest can provide helpful information for occupational therapy. For instance, evidence-based clinical practice guidelines for interdisciplinary rehabilitation of chronic nonmalignant pain syndrome patients (Sanders, Harden, & Vincente, 2007) provide guidelines for pharmaceutical and nonpharmaceutical interventions for people with chronic pain. Among the recommendations are "helping clients learn awareness of body mechanics and dynamic posture, initiation and activation of a long-term exercise program to gradually increase general fitness, strength, coordination, and a range of flexibility and motion, postural and muscle balance, as well as specific physical coping strategies" (p. 308). Additional recommendations include assisting clients to modify work and other activities and enabling clients to develop exercise routines they can incorporate into their daily routines.

It is important to know that not all CPGs are created equal. To considered high quality and trustworthy, a CPG must have been rigorously developed, using proper EBP principles and submitted for thorough, independent review. The AGREE II (an acronym for Appraisal of Guidelines for Research and Evaluation II) instrument can be applied to evaluate these and four other essential domains critical to a CPG that can be relied on to provide proper clinical advice (AGREE Next Steps Consortium, 2009). Applying this instrument to eight stroke-rehabilitation CPGs, Hurdowar et al. (2007) found widely varying quality. Therefore, it is helpful to be aware of the AGREE criteria when determining whether a particular CPG should be applied (Procedures for Practice 2-1).

To ensure that your interventions are informed by "integration of best research evidence with clinical expertise and patient values" (Sackett et al., 1997, p. 1), it is

Procedures for Practice 2-1

Criteria for Evaluating a Clinical Practice Guideline (AGREE II Instrument)

Domain 1: Scope and purpose

1. The overall objective(s) of the guideline is(are) specifically described.
2. The health question(s) covered by the guideline is(are) specifically described.
3. The population (patients, public, etc.) to whom the guideline is meant to apply is specifically described.

Domain 2: Stakeholder involvement

4. The guideline development group includes individuals from all the relevant professional groups.
5. The views and preferences of the target population (patients, public, etc.) have been sought.
6. The target users of the guideline are clearly defined.

Domain 3: Rigor of development

7. Systematic methods were used to search for evidence.
8. The criteria for selecting the evidence are clearly described.
9. The strength and limitations of the body of evidence are clearly described.
10. The methods used for formulating the recommendations are clearly described.
11. The health benefits, side effects, and risks have been considered in formulating the recommendations.

12. There is an explicit link between the recommendations and the supporting evidence.
13. The guideline has been externally reviewed by experts prior to its publication.
14. A procedure for updating the guideline is provided.

Domain 4: Clarity and presentation

15. The recommendations are specific and unambiguous.
16. The different options for management of the condition or health issue are clearly presented.
17. Key recommendations are easily identifiable.
18. The guideline describes facilitators and barriers to its application.

Domain 5: Applicability

19. The guideline provides advice and/or tools on how the recommendations can be put into practice.
20. The potential resource implications of applying the recommendations have been considered.
21. The guideline presents monitoring and/or auditing criteria.

Domain 6: Editorial independence

22. The views of the funding body have not influenced the content of the guideline.
23. Competing interests of guideline development members have been recorded and addressed.

important to abandon interventions that, although popular, have excellent evidence of *ineffectiveness*. That is, repeated well-designed studies have demonstrated that the interventions do not produce the intended effects. Also, you may wish to keep an open mind regarding new therapies with emerging research evidence. These interventions may not have been tested using RCT methods but may have some demonstrated evidence of effectiveness in studies such as single-case studies, which are often used to demonstrate potential effectiveness of an intervention before a full RCT is mounted.

Guidance from Qualitative Research

There is increasing interest in making use of the results of qualitative research in EBP. We return to our trip analogy to illustrate how this type of research can provide useful information for treatment planning.

Suppose that you and your partner have chosen to visit Nepal, a place you have never been before. In planning for the trip, you wish to learn a bit about the cultural aspects of Nepalese daily life, either from someone who has studied the culture (an ethnographer), gathered the stories of the people (a historian), or, better yet, from the Nepalese themselves. There may be specific aspects of life that most interest you. You may wish, for example, to better understand the experience of young children living at a very high elevation in the mountains of the Himalayas, the evolution of friendships in that context, or their family organization with regards to daily living. Qualitative research will be the best source for exploring these questions.

Qualitative research approaches are used to understand a phenomenon, provide an understanding of a historical and cultural view of a phenomenon (ethnography), a lived experience of people (phenomenology), a systematization of a social process (grounded theory), or the story of an individual living through a particular experience (biographical approach) (Creswell, 2013). Although quantitative evidence is often helpful in narrowing the choices so that intervention decisions can be made, qualitative evidence can help expand your understanding of issues related to developing a holistic view of a client. This might include issues related to practicing in a client-centered manner or interacting effectively with families and appreciating the experience of patients before, during, and after their treatments in rehabilitation—in short, multiple important aspects critical to the values and approach of occupational therapy.

Qualitative research reports can make you aware of a phenomenon, such as the lived experience of your client during occupational therapy, or provide you with a better understanding of a process, such as a patient's process of change during physical rehabilitation. For example, a metasynthesis of qualitative research done by an interdisciplinary team (Dubouloz et al., 2010) led to the construction of a model of personal change that patients may go through during rehabilitation.

Qualitative research uses three main tools to collect data: interviews, observations, and written and/or audiovisual documents. Semi-directed interviews are the most popular tool; they allow an open-ended style of interaction between researcher and participant in order to explore in-depth perceptions, values, and so on. Often, in the research report, key quotations from participants are used to express the essence of a phenomenon studied. Such quotations can enhance your ability to listen for the essence of your patients' experiences.

Just as with quantitative research, the results of some qualitative studies are more trustworthy than others. Those that can be most highly trusted clearly name the research process selected and plainly document the procedures used. In addition, four main criteria of rigor must be addressed: credibility, transferability, dependability, and confirmability (Lincoln & Guba, 1985).

The strategy of triangulation is well known as a way to assure credibility of the research process at the level of data sources (through use of multiple sources of data), data analysis (through the examination of data by more than one researcher), and data collection methods (through different ways of collecting data) (Creswell, 2013).

Practical Considerations for Using Evidence to Guide Practice

Sharing your findings with the patient regarding the best evidence available for decision making is an essential part of therapy. However, you must make sure that this evidence is understandable to the patient. Present it briefly and in plain language, with consideration of the strength of the evidence (Tickle-Degnen, 2008), providing details as requested. Finally, put the information in perspective. That is, the results of current research are the best estimates of average treatment effect for patients with similar characteristics rather than an exact prediction of what may happen with one particular patient.

It is very easy to become overwhelmed at the thought of having to review the evidence for every clinical situation. It is important to know that this is not possible or expected. Instead, we suggest four strategies to keep practice more evidence based (Straus et al., 2005). First, have a good idea of the major systematic reviews and CPGs available for patients with conditions you often see. Important EBP resources include the Cochrane Library, OTseeker, and American Occupational Therapy Association (AOTA) EBP resources. Second, if you work for an organization with a librarian, ask him or her to help you set up alerts for topics of particular importance to your patients. These regular e-mail notifications of relevant, new articles will help you remain aware of new and important research in your area. Third, set up a buddy system to share your information.

Fourth, keep a list of your clinical questions and review this list for themes. Do not hesitate to assign one of these questions to a student trainee (Phillips & Glasziou, 2008).

We see from the above discussion that EBP encompasses knowledge of quantitative and qualitative evidence, with consideration of the trustworthiness of this evidence. Tonelli (2006) points out that good clinical reasoning should take into consideration not only this research evidence but also experiential evidence, understanding of current theories of pathology and their relationship to function, patient goals and values, and aspects of the context in which one is working. These ideas are supported in discussions of client-centered, occupation-focused practice (Canadian Association of Occupational Therapists et al., 1999; Egan et al., 1998). Resources 2-1 provides evidence-based occupational therapy websites.

PLANNING INTERVENTION: YOUR JOURNEY WITH YOUR PATIENT PARTNER

Once the overall objective of occupational therapy is determined and the evidence has been considered, you begin to plan the specifics of your journey. The occupational therapist uses a practice model to begin to form a hypothesis regarding how best to understand the journey to the goal (i.e., what is causing current problems, what needs to be done to get to the overall objective, etc.). To do this, the occupational therapist carries out specific assessments and begins to estimate how the patient will journey toward this objective, reflecting on relevant research evidence. The occupational therapist shares these ideas

with the patient. Together they plot the *short- and long-term goals*, or milestones along the way to the objective, which interventions will be used, and how long it is likely to take to get to each step. Also, the occupational therapist and patient will discuss the anticipated outcomes of the current intervention (i.e., how far along the way to the overall objective the therapist will be able to accompany the patient and which resources the patient may use to continue this journey on his or her own).

Estimate Outcomes and Set Collaborative Goals

An outcome of therapy is an anticipated end result, given a specific set of parameters (Bryant, 1995). Outcomes are chosen, in part, according to expected length of stay, or anticipated number of outpatient or home-based sessions, and the type of funding available. The contemporary rehabilitation environment often requires clinicians to identify key expected outcomes for and with persons served, to measure these outcomes, and to determine how outcomes can be achieved in a resource-wise or cost-effective manner (Cope & Sundance, 1995). Interdisciplinary rehabilitation teams typically establish a plan of care for a given episode of care that delineates the overall patient-specific outcomes, with each discipline setting goals that contribute to these core outcomes.

The Occupational Therapy Practice Framework (OTPF) (AOTA, 2002, 2008b) suggests that the overarching outcome of occupational therapy intervention is to enable recipients to engage in occupations that allow them to participate in valued roles within their homes,

Resources 2-1

Evidence-Based Practice

The AGREE Collaboration (Appraisal of Guidelines Research and Evaluation) is an instrument for assessing the quality of clinical practice guidelines (www.agreecollaboration.org).

AOTA's Evidence Brief Series is a site available to members of AOTA that includes summaries of research related to occupational intervention related to various diagnostic groups (www.aota.org).

The Centre for Evidence Based Medicine is a site at University of Toronto that offers resources for understanding the steps for using evidence in practice and teaching others about this process (www.cebm.utoronto.ca).

The Cochrane Collaboration is the international organization that produces and disseminates hundreds of systematic reviews of health care interventions (www.cochrane.org).

Occupational Therapy Critically Appraised Topics contains critically appraised topics (short summaries of

evidence on a topic of interest focused around a clinical question) usually developed from several critically appraised papers (summaries of single studies) (www.otcats.com).

The Centre for Evidence-Based Rehabilitation is a site created by McMaster Occupational Therapy Evidence-Based Practice Group with results of systematic reviews of research evidence in interventions used by occupational therapists and forms and guidelines to critically review qualitative and quantitative research articles (www.srs-mcmaster.ca/ResearchResourcesnbsp/ResearchGroups/CentreforEvidenceBasedRehabilitation/tabid/543/Default.aspx).

OTseeker (Occupational Therapy Systematic Evaluation of Evidence) is a site created by a team of occupational therapists at the Universities of Queensland and Western Sydney with abstracts of systematic reviews and quality ratings of randomized controlled trials relevant to occupational therapy (www.otseeker.com)

schools, workplaces, and/or communities (AOTA, 2002, 2008b). This may be achieved through improvements related to (1) function (remediation of impairments); (2) occupational performance (independence in ADL, work, and play); (3) health and well-being (symptom status improvement and prevention of disability); and (4) quality of life (purposeful participation in community life, emotional well-being, balance of activity and rest, and life satisfaction) (Moyers, 1999). Global outcomes of occupational therapy intervention can also be identified according to resumption of self-maintenance, self-advancement, and self-enhancement roles (Trombly, 1993, 1995). In selecting and projecting treatment outcomes, occupational therapists are urged to look beyond functional independence or relearning of physical skills as the highest aims of occupational therapy (Radomski, 1995) and rather help patients attain wholeness, autonomy, meaning, and purpose in their daily lives (Crabtree, 2000).

Predicting therapy outcomes forces clinicians to answer two key questions in intervention planning: (1) In what broad ways will this client's life, health, and functioning improve as a result of therapy at this point in the recovery or adaptation process? and (2) How long will it take to realize these benefits? The answers require an appreciation for the continuum of care and a realization that not every dysfunction, impairment, or inefficiency can or should be addressed within a given episode of care. For example, resumption of self-maintenance roles may be an appropriate outcome for a patient who had a stroke and is expected to receive inpatient rehabilitation for 2–3 weeks. On the other hand, resumption of self-advancement roles would probably not be an appropriate outcome of inpatient rehabilitation. Occupational therapy services to promote work readiness can likely be provided more cost effectively when the individual is an outpatient. Treatment planning based on anticipated therapy outcomes not only reflects good stewardship but it is also required by accreditation bodies, such as The Joint Commission (TJC) and the Commission on Accreditation of Rehabilitation Facilities (CARF International).

Long- and Short-Term Goals

Once the occupational therapist and patient/family member conceptualize global therapy outcomes, they work backward to establish a sequence of long- and short-term goals to get there (Cope & Sundance, 1995). A goal is a measurable, narrowly defined end result of therapy to be achieved in a specified time (Bryant, 1995). Long-term goals reflect what will be achieved by the time the patient is discharged from treatment or discharged to the next level of care on the continuum (Moorhead & Kannenberg, 1997). In occupational therapy, long-term goals always relate to expectations of the patient's functional skills and/or resumption of roles. This is a tricky area insofar as attainment of

occupation-related goals among patients with very similar levels of disability varies widely. Therapists should always frame these expectations with the knowledge that individual patients may do better than expected. Because occupational performance is produced by a combination of person, environment, and occupation factors, there are many ways to reengage in valued occupations.

Short-term goals are the small steps that cumulatively result in long-term goal achievement. Short-term goals are based either on expected improvements specific to client factors (AOTA, 2002) or impairments that ultimately contribute to improved function or on the patient's improved ability to perform portions of the functional task (McGuire, 1997). A patient's occupational therapy goals are always linked to a predicted outcome and typically complement the work of other rehabilitation disciplines. Procedures for Practice 2-2 illustrates how long- and short-term goals support outcome realization. Definition 2-1 describes how to use goal-attainment scaling to measure progress.

Procedures for Practice 2-2

Linking Long- and Short-Term Goals to Anticipated Rehabilitation Outcomes

P. B. is a 20-year-old man with C8 tetraplegia beginning multidisciplinary inpatient rehabilitation. The following examples of outcome and long- and short-term goals are not meant to be exhaustive lists of intervention plans but rather to illustrate the linkage between global outcome projections and therapy plans.

- Projected outcome of rehabilitation stay: In 8 weeks, P. B. will resume self-maintenance roles, requiring no more than occasional physical assistance from family members to manage in the home environment.
- Examples of long-term occupational therapy goals (to be achieved in 8 weeks):

   1. P. B. will perform upper body dressing independently and require no more than moderate assistance for lower body dressing.
   2. P. B. will use adaptive equipment to feed himself independently.

- Examples of short-term occupational therapy goals (to be achieved in 2 weeks):

   1. P. B. will don a pullover shirt with no more than general verbal cues.
   2. P. B. will participate in the evaluation of various types of adaptive equipment for self-feeding and use selected aids to feed himself independently after set up by therapist.

Definition 2-1

Goal-Attainment Scaling

Goal-attainment scaling is a method for evaluating the effectiveness of therapy that produces a quantitative index of patient progress over time and a means by which one patient's progress can be compared with other patients in the same program (Ottenbacher & Cusick, 1990). Goal-attainment scaling was developed for use in the mental health field (Kiresuk & Sherman, 1968) and has been used to measure change as a result of cognitive rehabilitation (Rockwood, Joyce, & Stolee, 1997) and brain injury rehabilitation (Joyce, Rockwood, & Mate-Kole, 1994; Trombly, Radomski, & Davis, 1998; Trombly et al., 2002).

For each goal, a five-point behaviorally defined scale is constructed as exemplified below. Ottenbacher and Cusick (1990) provided an excellent summary regarding how quantitative outcome data can then be calculated and interpreted.

Problem area: Patient relies on other people to make transportation arrangements for her.

Predicted Attainment	Score	Goals
Most favorable outcome	+2	Patient accurately makes her own transportation arrangements without supervision or assistance.
Greater than expected outcome	+1	Patient accurately makes her own transportation arrangements with occasional cueing.
Expected outcome	0	Patient accurately makes her own transportation arrangements with ongoing supervision.
Current status	−1	Patient is provided with information about transportation arrangements made for her.
Least favorable outcome	−2	Patient is unable to successfully use transportation information provided for her.

Collaborating with Clients to Set Goals

Collaborative goal setting between clients and therapists, an accreditation requirement of CARF International (2011) and TJC (2011), presents benefits and challenges to both patients and therapists. Ponte-Allan and Giles (1999) suggest that the nature of goal setting may be linked with actual therapy outcomes. They compared patients whose goals were functional, independence-oriented statements with patients whose goals were general, less functional statements or who made no goal statements at all. Although there were no differences in age, sex, side of stroke, or levels of disability at admission, patients who had functional goals had higher discharge scores on the Functional Independence Measure™ for grooming, upper and lower extremity dressing, and toilet and tub transfers.

Collaborating with patients in goal setting is a critical counterbalance to therapist-biased expectations and priorities in treatment planning (Procedures for Practice 2-3); it reflects a philosophy of care rather than simply a periodic conversation between therapist and patient (Sumsion & Law, 2006). This practice philosophy requires that therapists tolerate the stress that can occur during goal setting (Foye et al., 2002) and remain attentive and flexible as patients' goals change throughout the recovery and adaptation process

(Donnelly et al., 2004). Therapists appreciate that many patients must be coached on how to participate in goal setting (Nelson & Payton, 1997), probing for concerns, goals, and ideas. Asking a patient, "What are your occupational therapy goals?" is likely to be met with a perplexed look and a vague response. As one patient put it, "Asking one question about goals on an initial evaluation is probably not adequate" (Nelson & Payton, 1997, p. 582). Clearly, the time and energy invested in collaborative goal setting not only benefits patients but also contributes to the empathic partnership that holds so much reward and satisfaction for therapists (Gahnstrom-Strandqvist et al., 2000).

Select Treatment Approaches and Methods

In Chapter 1, Trombly Latham outlines that intervention might focus on changes to the person, the environment, or the occupation to promote function. Intervention is also often discussed as focusing on remediation, adaptation, or metacognitive strategies.

Remediation

Remediation aims to restore an impaired capacity or ability with the expectation that this improvement will bring about

Procedures for Practice 2-3

Suggestions for Collaborating with Clients to Set Meaningful Occupational Therapy Goals

- Incorporate life history information into the assessment process so that you are able to get a glimpse of what the patient has found meaningful and important during the course of his or her life events (Spencer, Davidson, & White, 1997). Awareness of the patient's personal context enables the clinician to discuss, frame, or propose possible therapy outcomes and goals in ways that the patient will understand.
- Appreciate that patients' ability to identify and advance their goals for therapy will be influenced by where they are in the recovery and adaptation process. Individuals who are acutely ill or whose hospitalization has insulated them from the real-world impact of newly acquired disabilities will often be unable to anticipate the challenges that await them in the community. Outpatients or home-based clients are typically more able to articulate needs and hopes for therapy because of their experiences with performance gaps.
- Consider the broad continuum of care (inpatient to home health to outpatient to work reentry) as you aim to match the "right" goals with the "right" time frame by asking, "What does the person both value and need from occupational therapy at this point in his or her recovery?"

- Appreciate that many patients are unfamiliar with occupational therapy services and what we have to offer them and therefore are unable to independently generate goals for therapy. The therapist sometimes facilitates collaborative goal setting by proposing a menu of possible goals to address in therapy and modifying that list with the patient.
- Acknowledge the influence of cognitive function on a person's capacity to set meaningful goals. For a person to establish a meaningful goal, he or she must first accurately appraise his or her current status and compare it with past, or premorbid, performance. The individual must be able to imagine what is both possible and likely (given present condition and status) and how much time and effort is required to attain what is envisioned. Solicit input from family if the patient seems unable to independently determine or communicate his or her goals for therapy.
- If you are unable to arrive at consensus of broad therapy outcomes, try to agree on short-term goals. For example, a patient who is starting therapy 3 months after brain injury and wants only to work toward resuming his career as an air-traffic controller hopes for a broad outcome the clinician views as unrealistic. Instead of haggling over what the future may or may not hold for this individual (which dampens energy, hope, and motivation), the patient and therapist agree that, to return to work, he needs to be able to independently get ready each morning, so they can begin their work there.

general change in the patient's activities, tasks, and roles. Remedial approaches typically address body structures and functions (World Health Organization, 2001), which comprise client factors in the OTPF (AOTA, 2002, 2008b). Because it aims to fix underlying impairments, remediation may be somewhat slow to affect occupational function. Moreover, our current understanding of motor learning points to the importance of task-specific practice for improvement of particular tasks (Mastos et al., 2007; Mathiowetz & Haugen, 1995). A remedial approach is often emphasized when patients are in the early stages of recovery and rehabilitation.

Adaptation

An adaptive approach is used when the patient wants to optimize his or her level of independence while continuing to work toward restoration of fundamental capacities and abilities. Adaptive therapy entails three possible therapy actions: changing the context (e.g., modifying the environment or task demands), helping the patient reestablish habits and routines, and acquiring compensatory skills and metacognitive strategies.

Learning new skills and strategies generally takes longer to affect occupational function than, for example, does

changing elements of the physical context. Acquiring the skills to transfer in and out of a wheelchair, however, may have benefits that carry over to other activities also requiring such transfers, thus enabling performance of a number of occupational roles. To benefit from this approach, patients must value the new skills and strategies, wish to participate in training, and be capable of recognizing opportunities in which the new skills and strategies can be used.

Metacognitive Strategies

A promising new approach to adaptive therapy is the use of metacognitive strategies. Metacognition refers to the higher order thinking that allows individuals to set a goal, plan action(s) to meet the goal, monitor progress toward the goal, and adjust action plans accordingly. The approach was first applied in occupational therapy in child health, in programs such as the Co-op Approach (goal, plan, do, check) (Polatajko & Mandich, 2004). Using this approach, the occupational therapist acts as a coach, helping patients to move through the stages toward a self-identified goal. In later stages, the therapist helps the patient develop the ability to apply the strategy whenever he or she encounters a problem in occupational performance.

Early evidence strongly suggests that such strategies are also effective in improving performance in activities adults identify that they need and want to do and that these new problem-solving abilities may transfer to additional valued activities (McEwen et al., 2009; Skidmore et al., 2011; Toglia et al., 2010) (see further discussion in Chapter 24).

Determining the Optimal Treatment Approaches

As noted previously, wise treatment decisions are based on patient goals and values, research evidence, experiential evidence, understanding of current theories of pathology and their relationship to function, and aspects of the context in which one is working. Although the research literature and your own experience will often point you in the direction of a particular intervention, it is important to note that all interventions must be tailored to the specific patient.

For example, systematic review evidence demonstrates that occupational therapy is effective in improving ADL, such as dressing, following stroke (Steultjens et al., 2003). However, the patient you are working with, Jean, a 40-year-old woman who is the single parent of an 18-month-old girl, may be extremely concerned about how she will continue caring for her young daughter (see Case Example). You know, from your understanding of function, that she is probably quite capable of relearning to dress independently. However, she has told you that resuming child care is her only current goal. You use what evidence you can find on parenting and stroke (Rogers & Kirshbaum, 2010), what Jean tells you about her daughter, the tasks she needs to perform, her concerns, your knowledge of the stroke, and the common functional difficulties experienced by people who have similar stroke-related deficits (in this case, apraxia and fatigue). Working with Jean, you tailor an intervention that includes environmental adaptation, energy conservation, repetitive practice, and metacognitive techniques.

Required Documentation: Evaluation Note

An occupational therapy evaluation note is added to the medical record when assessment and treatment planning are complete.

Implementing Intervention

Once therapists collaboratively determine therapy outcomes, goals, and approaches, treatment begins. Clinicians continue to make decisions regarding how the treatment is best delivered (i.e., one-on-one or group treatment) and by whom.

How Treatment Is Delivered: Individual or Group Sessions

Occupational therapy occurs during one-on-one sessions with the patient or in pairs or small groups. Although clinicians must be sensitive to associated costs, they base scheduling decisions on each patient's unique needs and goals rather than solely on efficiency or the clinician's convenience.

Individual Treatment. Clinicians typically schedule individual sessions for assessment and reassessment. Individual sessions are also appropriate when patient privacy must be protected, such as during dressing training and when the patient seems particularly vulnerable or in need of emotional support. Patients who are easily distracted, such as those in early phases of recovery from brain injury, are also best treated individually.

Group Treatment. Groups typically consist of patients engaged in parallel activities, such as performing individualized exercise regimens at the same time and place, or in collaborative activity, such as preparing a meal together. Patients tend to be grouped according to similar goals, treatment, or education needs or to similar diagnoses, conditions, or limitations. Beyond its value from an economic standpoint, group treatment offers many benefits to patients. Group therapy can provide social support to patients as well as encouragement as they observe others mastering challenges similar to those they face.

Who Delivers Treatment

Economic trends in health care require that the most appropriate person perform therapeutic tasks to optimize efficiency (Russell & Kanny, 1998). Occupational therapists make decisions about who will carry out the treatment plan (occupational therapist and/or occupational therapy assistant. Occupational therapists orchestrate the treatment plan and are ultimately responsible for service delivery (AOTA, 2008a). They typically spend their time conducting evaluations, identifying problems, planning solutions, and supervising implementation (Dunn & Cada, 1998; Glantz & Richman, 1997). Occupational therapy assistants spend most of their time delivering direct service and documenting results (Dunn & Cada, 1998; Glantz & Richman, 1997).

Required Documentation: Daily Contact Notes

Each time the patient is seen for assessment and treatment, the clinician documents the contact (see Table 2-2).

Monitoring Progress

Clinicians continuously monitor client responses to intervention and their progress toward goals. At regular intervals, typically weekly for inpatients and at least monthly for outpatients, clinicians formally reassess status relative to goals, analyze barriers to and enablers of progress, evaluate effectiveness of the treatment approach, and make decisions about continuing, modifying, or discontinuing

treatment. If short-term goals are met but long-term goals are not, the short-term goals are upgraded (Moyers, 1999). If short-term goals are not met or performance has leveled off, the therapist examines and possibly modifies the treatment approach, reflects on the caliber of his or her skills with the treatment methods, looks for transient explanatory factors, consults with experts, and/or considers discontinuing therapy.

Required Documentation: Weekly and/or Monthly Progress Notes

Progress notes document the formal examination of the patient's progress toward treatment goals (Allen, 1997). For outpatients with Medicare, therapists also must complete monthly recertification forms detailing the patient's progress toward goals, which must be signed by the patient's physician every 30 days.

Discontinuing Therapy

Therapy is discontinued when goals have been met, the patient's performance has leveled off or deteriorated in such a way that he or she is not benefiting from services, or the individual chooses to stop. Ideally, the patient and family participate in discharge planning, which entails setting up a maintenance program, referring to other services, and/or planning for follow-up.

- Set up the maintenance program. Patients and families receive instructions that allow them to extend the benefits of treatment after discharge. Therapists typically provide written and oral information regarding continued exercise, recommended equipment, and strategies or techniques that optimize function. The plan must fit well with the patient's daily routine, incorporate the patient's goals, and be feasible given the patient's environment and resources. It is also essential that the patient has a clear idea of the goals of the program and how it works (Radomski, 2011).
- Help the patient establish an adherence plan. People with chronic health problems may have particular difficulty adhering to recommended maintenance plans for many reasons. It can be helpful to talk about this early on, normalizing the situation and allowing for later discussions of difficulties with adherence. The adherence plan can include ways to work the recommendations into daily routines, use of reminder systems, and provisions for monitoring outcomes, so that even slow progress or maintenance is recognized and provides reinforcement for adhering to the program (Radomski, 2011).
- Refer to other services. Many patients who discontinue occupational therapy at one site continue treatment at another level of care. For example, often persons receiving inpatient rehabilitation receive additional occupational therapy in long-term care facilities, through home health agencies, or as outpatients. To continue intervention seamlessly, therapists pass information along to the next tier of intervention. Therapists may also identify areas of need that are outside their scope of practice or competence and refer patients to appropriate disciplines or specialists.
- Plan for follow-up. Implicit in intervention plans geared to addressing the right issues at the right time in a patient's recovery and adaptation is the expectation that the therapist will not treat all possible problems during a given episode of care. A scheduled occupational therapy follow-up session is a mechanism by which the clinician can screen for the need for more services. A follow-up session is necessary when the patient improves, gets worse, or anticipates changed needs or goals or when the social or environmental context changes (Moyers, 1999). Some clients are ambivalent about discontinuing occupational therapy, recognizing lack of progress but fearing abandonment and stalled recovery or deterioration. Planned follow-up assures patients that occupational therapy services will be available to them if needed in the future.

Required Documentation: Home Program, Referrals, and Discharge Summary

Not only are written home programs and referrals provided to the patient and referral source, but these reports are also added to the medical record. The discharge summary provides an overview of services provided, outcomes, and recommendations. Allen (1997) suggested that creating this document can be a reflective process for the clinician, who considers whether goals were met and which factors contributed to or interfered with the patient's progress.

DOCUMENTATION: THE OFFICIAL RECORD OF THE TRIP

As a traveler, keeping detailed notes of your trip is a personal choice. However, occupational therapists are professionally and legally required to document their work with each patient in the medical record. This record is "a confidential, patient-identifiable, document or compilation of documents that chronicles the medical history of a patient throughout the course of his or her treatment at that facility or from that provider" (Iyer, Levin, & Shea, 2006, p. 3). This information will include therapy goals, assessment details, interventions provided, intervention outcomes, the patient's status at the end of therapy, and plans for discharge. Such plans may include further therapy or instructions to the patient regarding when he or she should contact the therapist again.

The AOTA (2008a) outlines several purposes of occupational therapy documentation. These purposes are to

- articulate the rationale for provision of occupational therapy services and the relationship of this service to the client's outcomes
- reflect the occupational therapy therapist's clinical reasoning and professional judgment
- communicate information about the client from the occupational therapy perspective
- create a chronological record of client status, occupational therapy services provided to the client, and client outcomes

In the course of their daily work, occupational therapists produce a number of reports, including daily contact notes, evaluation summaries, weekly or monthly progress notes, and discharge summaries (see Table 2-2). Documentation formats include computerized records, checklists, forms, and narrative notes. Regardless of format, to communicate in these documents, therapists must be clear about their target audience (McGuire, 1997; Robertson, 1997). That is, who will read this note and what do they need or want to know about the occupational therapy that was provided to this patient? Clinicians aim to provide succinct descriptions of functional status, anticipated outcome, and progress to date, so that a single document meets a number of stakeholders' information needs (McGuire, 1997). The reading audience may include members of the treatment team, who want to know how best to collaborate; the third-party payer, who wants to decide whether to pay for services; the accrediting agency, such as TJC or CARF International, which wants to determine whether quality services are provided at the institution; the legal system, which wants evidence in malpractice litigation; and the patient and significant others, who want to understand the care (Robertson, 1997).

McGuire (1997) outlined six principles that reflect excellent standards for occupational therapy documentation and meet the requirements of Medicare, the largest third-party payer in the United States.

1. Focus on function. Clinicians describe the patient's previous or premorbid level of function in key areas, review current status, and/or provide estimates of potential improvements or outcomes as a result of therapy.
2. Focus on underlying causes. Clinicians combine their understanding of the patient's medical condition with their assessment results to identify specific impairments that restrict or limit occupational performance.
3. Focus on progress. Clinicians describe the patient's progress toward goals according to objective measures, detailed observation, and/or standardized levels of independence.
4. Focus on safety. Many stakeholders look to the occupational therapist to provide information about the patient's safety and competence in self-management, self-advancement, and self-enhancement roles.
5. State expectations for progress or explain slow progress or lack of progress. Occupational therapists must "document a continued expectation that the patient's condition will continue to improve significantly in a reasonable and generally predictable amount of time" (McGuire, 1997, p. 441). Therapists should document setbacks that delay progress, such as medication changes, medical complications, and social disruptions.
6. Summarize needed skilled services. Occupational therapists avoid detailing the specific therapeutic interventions used during a given treatment session or period but emphasize the provision of skilled services. Skilled services include evaluations, direct intervention, such as training in techniques or strategies, task modification, selection or construction of equipment or orthotics, and instructions to the patient or caregiver about maintenance programs.

Because, as noted above, many of your readers will not be occupational therapists, ensure that the information is relatively jargon free. The greatest considerations for documentation, however, are accuracy and completeness.

Accuracy and completeness are essential because the document serves as a record of what you have done and found that others will refer to as they make their own treatment decisions. Importantly, in the event of legal action, the medical record will be called into evidence to act as a witness to the event. For this reason, all entries must be dated and signed, and any corrections made in such a way that the original entry can still be seen. Further charting guidelines and regulations may be obtained from TJC, your state department of health, and your employer (Iyer, Levin, & Shea, 2006).

The Health Insurance Portability and Accountability Act and Personal Health Information

The Health Insurance Portability and Accountability Act, 1996 (HIPAA) is a complex federal law designed, in part, to ensure the protection of personal health information (PHI). The "privacy standards" within this law present guidelines for the transfer of PHI (also known as *individually identifiable health information*) to another person or agency.

Individually identifiable health information refers to data that could be used to identify someone who has received health services. Any information that would allow another person to know that a particular patient has received health care services or to become aware of that patient's medical condition is individually identifiable health information. In addition to diagnosis, such information may include the treating physician, the patient's date of birth, the patient's social security number, and information regarding therapy.

Before transmitting PHI to another person or agency, therapists must explain to the patient where they plan to transmit the information and for what purposes. They must then obtain the patient's permission to do so. With the exception of emergency circumstances or when the information has been properly ordered as part of a judicial process, information cannot be transmitted without the patient's permission. Importantly, specific state legislation may have even stricter requirements for PHI transmission, and in these cases, state legislation determines the rules for such transmission (White & Hoffman, 2003–2004).

REFLECTION: BECOMING A BETTER TRAVELER

When a therapist considers what he or she has done, why it has worked or not worked, and what can be learned to strengthen work with future patients, the therapist is engaging in reflective practice (Crist, 2007).

Using Practice Experience to Improve Competence

You, as an occupational therapy professional, are ultimately responsible for assessing, improving, maintaining, and documenting your own competence to practice (AOTA, 2010; Youngstrom, 1998). As Holm (2000) reminded us, high standards of competence are inextricably linked to high ethical standards. Competence has many dimensions, including knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning (AOTA, 2010). Like occupational therapy services, continuing competence entails assessment, goal-directed action, and documentation.

Self-Assessment

The cornerstone of continuing growth of competence is reflection on yourself and your practice. Therapists deliberately and regularly take stock of their status and determine where they can grow. Clinicians interested in growth ask for feedback from peers and formally review their own performance. Schell (1992) recommended that clinicians annually outline their strengths, areas needing improvement, accomplishments of the past year, and goals for the coming year (see Procedures for Practice 2-3 for suggestions).

Goal-Directed Action

Having assessed your professional strengths and weaknesses, you have many ways to improve your competence, including the following:

- Participate in your professional national and state occupational therapy associations. During such volunteer service, you will encounter other occupational therapists who are committed to the profession and their own growth.
- Become a research-sensitive practitioner (Cusick & McCluskey, 2000). Make research evidence a vital part of the way that you provide services.
- Because even the most dedicated therapists make them (Scheirton, Mu, & Lohman, 2003), commit to learning from your mistakes. Reflect on your errors or inefficiencies, and consider what you would do differently should you face similar circumstances in the future. Be willing to discuss what you learn in this process with others.
- Establish a mentoring relationship. Mentors benefit from the relationship as they expand into new areas of practice, and protégés benefit from coaching and intellectual stimulation (Smith, 1992).
- Keep a journal to document information and questions; to reflect on ideas, concerns, and beliefs; and, ultimately, to identify learning needs (Tryssenaar, 1995).
- Start a journal club at work in which clinicians regularly read and discuss research articles relevant to their occupational therapy practice.
- Volunteer for medical record reviews and audits. By reviewing the documentation of others and submitting your documentation to the same scrutiny, you will learn how you can make your documentation clearer and more useful.

Documentation of Professional Continuing Education

Crist, Wilcox, and McCarron (1998) recommended that occupational therapists use "transitional portfolios" (p. 729) to plan and document their professional competence. More than a résumé or a curriculum vitae, the transitional portfolio features completed and exemplary work (e.g., certificates of attendance, awards, and articles), in-process projects and plans for professional development, and a reflective journal with ideas, goals, and feelings about one's reading, research, and work experiences. Resources available to clinicians include the professional development tool (which includes self-assessments, professional development plans, and portfolio template) developed for members of AOTA (AOTA, 2003). By systematically collecting and organizing information and artifacts specific to accomplishments, progress, and goals, occupational therapists take responsibility for their present and future professional competence.

In summary, occupational therapists feel competent when clients achieve results that translate into meaningful improvements in their daily lives (Gahnstrom-Strandqvist et al., 2000). Such results can be achieved as clinicians combine their knowledge of evidence with their insights regarding patients' values and goals to plan and implement intervention that is not only effective but also rewarding for patient and therapist alike.

case example
Ms. W.: Clinical Reasoning and Clinical Competence

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Jean W. is a 40-year-old woman who was admitted to a stroke rehabilitation unit 3 weeks after experiencing a stroke. She was referred to the unit for general rehabilitation.	Appreciate the context	"Why has Jean been referred to occupational therapy? How long will she likely be a patient on the unit? What does she want to achieve while she is here?"
In conversation with the therapist, Jean tearfully states that her only goal is to be able to care for her 18-month-old daughter, Annabel, who is currently staying with her sister. On the Canadian Occupational Performance Measure, Jean states that her only goal is child care and rates her current performance and satisfaction as 0. The occupational therapy discharge note from acute care mentions probable perceptual problems, possible memory problems, and lack of motivation for therapy.	Know the person	"I wonder if Jean's worry about being able to care for her child is sapping her energy to participate in therapy. I wonder about the current extent of her perceptual problems and how they might interfere with child care activities. I wonder if fatigue may also be a part of the picture."
The therapist and Jean agree that resuming her child care responsibilities will be the primary objective of her work in occupational therapy. The therapist explains what perceptual and cognitive problems are and how learning more about them can help the therapist suggest ways to work around their impact on daily functioning. The therapist consults Stroke Engine (strokengine.ca) for evidence-based advice regarding evaluation and carries out the recommended assessments. She also asks Jean to carry out a number of simulated child care tasks to get a preliminary idea of the probable impact of any perceptual problems on daily tasks.	Select evaluation tools and methods	"I wonder how the apraxia I'm seeing on evaluation will affect child care in real life? I wonder what the effect of fatigue is on these evaluations?"
The therapist tries to develop a deeper understanding of how the goal could be achieved, including environmental resources.	Consult others as needed	"Is there any literature about parenting and stroke? Or about parenting and other neurological conditions with similar impacts? Are there any experts in this area? Where does their knowledge come from? (This area seems to call for a combination of knowledge from research and personal experiences of other patients.) How can Jean's sister be a resource for her rehabilitation in this area? Does Jean consent to have me speak with her?"
The therapist explains to Jean that she has observed a mild apraxia on testing and some possible short-term memory problems that are worsened by fatigue. She states that she believes that within the 3 weeks of treatment available, Jean could likely get to the point of safely carrying out basic child care tasks with supervision. Further progression could be worked out through home-care occupational therapy.	Discuss evaluation impressions and findings with patient and possible course of intervention	"Jean's sister will be a key player in ensuring that Jean has the opportunity to progress after her work here (that is, through providing opportunities to gradually resume independent care of Annabel). I should include her as much as possible in planning and treatment, with Jean's continued consent."

Jean and the therapist work on daily sessions of graded activity and metacognitive strategies to solve problems related to child care tasks. In the second week of treatment, Jean's sister brings in Annabel so that she can practice these tasks in a more real-life situation. In the week prior to discharge, Jean tries these activities at home.	Specify treatment activities, time frame, and intensity; provide instructions for therapy exercises, tasks, and activities; and observe patient's performance	
On a reevaluation with the Canadian Occupational Performance Measure, Jean scores an 8 for performance and satisfaction with child care activities.	Discuss with patient; readminister selected assessments; and modify the treatment plan as needed	"Has the intervention led to the desired changes?"
Jean had no further financial resources for occupational therapy and was very concerned that she might not be able to continue moving forward in her ability to care for Annabel. During the last two sessions, the therapist provided Jean with general guidelines for grading her child care activities and provided a written copy of this document. Jean's sister attended the final occupational therapy session so that she could provide Jean with help and encouragement with future activity grading. The therapist also helped Jean find an online group for young stroke survivors.	Plan for follow-up	"What kind of support would help Jean continue to progress toward her objective? What resources are available (e.g., home care, support groups, etc.)? What kind of support would be acceptable to her?"

Clinical Reasoning in Occupational Therapy Practice

Going Home but Feeling Sad

After 3 weeks of occupational therapy intervention, you observe that Jean seems to have decreased interest and a slightly depressed mood during the intervention, especially when thinking about the near future of being home alone. What might be causing these feelings? How might these feelings be addressed during the occupational therapy sessions?

Summary Review Questions

1. You have just taken a position in small rural hospital where you, as the sole occupational therapist, see both inpatients and outpatients. You receive a referral to see Barbara Khouzam, a 63-year-old woman with osteoarthritis of the carpometacarpal joint of her dominant hand. Using the resources described in this chapter, find research evidence related to appropriate occupational therapy intervention.

2. Working in the role described in Question 1, you receive a referral to see George Lee, an 85-year-old man who has fractured a hip. He is being discharged tomorrow, and the referring physician is asking you to see him to recommend equipment to maximize his independence in toileting and bathing. In your interview with George, you learn that he is adamant that he does not need or want equipment. Write down your thoughts about this using at least three of the five clinical reasoning tracks described in the chapter.

3. You are working in a large rehabilitation center that employs 20 occupational therapists. You have been

assigned to a new unit for people who are experiencing disability as a result of lifesaving cancer treatment. List the types of information that Tonelli (2006) recommends should be included for best practice, and describe at least one specific source for each type as you take on your new responsibilities.

4. Draft two long-term and two short-term occupational therapy goals for a hypothetical client with multiple sclerosis who wishes to return to clerical work.

5. Write a brief statement (fewer than 25 words) that you could use to describe occupational therapy to a new client as a prelude to collaborative goal setting. Compare descriptions with classmates, and then share with family and friends who know little about occupational therapy.

6. Note which of the following pieces of information you can communicate under HIPAA provisions without the patient's consent:
   • The results of an assessment of ADL functioning to the patient's physiotherapist

   • The times and dates of occupational therapy sessions to the patient's employer
   • The results of cognitive testing to the patient's spouse

   For information that you are not allowed to communicate, state whether there are special conditions under which you would be allowed to communicate this information.

7. Knowing that the patient's file may be called into evidence as a "witness to the event" should legal action be taken, list everything that should be included in documentation and how corrections should be made if errors occur.

8. Describe what competence looks like in action regarding knowledge, critical reasoning, interpersonal abilities, performance skills, and ethical reasoning. Describe what incompetence looks like for each area.

Glossary

Accreditation—The process in which a health care agency is assessed by an outside body to determine whether it meets specific standards of quality and safe patient care (Nicklin, 2011).

CARF International—Founded in 1966 as the Commission on Accreditation of Rehabilitation Facilities, CARF International is an accrediting organization of health and human service agencies (CARF International, 2011).

Comorbidities—Medical problems additional to the diagnosis with which a person is referred to occupational therapy that may affect the anticipated outcome and/or treatment approach.

Continuum of care—A system of services of varying intensity that address the ongoing or intermittent needs of persons with disabilities, ranging from acute medical interventions to rehabilitation to subacute rehabilitation to home health services to outpatient treatment to community wellness opportunities (CARF, 2004).

Episode of care—A discrete interval of service provision related to the achievement of specific therapeutic goals. Patients typically participate in many episodes of care during the recovery and rehabilitation process.

Evidence-based practice (EBP)—The use of the current literature, client choice, expertise, and clinical judgment to best serve clients (Law & MacDermid, 2008).

Goal—Specific statements regarding key priority areas for intervention and specific performance levels to be attained by the patient for defined activities within a specified period (Holliday, Ballinger, & Playford, 2007).

Health Insurance Portability and Accountability Act, 1996 (HIPAA)—A U.S. Federal law that includes provisions to protect personal health information. The privacy standards within this law present guidelines for the transfer of personal health information to another person or agency (White & Hoffman, 2003–2004).

The Joint Commission (TJC)—A not-for-profit organization that is the oldest and largest health care facility accrediting body in the United States (TJC, 2011).

Outcome—The level of performance attained by the patient at the end of therapy.

Qualitative research—A type of inquiry carried out using inductive logic and an emergent design to describe, understand or explain a human phenomenon in depth and in relation to its context.

Randomized controlled trials (RCTs)—A type of study used to provide high quality evidence regarding the effectiveness of a particular intervention. Study participants are assigned by chance to either receive the treatment being studied or not. The average outcome of each group is compared to determine the effect of treatment.

Assessing Context: Personal, Social, Cultural, and Payer-Reimbursement Factors

Mary Vining Radomski and Pamela Roberts

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe personal, social, cultural, and payer-reimbursement contextual factors that influence occupational therapy assessment and inform treatment planning.
2. Employ methods for quantifying the influence of various contextual factors on performance.
3. Consider the ways in which contextual factors influence how the therapist delivers occupational therapy services.
4. Describe how contextual factors specific to payer and reimbursement shape the nature of occupational therapy services delivered within various levels of care.
5. Adopt clinical practices that combine "zooming in" to focus on the details of a given client's occupational performance and "zooming out" to examine the larger contextual picture.

M uch as a phrase, punch line, or couplet can be understood only in the larger context of a story, joke, or poem, a client's performance during occupational therapy assessment can be interpreted only in light of the broader context of his or her life, background, and/or circumstances. For example, lack of eye contact during an initial interview may easily be misinterpreted as lack of interest or motivation unless the therapist appreciates the contribution of cultural background—that avoiding eye contact is a way of showing respect in some cultures, including the Vietnamese culture (Farrales, 1996). Difficulty selecting clothing during a dressing assessment may be erroneously attributed to a patient's poor decision-making skills unless the therapist appreciates the contribution of social role experiences—that for 50 years, the patient's wife set out his clothing each morning.

The term *context* refers to the whole situation, background, or environment that is relevant to a particular event or personality. Contextual factors serve to characterize a situation and throw light on its meaning (*Webster's Third New International Dictionary*, 1993); together they provide the complete picture of an individual's life (World Health Organization, 2001). During the assessment process, occupational therapists try to obtain a complete picture of the patient's functioning, appreciating that a person's function at any moment is shaped by a dynamic array of contextual factors and not solely by his or her capacities, acquired skills, and abilities.

Occupational therapists are likely to best understand a client's occupational performance if viewed through a telephoto lens that zooms in and out. Borrowing from Kanter (2011), effective therapists are able to zoom in to bring details regarding a client's capacities, skills, and roles into focus and zoom out to see the bigger picture, including the influence of contextual factors on performance. Chapters 4–9 have to do with zooming in during the occupational therapy assessment process, and this chapter focuses on zooming out by describing examples of influential personal, social, cultural, and payer-reimbursement factors.

The role of context in occupational function cannot be exhaustively explored in one chapter; whole texts and careers have been devoted to each of these complex constructs. Clinicians need not obsess about correctly labeling or pigeonholing each and every contextual factor, but using these examples, readers are encouraged to reflect on other contextual factors not discussed herein. This overview, however, has one superordinate aim: to describe the potential contextual influences on occupational performance so that therapists may thoughtfully plan, conduct, and interpret the results of occupational therapy assessment.

CONTEXT AND OCCUPATIONAL FUNCTION

Occupational function is always embedded in context, with physical, cultural, social, and personal factors shaping its form (Nelson, 1988). Consider how contextual factors change the picture: a middle-aged homemaker preparing eggs and toast for her children before they leave for school versus a middle-aged homemaker preparing the same breakfast in an unfamiliar rehabilitation setting as part of an occupational therapy assessment to determine readiness for discharge after a mild stroke.

The important role of context in occupational function is described by a number of models and frameworks from occupational therapy, rehabilitation, and health fields. Each of the models or frameworks summarized in Table 3-1 emphasizes the dynamic relationship between a person; his or her cultural, social, and physical contexts; and the continuum of function to disability relative to chosen roles and tasks. The aforementioned models universally downplay the contribution of physical impairments and elevate the role of context in the explanation of human functioning and disablement but use slightly different terminology. Assessment Table 3-1 provides examples of measures that assess personal, social, and cultural context. In the occupational functioning model (OFM), occupation is presumed to occur and be understood within a unique contextual milieu that, while peripheral to a client's primary diagnosis, influences his or her occupational functioning (see Chapter 1).

- Personal context reflects an individual's internal environment derived from his or her gender, values, beliefs, cultural background, or state of mind.
- Social context refers to factors in the human environment (roles, resources, and structure) that enable or deter the person's occupational function.
- Cultural context has to do with the norms, values, and behaviors related to the community or society in which the occupational function occurs.
- Payer-reimbursement context refers to policies and regulations that determine availability and reimbursement of occupational therapy services in various settings.

The convenience of describing personal, social, cultural, and payer-reimbursement contextual factors as separate and distinct entities belies their complexity, interrelatedness, interactive, and dynamic influences. For example, one's culture may influence family structure, norms for coping, and such individual matters as food preferences, humor, and definition of personal space (that is, aspects of personal context). Likewise, personal context may influence social and cultural context in that a person's spiritual beliefs often shape his or her social network, preferred roles, and definitions of acceptable behavior. The relatively stable factors, such as age, generational

Table 3-1	Selected Models or Frameworks That Specifically Include Context as an Element in Human Function
Models and Frameworks	**Synopsis of Role of Context in Occupation and/or Human Function**
Ecology of Human Performance (Dunn, Brown, & McGuigan, 1994)	The interaction between a person and the environment affects his or her behavior and performance. Human performance can be understood only through the "lens" of context, which includes temporal (age, development, and health status), physical, cultural, and social features that operate external to a person. In essence, the interrelationship between person and context determines which tasks fall within the individual's performance range.
Person-Environment-Occupation Model of Occupational Performance (Law et al., 1996)	Occupational function is the result of the transactive relationship "between people, their occupations and roles, and the environments in which they live, work, and play" (p. 9). This model emphasizes the interdependence of person and environment (defined as those contexts and situations that occur outside the individual such as cultural, socioeconomic, institutional, and social considerations). It also recognizes the temporal or changing nature of person, environment, occupation characteristics, and their interrelationships.
Occupational Therapy Intervention Process Model (Fisher, 1998)	Occupational performance occurs as a "transaction between the person and the environment as he or she enacts a task" (p. 514). Therapists must be aware of the client's performance context (composed of temporal, environmental, cultural, societal, social, role, motivational, capacity, and task dimensions) in order to understand, evaluate, and interpret a person's occupational performance.
International Classification of Functioning, Disability, and Health (World Health Organization, 2001)	"A person's functioning and disability are conceived as a dynamic interaction between health conditions and contextual factors" (p. 10). Contextual factors include personal and environmental factors. Personal factors are internal influences of functioning that are not part of a health condition or functional state such as gender, age, social background, fitness, lifestyle, and habits. Environmental factors, external influences on functioning, include features of the physical, social, and attitudinal world.
Occupational Therapy Practice Framework (American Occupational Therapy Association, 2008)	The overarching outcome of occupational therapy is to advance clients' engagement in occupation to support life participation in the context of their unique situations. Defined as "a variety of interrelated conditions within and surrounding the client that influence performance" (p. 670), context (cultural, personal, temporal, and virtual) is included in the domain of occupational therapy.

cohort, and gender identity, may pervade most tasks and situations and are not easily changed in occupational therapy. For example, a patient's educational background may affect how the therapist provides home instruction but is unlikely to be a focus of intervention (Procedures for Practice 3-1). On the other hand, the more dynamic contextual factors, such as pain, stress level, and social dynamics, are transient, circumstantial, and potentially more responsive to environment, task, and therapy than stable contextual factors. For example, upper extremity pain that interferes with an individual's concentration likely varies with time of day and activity. Therefore, the therapist considers its effect on performance during all aspects of occupational therapy assessment and likely addresses the issue in the intervention plan.

Importance of Personal, Social, Cultural, and Payer-Reimbursement Context to Assessment

Paying attention to contextual factors is central to occupational therapy assessment for three key reasons. First, doing so provides the therapist with a more complete picture of the client, which in turn guides selection of assessments

and the interpretation of results. Scholar/researcher Mary Egan (2007) described an experience early in her career that illustrates the importance of considering contextual factors in planning the occupational therapy assessment. She reportedly started a cognitive-perceptual evaluation on a professor who was receiving rehabilitation after a stroke when 10 minutes into the session, he became enraged and demanded to return to his room. In hindsight, Dr. Egan realized how threatening her assessments must have been to a person whose livelihood and self-definition depended upon thinking, writing, and speaking. She speculated that the process would have been more effective had she begun by acknowledging his loss and suffering, educating him about the process and rationale, and then conducting the assessment with his approval.

Dr. Egan's experience highlights the importance of considering contextual factors when planning assessment. It is equally important to consider the influence of contextual factors when interpreting assessment findings as exemplified in the following scenario. Mr. S. appears to have difficulty attending to instructions during an occupational therapy homemaking assessment. The therapist might solely attribute the problem to cognitive

Assessment Table 3-1	Summary of Measures for Assessing Personal, Social, and Cultural Context				
Instrument and Reference	**Description**	**Time to Administer**	**Validity**	**Reliability**	**Sensitivity**	**Strengths and Weaknesses**
Rapid Estimate of Adult Literacy in Medicine (REALM) (Murphy et al., 1993)	Reading recognition test composed of a 66-item reading list that allows clinicians to estimate patients' reading skills	2–3 minutes	Concurrent validity: significant correlation ($p < 0.0001$) between REALM and standardized measures of reading including the Peabody Individual Achievement Test–Revised ($r = 0.97$), Wide Range Achievement Test–Revised ($r = 0.88$), and Slosson Oral Reading Test–Revised ($r = 0.96$) (Davis et al., 1993)	Excellent test–retest reliability ($r = 0.99$, $p < 0.001$)	No information	Strengths: Brief Minimal training needed Spanish version available The REALM-SF has only seven items on the reading list and has strong correlation with the REALM ($r = 0.94$, $p < 0.001$) (Arozullah et al., 2007).
CAGE Questionnaire (Ewing, 1984)	Involves asking four questions to persons seeking medical services to identify possible alcohol abuse	5–10 minutes	Convergent validity for four CAGE questions with alcohol-related items of the Army's Health Risk Appraisal ranged from (Φ coefficient) 0.1713–0.3496, moderately weak Criterion validity: persons with cutoff score of 2 were at 3.5 times greater risk for military discharge because of alcoholism (Bell et al., 2003).	Good test–retest reliability (2–30 days) for four questions (r ranged from 0.73 to 0.83) (Bell et al., 2003)	In a study of individuals with traumatic brain injury, specificity and sensitivity of CAGE were high (86% and 91%, respectively) (Ashman et al., 2004).	Strength: Appropriate for use with clinical populations Weaknesses: Poor sensitivity when modified to detect drug abuse or when used to determine preinjury substance abuse (Ashman et al., 2004) CAGE was shown to be unable to discriminate between those who were heavy drinkers and those who were not heavy drinkers in the general population (Bisson, Nadeau, & Demers, 1999).

(continued)

Assessment Table 3-1	Summary of Measures for Assessing Personal, Social, and Cultural Context (*continued*)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Numeric Pain Rating Scale (NPRS) (Jensen, Karoly, & Braver, 1986)	Presented as a vertical column of numbers (from 10 to 0), with 10 referring to "pain as bad as it can be" and 0 labeled as "no pain." The patient identifies the number (by pointing or circling) that best reflects pain intensity over the past 24 hours.	Approximately 2 minutes	Demonstrated construct validity in its ability to discriminate between patients with cervical radiculopathy (CR) who had made clinical improvements and those who did not (Young et al., 2010)	Moderate test–retest reliability, with an Intraclass correlation coefficient (ICC) of 0.76 (95% confidence interval of 0.51–0.87) for patients with mechanical neck pain (Cleland, Childs, & Whitman, 2008)	Minimal detectable change (MDC) (amount of change needed to exceed measurement error) of the NPRS varies by clinical population: 2.1 points for patients with mechanical neck pain (Cleland, Childs, & Whitman, 2008) and 4.1 points for patients with CR (Young et al., 2010). The threshold for minimal clinically important difference (MCID) (the smallest difference that patients perceive as beneficial) also varies by diagnosis: 1.3 points for those with neck pain (Cleland, Childs, & Whitman, 2008) and 2.2 points for those with CR (Young et al., 2010).	Strengths: Brief screening tool Widely used and understood by patients and professionals Involves interval data that can be analyzed using parametric statistics (Williamson & Hoggart, 2005) Weakness: Limited research regarding reliability and validity with neurorehabilitation populations
Fatigue Severity Scale (FSS) (Krupp et al., 1989)	Self-report questionnaire designed to evaluate the impact fatigue has on a patient. The patient rates the severity of his or her fatigue symptoms by reading each of the nine statements and circling a number from 1 to 7 (1 reflects strong disagreement with the statement, and 7 reflects strong agreement with the statement) based on how accurately it reflects his or her condition during the past week.	Relatively brief (approximately 3–5 minutes)	Convergent validity: FSS scores with other measures of fatigue including the Multidimensional Assessment of Fatigue and Rhoten Fatigue Scale (as summarized in Whitehead, 2009).	Test–retest reliability: Eleven subjects with fatigue-related conditions were retested after an average of 10 weeks in which no change in fatigue was clinically anticipated. Paired t-test differences were not significant; correlation coefficient was 0.84 (Krupp et al., 1989).	Based on test–retest values (Krupp et al., 1989), the minimal detectable change is 1.44 points.	Strengths: The FSS is brief and relates fatigue to daily functioning; it has been used on rehabilitation populations including multiple sclerosis, stroke, Parkinson's disease (Whitehead, 2009), and mild to moderate traumatic brain injury (Merritta et al., 2010). Weakness: Requires ability to read

	Description	Time	Correlation/Validity	Internal Consistency/Reliability	Sensitivity/Specificity	Strengths and Weaknesses
The Hospital Anxiety and Depression Scale (HADS) (Zigmond & Snaith, 1983)	Self-administered questionnaire designed to detect depression and anxiety in a medical outpatient clinical setting; composed of 16 questions related to psychological rather than somatic complaints	Less than 20 minutes	Moderate correlation between patient self-ratings on HADS and psychiatric interview assessment for anxiety ($r = 0.54$, $p < 0.05$); moderately strong for depression ($r = 0.79$, $p < 0.01$)	Good internal consistency (Cronbach alpha value of 0.83 for anxiety subscale and 0.84 for depression subscale) (Pallant & Bailey, 2005).	Good sensitivity and specificity for separate subscales with cutoff score of ≥8 (HADS anxiety: sensitivity 0.89, specificity 0.88; HADS depression: sensitivity 0.80; specificity 0.88) (Olsson, Mykletun, & Dahl, 2005).	Strengths: Brief screen such that patient could complete while waiting for appointment; Has been translated into Arabic, Dutch, French, German, Hebrew, Swedish, Italian, and Spanish; Appropriate for wide range of medical diagnoses. Weaknesses: Patients must be able to read in order to complete the HADS; Use of total score not adequately sensitive in identifying cases of psychiatric illness (Poole & Morgan, 2006)
Beck Depression Index (BDI) – FastScreen for Medical Patients (Beck, Steer, & Brown, 2000).	Self-report tool that screens for depression in adults and adolescents; composed of seven items extracted from the 21-item Beck Depression Inventory II.	Less than 5 minutes to complete	Construct validity: moderately strong correlation between BDI-FastScreen and HADS ($r = 0.62$, $p < 0.001$)	Good internal consistency (alpha values of the BDI-FastScreen for family practice, internal medicine, and pediatric patients were 0.85, 0.85, and 0.88, respectively) (Beck, Steer, & Brown, 2000)	BDI-FastScreen cutoff score of ≥4 had 100% sensitivity and 84% specificity rates (Scheinthal et al., 2001).	Strengths: Very brief with good psychometric properties; Responses to BDI-FastScreen not related to sex, ethnicity, age, or total number of medical conditions (Beck, Steer, & Brown, 2000). Weakness: Does not specifically inform occupational therapy intervention planning; serves only to identify persons in need of referral for more in-depth psychiatric assessment
Norbeck Social Support Questionnaire (NSSQ) (Norbeck, Lindsey, & Carrieri 1981)	Self-administered questionnaire consisting of nine items; patients list individuals in their personal network and specify the nature of their relationship; measures three functional types of social support (affect, affirmation, and aid)	Approximately 10 minutes	Concurrent validity: statistically significant correlation with the Personal Resources Questionnaire, another measure of social support ($r = 0.35-0.41$, $p < 0.05$) (Norbeck, Lindsey, & Carrieri, 1983)	High degree of test-retest reliability (0.85–0.92) High internal consistency within three types of support (0.89–0.97) (Norbeck, Lindsey, & Carrieri, 1981)	No information	Strength: Instrument may provide useful structure for interviewing clients about the nature of their social support. Weakness: Specific subscale scores may be more relevant to research than practice.

Procedures for Practice 3-1

Assessing Literacy

Health literacy pertains to a person's ability to process and comprehend basic health information necessary to make decisions (Institute of Medicine, 2009); a person's ability to read is part of this basic competency. Clients with low literacy may try to hide their difficulties with reading, compromising the assessment and the value of written home instructions (Parikh et al., 1996). Occupational therapists use written materials in assessment and treatment. Use of a reading screen allows the clinician to identify patients who need simplified, audiotaped, or pictorial education materials.

The Rapid Estimate of Adult Literacy in Medicine (REALM) (Murphy et al., 1993) is a widely used reading recognition test that takes 2–3 minutes to administer and score. It contains three columns of health-related words of increasing difficulty, 66 words in all. The client is asked to start at the top of list 1 and read the words aloud until he or she completes the three lists or is unable to read additional words. He or she is allowed 5 seconds to pronounce each word. The clinician takes note of all words pronounced correctly; this number becomes the raw score that is converted to grade range estimates.

Recently, researchers developed a seven-item version of the REALM, called the Rapid Estimate of Adult Literacy in Medicine–Short Form (REALM-SF) (Arozullah et al., 2007). The REALM-SF has excellent agreement with the original instrument. Online access to the REALM-SF word list, scoring instructions and interpretation, and a Spanish version is available from the Agency for Healthcare Research and Quality (2009).

impairment related to his right cerebrovascular accident if she did not know that Mr. S. was awake much of the previous night, as nurses addressed his roommate's deteriorating medical condition.

Second, paying attention to contextual factors may impact the outcome of occupational therapy services by informing the focus of intervention. A qualitative study involving rural women with HIV/AIDS underscores that sometimes patients care more about contextual factors (such as paying the bills and interacting with family) than the illness or condition itself (Phillips et al., 2011). The following example illustrates how the therapist may need to address issues related to social context in order to help the patient achieve his or her goals. Even with adequate strength and mobility, Mrs. P. remained dependent in lower extremity dressing after her total hip replacement because her husband, fearful that she may overexert, insisted on assisting with dressing. Because independence was important to Mrs. P., the therapist taught Mrs. P. lower extremity

dressing techniques and taught Mr. P. how to support the process without providing physical assistance.

Finally, therapists employ what they learn about the context of patients' lives (past and present) during assessment to improve engagement in the occupational therapy intervention process itself. For example, "knowing what makes them tick" can improve participation for persons with dementia (Galik, Resnick, & Pretzer-Aboff, 2009), and simple awareness of nursing home residents' life story appeared to help staff form empathetic relationships, which in turn appear to help reduce agitation (Egan et al., 2007).

Looking in the Mirror: Therapist as Contextually Influenced Being

Appreciating the influence of context on function requires that therapists acquire a complex combination of knowledge, attitudes, and skills. Rather than focusing on how a client fits into the therapist's world (via assumptions, schedule, and conventions), the therapist examines how he or she can understand and fit into the client's world (St. Clair & McKenry, 1999). To accomplish this shift, therapists must acknowledge and inventory the contextual factors that influence their own function. As I become aware of my own beliefs and biases, social background, and culturally based expectations, I will be able to appreciate their influence on collaborations with patients and coworkers (Odawara, 2005).

PERSONAL CONTEXT

"Life is suddenly reduced to a one dimension picture, known as physical function, and continually referred to as 'outcome.' The typical outcome process ignores . . . emotional and interpersonal needs and skills. Within those parameters lies the answer to true recovery . . . I refuse to have an 'outcome.' I do have a *life*!" (Cannon, 1994, p. 3)

Personal context refers to the intrapersonal environment that shapes an individual's experience. These factors play a role in determining the client's unique response to the onset of illness or impairment and contribute to his or her ability to adapt (National Center for Medical Rehabilitation and Research, 1993). Some aspects of a person's internal environment, such as age and long-standing beliefs, are stable; others, such as pain, mood, and adaptation to illness or injury (see Chapter 30), may be constantly in flux.

Age and Generational Cohort

A person's age or age at onset of disability appears to have implications for length of stay and outcome of rehabilitation, with elders generally having longer lengths of stay and poorer outcomes (Graham et al., 2010; Sendroy-Terrill, Whiteneck, & Brooks, 2010). A person's age may influence

rehabilitation outcomes and his or her occupational functioning in three primary ways: (1) age-related changes in capacities and abilities; (2) developmental shifts in goals, values, and priorities; and (3) the individual's generation-based worldview.

In tandem with age-related changes in capacities (which are discussed in Chapter 32), Royeen (1995) hypothesized that people undergo "occupational shifts" (p. 11) during the life cycle that lead to major changes in patterns of activity. She posited that early adulthood is characterized by establishing worker roles while realigning social roles to adjust to marriage and parenthood. In middle adulthood, people maintain work and leisure roles but may undergo sudden occupational shifts related to caregiving roles of parents, children, and grandchildren. During maturity (age 45 years to retirement), people continue their work and leisure roles, but occupational shifts arise from death of family members, loss of provider status, and adjustments in life goals. An increased awareness of the limits of time appears to shape people's priorities and occupations as they age (Carstensen, Fung, & Charles, 2003). Older people tend to seek activities that create or develop emotional bonds and that contribute to life meaning more so than young adults, and these motivations actually have a positive impact on well-being for many elders (Carstensen, Fung, & Charles, 2003).

A person's generational cohort (group who share the same birth years and specific defining experiences) may also impact occupational performance through his or her attitudes and beliefs (Kramer, 2010). Consider the ways in which generational identity may influence participation in occupational therapy and interactions among intergenerational occupational therapy colleagues from four contemporary generational groups in the United States:

- The Veterans (born 1925–1945) respect authority, hierarchy, and believe that sacrifice and hard work pay off (Kramer, 2010).
- Baby Boomers (born 1946–1964) value independence, creativity, and prefer work that offers both personal reward and public recognition (Kramer, 2010).
- Generation Xers (born 1963–1980) tend to prioritize work-life balance and self-reliance and may need clarification regarding how tasks perceived as menial relate to larger goals (Kramer, 2010).
- Millennials (born 1980–2000), who tend to be practical and techno-savvy, have a unique appreciation for diversity—variety in people, environments, and activities. They are accustomed to participant-oriented decision making and expect to work in collaboration with others in their endeavors (Lancaster & Stillman, 2002).

Of course, generalizations about patterns of aging may or may not apply to specific individuals, and therapists are cautioned against age-related patient biases (Rybarczyk et al., 2001). Catastrophic loss of function, as with illness or disability, is an individual experience that takes place against a backdrop of other age-related changes, developmental tasks, and worldviews. For example, a person's adaptation to a spinal cord injury (SCI) may occur as he or she is also adapting to a new marriage or career. An elderly patient's efforts to relearn motor skills and standing balance may be complicated by declines in capacities associated with age and beliefs that if a person works hard enough, he or she will always achieve goals. A client who has lived and aged with a long-standing disability will likely have different health concerns and vulnerabilities than a young person with a new injury (Amsters et al., 2005).

Symptoms: Pain and Fatigue

A patient's intrapersonal environment is also shaped by his or her ongoing experience with symptoms such as pain and fatigue that influence both assessment and functioning. Occupational therapists try to understand the extent to which these symptoms contribute to the patient's performance during assessment.

Pain

Pain, acute and chronic, interferes with occupational function and quality of life for many people receiving occupational therapy services (Ehde et al., 2003). People with spinal cord injury who use manual wheelchairs report upper extremity pain, with the most severe pain occurring while pushing the wheelchair up an incline and during sleep (Curtis et al., 1999). Dalyan, Cardenas, and Gerard (1999) found that upper extremity pain was associated with lower employment rates and greater disability for outpatients with spinal cord injury. Many stroke patients have upper extremity pain as well, typically beginning 2 weeks after the onset of stroke (Chantraine et al., 1999). In addition to its contribution to disability and to decreased quality of life, pain is linked to depression (Dalyan, Cardenas, & Gerard, 1999), inefficiencies in information processing (Luoto et al., 1999), and coping strategies (Molton et al., 2009).

Many people with disabilities are used to living with pain and differentiating between usual pain and unexpected pain (Dudgeon et al., 2006). Because many recipients of occupational therapy services may be reluctant to mention their concerns about pain to therapists (Dudgeon et al., 2002), therapists take responsibility to routinely ask and/or assess. One commonly used subjective measure of pain is the Numeric Pain Rating Scale (NPRS) (Jensen, Karoly, & Braver, 1986).

Numeric Pain Rating Scale. The NPRS is a brief self-report questionnaire in which patients rate their pain intensity using an 11-point scale (Jensen, Karoly, & Braver, 1986).

Patients are asked to circle or point to one of the numbers that are listed vertically on the page (where 10 indicates pain as bad as it can be and 0 indicates no pain). If administered by interview, the therapist describes the scale and reference points and asks the patient to describe his or her level of pain by specifying a numeric rating. The NPRS may be used to better understand the patient's overall pain experience or how pain changes during an activity.

Fatigue

Fatigue is the subjective experience of lacking the physical or mental energy necessary to do usual and desired activities (Besharat et al., 2011). Many people with disability or chronic health conditions appear to experience fatigue, including those with stroke (Lerdahl et al., 2009), multiple sclerosis (Besharat et al., 2011), and brain injury (Gordon, 2008). Fatigue appears to be associated with personality characteristics (Besharat et al., 2011), depression (Merritta et al., 2010), and the nature of the neurological impairment itself (Cantor et al., 2008). If significant fatigue is suggested, clinicians try to quantify or characterize the patient's level of fatigue using a fatigue visual analog scale or a standardized questionnaire such as the Fatigue Severity Scale (Krupp et al., 1989)—information that is used during assessment and to inform referrals to other professionals.

In summary, because people who are fatigued or in pain generally do not perform at their best, occupational therapists often try to understand patients' status and experience in order to plan the assessment process, interpret findings, and determine the focus of occupational therapy intervention. If pain or fatigue management becomes the focus of intervention, therapists use assessments with good psychometric properties and known responsiveness to change (such as the NPRS and Fatigue Severity Scale), so that these measures can be readministered to ascertain progress. During assessment, questionnaires and numerical or visual analog scales should be the catalysts for, rather than replacements of, more in-depth conversations with clients about their experience with pain and fatigue. Conversations to explore the extent to which pain and fatigue levels are manageable or tolerable will be a prelude to problem solving about the kinds of strategies that might help (Zelman et al., 2004).

Coping and Beliefs

People's coping strategies, mental health, and spirituality may impact the ways in which they deal with sudden-onset disability and the experience of loss and ambiguity. During the assessment process, occupational therapists try to understand these aspects of personal context in order to understand their possible influence on performance; make referrals to specialists, if needed; and lay the groundwork for engaging with the patient in ways that advance adaptation and wholeness.

There is no question that persons with disabilities are at risk for anxiety and depression during the acute and chronic stages of injury (Hart et al., 2011; Kennedy & Rogers, 2000). Even so, most people with disability find that they are able to adjust to physical changes and live a happy, relatively normal life (Quale & Schanke, 2010); that is, most people are resilient.

Resilience in a rehabilitation setting is defined as "the ability of adults who are facing a severe and potentially disabling physical injury to maintain relatively stable, healthy levels of psychological and social functioning and to maintain positive emotions and a positive perception of self and the future" (Quale & Schanke, 2010, p. 13). A person's mood and coping strategies contribute to resilience, and both have far-reaching consequences (Pollard & Kennedy, 2007) and can be modifiable (Kennedy et al., 2011). In a study in which mood, coping, independence, and social support were assessed at 12 weeks post-SCI and 10 years later, Pollard and Kennedy (2007) found that rates of anxiety and depression and coping strategies changed little over the 10-year period. This underscores the importance of identifying problems with emotional distress and maladaptive coping early in the recovery period, because left untreated, they are unlikely to resolve over time (Pollard & Kennedy, 2007).

Identifying Emotional Distress

Early identification and treatment of mood disorders is important, as depression and anxiety appear to interfere with attention and concentration during assessment (Eysenck & Keane, 1990) and negatively influence outcome of intervention (Lai et al., 2002). Although occupational therapists do not diagnose mood disorders, they have numerous opportunities to observe behavior. According to Scherer and Cushman (1997), certain patterns of behavior may indicate psychological distress and warrant referral to a psychologist or psychiatrist for further assessment and treatment.

Depression. People feeling transitory sadness and discouragement or normal grief may display signs that are similar to those of depression but will differ in terms of persistence of symptoms and their effect on self-esteem (Gorman, Sultman, & Luna-Raines, 1989). That is, sadness and normal grief resolve with time and generally do not lead to lowered self-esteem, as suggested by the following signs of possible clinical depression (Gorman, Sultman, & Luna-Raines, 1989; Scherer & Cushman, 1997):

- Significant declines in functioning lasting 2 weeks or more
- Feelings of worthlessness, inadequacy, or self-doubt
- Diminished interest in virtually all activities, even formerly enjoyable activities

- Depressed or irritable mood most of the time
- Vegetative disturbances: lethargy, insomnia or excessive sleep, change of appetite with weight change of more than 5%, or periods of excessive activity or slowness almost every day
- Very poor concentration
- Withdrawal from social interaction
- Recurrent thoughts of death or suicide

Anxiety. Anxiety is defined as a "subjectively painful warning of impending danger, real or imagined, that motivates the individual to take corrective action to relieve the unpleasant feelings and is experienced both psychologically and physiologically" (Gorman, Sultman, & Luna-Raines, 1989, p. 51). Anxiety is different from fear. Anxiety is characterized by a diffuse feeling of dread, whereas fear is a reaction to a specific temporary external danger (Gorman, Sultman, & Luna-Raines, 1989). Here are some signs of possible anxiety disorder (Gorman, Sultman, & Luna-Raines, 1989; Scherer & Cushman, 1997) that may prompt referral to a psychiatrist or psychologist:

- Panic attack (choking feeling, nausea, dizziness, palpitations or chest pain, fear of dying, or losing control)
- Distorted, unrealistic fears or perceptions of a situation or object
- Disruption of normal routines or daily activities associated with irrational fears

Despite their best intentions, occupational therapists often have difficulty recognizing these disorders. Therefore, occupational therapists are advised to use standardized screens to identify patients in need of psychological or psychiatric services (Ruchinskas, 2002). The Hospital Anxiety and Depression Scale (Zigmond & Snaith, 1983) and the Beck Depression Index-FastScreen for Medical Patients (Beck, Steer, & Brown, 2000) are good examples.

Identifying Coping Strategies

Coping strategies are things people do to maintain psychosocial adaptation during stressful periods (Holahan & Moos, 1987). Like mood disorders, how a person copes with stress impacts the outcome of rehabilitation efforts (Kennedy et al., 2011). In general, active coping strategies are oriented toward confronting, addressing, and/or cognitively reinterpreting the problem, and avoidance strategies are oriented toward reducing tension by avoiding the problem (Holahan & Moos, 1987). Active coping strategies such as accepting an intractable situation, trying to see the positive side, and learning more about the problem are associated with adaptation and improved rehabilitation outcomes (Kennedy et al., 2011). Avoidance strategies, such as trying to reduce tension by drinking (see Procedures for Practice 3-2) and avoiding people in general, are associated with distress and compromised effort in rehabilitation (Kennedy et al., 2011).

Procedures for Practice 3-2

Assessing Possible Substance Abuse

Alcohol use is a risk factor for traumatic onset of injury and disability such as spinal cord and brain injury (Andelic et al., 2010) and may be a factor in long-term adjustment to disability (Koponen et al., 2011; Tate et al., 2004). Kolakowsky-Hayner et al. (1999) found alarmingly high rates of preinjury heavy drinking among patients who were treated in a level I trauma center and subsequently in rehabilitation (57% of patients admitted with spinal cord injury and 42% of patients admitted with traumatic brain injury). Preinjury substance abuse has been associated with worse rehabilitation outcomes (Bogner et al., 2001) and predicts postinjury substance abuse (Kolakowsky-Hayner et al., 1999). Despite the implications for rehabilitation, health care providers are often reluctant to ask patients about substance use because of time constraints, lack of knowledge, and reluctance to intervene (Taj, Devera-Sales, & Vinson, 1998).

An occupational therapist who suspects that a patient is a substance abuser has an ethical obligation (Moyers & Stoffel, 1999) to perform a screening test and, if indicated, refer the patient for further assessment and intervention. Here are two screening methods.

- Ask a pointed question. Taj, Devera-Sales, and Vinson (1998) were able to identify 74% of at-risk or problem drinkers when physicians incorporated a simple question into their routine examinations ("On any single occasion during the past 3 months, have you had more than five drinks containing alcohol?"). They presented the alcohol screening question between two other general health questions ("In the past 3 months, have you used tobacco?" and "Do you regularly wear your seat belt when riding in the car?"; p. 329).
- Use a mnemonic when interviewing clients about suspected alcohol abuse. The CAGE Questionnaire (Ewing, 1984) asks four questions related to patients' perceptions of need to **cut** down, **annoyance** with criticism, **guilt** about drinking, and need for a drink as an **eye-opener** first thing in the morning.

The good news is that anyone can learn active coping strategies, thoughts, and actions (Quale & Schanke, 2010). Experts recommend trying to identify maladaptive coping strategies early on in the rehabilitation process and then promoting active coping strategies in rehabilitation to maximize treatment efficacy (Hall et al., 2011). Throughout the episode of care, occupational therapists informally take notice of patients' coping patterns and talk with patients about how they have coped with other stressful events, reinforcing past episodes of resilience when possible.

Spirituality

Spirituality refers to the beliefs and practices about the world and one's place in it that give a person transcendent meaning in life (Egan & Swedersky, 2003; Pulchaski & Romer, 2000). These beliefs may be expressed as a religious faith or directed toward nature, family, or community. It reflects a person's overriding system of meaning that influences use of time, choice of actions, and perceptions of purpose. As such, spirituality is central to a person's coping and occupational function (Christiansen, 1997). Therapists who incorporate spirituality into their practice do so by dealing with clients' religious concerns, encouraging patients' core sense of self, and addressing or confronting patients' experience of suffering (Egan & Swedersky, 2003). These connections with clients become opportunities for the therapist's development as well (Egan & Swedersky, 2003). Procedures for Practice 3-3

describes ways to discuss coping, spiritual beliefs, and meaning systems with patients.

Cultural Background and Identity

Because of the increasingly diverse populations in most communities, occupational therapists consider the influence of culture on occupational therapy assessment and occupational functioning (Suarez-Balcazar et al., 2009). Culture is broadly defined as a system of learned and shared guidelines for perceiving, interpreting, and interacting with others and the environment that informs values, beliefs, and behavior (Jezewski & Sotnik, 2001).

Culture is not biologically inherited or determined by geography or ethnicity (Krefting, 1991). Ethnicity has to do with group norms and practices associated with a person's culture of origin (Breland & Ellis, 2012). It may

⟳ Procedures for Practice 3-3

Assessing Patients' Coping, Spiritual Beliefs, and Meaning Systems

People typically share personal information with those they trust. Therefore, to explore patients' beliefs and meaning systems, therapists invest in establishing therapeutic rapport (see Chapter 14). Without the rapport that comes with time and consistency of care providers, patients may perceive questions about their spirituality, for example, as intrusive or offensive. Therapists who are aware of their own coping strategies and belief systems will be best able to comfortably discuss these issues with their patients.

In general, discussions of these very personal and potentially sensitive matters begin at a superficial level and progress to deeper, more personal levels as dictated by the patient and therapist's comfort with each other and the subject matter. Here are examples of this progression.

- Ask the client to provide an hour-by-hour account of a typical day prior to the injury or onset of illness (Radomski, 1995). How a person is used to spending his or her time richly defines his or her valued activities and priorities.
- Take a brief life history, asking the patient to give you an overview of his or her life course, including past goals and obstacles (Kleinman, 1988). People often use stories or narratives to make connections and meaning attributions between a series of life events (Mattingly, 1991).
- Ask the patient about his or her explanatory model of the illness or disability. Kleinman (1988) suggested that faced with illness, disability, or suffering, people attempt to construct models to explain the whys of their experiences. They make attributions about causation and outcome that are more likely to be based on personal beliefs and culture than on facts or medical information. For example,

patients may feel responsible for permanent impairments because they did not try hard enough in rehabilitation to overcome them (Luborsky, 1997). If the person views onset of illness or disability as God's punishment for a past sin or mistake, he or she may not feel empowered to invest in rehabilitation efforts. Only as patients' explanatory models are acknowledged may they be negotiated with the therapist or health care team (Kleinman, 1988).

- To begin to understand the role of spirituality in patients' lives, ask them questions about meaning and past experiences in which their coping skills were taxed, such as the following (Cox & Waller, 1991; Mattison, 2006):
  1. What gives your life meaning? What is your greatest hope?
  2. When you are discouraged and feeling despondent, what keeps you going?
  3. What comforts or encourages you? Where have you found strength in the past?
  4. What have you done in the past when you have lost someone or something important?
  5. What do you think the message in this is for you?
- Pulchaski and Romer (2000) recommended an acronym (FICA) for aspects of a spiritual assessment: *F*, faith; *I*, importance and influence; *C*, community; and *A*, address.
  F. What things do you believe in that give meaning to your life?
  I. How have your beliefs influenced your behavior during this illness? What roles do your beliefs play in regaining your health?
  C. Are you a part of a spiritual or religious community? Is this a support to you and how?
  A. How would you like me, your health care provider, to address these issues in your health care?

have implications in economic, social, and political realms but contributes little to a therapist's appreciation of a patient's personal context. Furthermore, clinicians are cautioned about the reliability and accuracy of ethnic designations in hospital records (Stansbury et al., 2004). Because there is as much variation within ethnic groups as between them, a person's ethnic background is not a reliable gauge of his or her cultural identity.

The influence of culture on a person's experience is dynamic and individualized and may exert obvious or subtle influences on how people cope with disability. Consider the rehabilitation challenges of a recent immigrant from India with a right hemiplegia who refuses to feed herself with her left hand because in her culture, the left hand is always relegated for personal hygiene tasks (Pinto & Sahu, 2001). Although cultural rules are learned, they are also graded, flexible, task- and environment-specific, and often self-selected. For example, the degree to which immigrants have assimilated the customs and patterns of behavior of their new country or region is determined by how recently they emigrated, the primary language spoken at home, and the amount of contact with their homeland (Krefting, 1991). People adopt the culture of specific subgroups and environments; the expectations for behavior of a clinician in an occupational therapy clinic are different from expectations for a broker working at the New York Stock Exchange.

Culture and Occupational Performance

Cultural background and identity have implications for the ways in which occupational therapists understand social interactions, activities of daily living (ADL), and performance on standardized assessments. As illustrated earlier, occupational therapists consider the influence of various cultural aspects of communication, such as beliefs about communication based on social hierarchy, turn-taking in conversation, forms of address (using first or surnames), use of gestures, and concept of personal space (Hearnden, 2008). The cultural overtones of ADL are also particularly salient to occupational therapists. Because the nature of ADL routines (importance and frequency) is highly personal and differs between cultural groups and even between generations within the same ethnic group, Jezewski and Sotnik (2001) recommend considering three key questions when working with patients who are members of foreign-born groups:

- Are there differences in ADL activities in the person's country of origin in comparison to how they are performed in the United States?
- How do persons with disabilities perform ADL in the culture of origin?
- Given his or her cultural background, how might the individual respond to receiving assistance in these personal activities (p. 19)?

Culturally Aware Therapists

Although therapists' cultural awareness appears to be associated with more years of experience (Suarez-Balcazar et al., 2009), all occupational therapists take responsibility for providing culturally sensitive services. Clinicians can begin to understand potential cultural influences on performance by using resources such as those available through the Center for International Rehabilitation Research Information & Exchange (CIRRIE) (http://cirrie.buffalo.edu/). However, the dynamic influence of culture on human experience requires that clinicians resist attempts to characterize or stereotype clients based on ethnic or geographical background. Rather, occupational therapists attempt to recognize and then step outside of their own cultural backgrounds and biases to appreciate and accept the culturally based customs, values, and beliefs of each client (Procedures for Practice 3-4).

Procedures for Practice 3-4

Cultural Assessment

Experts advise against using cultural cookbooks to gain insights about culturally based habits and behaviors of various ethnic groups, as they can lead to stereotyping individual patients (Lipson, 1996). Instead, therapists consider the unique influence of culture on each individual's experience by carefully attending to nuances of body language, word choice, and gestures and adopting an attitude of curiosity about each client's situation and background (Bonder, Martin, & Miracle, 2004).

Lipson (1996, p. 3) suggested the following questions as key elements of a cultural assessment of any patient. Occupational therapists may get the answers to these questions in the medical record or talk directly with patients or loved ones.

- Where was the person born? If an immigrant, how long has the patient lived in this country?
- What is the patient's ethnic affiliation and how strong is the patient's ethnic identity?
- Who are the client's major support people, family members or friends? Does he or she live in an ethnic community?
- What are the primary and secondary languages and the speaking and reading ability?
- How would you characterize the nonverbal communication style?
- What is the person's religion, its importance in daily life, and current practices?
- What are his or her food preferences and prohibitions?
- What is the person's economic situation, and is the income adequate to meet the needs of the patient and family?
- What are the health and illness beliefs and practices?
- What are the customs and beliefs around such transitions as birth, illness, and death?

Finally, culturally aware occupational therapists understand that many evaluation tools are based on norms developed for a white middle-class population (Krefting, 1991; Paul, 1995). Culturally reflective clinicians assess the cultural validity of their standardized assessment tools (Krefting, 1991). While clinicians try to select criterion- and norm-referenced tests appropriate for the person's background, it is very difficult to devise culturally unbiased tests that include only items that reflect the knowledge, experience, and skills common to all cultures (Paul, 1995). Because it is nearly impossible to locate culture-specific tools for all of the diverse cultural groups in North America, therapists must make every effort to attempt to understand a client's individual cultural background before interpreting performance on the most appropriate standardized tests.

SOCIAL CONTEXT

"Every long winded well-meaning expression of sympathy was a giant highlighting marker over the fact that I was different. Our family's misfortune now set us apart. More than anything I wanted people to treat me like the old Lee" (Woodruff & Woodruff, 2007, p. 253).

Onset of disability occurs within the social context of the person's social resources, roles, and preferences that together influence occupational pursuits, satisfaction, health, and well-being (Helliwell & Putnam, 2004). For example, some people select tasks and activities that put them in contact with a social network; others select occupations that allow them to avoid social interaction, as in the case of individual preferences for hobbies or careers. Social networks may facilitate an individual's chosen occupations through emotional support, assistance, or instruction; unfortunately, some social relationships interfere with a person's optimal function. Only if occupational therapists are aware of the social context in which occupational function occurs can they orchestrate intervention that will outlive their own involvement in a client's recovery and adaptation.

Social Network and Support

The characteristics of a person's social network and support are relatively stable social contextual factors that influence his or her identity, opportunities, and function. Langford et al. (1997) suggested that a social network is an interactive web of people who provide each other with help and protection; that is, they give and receive social support. Social networks vary in terms of the following characteristics: reciprocity (extent to which resources and support are both given and received), intensity (extent to which social relationships offer emotional closeness), complexity (extent to which social relationships serve many functions), and density (extent to which network members know and interact with each other) (Heaney & Israel, 1997). Social support is defined as aid and assistance exchanged through social relationships and interactions (Heaney & Israel, 1997). This dynamic construct is composed of (1) social companionship and daily emotional support, (2) assistance (physical, informational, and emotional) during times of trouble, and (3) exchanges that contribute to self-esteem and approval (van Leeuwen et al., 2010).

Occupational therapists are fundamentally interested in patients' social networks because families and caregivers play a pivotal role in the patients' care and quality of life (McPherson et al., 2011). Additionally, the nature of a patient's social support appears to influence his or her life satisfaction over time, with functionally dependent persons who receive little social support at particular risk for poor adjustment (van Leeuwen et al., 2010). Therefore, during the assessment, occupational therapists first try to identify the composition and characteristics of the client's social network (i.e., who these individuals are and the nature of their relationships). Occupational therapists must step outside of their own possible biases and expectations to appreciate that patients' social networks take many forms, including traditional nuclear families, same-sex partners, friendships, and acquaintances. Any biases against nontraditional families are not aligned with the profession's stance on nondiscrimination and inclusion (American Occupational Therapy Association, 2009).

Therapists also attempt to determine the types of support that individuals in the social network are willing and able to provide. For example, long-standing intimate ties typically provide emotional support and long-term assistance, whereas neighbors and friends most often provide short-term instrumental and informational support (Heaney & Israel, 1997). Key players in the social network assume as much or as little responsibility as they are able, and the patient–family unit becomes the primary recipient of occupational therapy services (Brown, Humphry, & Taylor, 1997). Therapists can learn a lot about patients' social networks and resources by simply talking with them. An alternative method of assessing a patient's social network and resources is the Norbeck Social Support Questionnaire (Norbeck, Lindsey, & Carrieri, 1981). It is a standardized, self-administered questionnaire consisting of nine items and taking about 10 minutes to complete. Patients list individuals in their personal network and specify the nature of these relationships, the frequency of contact, and the extent to which they provide emotional and tangible support

Finally, occupational therapists appreciate that some social relationships are harmful to patients. Accredited hospitals and rehabilitation facilities are mandated to have policies in place to identify patients who may be victims of physical assault, sexual assault, and domestic or

elder abuse or neglect (Joint Commission on Accreditation of Healthcare Organizations, 2010). Therapists must familiarize themselves with employers' policies and procedures that describe how to report, document, and respond to cases of suspected maltreatment. For example, at Mercy and Unity Hospitals in suburban Minneapolis, physical and occupational therapists are expected to screen all outpatients for family violence (J. L. Miller, personal communication, August 26, 2011).

Caregiver Adaptation: A Dynamic Social Factor

Long-standing intimate ties in the patient's social network (hereafter also referred to as family) are critical to the patient's ability to adapt to chronic illness and disability. Families influence outcome of services because they provide a context for individual change and because they represent continuity in patients' lives (Brown, Humphry, & Taylor, 1997). The ability of significant others to provide needed support, however, is shaped by their own emotional and physical health and place in the adaptation process (Grant et al., 2000). Many relatives of persons with traumatic brain injury (Webster, Daisley, & King, 1999), stroke (Epstein-Lubow et al., 2009), multiple sclerosis (Figved et al., 2007), and Alzheimer's disease (Pruchno & Potashnik, 1989), for example, experience significant levels of subjective burden and mood disorders as well as role changes in work, leisure, and social life (Frosch et al., 1997). To contribute to patients' long-term quality of life, occupational therapists assess family members' adaptation needs on an ongoing basis.

All of the personal, social, and cultural contextual factors described in this chapter can be applied to the significant other's occupational functioning as caregiver. That is, a spouse's ability to learn and reinforce new techniques and strategies is affected by his or her own health concerns and distractions, age and generation, sex, mood, cultural background, makeup of the social network, and culture of the community (Murray, Manktelow, & Clifford, 2000). Furthermore, caregivers' goals and perceptions of need from health providers change as they adapt to the patient's illness or injury.

In their pioneering study, Corbin and Strauss (1988) described the work of adapting to chronic disability over time as "a set of tasks performed by an individual or couple, alone or in conjunction with others, to carry out a plan of action designed to manage one or more aspects of the illness" (p. 9). This work consists of not only adjustments to self-maintenance tasks and roles but also the work involved in redefining one's identity. Corbin and Strauss used the term *illness trajectory* to refer to the sequence of physiological changes associated with an illness, injury, or disorder and the adaptive work demanded of a patient and family that accompanies each phase. They further suggested that most trajectories have five types of phases, distinctly ordered according to various diagnoses and individual courses: acute, comeback, stable, unstable, and downward.

- Acute phase. The patient requires immediate medical attention and focuses on physiological stabilization and recovery. Patient and family may wonder how life will change because of the illness, injury, or disorder.
- Comeback phase. The patient is in the midst of physical and emotional recovery and focuses on getting physically well and regaining functional abilities. Patient and family may ask questions such as these: Will I (he or she) come back? How long will it take before I (he or she) peak? Corbin & Strauss (1988) explain that "in the comeback trajectory, the present is seen as overbearing, and the future is put on hold while one awaits answers to the foregoing questions" (p. 46).
- Stable phase. The patient undergoes very few changes in the course of illness or functional abilities, as in the remission phase of multiple sclerosis or permanent spinal cord injury. Patient and family focus on maintaining stable health while wondering how long the phase will last and what can be done to extend it.
- Unstable phase. The patient has periodic but erratic downturns in function or exacerbations of illness (as might come, for example, with bladder infection). Unstable phases hamper normal living, and people in this phase ask questions like these: How long until we get this under control? How much longer can I (or we) go on like this?
- Downward phase. The patient slowly or rapidly loses health and function. With increasing incapacity, the patient and family view the present as temporary and the future as unknown. They are concerned with questions such as these: How fast and how far? When will it end? What can we do to slow it down?

Although there are no standardized methods for determining a person's phase in an illness trajectory, sensitivity to each person's changing path in this journey is prerequisite to creating a treatment plan that meshes with patient and family real-time needs and priorities. A family-centered approach allows the therapist to capitalize on the family's priorities and contributions to the patient's recovery and adaptation. This mindset, however, requires that therapists "follow the family's lead rather than impose professional decisions" (Brown, Humphry, & Taylor, 1997, p. 598).

Patient–Therapist Social Interactions

Occupational therapy assessment is not a neutral process (Luborsky, 1997). Gans (1998) suggests, "Part of the way the patient behaves with you is a function of the way you are with the patient. This effect may comprise 75%, 25%, or 2% of what goes on between you and the

patient, but it is there" (p. 4). The therapist is endowed with power to shape the interaction by selecting certain questions and omitting others (Luborsky, 1995), to judge or evaluate the responses of the patient, and even to determine whose expectations and "reality" are correct (Abberley, 1995). Therapists' communication patterns set the tone for patient experience. For example, when providers are perceived as unfriendly, interrupt, or fail to encourage questions and dialogue about concerns, patients report less satisfaction with the services they receive (Abdulhadi et al., 2007).

Perhaps to meet self-imposed expectations around outcome, Abberley (1995) suggested that some occupational therapists unwittingly define the client as the problem and themselves as the solution, with failure of intervention always attributed to the patient and success always credited to the clinician's efforts. Gans (1998) believes that a primary source of clinician gratification should stem from "the privilege of participating intimately in another person's life" (p. 5). He further suggests that when the work no longer feels like a privilege, one should try to figure out why (e.g., volume of caseload, private life that is distracting or burdensome, burnt out, or ethically questionable employer expectations that corrode integrity). Effective occupational therapists take steps to manage the stresses associated with patients' overwhelming challenges (Stevenson, Phillips, & Anderson, 2011) so that their personal needs do not infiltrate into social interactions with patients.

Clinicians also examine their expectations of their own supportive roles in patients' lives. They recognize that professional helpers are typically not able to provide support over long periods. They realize that professional–lay relationships are not characterized by reciprocity typical of social networks and often entail invisible but palpable power differentials that interfere with the provision of genuine emotional support (Heaney & Israel, 1997). In essence, they realize that, as professionals, they should not attempt to assume a long-term role in the social network but rather work with the patient and family to create permanent social links that meet the patient′s needs.

CULTURAL CONTEXT OF THE LARGER SOCIETY AND COMMUNITY

"I used to dream about being in a world where being disabled was no big deal, where no one considered it a tragedy. No one thought you were inspiring or felt sorry for you. . . . I imagined what a relief it would be to be seen every day as perfectly ordinary." (Tollifson, 1997, p. 105)

The dominant culture influences the ease with which a person with a disability feels accepted and integrated into the community. Luborsky (1994) suggested that culturally based requirements for the status of a full adult person

in Europe and North America, such as self-sufficiency, activity, and upright posture, are often at odds with full participation for persons with disabilities. Adapted equipment may be rejected because of its appearance and acceptability in public rather than its functional value (Luborsky, 1994, 1997). Patients and family may respond to embarrassment or guilt over disability by attempting to keep the disability private and refusing help from friends or neighbors (Armstrong & Fitzgerald, 1996). Loss of social status is further compounded when insidious cultural beliefs hold persons with disabilities responsible for their impairments or as having varying degrees of deservedness in terms of accommodation and assistance (Askew, 2011). "At a deep level there is a bias that either they are culpable for the cause of the impairment, or for not working harder at rehabilitation to be able to 'overcome' the odds regardless of how realistic that is" (Luborsky, 1994, p. 251). As abhorrent and illogical as such notions are, patients, families, and occupational therapists are not immune to the subtle but pervasive influences of the sociocultural context in which they live.

Occupational therapists are challenged to check many of their own assumptions about people with disabilities. For example, Kielhofner (2005) reminded us that the person-first terminology that therapists are urged to use is objectionable to some disability activists and scholars who suggest that the term "disabled person" more accurately reflects his or her true minority status. Many people resent the notion that their impairments reflect some sort of personal tragedy (Wakefield, 2005; Watson, 2002) and, instead, view their disability with pride as a part of their identity (Eddey & Robey, 2005). However, while some interpret rehabilitation and remediation of impairments as an effort to remove a flaw or a negative characteristic (Kielhofner, 2005), rehabilitation hospital settings may nurture growth, self-redefinition, and even personal transformation after sudden-onset disability (Devlieger, Albrecht, & Hertz, 2007).

PAYER-REIMBURSEMENT CONTEXT

Laws and health care policies influence the nature and intensity of occupational therapy services available to a given patient by dictating the services he or she is eligible to receive and the extent to which services are reimbursed. The payer-reimbursement context for various health care settings may drive the type and length of assessment, availability of tools and equipment, and methods used in practice.

Consider how the payer-reimbursement context influences the nature of occupational therapy assessment and intervention in the following scenario. Mrs. J. is a 60-year-old woman who experienced sudden-onset left hemiparesis. An ambulance transported Mrs. J. to a certified stroke center, at which she received evaluation by

medical specialists, imaging, and tissue plasminogen activator (tPA). (If provided within an established time frame, tPA can significantly reduce the effects of stroke and permanent disability.) Mrs. J. was admitted to the neurointensive care unit and within 2 days was evaluated by an occupational therapist. The occupational therapy assessment suggested that Mrs. J. had a very active lifestyle before her stroke but now has left hemiparesis of the arm and leg and slight left facial droop. She required moderate assistance for eating, grooming, dressing, bathing, toileting, functional transfers, and mobility. Mrs. J.'s ability to perform instrumental activities of daily living was not assessed. Occupational therapy in the intensive care unit and on the acute stroke floor was provided at bedside because Mrs. J. had multiple IVs and was being monitored for cardiac arrhythmias. The goals were to improve participation in activities of daily living and functional mobility. Because her stroke diagnosis was included in the Centers for Medicare and Medicaid Services (CMS) 13 qualifying diagnoses for inpatient rehabilitation and she required multiple therapies (physical therapy, occupational therapy, and speech-language pathology), Mrs. J. was admitted to the inpatient rehabilitation unit 5 days after the onset of her stroke. Her therapy focus shifted from basic daily activities to restoration of function for eventual return home. Mrs. J. continued to demonstrate significant improvement and progressed to supervision for daily activities. She had hoped to stay in the inpatient rehabilitation setting until she reached an independent level; however, her insurance placed a limit on her length of stay. After discharge, Mrs. J. planned to transition to outpatient rehabilitation with the goals of increased independence for home and community reintegration, including eventual return to work and driving.

This scenario illustrates how occupational therapists need to understand payer-reimbursement aspects of the contextual picture so that they use patients' covered services in ways that yield the most benefit and value. To that end, occupational therapists understand governmental policies and laws and stay abreast of ongoing changes to the health care system.

Governmental Policies and Laws

Many Americans' health care services are paid for by government-funded programs such as Medicare and Medicaid. One of the largest payers of occupational therapy services is Medicare, a federally administered health insurance program for people age 65 years and older, those of all ages with end-stage renal disease, and those under age 65 years with certain qualifying disabilities. Divided into two parts, Medicare A and Medicare B, this program helps to cover inpatient care in hospitals and skilled nursing centers, as well as some aspects of hospice and home health care, and outpatient services, including physician visits and those medically necessary services provided by occupational therapy practitioners (CMS, 2005b).

Another government-administered health insurance program is Medicaid. Medicaid is designed to assist low-income individuals and families who fit into specific eligibility groups that are established by federal and state law (CMS, 2005a). Although funded by the federal government, Medicaid is administered individually by states. Each state is permitted to establish its own guidelines for both Medicaid eligibility and the coverage of services (CMS, 2005a). Requirements can vary significantly from state to state for both recipients and service providers. Occupational therapy services may or may not be covered under Medicaid. When services are covered, the conditions warranting care are specifically identified, and there may be requirements regarding the frequency and duration of occupational therapy services for which Medicaid will pay.

According to the CMS (formerly the Health Care Financing Administration), private insurance funds approximately one-third of total health care service and primarily cover children and adults under the age of 65 years who are not disabled (Federal Interagency Forum on Aging-Related Statistics, 2004; Henry J. Kaiser Family Foundation, 2007). Public programs including Medicare, Medicaid, and the State Children's Health Insurance Program fund approximately 45% of health care spending for Americans (Federal Interagency Forum on Aging-Related Statistics, 2004; Henry J. Kaiser Family Foundation, 2007). Medicaid covered 7% of health care costs of Medicare enrollees age 65 years and older; out-of-pocket costs account for approximately 19%, with another 4% from other funds such as foundations (Federal Interagency Forum on Aging-Related Statistics, 2010).

Beyond Medicare and Medicaid, there are other government-sponsored health programs. Depending on state law, those who are injured on the job are frequently covered under workers' compensation. People who are under the age of 65 years and are disabled may be able to apply for state or federal assistance. Health care from the Veterans Administration is available for veterans of the U.S. military. Those who are uninsured may be eligible to apply for state assistance under the Medicaid system or may need to pay privately for health care services.

Consider how payer-reimbursement factors have influenced occupational therapy practice in the following brief history of Medicare. In 1966, Medicare was enacted as a means of providing health coverage for the elderly (age 65 years and older) and the disabled. In 1983, Congress implemented the Medicare Prospective Payment System (PPS) for acute care hospitals in an effort to contain costs and standardize care. Acute care hospital PPS is based on more than 490 diagnostic related groups (DRGs). Since the enactment of the DRGs, temporary exemption has been in effect for rehabilitation hospitals and units, children's hospitals and units, alcohol and drug programs,

long-term care, cancer specialty hospitals, and psychiatric hospitals and units. The impact of the DRGs was significant. Hospital lengths of stay became shorter, and discharges to all types of postacute care providers rose (such as inpatient rehabilitation facilities, skilled nursing facilities, and long-term care hospitals). The Balanced Budget Act (Balanced Budget Act of 1997) enacted and mandated PPS for nursing facilities, rehabilitation hospitals and units, and home health agencies. Skilled nursing was included in the PPS in 1998 that based payment on a per diem allowance. Home health was included in 2000, and payment for that was based per episode of care. Inpatient rehabilitation was included in 2002, and payment was based per discharge.

Changes in Medicare policy over time have influenced occupational therapy practice in all of the aforementioned settings. Shorter acute care lengths resulted in fewer occupational therapy sessions, with a greater focus on discharge-readiness assessment than intervention. Similarly, the duration of inpatient rehabilitation services is shaped, in part, by condition-specific Medicare payment. As a result, occupational therapists often focus on helping patients meet self-care goals during inpatient rehabilitation and address issues associated with community and work reintegration during other phases of the continuum of care.

Standards of occupational therapy practice also reflect priorities of regulatory agencies such as the Joint Commission on Accreditation of Healthcare Organizations (TJC), the U.S. Department of Health and Human Services, fiscal intermediaries, and the Commission on Accreditation for Rehabilitation Facilities (CARF). For example, within hospital or institutional care settings, services must be prescribed by a physician and provided under a physician-approved plan of care; services must be performed by a qualified occupational therapist or an occupational therapy assistant under the supervision of an occupational therapist; and services provided must be reasonable and necessary for the individual's illness or injury. In addition to these requirements, regulations can also place limits on the amount of therapy intervention, including the amount of time services are provided and the overall length of service provision, requiring the therapist to outline and provide a plan of care within these guidelines.

Health Care Reform

There are continual changes to the health care delivery system that will shape the future payer-reimbursement context. The Patient Protection and Affordable Care Act of 2010 will bring the most significant changes to American health care since the prospective payment reform in 1983. Health reform law introduces important changes for health care providers that will unfold over the next decade. Between the years 2010 and 2013, we will see regulation and coverage changes. Major changes slated to occur in 2014 are expected to bend the cost curve by 2015–2020. The health care landscape will continue to evolve as providers experiment with new models and work to achieve integration through accountable care organizations, medical homes, value-based purchasing, and/or bundling.

Accountable Care Organizations

Many believe the key to health care reform is the development of an efficient, affordable primary care delivery system that is patient-centered, coordinated, team-based care and supported by health information technology. Accountable care organizations, or ACOs, are a proposed system design and payment reform solution to address rapidly rising health care costs, related inefficiencies within the current health care delivery system (duplication of services, for example), and poor health outcomes experienced by many Americans. The goal of an ACO is to create an integrated network of providers in order to improve individual and population level health outcomes and control costs. Services delivered across the continuum of care (in hospitals, outpatient clinics, primary care centers, community clinics, inpatient rehabilitation, skilled nursing facilities, etc.) and throughout the life span will be integrated and coordinated, and providers will be held jointly accountable for patients' outcomes (Lowell & Bertko, 2010; McClellan et al., 2010). Occupational therapy practitioners have roles to play in every facet of an ACO, including providing expert guidance on client-centered care and contributing to the governance structure that oversees the management of the ACO.

Medical Home

The medical home has emerged as a promising model for transforming organization and delivery of primary care to address care fragmentation and dismantling the silos in health care delivery. The medical home is also known as the primary care medical home, advanced primary care, and the health care home. However, the model is most commonly referred to as the patient-centered medical home (PCMH), emphasizing the central tenet that quality care is always patient centered. Under the PCMH, each patient is assigned to a personal physician practice that is held accountable for providing, coordinating, and evaluating care (Gulley et al., 2011). Many of the principles driving the efforts to transform primary care align with core occupational therapy beliefs and values and thus the opportunity exists for occupational therapy practitioners to engage in educating primary care providers on how to provide care that is truly patient centered and relevant to daily life across the life span.

Value-Based Purchasing

On May 6, 2011, the CMS released its hospital value-based purchasing final rule, which was required under the Patient Protection and Affordable Care Act (U.S. Department of Health and Human Services, 2011). This final rule relates specially to Medicare reimbursement; however, private payers may follow CMS's lead. Value-based purchasing means that Medicare reimbursement will be based on quality achievements that link payment to performance. Higher quality achievements will receive higher payment. Medicare value-based purchasing will likely include four components: reporting hospital quality data for annual payment update (RHQDAPU) based on specific quality indicators, a penalty/reward system based on metrics from the RHQDAPU, a payment penalty for certain negative conditions that are hospital acquired, and a payment penalty for high readmissions rate as compared to peers (Department of Health and Human Services, 2011). Value-based purchasing aims to transform Medicare from a passive payer of claims based on volume of care to an active purchaser of care that is based on quality of services.

Bundling

Bundling payment, especially bundling acute and post-acute payment into one payment is a potential way to make acute care hospitals accountable for hospital readmissions, as well as bring greater efficiencies and cost savings to an entire episode of care. Bundling across providers for services is designed to result in better coordination and continuity of care across settings. Better coordinated care may reduce unnecessary duplication of services and potentially decrease medical errors and cost. Bundling payment, which seems conceptually quite simple, is complex and will require testing and demonstrations that will allow health systems to experiment with various models (MedPAC, 2008). It is important for occupational therapy services to be involved in the testing of these models to ensure that occupational therapy remains an important and viable service.

Staying Engaged and Informed

Health care reform needs to equally and equitably distribute the costs and benefits of quality health care to all individuals. To that end, occupational therapy professionals must be aware of legislative and regulatory activities that may impact the practice of occupational therapy. For example, yearly in the *Federal Register*, revisions to payment policies under the physician fee schedule are published. These revisions impact reimbursement for health care services including the reimbursement and regulatory situations that impact the delivery of occupational therapy.

Ultimately, each practitioner needs to be accountable for the value of services provided and integrated with other practitioners to ensure optimal outcome. Measuring and improving the value of occupational therapy remains a central priority of the profession (Porter, 2010). **It is important for every occupational therapy practitioner to be a member of their national and state occupational therapy organizations in order to shape the future of occupational therapy for the clients we serve in the context of health care reform.**

GENERAL COMMENTS ON CONSIDERING PERSONAL, SOCIAL, CULTURAL, AND PAYER-REIMBURSEMENT CONTEXT

Zooming in to identify and quantify specific barriers to occupational functioning and zooming out to observe contextual factors that may influence assessment methods and a patient's performance promise to result in the client-centered services to which our profession aspires. Enacting such practices in real life requires clinician commitment and vigilance. If nothing else, the discussion of contextual factors underscores that occupational therapists ought to not get too comfortable with their findings, scores, or impressions and ought to learn to tolerate the ambiguity of "it just depends." The imposing influence of contextual variables serves to keep us humble and on-guard against jumping to the wrong conclusions about assessment findings and our clients.

Occupational therapists struggle to balance their preeminent concerns for service to patients with very real demands for efficiency and productivity. Clinicians typically devote 30 minutes to 3 hours assessing each patient; the short lengths of stay in acute settings allow less time; inpatient rehabilitation settings (with possibly longer stays) allow somewhat more. How does one have time to assess the web of personal, social, and cultural contextual factors on top of all pertinent areas of occupational function (roles, tasks, activities, abilities and skills, and capacities)? Here are some general guidelines:

- Review the assessments of other professionals. Many patients who are referred to occupational therapy are also assessed by social workers, psychologists, speech-language pathologists, physical therapists, physicians, therapeutic recreation specialists, chaplains, and/or nurses. Reviewing the assessments of team members greatly adds to the occupational therapist's ability to understand a patient's personal, social, and cultural context without using limited assessment time to do so.
- Take advantage of informal conversations with patients. Luborsky (1997) pointed out the value of attending to patients' informal remarks made during structured assessments. He described how a patient's

comments during transitions between various standardized tools provide insights not captured by the tools themselves. He further stated that patients' informal remarks "can be essential to gaining an understanding of the way subjects make sense of the assessment; to providing us with important information on the validity of the assessment tool; and to identifying important areas for clinical intervention" (p. 12).

- Keep in mind that contextual factors influence your clinician attitudes, habits, and practices as much as they are likely to impact the patient's occupational performance. Try to notice when you find yourself responding to situations and rushing to conclusions in ways that might be unduly influenced by contextual factors.

It is advisable to use each and every moment with patients to try to understand who they are, where they come from, and how they are interpreting their experience in therapy. Gans (1998) links this investment to patient outcome: "Our ongoing, relentless determination to understand the uniqueness of each patient is what the patient, to the degree he or she can, experiences as love . . . [and] patients who feel cared about and valued make the most gains in therapy" (p. 5). It is unrealistic to expect therapists to understand the full picture of all the factors that shape a patient's life and performance during an arbitrarily defined assessment period. The richness of conversations that relate to important contextual factors grows as the therapeutic relationship deepens and continues to inform the intervention process.

case example
Mrs. N.: Appreciating Context During Assessment

Clinical Reasoning Process

Occupational Therapy Assessment Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mrs. N., a 30-year-old wife and mother of three young children, was referred to outpatient occupational therapy for assessment and treatment approximately 6 months after a suspected brain injury. She was injured when a shelf at a convenience store broke and its contents fell on her head. After the accident, Mrs. N. frequently complained of headaches, fatigue, and dizziness accompanied by dramatic decrease in her activity level and was observed to be forgetful, even unsafe (e.g., leaving stove burners turned on, losing track of her children, forgetting to take medication). With a high school education, Mrs. N. worked full time as a teaching assistant at a day care center but was unable to return to work following her injury. As a recent immigrant from Saudi Arabia, Mrs. N. spoke very little English. (She spoke and wrote in Arabic.) The consulting neuropsychologist opted not to perform a battery of standardized cognitive assessments because of concerns about communication, cultural biases of the tests themselves, and possible religious discomfort associated with spending hours of assessment time with the neuropsychologist, a man. Therefore, assessment and observations in occupational therapy were particularly important in establishing her rehabilitation needs.	Understand the patient's diagnosis or condition	"Mrs. N.'s complaints and presentation are certainly consistent with a brain injury. It appears that she did not seek medical attention immediately after the accident and that she has never received any rehabilitation services. These symptoms must be frightening for her."
	Know the person	"It is going to be challenging for me to try to get to know Mrs. N. and to provide the kind of encouragement and support that I feel is so important to my approach with patients, given our language barriers."
	Appreciate the context	"I realize that I need an assessment strategy that is different from what I am used to. It would not make much sense for me to rely on scores from standardized tests. I will also be sensitive to the fact that it is possible that some of what Mrs. N. says to me may be lost in translation."
	Develop provisional hypotheses	"My guess is that some of Mrs. N.'s problems can be attributed to brain injury, but I wonder what effect anxiety and/or depression may have on her overall functioning."

Assessment Process

Mrs. N. appeared to doze in the waiting room prior to her initial occupational therapy session. She was cooperative and soft-spoken; she was able to respond in English to approximately 30% of the questions. She stayed awake for most of each of the three 1-hour assessment sessions. Mr. N., also a native of Saudi Arabia, served as translator but often dominated interactions with details of his own stress related to his wife's status. He appeared to be on the verge of tears on at least two occasions as he described his inability to work full time because of his wife's need for supervision, assistance, and transportation to medical appointments.

| Consider evaluation approach and methods | "I think that I can learn the most about Mrs. N.'s functioning with a dynamic assessment approach—observing her response to various demands and challenges that I set up." |

Patient's and Husband's Report of Abilities and Limitations

Through her husband, Mrs. N. indicated that she was primarily concerned about her memory and endurance and that her ultimate goals were to completely resume her roles as mother, homemaker, and worker. (At the time of her assessment, Mr. N. prepared all of the family meals, and their oldest daughter, age 9 years, did most of the household chores.) Through her husband, Mrs. N. indicated that she had very little activity or routine in her day. She woke anywhere between 8:00 am and noon. After rising, she sat for approximately half an hour, avoiding movement so as to avoid dizziness. She did not prepare meals for herself, eating only a cookie with tea instead of breakfast or lunch. She typically spent her afternoons napping, sitting alone at the window, or watching television. She fell asleep at approximately 9:00 pm, but her husband reported that he regularly found her crying in the middle of the night. Her inactivity contrasted dramatically with reports of her premorbid status: working full time, attending language and driving classes, managing all household tasks, caring for her children, and socializing with friends. With the patient's permission, the therapist also contacted Mrs. N.'s American-born, English-speaking sister-in-law, who confirmed the dramatic decline in Mrs. N.'s activity level and abilities, Mr. N.'s understandable stress given these changes, and her own willingness to serve as a resource.

Interpret observations

"Descriptions of Mrs. N.'s premorbid activities and her self-reports of long-term goals contradict my assumptions about Muslim women from the Middle East. Prior to meeting Mrs. N., I expected that Mrs. N. would have a narrow sphere of activities that centered exclusively on her home and children. Mrs. N.'s premorbid engagement in work outside of her home and language and driving lessons and her goals to return to these roles reminds me of the importance of trying to understand each patient as an individual rather than drawing conclusions based on cultural or ethnic stereotypes."

"It is helpful to get a snapshot of Mrs. N.'s functioning through her husband and her sister-in-law. I feel fairly confident that I am following all that Mr. N. is telling me, as his sister-in-law tells me much the same thing."

Observations of Cognitive Function

Mrs. N. performed the Contextual Memory Test (CMT) (Toglia, 1993), a test of immediate and delayed recall of 20 pictures associated with morning hygiene. Her performance on this test suggested moderate memory deficits but adequate awareness of these limitations. Her husband translated instructions to a 10-step task to which she jotted notes. After a 25-minute delay and interference activities, she was able to use her own notes to carry out the task with 70% accuracy. She appeared to make errors because she did not carefully review her notes and approached two steps in what appeared to be a hasty and impulsive manner.

"I know that I am supposed to follow the CMT's administration protocol, but under these circumstances, I just cannot. However, the picture format of this test might give me a sense of her ability to learn new information. I appreciate that the veracity of assessment findings are in question, as all responses were reported through her husband."

Observations of Performance of Functional Tasks

The therapist requested that Mrs. N. select a familiar stove-top meal to prepare in occupational therapy and asked her to bring necessary supplies and ingredients to one of her assessment sessions. Mr. N. reportedly reminded Mrs. N. to do so. As instructed by the therapist, Mrs. N. made an obvious effort to remember to turn off the stove burner once she finished preparing her dish. She sat next to the stove throughout the task, but having removed the pan from the stove to serve the food, she did not return to turn off the burner (which was left on for 5 minutes, until the therapist turned it off). She appeared well organized in her approach to the task, removing all ingredients and supplies from the cupboard ahead of time and cleaning up as she proceeded. Despite these efforts, she forgot to add one of the ingredients she had set out on the table and asked the therapist whether she had added another. Mrs. N. frequently requested rest during occupational therapy sessions that entailed physical activity. She generally tolerated approximately 5 minutes of standing or walking before requesting to sit and rest because of fatigue and dizziness. During one of the three sessions, Mrs. N. complained of headache and intermittently rested her head on the table.

"I thought it would be a good idea to have Mrs. N. prepare a familiar dish so as to remove at least one novelty variable. I am impressed that she is willing to try every activity that I propose and that says a lot to me about her motivation to use therapy to improve her functioning."

Analysis of Results

Mrs. N.'s performance of functional tasks in occupational therapy seemed consistent with the kinds of problems reported at home by Mrs. N., her husband, and her sister-in-law. Specifically, Mrs. N.'s performance on pencil-and-paper and kitchen tasks were marked by forgetfulness, absent-mindedness, and poor endurance. Furthermore, given her dramatic decline in activity, reports of frequent crying and decreased appetite, the therapist was concerned about depression. Given his own stress, the therapist questioned whether Mr. N. would be able to maintain all of the roles he had assumed since his wife's injury.

The following recommendations were suggested as prerequisite to commencing occupational therapy treatment:

- Referral to a woman psychologist for further evaluation and treatment of possible mood disorder
- Referral to a neurologist specializing in balance disorders (she had never had this complaint exhaustively evaluated)
- Schedule of a family conference with Mrs. N.'s sister-in-law, brother-in-law, and attorney to make arrangements to assist Mr. N. at home, enabling him to put in more hours at work
- Work with the hospital patient representative to provide a translator for future occupational therapy sessions

"I requested an interpreter from the patient representative, but it has taken a little longer than I would like to find someone. Our policies and procedures recommend against using a family member as an interpreter, and I can see that logic. Mr. N. has is own stresses and maybe his own agenda. He needs to be freed up to take care of his other responsibilities and I think it would be beneficial for Mrs. N. to participate in occupational therapy sessions on her own."

"I am concerned that Mrs. N. may not make substantive progress toward her goals if she is depressed, and so I recommended that she see a psychologist or psychiatrist before beginning occupational therapy intervention. Similarly, her complaints about dizziness have never been medically evaluated, and we need to find out what is going on. Given what Mr. and Mrs. N. have told me and what I have seen of Mrs. N.'s performance, I am very concerned about her safety at home. I am not confident in offering any definitive suggestions until I observe her in her own environment."

Occupational Therapy Problem List

1. Decreased memory and concentration capabilities and inadequate strategies to compensate for these problems
2. Deconditioning associated with prolonged inactivity complicated by poor nutrition
3. Lack of structure or routine for daily activities and inability to judge independently which tasks were within her competence level

Synthesize results

"I have addressed similar issues with other clients, and I am confident I can help Mrs. N. address these problems as well."

Clinical Reasoning in Occupational Therapy Practice

Effects of Payer-Reimbursement Context on Occupational Therapy Service Provision

D.W. is a 58-year-old widowed man who was admitted to the hospital after a fall from a ladder during which he suffered a traumatic brain injury. D.W. underwent a craniotomy because of a subdural hematoma. Prior to the accident, he lived alone and worked full time as a construction worker. He does not have any family in the area but does have a son and daughter who live in another state. After the accident, he has both motor and cognitive deficits. D.W. has executive functioning cognitive deficits, is unable to utilize his dominant right upper extremity, requires maximal assistance with his activities of daily living (ADL), and is dependent with his instrumental activities of daily living (IADL). D.W.'s insurance is a health maintenance organization (HMO) that limits inpatient rehabilitation coverage and also limits outpatient occupational therapy coverage to 12 visits in a calendar year. Identify the contextual factors that affect occupational therapy service delivery. What considerations would need to be given for occupational therapy service provision?

Summary Review Questions

1. Consider your morning self-care routine—the activities you performed today to get ready to leave for school or work. List the personal, social, and contextual factors that influenced your performance. If someone who did not know you judged your performance, what aspects might they consider unusual? What aspects might he or she consider normal for someone of your age and background?
2. Write a paragraph describing the possible influences on occupational functioning of one of the contextual factors not discussed in this chapter. For example, how might geography, social class, or gender help or hinder performance?
3. Outline circumstances in which you would use standardized instruments to assess contextual factors and those in which you would use more informal methods.
4. Make a private list of your own biases. What assumptions do you have about people who are different from you in terms of age, sex, cultural and educational background, sexual orientation, and abilities (physical, cognitive, and emotional)? List the steps you can take to debunk these biases and measures to minimize their effects during interactions with patients.
5. Why is it important to identify maladaptive coping strategies during the occupational therapy assessment process?
6. If a patient reports low back pain during a homemaking assessment, what methods might you use to obtain more specific information about his or her complaints?
7. Summarize at least three ways in which social context may influence a stroke survivor's occupational performance.
8. Describe at least three ways in which a patient's cultural background might influence occupational therapy assessment.
9. What are at least two ways in which government and third-party reimbursement impact occupational therapy for patients with physical dysfunction?

Glossary

Context—The interrelated conditions or circumstances in which something occurs (*Webster's Third New International Dictionary*, 1993).

Cultural context—Stable and dynamic norms, values, and behaviors associated with the community or societal environments in which occupational functioning occurs.

Culture—A system of learned and shared guidelines for perceiving, interpreting, and interacting with others and the environment that informs values, beliefs, and behavior (Jezewski & Sotnik, 2001).

Ethnicity—Group norms and practices associated with one's culture of origin (Breland & Ellis, 2012). In and of itself, ethnicity does not predict cultural identity.

Payer-reimbursement context—Policies and regulations that determine availability and reimbursement of occupational therapy services in various settings.

Personal context—A person's internal environment, derived from stable and dynamic factors such as sex, age, mood, and cultural identity.

Social context—The social environment consisting of stable and dynamic factors such as premorbid roles, social network, and support resources.

Social network—An interactive web of people who provide each other with helpfulness and protection. Social networks typically vary in terms of reciprocity, complexity, intensity, and density (Heaney & Israel, 1997).

Social support—The aid and assistance (emotional, instrumental, information, and appraisal) exchanged through a social network (Heaney & Israel, 1997).

Spirituality—Beliefs and practices that give a person transcendent meaning in life (Pulchaski & Romer, 2000).

Assessing Roles and Competence

Susan E. Fasoli

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Understand the nature and importance of assessment in occupational therapy.
2. Evaluate roles, competence, and occupational functioning, beginning with clients' perception of their occupational performance concerns.
3. Understand the measurement criteria necessary for reliable and valid assessments used in occupational therapy practice.
4. Describe and select appropriate validated assessments of occupational performance (roles, tasks, and activities) based on client needs.

Sense of self-efficacy
and self-esteem

**Satisfaction with
life roles**
• Self-maintenance
• Self-advancement
• Self-enhancement

**Competence in tasks
of life roles**

Activities and habits

Abilities and skills

Developed

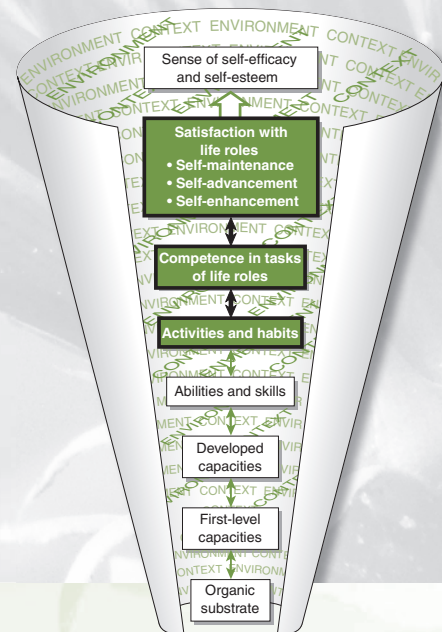
Organic
substrate


Participation in the occupations of everyday life is a vital part of human development and the lived experience (Law, 2002). Occupational therapists provide services to optimize the occupational performance of persons who have or are at risk for developing occupational dysfunction. This chapter describes many assessments of occupational performance and competence in valued life roles, tasks, and activities. Later chapters discuss assessment of the abilities and capacities (components of occupational function) required to carry out the tasks and activities involved in various life roles.

The goal of occupational therapy is to enable individuals to achieve competency and satisfaction in their chosen life roles and in the activities that support function and participation in these roles. Such competency and satisfaction can be achieved through personal independence or by directing others, such as a caregiver or attendant. Occupational performance is the ability to carry out basic activities of daily living (BADL) or activities of daily living (ADL), instrumental activities of daily living (IADL), education, work, play or leisure, and social participation (American Occupational Therapy Association [AOTA], 2008). Whenever a person has a health disorder, injury, or disease that results in a physical and/or cognitive impairment, independence in these areas of occupation may be jeopardized.

The evaluation of occupational performance often begins with a semistructured interview to assess the client's needs, problems, and concerns regarding role participation and competence in daily living tasks and activities (AOTA, 2008). During this interview, the therapist gathers valuable information from the client and family members about the tasks and roles that are most important to them and about activities that the client can and cannot do. After identifying the client's areas of difficulty in occupational performance, the therapist completes further assessments (either impairment-based or disease-specific) to clarify the factors that limit performance. If the limiting factors can be improved or eliminated by direct intervention, the therapist chooses an intervention approach that is appropriate for the problem. When the limiting factors are not amenable to change, the therapist teaches the individual to compensate for these limitations by adapting the task or by changing the environment in which it is performed.

It is important to recognize that occupational performance, or the ability to carry out activities during daily life, depends on the individual's culture, gender, roles that he or she wishes to undertake, and environment. Thus, occupational performance is a personal concept. The individuality of a person's roles and his or her day-to-day functioning make it both difficult and time consuming to assess all aspects of occupational performance. Therefore, it is important for the occupational therapist to carefully select evaluations that best measure a client's occupational performance needs. As outlined by Trombly Latham (see Chapter 1), assessments should be done using a top-down approach that begins with an evaluation of roles, tasks, and activities.

Life roles include self-maintenance (e.g., independent person, caregiver and home maintainer), self-enhancement (e.g., friend and moviegoer), and self-advancement (e.g., worker and student) (Trombly, 1995).

This top-down approach to assessment includes consideration of the environment in which a person lives (see Chapter 10) and incorporates considerations of personal, social, and cultural context (Chapter 3). Assessment does not ignore the more basic abilities, or performance skills, that enable occupational performance, such as strength, endurance, problem solving, or depth perception. Rather, it begins with a function-based assessment of the tasks and activities that the client needs, wants, or is expected to accomplish and is having difficulty performing (Law et al., 2005). Looking at this process from the perspective of the World Health Organization's International Classification of Functioning, Disability and Health (ICF) (World Health Organization [WHO], 2001), occupational therapists first assess activities and participation, evaluating impairments in body functions (i.e., performance skills) as needed to explain difficulties in performance. By beginning with a focus on clients' needs and considering their roles and the environment in which they live, therapists acknowledge the values and goals that these individuals bring to occupational therapy. This approach reflects a client-centered philosophy, recognizing that it is the person who is engaged in therapy who should articulate the goals of therapy and drive the rehabilitation process (Law, 1998).

TIMING, SEQUENCE, AND SETTINGS FOR EVALUATING OCCUPATIONAL PERFORMANCE

Competence in occupational performance areas (e.g., ADL, IADL, leisure, and work) is evaluated over time based on the client's identified needs and interests. Assessments of self-care and personal mobility are usually done early because they form the basis for planning restorative therapy and/or adaptations to optimize ADL. As recovery continues and discharge plans are considered, further evaluations are used to assess a client's ability to manage home and child care responsibilities, gain access to home and community, engage in leisure activities and family recreation, or return to valued education or work pursuits.

Assessment of roles and competence by occupational therapists can take place in many environments, such as a hospital, rehabilitation center, workplace, school, or community setting. It is important to note that the setting in which an assessment is performed can affect a client's performance. Research indicates that the results of an assessment performed at one location (e.g., rehabilitation center) do not necessarily predict performance in another location (e.g., home) (Rogers et al., 2003). For example, Park, Fisher, and Velozo (1994) reported that process skills were better when older adults completed IADL tasks in the familiar environment of their homes rather than the occupational therapy clinic, whereas motor skills

remained stable across settings. This research supports evaluation of a client's performance in the environment in which tasks typically occur, whenever possible.

MEASUREMENT CONCEPTS

Several important measurement concepts must be considered when choosing evaluations to assess roles and competence in occupational therapy. These concepts include whether the assessment is a standardized measure with established reliability and validity, its responsiveness to change, its level of measurement and clinical utility, and whether it involves direct observation or self-report.

Properties of the Assessment

A standardized measure is a published assessment tool that provides detailed instructions on test administration and scoring and has published results of reliability and validity (Finch et al., 2002). A reliable assessment is one that consistently measures the attribute under study, no matter who is scoring (interrater reliability) or when the assessment occurs (test–retest reliability). A valid assessment is one that measures what it claims to measure. Most evaluations of occupational performance have content validity, meaning that the test items well represent the area being tested. Some items of a valid assessment, however, may be more important than others. For example, when assessing homemaker competence during meal preparation, "can use the stove safely" is more critical in many ways than "can stir batter."

The use of nonstandardized checklists commonly found in the clinic is not recommended because of their inherent lack of reliability and validity. Because the tasks listed in nonstandardized checklists are rarely operationally defined, the same methods are not necessarily used to evaluate task performance across clients and therapists. The Centers for Medicare and Medicaid Services (CMS) recommend the use of validated tests and measures when assessing a client's functional abilities and needs (Centers for Medicare & Medicaid Services, 2011). Because many private insurers follow CMS guidelines when establishing their own standards, it is critically important that occupational therapists use objective measures to reliably document occupational performance for all clients receiving services. When using standardized assessments, occupational therapists can more efficiently target client needs and goals and accurately measure changes in occupational performance that are both clinically significant and meaningful to their clients. In order to best meet patient needs, the therapist should select assessments based on the population for which it was validated and adhere to administration instructions exactly as directed (e.g., not adding or dropping items) so that reliability is not reduced across multiple testing sessions.

An assessment that includes a wide range of test items will be more responsive to detecting decrements in occupational performance. For a therapist working on a day-to-day basis with a client to improve her ability to dress, the assessment should be sensitive enough to allow progress to be noted when different areas of the body can be dressed or different articles of clothing are donned. Responsiveness is directly related to the number of items on an assessment and to the number of categories on the scoring scale. An assessment with 50 items is likely to be more responsive than one with 10 items. The level of measurement also contributes to the test's responsiveness or sensitivity in detecting clinical change. For most evaluations of roles, tasks, and activities, the level of measurement is ordinal; that is, the scores are rank ordered to indicate the client's performance. For example, scores might range from 1 (dependent, is unable) to 7 (independent, is able). The range of ordinal scores varies depending on the assessment scale. A scoring system that uses a 1 to 7 Likert-type scale is likely to be more responsive to changes in performance than one using a 1 to 3 scale.

Reevaluation

Periodic reevaluations are performed to monitor the client's response to therapy. At a minimum, it is important to record the level of performance at admission and discharge because these records may be used for program evaluation, to justify occupational therapy services to third-party payers, in legal actions, or when determining whether a patient will be discharged home or to an extended-care facility. Discharge evaluations can also aid transitions from one level of care to the next (e.g., rehabilitation hospital to home-based therapy) by providing valuable information about the client's abilities and occupational performance needs.

In order to interpret whether changes in test scores are meaningful, it is important to understand what constitutes a clinically significant difference. From a client's perspective, a clinically significant change could reflect greater independence in valued activities, such as transferring into the tub or completing lower body dressing. The therapist may use the concept of clinically significant change to determine whether her treatment methods are effective or whether the course of intervention needs to be altered to better impact performance. A clinically significant change score is one that exceeds the measurement error that typically occurs during routine test administration. One more commonly used index of change is the minimal clinically important difference (MCID) (Haley & Fragala-Pinkham, 2006). The MCID can be calculated for a standardized assessment and used to demonstrate that changes in occupational performance exceed measurement error and are clinically meaningful. An increasing number of standardized assessments used by occupational therapists, such as the Barthel Index and Functional Independence Measure™ (FIM™), have documented MCIDs to aid interpretation of patient outcomes. The concept of clinically significant change is gaining research attention and will be increasingly important as occupational therapists are required to better substantiate the effectiveness of their interventions.

Clinical Utility

The clinical utility of an assessment tool is another important consideration. Clinical utility refers to all of the practical factors of an instrument, such as its cost, the amount of training needed, availability of a manual with clear instructions, and ease of administration and interpretation. In most occupational therapy settings, managers prefer to use assessments that efficiently provide useful information for treatment planning and evaluating client outcomes.

Direct Observation versus Self-Report

Standardized assessments gather information about occupational performance from either direct observation or self-report by the client or family members. Observation of activities that are important to the client is the most direct method of assessing competence in occupational performance. This method is preferred for accuracy, detection of inefficient or unsafe methods, and determining the underlying reason(s) that a particular task cannot be performed. Direct observation of the wide range of occupational performance areas, however, can be time consuming and costly (Law & Letts, 1989). Self-report of one's competence in occupational tasks and roles through interview is often the easiest, fastest, and least expensive method of assessing functional abilities and may inform the direct observation of selected activities.

There is a concern that self-reports and interviews may not accurately reflect what the person can do. Studies that compared self-report ratings with direct observation of functional performance have yielded conflicting results. Some researchers reported high levels of agreement between these two methods, especially for daily self-care tasks (Collin et al., 1988); others found that clients consistently overrated their abilities (Edwards, 1990; Sagar et al., 1992). If a client reports questionable data and does not allow direct observation, the therapist should verify the report with others who have knowledge of his or her actual performance. False information may be related to the client's lack of insight and limited awareness of abilities and needs and is not necessarily a conscious intent to deceive. In these cases, proxy reports and interviews with family members or caregivers can provide additional information about client performance from the family's perspective. Although self-report and direct observation in the environment where the task ordinarily occurs are preferred, the assessment methods chosen for a particular client ultimately will depend on the nature of the disability, the supportiveness of the client's environment, and the time constraints encountered during rehabilitation.

Assessing Outcomes

As indicated earlier, occupational therapists administer various assessments to obtain information for the purpose of planning intervention. Some measures are administered in order to quantify the overall benefits of intervention (also referred to as outcomes of intervention). Recent studies have shown initial reliability and validity of the Australian Therapy Outcome Measures for Occupational Therapy (AusTOMS-OT) (Perry et al., 2004; Unsworth, 2005; Unsworth et al., 2004). The AusTOMS-OT was developed to be consistent with ICF terminology and provides a snapshot of the client's occupational performance across four domains of functioning: impairment, activity, participation, and distress/well-being. The AusTOMS-OT is suitable for clients of varied diagnoses and ages across treatment settings (hospital, outpatient clinics, and home or extended care) and consists of 12 function-focused scales, including learning and applying knowledge, upper limb use, self-care, and domestic life, among others. To use the AusTOMS-OT, the therapist administers standardized assessments as described below, works collaboratively with the client to select goals for therapy, and then chooses related AusTOMS-OT scales (e.g., self-care or functional walking and mobility) for scoring. Four scores are given for each of the selected scales to reflect the therapist's perception of performance impairments in relation to the four domains. This quick and easy-to-use measurement tool has strong potential to document change in patient status over the course of therapy and allows the therapist and client to examine the effectiveness of intervention. This unique approach, although focused on occupational performance, allows for a single assessment of the client's strengths and limitations across ICF domains. Although it is currently used extensively in the United Kingdom and Australia, more widespread use in the United States is expected.

The assessments discussed in this chapter are generic measures that can be used to evaluate occupational performance of clients with a variety of diagnoses and levels of disablement. Refer to the chapters that follow for specific measures that assess the effects of a particular disease or condition (e.g., orthopedic injuries and chronic obstructive pulmonary disease) on occupational performance.

ASSESSMENT METHODS AND TOOLS

A comprehensive top-down assessment of occupational performance begins with an overview and identification of a client's occupational needs, is followed by evaluation of his or her engagement and competence in life roles and tasks, and continues with an assessment of the abilities or performance skills (e.g., coordination, strength, and organization) needed to accomplish valued activities. See Assessment Table 4-1 for descriptions, reliability and validity data, and strengths/weaknesses of many of the evaluations discussed in this chapter. Resources 4-1 has contact information regarding purchase of these assessments.

Assessment Table 4-1 | Summary of Assessments of Occupational Function

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Occupational Performance Needs						
Canadian Occupational Performance Measure (COPM), 4th edition (Law et al., 2005)	Semistructured interview with ordinal scale to measure changes in client perception of performance and satisfaction with performance in self-care, productivity, and leisure occupations	30–40 minutes	Numerous studies support COPM as a valid measure of occupational performance. Combined COPM and Functional Independence Measure (FIM™) scores were 65% accurate in predicting discharge status (Simmons, Crepeau, & White, 2000).	Test-retest reliability at 1–2-week intervals ranges from 0.63 to 0.89 for performance; and 0.76 to 0.88 for satisfaction (AOTA, 2007).	Carswell et al. (2004) report COPM is more sensitive to perceived changes in client status than other disability measures, including Short Form 36 and FIM™. A 2-point change in score is clinically significant (AOTA, 2007).	Strengths: Psychometrics studied in wide range of diagnoses (Carswell et al., 2004). Translated into 20 languages and used in more than 35 countries around the world.
Australian Therapy Outcome Measure for Occupational Therapy (AusTOMs) (Unsworth, 2005)	Consists of 12 function-focused scales (e.g., self-care and domestic life) that are scored across four domains derived from International Classification of Functioning, Disability and Health (ICF). Occupational performance is rated by therapist after completion of other standardized assessments. Useful tool for documentation of progress, program evaluation, etc.	5–10 minutes (scores based on other standardized assessment outcomes)	Construct validity established with EuroQuol-5D (Unsworth et al., 2004).	Self-care scale: Moderate to high interrater reliability across three domains (Intraclass Correlation Coefficient (ICC) ≥ 0.79); somewhat lower for impairment domain (ICC = 0.70). Intrarater reliability also moderate to high (ICCs = 0.74–0.94) across domains (Scott et al., 2006).	Sensitivity to change is documented, particularly in clients at acute and subacute facilities and for those with neurological diagnoses.	Strengths: Scoring allows holistic assessment across levels of occupational performance (impairment through participation). Tests are quick to administer/complete. Weaknesses: Scores are based on therapist perception of client outcomes. Reliability studies ongoing.

Assessment	Description	Time	Validity	Reliability		Strengths/Weaknesses
Occupational Performance History Interview-II (OPHI-II, version 2.1) (Kielhofner et al., 2004).	Semistructured interview intended to give a broad and detailed appreciation of a person's life history, the impact of disability, and the direction in which the person would like to take his or her life. Specific criteria are provided to rate performance on three scales: occupational performance, identity, and behavior. Rasch analysis has been used to calibrate and convert ordinal scores to interval data.	45–60 minutes	Validity for all three scales is excellent. More than 90% of subjects tested (with varied ages, nationalities, and diagnoses) were validly measured, and over 90% of raters used scales validly, with approximately the same degree of severity or leniency. (Kielhofner et al., 2001).	Test–retest reliability studies not available; manual provides detailed information on the rating process to improve observer reliability.	Adequate. Person separation statistic showed that the scale can distinguish meaningful differences among persons of approximately three different levels of competence, identity and environmental support (Kielhofner et al., 2001).	Strengths: Specific criteria assist with rating. Rasch analysis has been used to calibrate and convert ordinal scores to interval data. Weakness: Evidence of rater reliability not well reported in research literature.
Life Balance Inventory (LBI) (Matuska, 2012a, 2012b). Available online at http://minerva.stkate.edu/lbi.nsf	Self-report questionnaire used to rate satisfaction with amount of time spent on activities the client does or would like to do. Life balance ratings are provided for four dimensions: health, relationships, challenge/interests, and identity needs (Matuska, 2012a).	10–15 minutes	Acceptable content validity; combined congruence and equivalence model provided best fit with measures of stress and personal well-being (Matuska, 2012b)	Internal consistency was very good (Cronbach's $\alpha = 0.89$–0.97).	Not established	Strengths: Theory-based assessment, low cost, and easily accessed; useful for treatment planning. Weaknesses: Its use with varied patient groups and sensitivity to change have not been examined.

(continued)

Assessment Table 4-1 | Summary of Assessments of Occupational Function (*continued*)

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Roles and Community Integration						
Role Checklist (Oakley et al., 1986) Available from: Frances Oakley, MS, OTR, FAOTA Board Certification in Gerontology National Institutes of Health Building 10, CRC, Room 1-1469 10 Center Drive MSC 1604 Bethesda MD 20892-1604 E-mail: foakley@cc.nih.gov	Written inventory/ checklist that provides data on client perceptions of role participation and values throughout the life span	15 minutes	Content validity of role taxonomy is based on literature review and expert opinion; construct validity based on Model of Human Occupation (MOHO) (AOTA, 2007).	Test–retest reliability ranged from 73% to 97% agreement for three time categories (mean = 88%); agreement for roles was 77%–93% (mean = 87%) (AOTA, 2007).	Not established	Strengths: Appropriate across age groups. Translated into 10 languages. Can be adapted for verbal administration by therapist.
Reintegration to Normal Living Index (RNL) (Wood-Dauphinee et al., 1988).	Eleven declarative statements regarding how well clients perceive their return to normal living after a disabling event (e.g., "I am comfortable with how my self-care needs are met.") are rated by either a visual analog scale or 3- or 4-point categorical scale. A validation study (Stark et al., 2005) used a 10-point Likert-type scale to increase precision of scoring. Recently modified version (mRNL) rephrased questions to improve validity (Miller, Clemson, & Lannin, 2011).	Less than 10 minutes	Good construct validity of mRNL confirmed by Rasch analysis (Miller, Clemson, & Lannin, 2011).	Internal consistency (Cronbach's α = 0.80) and test–retest reliability (ICC (3,1) = 0.83, p = 0.0001) both acceptable (Miller, Clemson, & Lannin, 2011).	Not established	Strengths: Emphasis placed on client's perceptions of autonomy in life situations. Weakness: Initial problems in RNL domains were more likely reported by proxy than client scores; important to compare client and proxy reports.

Assessment	Description	Administration Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Community Integration Measure (CIM) (McColl et al., 2001). Primary author M. A. McColl may be contacted at mccollm@post.queensu.ca	Ten-item, qualitative measure based on client-centered model of community integration. Client agreement with test statements is measured by 5-point scale. Sample items include "I feel that I am accepted in this community" and "I know my way around this community."	Approximately 5 minutes	Criterion validity supported by comparisons with Community Integration Questionnaire and Satisfaction with Life Scale (Reistetter et al., 2005). Discriminates well between persons with brain injury and neurologically intact controls.	Cronbach's α for internal consistency originally reported at 0.87. Replication study reported slightly lower yet acceptable internal consistency (0.72–0.83).	Not established	Strengths: Quick and easy to administer and score and readily understood by clients and families. Weakness: Psychometrics to date have only been examined with clients diagnosed with traumatic brain injury (TBI), potentially limiting generalizability of this tool to other disability groups. Specific instructions to relate test results to treatment planning are not provided.
Activities of Daily Living						
Barthel Index (Mahoney & Barthel, 1965). Information available online at www.strokecenter.org/trials/scales/barthel.pdf	Self-report and direct observation used to evaluate 10 activities: feeding, bathing, grooming, dressing, bowel and bladder control, toilet use, transfers between chair and bed, mobility, and stair climbing. The total score ranges from 0 (total dependence) to 100 (total independence).	5–10 minutes if verbal report; 25 minutes or longer for direct observation	High correlations between Barthel Index and clinical judgment. Well correlated with index of motor ability (r = 0.73–0.77) (AOTA, 2007).	Internal consistency α coefficients 0.87–0.92 for original version; 0.90–0.93 for modified scoring (Shah, Vanclay, & Cooper, 1989). Test–retest reliability κ = 0.98 in clients with stroke (Wolfe et al., 1991).	Lacks sensitivity to amount of assistance needed. Initially high functioning clients can reach "ceiling" score and show no further improvement (Shah, Vanclay, & Cooper, 1989).	Strengths: Excellent reliability and validity. Widely used. Time to administer. Minimal clinically important difference (MCID) established for 20-point scale of Barthel Index (MCID = 1.85) (Hsieh et al., 2007). Weaknesses: "Ceiling" effect for higher level clients. Only fair sensitivity to change.

(continued)

Assessment Table 4-1 | Summary of Assessments of Occupational Function *(continued)*

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Functional Independence Measure (Granger et al., 1993)	Eighteen items (13 motor and 5 cognition) in the areas of self-care, sphincter control, transfers, locomotion, communication, and social cognition. A 7-point ordinal scale rates level of independence in activities of daily living (ADL) (independent without equipment = 7). Scores are based on clinical observation. Follow up data can be gathered from phone interviews.	Approximately 45 minutes, depending on client abilities	Excellent validity reported. Motor FIM™ able to predict level of assistance required in 83% of TBI clients tested; cognitive FIM™ predicted 77% of those requiring supervision (Corrigan, Smith-Knapp, & Granger, 1997).	Numerous studies have reported excellent reliability in wide range of diagnostic groups. Chau et al. (1994) reported interrater ICC at 0.94, test–retest ICC at 0.93.	Greater sensitivity to change reported in motor than cognitive scales in persons with stroke (van der Putten et al., 1999) and multiple sclerosis (Sharrack et al., 1999).	Strengths: Extensive validation, widely recognized and used. Excellent reliability and validity in measuring disability. MCID established for stroke: Total FIM™ (MCID = 22); motor FIM™ (MCID = 17); cognitive FIM (MCID = 3) (Beninato et al., 2006). Weaknesses: FIM™ scores do not provide information regarding factors (e.g., body functions and environmental support) that influence occupational performance.
Klein-Bell Activities of Daily Living Scale (Klein & Bell, 1982)	Behavior rating scale consists of 170 specific items to rate performance in six ADL areas: dressing, elimination, mobility, bathing/hygiene, eating, and emergency phone communication. Performance is observed and scored as either able or unable; scores also are weighted from 1 to 3 points based on item difficulty.	30 minutes depending on client's level of ability and fatigue	Validity was established on 14 patients by comparing the total score at discharge against the hours of assistance required. A correlation of −0.86 ($p < 0.01$) was obtained, indicating that the amount of assistance decreases as the Klein-Bell score increases.	Interrater agreement = 0.92 even without extensive training (Klein & Bell, 1982).	Specificity of test items makes this test highly responsive to changes in client status.	Strengths: Highly responsive. Excellent reliability and validity. Appropriate for clinical purposes and research. Weaknesses: Higher level subjects may reach test "ceiling."

Instrumental Activities of Daily Living (IADL)

Assessment	Description	Time	Validity	Reliability	Responsiveness	Strengths and Weaknesses
Nottingham Extended Activities of Daily Living (NEADL) Scale (Nouri & Lincoln, 1987). Available at http://www.nottingham.ac.uk/iwho/documents/neadl.pdf	Quick to administer self-report questionnaire consisting of 22 items in four sections: mobility, kitchen, domestic, and leisure tasks. Respondents rate amount of assistance needed to complete tasks on 4-point scale.	10–15 minutes	Validity was established when compared to Frenchay Activities Index and Stroke Impact Scale (Wu et al., 2011).	High interrater reliability reported with stroke (Schlote et al., 2004). Satisfactory test–retest reliability with multiple sclerosis clients ($r = 0.81–0.90$) (Nicholl, Lincoln, & Playford, 2002).	Contradictory reports may be due to comparison to different measures. More responsive than Frenchay Activities Index (Wu et al., 2011); insensitive to change when compared with components of SF-36 and London Handicap Scale (Harwood & Ebrahim, 2000).	Strengths: Quick to administer, easily understood by clients; appropriate for mail surveys. Weaknesses: Questionable responsiveness to change over time; not as specific as semistructured questionnaires (e.g., COPM) for guiding treatment planning.
The Assessment of Motor and Process Skills (AMPS) (Fisher, 1993, 1995)	The AMPS is an observational assessment that evaluates motor and process skills that directly impact occupational performance. Client chooses 2 or 3 ADL tasks for assessment from a list of more than 100. Computerized scoring and Rasch methods are used to generate adjusted instrumental activities of daily living (IADL) ability measures. These take into account severity of the rater who scored performance and the relative challenge of tasks performed.	30–60 minutes for administration and scoring	Many published studies have demonstrated the validity of the AMPS. Validity as a cross-cultural measure has been reported.	Extensive research documents reliability across cultural and diagnostic groups. Intrarater reliability is excellent ($r = 0.93$). Test–retest reliability reported to be $r = 0.88$ for motor skills, $r = 0.86$ for process skills. (Fisher, 1995).	Excellent responsiveness to client change has been reported.	Strengths: Excellent reliability and validity. Evaluation tasks are chosen by client and are meaningful and relevant to his daily life situation. Appropriate for use across ages (3 years to adult) and diagnostic groups. Weaknesses: Training requirements are extensive, which limits clinical utility.

Assessment Table 4-1 | Summary of Assessments of Occupational Function *(continued)*

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
The Kohlman Evaluation of Living Skills (KELS) (Kohlman Thomson, 1993)	Self-report and observation assessment of 17 IADL tasks in five areas: self-care, safety and health, money management, transportation and telephone, and work and leisure. Items such as "use of money to purchase items" or "use of phone book and telephone" are scored as 0 (independent) or 1 (needs assistance). A score of 5.5 or less indicates that client is able to live independently.	30–45 minutes	Concurrent validity studies that compared KELS with Global Assessment Scale (0.78–0.89) and BaFPE (−0.84) indicate high agreement.	Interrater reliability in multiple studies is reported to be high (r = 0.84–1.00) (Kohlman Thomson, 1993).	Not established	Strengths: Easy to administer. Few materials are required. Can be used in many settings and with many diagnostic groups. Weaknesses: Tasks provide good screening of basic abilities, but higher level clients may reach test "ceiling."
Performance Assessment of Self-Care Skills (PASS) version 3.1. (Holm & Rogers, 2008; Rogers & Holm, 1989a, 1989b). Contact: mbholm@pitt.edu	Performance-based, criterion-referenced assessment of functional status and change consisting of 26 core tasks organized in four domains: functional mobility, personal self-care, and IADL tasks with either a cognitive emphasis or physical emphasis. Observed performance is rated for independence, safety, and adequacy.	Varies widely depending on number of items administered. Entire test requires 1.5-3 hours to complete.	Content and construct validity established (AOTA, 2007).	Interrater reliability percentage of agreement for PASS-C and PASS-H was 0.80–0.99. Test–retest reliability ranged from 0.82 to 0.97 with 3-day interval (Rogers & Holm, 1989a, 1989b).	Authors report sensitivity to change at discharge.	Strengths: Actual objects are used during performance of test items, increasing ecological validity. Clear instructions for administration and scoring. Criterion referenced. Low cost. Weaknesses: Time needed to assemble items. Materials for test kit.

Assessment	Description	Administration Time	Validity	Reliability	Sensitivity	Strengths/Weaknesses
Safety Assessment of Function and the Environment for Rehabilitation (SAFER-HOME) (Chiu et al., 2006; Oliver et al., 1993)	The SAFER-HOME tool consists of an easy-to-use checklist of 75 items grouped into 12 areas of concern including living situation, mobility, kitchen, household management, self-care, and recreation. A combination of observation, interview, and task performance is used to rate each item.	Approximately 1 hour, depending on administration method, client's functioning level, and home environment.	Construct validity has been supported in relation to cognitive impairment, but further research is needed. (Chiu & Oliver, 2006).	Interrater and test-retest reliability demonstrated via κ or percentage agreement was acceptable to excellent (Letts et al., 1998). Internal consistency of SAFER-HOME version 2 is good with Cronbach's α = 0.859 (AOTA, 2007).	Fair. The revised 4-point rating scale of *SAFER-HOME* version 2 may better measure changes postintervention than original tool.	Strengths: Clear assessment guidelines and recommendations. Revised 4-point scoring may increase sensitivity to change. Weaknesses: Lack of sensitivity to change. Reliability and validity of the revised scale (SAFER-HOME, version 3) are not established.
The Kitchen Task Assessment (KTA) (Baum & Edwards, 1993).	The KTA assesses six cognitive abilities during the task of making cooked pudding from a package: initiation, organization, inclusion of all steps, safety and judgment, and task completion. The level of support needed from the therapist is scored from 0 (independent) to 3 (not capable). Unlike the AMPS, this measure does not evaluate motor skills during task performance.	Less than 30 minutes	Construct validity was supported by highly significant correlations between KTA scores and other cognitive measures, including the Token Test, Clinical Dementia Rating, and Short Blessed Dementia Scale.	Internal consistency of the KTA ranges from 0.87 to 0.96, and interrater reliability for the total score is 0.85.	KTA scores significantly differentiated cognitive performance across all stages of dementia (Baum & Edwards, 1993). Sensitivity to client change over time has not been established.	Strengths: Good reliability and validity in lower functioning adults with dementia. Quick and easy to administer. Weaknesses: Little data to support KTA use with other rehabilitation populations (Duncombe, 2004). Higher functioning clients will easily reach test "ceiling."
Rabideau Kitchen Evaluation Revised (Neistadt, 1992, 1994)	Direct observation of meal preparation tasks that involve preparing a hot beverage and cold sandwich. Each task is broken down into component steps that are rated on a 0- (no assist needed) to 3-point scale (unable and requires direct intervention) (Neistadt, 1994). Six levels of task difficulty help guide the grading of tasks, based on client abilities (highest level involves preparation of fruit salad or baking frozen pastries).	20–30 minutes depending on tasks performed	Criterion validity reported with the Wechsler Adult Intelligence Scale-Revised (WAIS-R) block design test ($r = 0.60$, $p = 0.0002$), suggesting that both tests measure common skills.	Interrater reliability is $r = 0.86$. Test–retest reliability on a small sample yielded was $r = 0.80$ (Neistadt, 1992).	Not established	Strengths: Reliable kitchen assessment based on information-processing theory. Dynamic assessment approach indicates amount of cognitive support needed for task completion. Weaknesses: Primarily validated with persons with TBI, limiting generalizability to other diagnostic groups. Choice of tasks is limited by test design.

Assessment Table 4-1 | Summary of Assessments of Occupational Function *(continued)*

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Work Assessments						
VALPAR Component Work Sample Series & Dexterity Modules (Valpar Corp.)	Direct observation of work tasks selected to evaluate client's specific job requirements and needs. Each work sample consists of a scoring manual and standardized equipment ranging from common items to large equipment. Examples of dexterity module include small parts assembly, tool manipulation, and bimanual coordination.	Dependent on number of work samples tested. Samples range in time from 20 to 90 minutes.	The work samples have been criterion-referenced according to the Department of Labor's *Dictionary of Occupational Titles (DOT)*, yielding good face and content validity (AOTA, 2007).	Test–retest reliability for work samples 1–16 of the original series ranged from 0.70 to 0.99 for work rate and accuracy scores over a 1-week interval (AOTA, 2007).	Measures are highly sensitive to detecting changes in client performance over time.	Strengths: High face validity and reliability. Normative tables provide error and time percentiles for each sample. Weaknesses: Work samples emphasize physical components of work tasks and should be supplemented with assessments of worker interests, goals, and psychosocial/contextual factors influencing performance.
Worker Role Interview (WRI) version 10.0 (Braveman et al., 2005; Velozo, Kielhofner, & Fisher, 1998)	A semistructured interview that assesses psychosocial/environmental factors of concern to the injured worker or client with a long-term disability and poor/limited work history. Complements observations made during other physical or behavioral work assessments: designed to identify specific variables influencing client's ability to return to work.	30–60 minutes and 15 minutes for scoring	Content areas were based on MOHO, and extensive literature review of factors that influence return to work.	Test–retest reliability for total score with a 6–12-day interval was 0.95. Interrater reliability was 0.81 with three raters (Biernacki, 1993).	Not established	Strengths: Test items reflect occupational therapists' interest in the meaning of work. Psychometrics of WRI (version 9.0) confirmed (Forsyth et al., 2006). Weaknesses: Time to administer can be lengthy.

Leisure Assessments

Assessment	Description	Time	Validity	Reliability	Sensitivity	Strengths/Weaknesses
Activity Card Sort (ACS), 2nd edition (Baum & Edwards, 2008)	Card sort consists of 89 photographs depicting instrumental, leisure, and social activities. Respondent is asked to sort cards into categories related to activity performance prior to injury/illness, current patterns, and most important. Comparison of previous to current scores for each area of occupation reflects change in activity participation that can be addressed in treatment planning. Three test versions allow use in multiple settings.	20–30 minutes	Content, construct, and predictive validity well established (Baum & Edwards, 2008).	Test-retest reliability for 1-week interval was 0.89. Reliability also studied in Israeli and Hong Kong samples (Baum & Edwards, 2008).	Good sensitivity for clinical and research purposes	Strengths: Strong psychometrics. Easy to administer and use. Provides useful data for treatment planning. Weaknesses: Addresses activity participation of older adults; not appropriate for young clients.
Modified Interest Checklist (Kielhofner & Neville, 1983). Derived from Interest Checklist (Matsutsuyu, 1969; Rogers, Weinstein, & Figone, 1978)	Self-report questionnaire and 68-item interview checklist. Gathers data about a client's interest patterns over time (past, present, and future). Activities range from gardening and yard work, to bowling, watching television, and driving. Recommended for use MOHO.	10–15 minutes	Face validity evident. Rogers (1988) reported that Interest Checklist discriminates among diagnostic groups and normal control subjects.	Good test-retest reliability (0.92) within 3-week interval for original version (Rogers, Weinstein, & Figone, 1978).	Not established	Strengths: Quick to administer. Participation in wide range of activities is assessed over time. Provides activity ideas for treatment planning (Klyczek, Bauer-Yox, & Fiedler, 1997). Weaknesses: Lack of strong validity and sensitivity data. Clients may misinterpret some items (e.g., level of participation is unclear: do clients perform versus watch activities such as auto racing or concerts?). Limited testing with clients who have physical versus psychosocial disabilities.

Identification of Occupational Performance Needs

A client-centered occupational therapy assessment recognizes that engagement in life roles and occupations of one's choice is a personal issue and that the client's perception is an important force that drives the occupational therapy process (Law et al., 2005). Information about a person's occupational roles and tasks, developmental stage, and the environment in which he or she lives is best obtained through interview. Although this can be done through informal narrative interviews, more structured interview-based assessments are recommended. Neistadt's (1994) research indicated that informal client interviews often lead to goals that are vague and not specifically related to occupation. The occupational therapist is advised to select a range of standardized assessments that incorporate semistructured interviews to identify occupational need areas, as well as direct measures of abilities and skills during observation of task performance.

Semistructured Interview Assessments

A semistructured interview assessment that is widely used to evaluate a client's perception of his or her occupational performance is the Canadian Occupational Performance Measure (COPM) (Law et al., 2005). The COPM helps clients to identify concerns with occupational performance, assists in goal setting, and measures changes in client perceptions of occupational performance over the course of therapy. The COPM is a generic measure that can be used with clients across all developmental stages who have a variety of disabilities. It is client centered and addresses roles, role expectations, and activity performance within the client's own environment.

The COPM is administered in a four-step process that includes problem definition, priority setting, scoring, and reassessment. During the initial COPM interview, clients or caregivers identify activities that are important to them and are in need of occupational therapy intervention in the areas of ADL, work, and leisure. After all of the occupational performance problems are identified, clients score them in terms of importance, their perception of current performance, and satisfaction with that performance. It is important to be aware that a client with a new illness may not recognize or be ready to identify these issues. The therapist and the client may begin treatment by working on identified concerns and can return to this semistructured interview process later to see whether other issues emerge. Reassessment is completed at discharge or when the client and the therapist consider it necessary for further treatment planning (Fig. 4-1).

Another semistructured interview assessment that is used to identify occupational performance needs is the Occupational Performance History Interview-II (OPHI-II),

Through an interview, clients identify occupational performance activities that are important to them and which they are having difficulties performing satisfactorily. These are scored on a 1–10 scale.

Activity Problems	Importance	Performance	Satisfaction
Doing up fasteners	9	3	1
Washing face and hands	10	1	1
Preparing sandwich	5	1	4
Holding a book	7	3	5
Visiting friends	9	2	4

Figure 4-1 Example of the scores for the Canadian Occupational Performance Measure.

version 2.1 (Kielhofner et al., 2004). OPHI-II is a broad assessment of occupational life history in work, leisure, and daily activities that was developed using the Model of Human Occupation (Kielhofner, 2008). The OPHI-II contains three valid scales that provide insight into the nature of occupational performance and adaptation (see Assessment Table 4-1). Test items explore a client's ability to organize time for responsibilities; identify interests, goals, and role expectations; recognize personal responsibilities and values; and participate in varied environments (e.g., leisure, home, and work settings). OPHI-II, version 2.1 includes paper key forms that can be used to easily obtain interval measures without computer analysis. These measures can identify when performance in one area (e.g., works toward goals) deviates from others, indicating needs for intervention. An accompanying Life History Narrative Form is used to document qualitative information from the interview. OPHI-II can be used with occupational therapy clients who are adolescents or older and who are seen in psychiatry, physical disability, or gerontology practices (Kielhofner et al., 2004).

Another concept related to occupational performance is that of life balance. The life balance model proposes that a person's activity configuration should meet important needs, which are "(1) basic instrumental needs necessary for sustained biological health and physical safety; (2) to have rewarding and self-affirming relationships with others; (3) to feel engaged, challenged and competent; and (4) to create meaning and a positive personal identity" (Matuska & Christiansen, 2008, p. 11). The Life Balance Inventory (LBI) is based on this model, in which the balance of one's everyday activities is measured in terms of activity configuration *congruence* and activity configuration *equivalence*. Congruence is high when there is a match between the *actual* activities a person engages in regularly and his or her *desired* activity configuration or engagement. Activity configuration equivalence is conceptualized as a satisfactory balance of activity engagement across four dimensions: health,

relationships, challenge/interests, and identity needs (Matuska, 2012a).

The LBI is a reliable and valid online tool (Matuska, 2012b) in which respondents first identify daily activities they do or want to engage in (e.g., gardening and participating in professional organizations) and then rate their perceived satisfaction with the amount of time they spent doing those activities within the past month. A printout provides life balance scores for each of the four dimensions above. The LBI and this conceptualization of life balance can facilitate interview discussions about client-centered goals and help identify ways in which the client can improve satisfaction and reduce stress while engaged in occupational roles and routines.

Assessing Roles and Community Integration

Trombly (1995) sorts life roles into three domains that correspond well to the Occupational Therapy Practice Framework (OTPF) (AOTA, 2008): self-maintenance, self-advancement, and self-enhancement (see Chapter 1). Widely used role assessments in occupational therapy include the OPHI-II, discussed above, and the Role Checklist (Oakley et al., 1986). The Role Checklist is a two-part self-report assessment. Part I assesses participation in 10 major life roles: student, worker, volunteer, caregiver, home maintainer, friend, family member, religious participant, hobbyist/amateur, participant in organizations, and other. Test items address past, present, and future performance of these roles. Part II measures how valuable or important each role is to the client. This assessment has been used to evaluate perceptions of role participation in persons with mental illness, mothers with young children, persons with physical disabilities, and adolescents.

Community integration refers to the ability of a person to live, work, and enjoy his or her free time within the community setting. A client's competence and ability to engage in community tasks and roles after a disabling event or illness are related to intrinsic abilities or performance skills as well as characteristics of the environment in which he or she lives. Although most of the following assessments emphasize the client's perception of his or her competence in community or societal integration, others, such as the Craig Hospital Inventory of Environmental Factors (CHIEF) (Whiteneck et al., 2004), focus on environmental factors that limit community integration. For example, questions on the CHIEF address how the design and layout of the home or workplace, or features of natural or man-made environments (e.g., terrain, noise, and lighting) impact occupational performance and participation. Knowledge of the content and focus of these and other assessments will help the occupational therapist choose tools that best measure and identify occupational performance areas in need of intervention.

The Reintegration to Normal Living (RNL) Index (Wood-Dauphinee et al., 1988) is an easy-to-use 11-item assessment of how well individuals return to normal living patterns following incapacitating disease or injury. Client perceptions of reintegration are measured along several domains: mobility, self-care, daily activity, recreational activity, and family roles. This assessment has been tested with a wide variety of diagnostic groups including patients with arthritis, fractures, amputations, stroke, spinal cord injury, traumatic brain injury, and hip fracture. A validation study of community-dwelling persons with limited mobility (Stark et al., 2005) replaced the original visual analog scale with a 10-point Likert-type scale so clients could more accurately rate their performance. A recent study yielded good construct validity and internal consistency with a mixed sample of community dwelling individuals after rehabilitation (Miller, Clemson, & Lannin, 2011).

The Community Integration Measure (CIM) (McColl et al., 2001) uses 10 items to gather qualitative information about a person's experience with community integration and participation. It is based on a theoretical model that is client centered and differs from other community assessments because it makes no assumptions about the relative importance of particular activities or relationships (McColl et al., 2001). For example, the CIM does not assume that independent participation is a better measure of community integration than supported or mutual participation with others. Although this easy-to-use measure was developed for and tested primarily with persons diagnosed with traumatic brain injury, it has been used in practice with clients who have a wide range of disabilities (McColl et al., 2001). The CIM is able to differentiate persons with and without disabilities and correlates significantly with other measures of community integration and life satisfaction. A replication study (Reistetter et al., 2005) showed that the CIM correlated better with the Satisfaction with Life Scale than the Community Integration Questionnaire (CIQ) (Willer, Ottenbacher, & Coad et al., 1994).

Many assessments of health-related quality of life have been developed for use with persons with chronic illness. Examples of these assessments that have excellent reliability and validity include the Sickness Impact Profile (Bergner et al., 1981) and the Medical Outcomes Study Short Form 36 (SF-36) (Jenkinson, Wright, & Coulter, 1994).

Assessing Tasks and Activities

Occupational therapists use a variety of assessment tools to measure baseline and discharge performance in tasks and activities of importance to the client, including ADL, IADL, work, and leisure.

Activities of Daily Living

ADL generally include mobility at home, feeding, dressing, bathing, grooming, toileting, and personal hygiene (AOTA, 2008). Direct observation of problem activities identified by the client should be done at the time of day when they are normally performed and, if possible, in the place where they usually occur. Remember that many people may have strong feelings of modesty regarding personal care, and those feelings should be respected. The client's endurance and safety should be closely monitored, and ADL performance can be evaluated over several therapy sessions if slow performance or fatigue occurs. Items that would be unsafe or obviously unsuccessful (such as tub transfers) are postponed until the patient's physical status improves. When the patient is not independent in a required task at the time of discharge, plans are developed to ensure that others can assist with this task and that additional therapy is received if warranted.

Most standardized ADL evaluations were designed for program evaluation to document the level of independence achieved by patients as the result of a particular program. Several ADL assessments used by occupational therapists are briefly described in the following paragraphs. The Barthel Index (Mahoney & Barthel, 1965) is a reliable and valid assessment of 10 activities (see Assessment Table 4-1). The total score for these 10 activities can range from 0 to 100 (total independence), and the score for each activity is weighted according to its importance for independent functioning (Mahoney & Barthel, 1965). A score of 60 seems to be the transition point from dependency to assisted independence. Scores may be derived from client interview or direct observation. The reliability and validity of the Barthel Index also has been established when administered during telephone interviews (Della Pietra et al., 2011).

The Modified Barthel Index (Shah, Vanclay, & Cooper, 1989) was developed to increase sensitivity to changes observed when patients progressed from one level of assist to another during rehabilitation. A third 20-point Barthel Index includes the same test items with weighted, variable subscores ranging between 0 and 1 (e.g., bathing) or between 0 and 3 (e.g., transfers) (Collin et al., 1988). Differences in sensitivity were not found between these two modified versions of the Barthel in a sample of stroke survivors requiring rehabilitation (Hocking et al., 1999). The original 10-item version of the Barthel Index, scoring 0 to 100 with 5-point increments, continues to be most widely used and recommended for stroke research (Quinn, Langhorne, & Stott, 2011).

The FIM™ (Granger & Hamilton, 1992) uses a 7-point ordinal scale to evaluate occupational performance for 18 items (13 motor and 5 cognition) (see Assessment Table 4-1) and is a basic measure of the severity of disability based on burden of care, not impairment.

(Granger et al., 1993). The scale rates a client's performance by taking into account his or her need for assistance from another person or a device. The FIM™ instrument is intended to measure what the person with disability actually does, whatever the diagnosis or impairment, and is scored according to information gathered by members of the rehabilitation team during client observation. The FIM™ can be used during rehabilitation to track changes in ADL and provide data for program evaluation. It has been shown to predict functional status at discharge and length of rehabilitation stay (Heinemann et al., 1994). The FIM™ is part of a uniform data system that collects information about rehabilitation outcomes and effectiveness and is an integral part of the Inpatient Rehabilitation Facility–Patient Assessment Instrument (IRF-PAI) (University at Buffalo Foundation Activities, Inc., 2004) (see Fig. 10-6, Case Example: FIM™ assessment). Researchers have established MCID values for the modified 20-point Barthel Index (Hsieh et al., 2007) and FIM™ (Beninato et al., 2006) (see Assessment Table 4-1 for specifics).

The Klein-Bell Activities of Daily Living Scale (Klein & Bell, 1982) documents a client's ability to perform in six BADL (see Assessment Table 4-1). These ADL are broken down into 170 simple behavioral items, each of which is scored separately. The large number of items makes the Klein-Bell one of the most responsive ADL assessments. Each item is scored as achieved (no physical or verbal assistance) or unable (assistance needed), and raw scores are converted to percentage scores to make communication of results easier to understand. If the client can perform the test item with adapted equipment during the discharge evaluation, he or she is given credit for accomplishing that activity. Emphasis is placed on the person's ability to physically complete components of ADL tasks (e.g., inserting foot into pant leg, grasping waistband to pull up pants, and zipping). It does not well distinguish when a client is unable to complete the task because of other factors, such as impaired organization or safety awareness. When impairments become apparent during ADL assessment, the therapist will further evaluate performance skills (e.g., sequencing, coordination, and balance) as needed for comprehensive treatment planning.

Instrumental Activities of Daily Living

Although many IADL assessments include a few self-care items, their focus is primarily home management tasks such as meal planning, preparation, and cleanup; laundry; shopping for food and clothing; routine and seasonal care of the home; and yard work and other maintenance tasks that were the responsibility of the patient prior to therapy and may require assessment and intervention. Several standardized IADL assessments used by occupational therapists are described in the following paragraphs.

The Nottingham Extended ADL Scale (Nouri & Lincoln, 1987) is a self-report questionnaire that assesses occupational performance of 22 daily activities during the previous few weeks (see Fig. 4-2 and Assessment Table 4-1). Although originally developed for use with stroke survivors, its use has also been studied in clients after hip replacement surgery (Harwood & Ebrahim, 2000), with multiple sclerosis (Nicholl, Lincoln, & Playford, 2002), and with Parkinson's disease (Clarke et al., 2009). The Nottingham Extended ADL Scale is a reliable and valid

Nottingham Extended ADL Scale

The following questions are about everyday activities. Please answer by ticking ONE box for each question. Please record what you have ACTUALLY done in the last few weeks.

DID YOU.... / Not at all / with help / on your own with difficulty / on your own

1. Walk around outside?
2. Climb stairs?
3. Get in and out of a car?
4. Walk over uneven ground?
5. Cross roads?
6. Travel on public transport?
7. Manage to feed yourself?
8. Manage to make yourself a hot drink?
9. Take hot drinks from one room to another?
10. Do the washing up?
11. Make yourself a hot snack?
12. Manage your own money when out?
13. Wash small items of clothing?
14. Do your own housework?
15. Do your own shopping?
16. Do a full clothes wash?
17. Read newspaper or books?
18. Use the telephone?
19. Write letters?
20. Go out socially?
21. Manage your own garden?
22. Drive a car?

measure of functional independence; however, conflicting reports of its responsiveness to change have been published (Harwood & Ebrahim, 2000; Wu et al., 2011).

The Assessment of Motor and Process Skills (AMPS) (Fisher, 1993, 1995; Fisher & Bray Jones, 2010) is an innovative observational assessment. It uses a 4-point scale to rate 16 motor and 20 process skill items during performance of client-selected, challenging IADL tasks. The motor skills (e.g., stabilizes, reaches, and transports) are the actions observed during task performance that are thought to be related to underlying abilities in postural control, mobility, coordination, or strength. Process skills (e.g., sequences, initiates, and adjusts) are used to organize and adapt actions during actual performance and represent the underlying attentional, conceptual, organizational, and adaptive capacities of the client (Park, Fisher, & Velozo, 1994). It is important to note that the AMPS is a test of skill in occupational performance and is not designed to evaluate the presence of neuromuscular, biomechanical, or cognitive impairments (e.g., strength, range of motion, and memory) or underlying capacities. Unlike impairments and underlying capacities that often are evaluated separately from task performance, the motor and process skills of the AMPS are goal-directed actions that occur in the context of occupation. As a result, the AMPS is used to assess activities and participation, not body functions or contextual factors (WHO, 2001). A pilot study to develop a driving task for the AMPS provides an example of the range of test items used to evaluate occupational performance (Robertson & Carswell, 2011).

Occupational therapists must attend a training workshop and become calibrated as a reliable rater before using the AMPS. Once trained, scoring is done by computer. The AMPS has been shown to discriminate well between people without disabilities and those with cognitive or physical disabilities. A significant advantage of AMPS is its flexibility in allowing the client to choose which tasks are used for assessment.

The Kohlman Evaluation of Living Skills (KELS) is a short living skills assessment that is administered through interview and direct observation (Kohlman Thomson, 1993) (see Assessment Table 4-1). Individual items are scored as independent, needs assistance, or not applicable. Although originally created for use in short-term psychiatric units, it is also a good measure of IADL performance in elderly clients. When compared with standardized assessments for cognition, affect, and functional status of community living older adults, the KELS showed good convergent validity and strong correlations with executive function measures (Burnett, Dyer, & Naik, 2009). When combined with other assessments and client input, the KELS data can help determine the environment that will allow a person to live as independently and safely as possible.

The Performance Assessment of Self-Care Skills (PASS), version 3.1 (Rogers & Holm, 1989a, 1989b) is a performance-based observational tool to document functional status and change during rehabilitation (Fig. 4-3) (see Assessment Table 4-1). The PASS has both clinic and home versions and is designed to assess the types of assistance needed for home and community safety. Unlike the KELS, the PASS is criterion referenced, meaning that only selected items or the entire test can be administered depending on the client's needs and time availability. The PASS provides input regarding the client's level of independence in task completion, safety needs, and quality of task outcome. It is appropriate for use with adults of varied diagnoses (e.g., arthritis, cardiopulmonary disease, and dementia) and provides excellent data for treatment planning and documentation of patient outcomes (AOTA, 2007).

The Safety Assessment of Function and the Environment for Rehabilitation-Health Outcome Measurement and Evaluation (SAFER-HOME) was developed to provide occupational therapists with a comprehensive, consistent measure to simultaneously assess safety and occupational performance in the home (Chiu et al., 2006; Oliver et al., 1993). Test items assess both the environmental situation and functional ability of the client in 12 categories (see Assessment Table 4-1). For example, the living situation category addresses whether stairs are in good condition, the presence of scatter rugs and electric cords, and environmental clutter that might impact home safety. Level of safety risk is rated on a 4-point scale ranging from 0 (no problem) to 3 (severe problem) (AOTA, 2007). The instruction manual includes a list of recommendations to help the occupational therapist identify solutions to difficult problem areas.

Kitchen Tasks. Two assessments of performance during kitchen tasks have been developed for use in occupational therapy. The Kitchen Task Assessment (KTA) (Baum & Edwards, 1993) uses the task of making pudding to assess the cognitive support required by persons with dementia and Alzheimer's disease to complete a basic cooking task. Thus, the KTA provides information about performance as well as components of occupation, such as initiation, sequencing, organization, and problem solving. There is a significant relationship between scores on the KTA and other neuropsychological assessments but limited evidence of its use with clients who have physical versus psychosocial and cognitive disabilities.

The Rabideau Kitchen Evaluation Revised (RKE-R) (Neistadt, 1992, 1994) is an assessment of meal preparation that was primarily developed for adults with brain injury. All task components are scored according to the number of verbal cues or the amount of physical assistance required for safe completion. This quick assessment can help with discharge planning by providing information about a client's safety and independence during basic kitchen tasks. The RKE-R was found to differentiate among stroke survivors with/without unilateral spatial neglect (Katz et al., 1999) and was significantly related to neuropsychological measures of verbal memory, simple auditory attention, visuospatial skills, and overall cognitive performance (Yantz et al., 2010).

Child Care

Child care and parenting activities include but are not limited to the physical care and supervision of children and the use of age-appropriate activities, communication, and behaviors to facilitate child development (AOTA, 2008). Because no standard evaluations exist, the occupational therapist must work with the client to identify and assess performance needs during required and valued child care tasks, while taking into account the ages and personalities of the children involved. The COPM can be used to assess child care concerns and to determine what interventions and adaptations may be needed to enhance a client's competence and satisfaction in this area. The AusTOMS-OT provides a means to document the degree to which limitations in child care and parenting abilities are related to impairments in structure or function, activity limitations, participation restrictions, and level of distress/well-being (Unsworth, 2005) and how these change in response to intervention.

Work

Work assessments are used to determine whether an individual has the ability to perform necessary job skills and is otherwise prepared for employment in terms of work habits, work quality, ability to learn or acquire new skills, and ability to work with others as a team member, supervisor, or supervisee. Velozo (1993) described two categories of work evaluations: (1) standardized commercial evaluations such as those used in vocational rehabilitation and (2) highly technical evaluations of physical and work capacity. He questioned whether these work evaluations truly reflect occupational therapists' interest in the meaning of work and emphasized our unique role in linking work evaluations to the psychosocial and environmental factors that contribute to client performance.

Standardized vocational evaluation systems use job analysis or work samples to determine an individual's ability to perform tasks similar to those encountered at work. In the United States, the Dictionary of Occupational Titles (U.S. Department of Labor, 2011) provides a taxonomy for measurement of work performance that lists specific job requirements, including skills and equipment. One standardized work assessment system that

Figure 4-3 Performance Assessment of Self-Care Skills (PASS), version 3.1. Score sheet to record type of assistance needed, safety, and adequacy of performance during assessment. Summary scores (0–3), based on the client's level of independence, safety awareness, and overall performance, are described in test manual. © Rogers & Holm, 1989, 1994. Used with permission.

is often used is the VALPAR Component Work Samples (see Resources 4-1). The VALPAR system consists of a wide range of work samples that evaluate specific occupational performance skills (e.g., range of motion, problem solving, physical capacities, and mobility) during simulated job tasks. Although evidence of the reliability and validity for this standardized evaluation system is extensive, a potential disadvantage of the VALPAR Component Work Samples is its expense.

Because a large proportion of work evaluations are administered to clients who have musculoskeletal or soft-tissue injuries, their primary focus is on the physical capacities required for work tasks. Many standardized functional capacity evaluations (FCE) are available to measure physical capacity (e.g., strength, endurance, and freedom from pain) during work-related tasks, such as lifting, sitting, and standing (AOTA, 2007). In addition to evaluating a client's physical performance, a comprehensive work assessment must also include contextual information regarding the client's work environment and history, his medical condition and contraindications, and the whole person context in which he lives (e.g., information about nonwork occupations such as homemaker, caregiver, or recreational roles) (Strong et al., 2004).

Semistructured interviews, such as the Worker Role Interview (WRI) (Braveman et al., 2005; Velozo, Kielhofner, & Fisher, 1998), can complement fce by providing important information regarding the psychosocial and environmental factors that influence return to work. This well established tool can be used to assess other behaviors considered important for work, such as punctuality, communication skills, ability to work with others, and grooming. The WRI is well suited to the needs of clients from varied cultures and diagnostic groups (Forsyth et al., 2006).

Leisure

Leisure involves engaging in self-chosen, motivating, and goal-directed activities for amusement, relaxation, spontaneous enjoyment, and/or self-expression. Hersch (1990) pointed out that "the concept of leisure encompasses a multitude of meanings: the leisure event itself, the amount and frequency of the activity, its meaningfulness to the participant, and the social context" in which it is performed (p. 55). Leisure serves many purposes in one's life by fulfilling physical, social, and intellectual needs, particularly for the older adult (Hersch, 1990). Participation in leisure is an important area of occupation that is closely related to life satisfaction (AOTA, 2007). The occupational therapist can facilitate leisure exploration with clients through use of checklists and semistructured interviews that focus on identifying interests, skills, opportunities, and leisure activities that are appropriate for the individual. Leisure participation

involves the planning and engagement in appropriate leisure activities, maintaining a balance of leisure activities with other areas of occupation, and obtaining needed supplies and adaptations to allow for successful engagement (AOTA, 2007).

Because participation in leisure is viewed as an integral component of occupational performance and functioning, many IADL assessments address the client's leisure interests and pursuits along with IADL (e.g., home management and community mobility), work/education, and social/participation needs. The LBI (Matuska, 2012a), the COPM (Law et al., 2005), the OPHI-II, version 2.1 (Kielhofner et al., 2004), the Nottingham Extended ADL Scale (Nouri & Lincoln, 1987), and the RNL Index (Wood-Dauphinee et al., 1988) all include items related to leisure activities. The Activity Card Sort (2nd edition) (Baum & Edwards, 2008) is another reliable and valid assessment of actual and desired activity engagement that crosses the domains of IADL, leisure and social activities. The Activity Card Sort (2nd edition) captures changes in activity patterns related to the impact of a disability or illness and provides the therapist with immediate feedback regarding valued activities for treatment planning. Any of these assessments can help the therapist identify the client's leisure interests within the context of other occupational performance needs.

Several assessments specific to evaluation of leisure interests and participation continue to be used by occupational therapists. For example, the Modified Interest Checklist (Kielhofner & Neville, 1983; Matsutsuyu, 1969) gathers information about a client's level of interest and participation in 68 different leisure activities. Activities are rated on a 3-point scale ranging from no interest to strong interest. This modified scale assesses current interests, how these have changed over time, and whether the client wishes to participate in these and other activities in the future. The Modified Interest Checklist is particularly useful for appreciating the impact of disability or illness on the client's experiences and engagement in meaningful leisure activities (Kielhofner, 2008). It can be used for treatment planning with clients throughout the life span, from adolescence through old age.

Other leisure assessments, such as the Nottingham Leisure Questionnaire (Drummond et al., 2001) and the Leisure Diagnostic Battery (Witt & Ellis, 1984), are reliable and valid tools that have been frequently used in research but are not readily available for clinic use. The Idyll Arbor Leisure Battery (IALB) (Hawkins et al., 2002) is composed of several scales to assess client attitudes, interests, motivation, and satisfaction with leisure pursuits. Although used primarily by recreational therapists, this battery has established reliability and validity and may be used by occupational therapists for program development and evaluation (AOTA, 2007). Please refer to Resources 4-1 for more information.

case example
Mrs. B.: Assessing Roles and Competence after Stroke

	Clinical Reasoning Process	
Occupational Therapy Assessment Process	**Objectives**	**Examples of Internal Dialogue**
Patient Information Mrs. B. is a 53-year-old married woman who experienced a left ischemic cerebrovascular accident 1 month ago while at work. She received a thrombolytic medication within the first 3 hours of her stroke and is reported to have made excellent progress during 3 weeks of inpatient rehabilitation. She has recently been discharged home and is now being referred to outpatient rehabilitation for continued occupational, physical, and speech therapy. The occupational therapy discharge summary reports continued limitations in instrumental activities of daily living (IADL) tasks, with mild to moderate right-sided paresis and mild aphasia. Mrs. B. lives with her husband and 15-year-old daughter. Her 19-year-old son is a college freshman, living 4 hours from home. Mrs. B. is an elementary school teacher who also coaches her daughter's skating team and volunteers at the town library. Her husband has a demanding full-time job and travels 1–2 weeks per month. The occupational therapist focuses the initial occupational assessment on Mrs. B.'s ability to resume self-maintenance roles and to engage in valued life roles and tasks now that she is home.	Understand the patient's diagnosis or condition Know the person Appreciate the context Develop provisional hypotheses	"Mrs. B. had a pretty significant stroke and would likely have had greater limitations in motor abilities and language if she had not received such good care from emergency services. She is probably having difficulty using her dominant hand for daily tasks, and I wonder how she is getting around and managing at home when her husband is at work." "It must have been terrible for her to have a stroke while she was at work—at least it happened during lunch and not while she was in the classroom with her students. It sounds like she was pretty busy managing multiple roles—as mother, teacher, coach, and volunteer—in addition to taking care of home responsibilities. I wonder how she is dealing with this sudden change in routine." "It must be difficult for her husband and daughter to take on more home management tasks while Mrs. B. is recovering from her stroke. I wonder if they have friends or other family members who can help with shopping, driving, etc." "Given her diagnosis and good rate of recovery, I think she will do well in therapy. I expect that her motor impairments will be the biggest barrier to regaining independence in home and leisure tasks. Her mild aphasia will likely limit her return to teaching, at least in the short term."
Assessment Process The therapist selected the following evaluation tools: Canadian Occupational Performance Measure (COPM) to obtain information about the client's perceived problems and priorities and the Assessment of Motor and Process Skills (AMPS) to assess IADL motor and process skills.	Consider evaluation approach and methods	"Because of her mild aphasia, it might be difficult and a bit frustrating for her to verbally describe her priorities for therapy on the COPM. I will talk with the speech therapist to see whether she might benefit from using a written list of activities to report concerns during this evaluation. It might also be helpful to have her husband present during the COPM to help clarify issues, as needed. The AMPS will give me the chance to observe how her right-sided paresis affects IADL performance and whether other cognitive and process-related impairments are a concern."
Assessment Results During an interview using the COPM, Mrs. B. reported that it was very important for her to resume responsibilities in managing household tasks and fulfilling her roles as wife and mother. Planning and preparing meals and grocery shopping were also very important to her. She expressed frustration with the clumsiness in her dominant right hand and with her low endurance and fatigue when walking a distance with a cane. She was very concerned about returning to her job as a teacher because of her mild aphasia and expressed a strong desire to help prepare her daughter's skating team for the state finals in 2 months.	Interpret observations	"Mrs. B. seems to have good awareness of her impairments and needs for therapy and is generally able to make her needs known despite her mild aphasia and word-finding problems." "I wonder whether the problems Mrs. B. had with sequencing and organizing tasks during the AMPS are related to the fact that she performed these in the rehab clinic, not at home. As she begins to take on more challenging tasks, it will be important to see how she performs in familiar versus unfamiliar settings."

The AMPS revealed that process skills were mildly impaired in the sequencing and organizing of chosen tasks. Although she required additional cues/support to initiate tasks, she showed good pacing once engaged and was able to adjust and adapt her approach to tasks when difficulties arose. Motor skills were mildly to moderately impaired, as she had difficulty reaching for items at or above shoulder height, lifting a medium-sized sauce pan from the stove to sink and manipulating items with her right hand. However, she was able to use her paretic right hand to stabilize and transport items during bilateral tasks. Extra time was needed for task completion, because she needed frequent rest breaks when performing IADL from an ambulatory level.

"It seems like Mrs. B.'s mild hemiparesis is having the greatest impact on her performance of IADL, and she shows great determination and desire to improve the functional use of her right arm and hand. I'll administer a couple of stroke-specific assessments to get a better handle on her motor strengths and weaknesses so we can decide on a therapy program to best address these concerns. She is a great candidate for outpatient therapy."

Occupational Therapy Problem List

Decreased participation and independence in IADL.

Impaired endurance and functional mobility, contributing to decreased productivity during IADL.

Reduced organizing and sequencing skills during IADL in an unfamiliar environment.

Mild to moderate hemiparesis in right arm, impeding functional use of the limb during occupational tasks.

Synthesize results

"Mrs. B. has experienced significant changes in her daily routine and ability to engage in important life roles and tasks since her stroke. I will talk more with her family to see how they think she is coping with these changes. Although fatigue is common during early recovery from stroke, depression might also be affecting her initiation and reports of fatigue during IADL."

"It will be important to get a better handle on Mrs. B.'s ability to return to her coaching and teaching roles, but this will be a longer term process. First, I'll use the Modified Interest Checklist to help identify meaningful activities to use in therapy so we can begin to work on problem areas and help her to feel more productive as she continues to recover from her stroke."

 ## Clinical Reasoning in Occupational Therapy Practice

Relating assessment to intervention and outcomes in occupational performance

During her first outpatient treatment session, Mrs. B. described frequent difficulties when using her right hand to carry items from the fridge or trying to grasp and place laundry items into the washer. She described feeling "tired all the time" and was frustrated by the extra time and effort needed to do previously simple tasks, such as paying household bills.

How might the occupational therapist address Mrs. B.'s concerns? How might the results of occupational therapy assessments guide the use of occupation as both an intervention and outcome of occupational therapy services?

Summary Review Questions

1. Define self-report and direct observation methods of assessment. What are the advantages and disadvantages of these methods when evaluating a client's occupational performance?
2. Distinguish between IADL and BADL, and describe one standardized assessment for each.
3. What are three measurement concepts or psychometric properties of standardized evaluation instruments? Define each and provide an example of how these properties might affect the results of occupational therapy assessments administered in the clinic.
4. Describe how a semistructured assessment such as the COPM can be used to measure occupational performance and establish the client's treatment plan.
5. Compare two different IADL measures. Describe the assessment and its psychometric properties, strengths, and weaknesses. Based on this information, which measure would you choose to evaluate a client recently admitted for outpatient rehabilitation services following stroke? Why?
6. A client-centered approach has been emphasized when assessing occupational roles and competence. List three ways in which this approach might influence occupational therapy intervention.

Glossary

Activities of daily living (ADL)—Activities or tasks that a person does every day to maintain personal care. Also referred to as basic activities of daily living (BADL).

Instrumental activities of daily living (IADL)—Complex activities or tasks that a person does to maintain independence in the home and community.

Leisure—Activities or tasks that are not obligatory, are intrinsically motivating, and are done for enjoyment.

Life balance—A satisfying pattern of daily activity that is healthful, meaningful, and sustainable to an individual within the context of his or her current life circumstances (Matuska & Christiansen, 2008).

Life roles—Areas of occupation associated with self-maintenance (e.g., ADL and IADL), self-advancement (e.g., work and education), and self-enhancement (e.g., leisure) that involve specific tasks and activities (see Chapter 1).

Occupational performance—Ability of individuals to satisfactorily perform purposeful daily activities (occupations). This involves the dynamic transaction among the client, the context or environment, and the activity.

Reliability—The ability of an assessment to consistently measure performance and to differentiate among clients under various conditions (Finch et al., 2002).

Validity—The extent to which an instrument measures what it is intended to measure (Finch et al., 2002).

Work—An area of occupation that includes activities needed for engaging in remunerative employment or volunteer pursuits (AOTA, 2008).

Assessing Abilities and Capacities: Vision and Visual Processing

Orli Weisser-Pike

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define and differentiate between visual functions and functional vision.
2. Identify some conditions in adults that cause vision-related problems.
3. Differentiate between correctable and uncorrectable vision impairments.
4. Describe screening techniques for visual acuity, visual fields, and oculomotor control.
5. Understand the impact of vision impairments on performance skills, patterns, and activity demands.
6. Become familiar with other vision-related professions.

Eyes are remarkable organs that must shrink life-size images so that the reflected light from those images fits through a small aperture, the pupil, and lands perfectly in focus on the retina, the only place in the human body where nerve tissue—indeed the brain—can be seen by the naked eye. Upside down and inverted on the retina, light is converted into an electrical impulse that makes its way to the back of the head, the primary visual cortex, where the image is further processed and assigned meaning. *This is the sensory component of vision.* Additional features of the image are identified and recognized, compared with previously memorized images, and assigned meaning. *This is the cognitive component of vision* where interpretation occurs. Furthermore, the eyes have to point to the same target to produce a unified image. They must work together in a smooth and coordinated manner to follow a moving target. They also must be able to move as a team when searching for information in the environment, jumping from one target to the next, and be able to keep the target in focus regardless of whether it is near or far. *This is the motor component of vision.*

Occupational performance problems can occur when a deficit arises in any of these components. Take, for example, Mr. K., a 78-year-old man who was admitted to the hospital following a cardiac event. In the rush to get him to the hospital, his wife removed his spectacles so that he would not worry about keeping track of them while admitted for medical care. On the third day following his admission, the occupational therapist administered a cognitive screening test. Mr. K. scored poorly on the test not because he experienced a cognitive decline but because he could not see to read the instructions he was given. This example illustrates how important it is for occupational therapy practitioners to screen a client's vision in order to determine factors that hinder or support engagement in desired occupations.

Because occupational therapy practitioners are likely to see people of all ages who have problems with sensory, cognitive, or motor aspects of vision, it is useful to distinguish between key terminology, such as "visual functions" and "functional vision." Note, however, that vision specialists often do not use the same terminology to describe how vision works. In this chapter, the term *visual function* refers to the integrity of the visual system, whereas *functional vision* tells how the person operates.

MODELS OF VISUAL FUNCTIONING

Warren (1993a, 1993b) described a visual perceptual hierarchy in adults with acquired brain injuries (Fig. 5-1). This model suggests that higher level skills (such as visual attention and visual memory) are built on the foundations of visual acuity, visual fields, and oculomotor control. The components in the hierarchy are as follows:

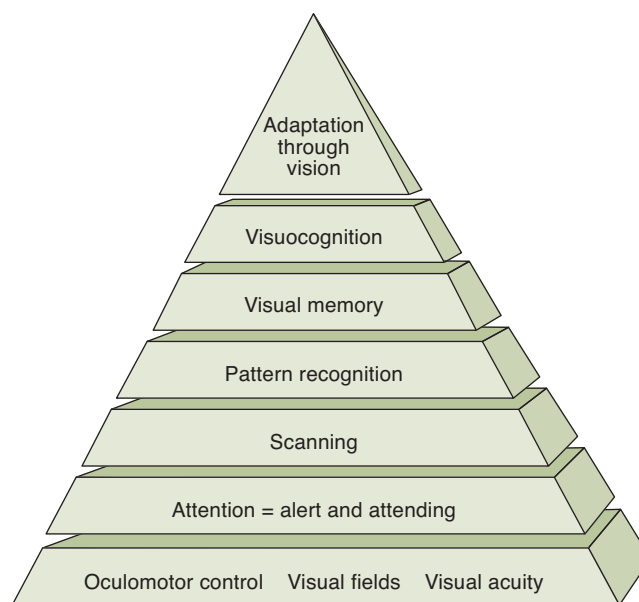
1. Visual attention and alertness
2. Visual scanning


Figure 5-1 Hierarchy of visual perception. (From Warren, M. [1993a]. A hierarchical model for evaluation for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, Part 1. *American Journal of Occupational Therapy, 47,* 43. Copyright 1993 by the American Occupational Therapy Association, Inc. Reprinted with permission.)

3. Pattern recognition
4. Visual memory
5. Visual cognition

The model illustrates that without good foundational sensory or motor components, faulty visual perception may occur, leading to faulty learning.

More recently, Colenbrander (2009) described three distinct stages of visual functioning: optical, retinal, and neural. In the optical stage, light enters the eyeball and lands onto the retina. Any abnormalities of the eyeball that might interfere with the path of the light reaching the retina will likely cause visual problems. Refractive errors are some examples of problems in the optical stage. If the eyeball is too long, for example, as in the case of shortsightedness, the light does not reach the retina at the right spot, leading to blurry vision.

In the retinal stage, light landing on the retina is translated into neural impulses. Retinal diseases, such as macular degeneration, can cause problems at this stage. A person with macular degeneration may not notice areas of missing information from the visual field and may only discover vision loss when shutting one eye.

In the third stage, neural impulses are processed by the inner retina and other centers in the brain. At this stage, the image is analyzed, interpreted, and translated into a mental picture, which Colenbrander (2009) terms as the "mental model of the environment" (p. 120). The mental model is one in which the environment appears to be stable in spite of a constantly changing retinal image.

Colenbrander (2009) proposed use of the term "cognitive visual dysfunction" (p. 122) to describe problems that exist in the presence of normal input to the brain, such as failure to recognize familiar faces (prosopagnosia), difficulty visually attending to one side, and difficulty naming colors.

POPULATIONS AND VISION PROBLEMS

Many recipients of occupational therapy services may have correctable vision impairments. However, some vision impairments are not correctable, and visual dysfunction can persist despite vision correction. All of these conditions may coexist in the same client. Because most visual impairments are "hidden" problems, the occupational therapist should not assume that a person's vision problem has been, or can be, corrected just because that person wears glasses.

Correctable Vision Impairments

The most common correctable vision impairments are refractive errors, which affect approximately 42.2 million (35.3%) of Americans age 40 years or older (National Eye Institute, 2006). Refractive errors include myopia (nearsightedness), hyperopia (farsightedness), astigmatism (asymmetrical or distorted vision at any distance), and presbyopia (loss of accommodation of the lens, which occurs around age 40 years). Occupational therapy practitioners are likely to encounter clients across the life span who wear glasses or contact lenses to help focus the incoming image on the retina. Lenses may be designed to correct for one particular distance, as in the case of single vision lenses, or for multiple distances, as in the case of bifocals, trifocals, or progressive lenses. Surgical procedures, such as LASIK and cataract extraction, can also improve refractive errors.

Uncorrectable Vision Impairments and Low Vision

Massof (2002) estimated that there are 1.5 million Americans older than age 45 years with uncorrectable vision impairments; there are approximately a quarter of a million new cases each year. Nearly 12% of individuals ages 55–64 years and 27% of individuals age 85 years and older report some form of visual impairment that impacts their ability to complete everyday activities such as walking outside, managing medications, or preparing a meal (Campbell et al., 1999; Schoehborn & Heyman, 2009). People with uncorrectable losses of visual acuity and visual field are considered to have low vision or blindness, a condition that supports medical necessity for rehabilitation by an occupational therapy practitioner (Centers for Medicare & Medicaid Services, 2002). Table 5-1 shows levels of visual impairment.

Table 5-1   **Levels of Vision Impairment**

Definition of Levels of Vision Impairment	
Moderate	Best corrected visual acuity is less than 20/60.
Severe	Best corrected visual acuity is less than 20/160, or visual field is 20° or less (legal blindness).
Profound	Best corrected visual acuity is less than 20/400, or visual field is 10° or less (moderate blindness).
Near-total	Best corrected visual acuity is less than 20/1000, or visual field is 5° or less (severe blindness).
Total	No light perception (total blindness).

Neurologically Based Visual Dysfunction

Beyond age-related vision loss and impairments, many clients experience vision problems because of neurologically based disability or illness. In a study of 328 patients who suffered a stroke, over 90% had visual problems in eye alignment, visual fields, and visual attention (Rowe et al., 2009). Many service members with blast-related brain injuries receive occupational therapy screening for vision problems (Brahm et al., 2009; Cockerham et al., 2009; Dougherty et al., 2010).

ASSESSING VISION

The purpose of assessing vision as part of the occupational therapy evaluation is to elucidate client factors—visual functions and functional vision—that hinder or support engagement in desired occupations (American Occupational Therapy Association, 2008; Warren, 2011). Insofar as observed behaviors are frequently attributed to cognitive changes rather than impaired vision, all neurologically impaired clients should receive an occupational therapy vision screen to rule out visual dysfunction (Warren, 2011). Screening is also considered for older clients whose vision may have been affected by age-related eye diseases. See Definition 5-1 for other professions involved in vision assessment and treatment.

The occupational therapy assessment of vision includes a basic eye history; interviews with the client and/or family about subjective complaints (e.g., difficulty concentrating, double vision, eye strain, and bumping into objects on one side); screening of visual acuity, visual fields, and ocular motility; screening for visual attention and visual search; observations of functional tasks (Table 5-2); and formal vision-related questionnaires. Assessment Table 5-1 describes and summarizes the psychometric properties of various occupational therapy vision assessments. Also see information about how to obtain some of these assessments in the Resources 5-1.

Definition 5-1

Vision-Related Professions

- Ophthalmologist—Medical doctor with an additional year of training in general medicine followed by a minimum of 3 years in organ-specific training. Ophthalmology is concerned with the anatomy and function of the eye, including prevention, diagnosis, and medical and surgical treatment of eye conditions and diseases. Additionally, there are numerous subspecialties in ophthalmology (such as glaucoma and neuro-ophthalmology), which necessitate additional years of training (American Academy of Ophthalmology, 2011).
- Optometrists—Primary eye care providers who receive a doctorate in optometry after 4 years of postgraduate training but are not medical physicians. Although they are educated in limited management of eye diseases (e.g., they cannot perform surgery), their focus is primarily on correcting refractive impairments. There are also subspecialties within optometry, such as behavioral optometry and developmental optometry, which are aimed at treating the functional impact of vision impairments (American Optometric Association, 2011).
- Orthoptist—Eye care specialist who works in ophthalmology and is trained in a 2-year fellowship at an accredited program following a baccalaureate degree. Emphasis is on evaluation and treatment of disorders of binocular vision, eye movements, and eye alignment in children and adults (American Association of Certified Orthoptists, 2011).
- Low-vision therapist—Practitioner who works with an ophthalmologist, optometrist, or orthoptist to provide the client training in use of optical devices and methods to compensate for vision loss (Academy for Certification of Vision Rehabilitation and Education Professions, 2011).
- Orientation and mobility specialist—Trains the client with low vision and blindness to independently and safely travel from one place to another (Academy for Certification of Vision Rehabilitation and Education Professions, 2011).
- Vision rehabilitation therapist—Teaches people with low vision and blindness to compensate for vision loss using nonvisual strategies and technologies, including braille (Academy for Certification of Vision Rehabilitation and Education Professions, 2011).
- Teachers of the visually impaired—Also known as itinerant teachers; work in the educational system and are trained in special education to provide specific instruction to students with visual impairments, their teachers, and their families (Olmstead, 2005).
- American Occupational Therapy Association specialty certification in low vision—Recognition of occupational therapy practitioners with specialized knowledge and skills in low vision (Warren et al., 2006).

Table 5-2 Observation of Functional Tasks

Impact of Client Factors on Performance Patterns, Performance Skills, and Activity Demands	Possible Visual Function Problem	Possible Functional Vision Problem
The client fails to visually identify a close family member entering the room. The client feels embarrassed and decides henceforth not to have any visitors.	**Reduced visual acuity** caused by opacity of the lens (e.g., cataract) leading to difficulty distinguishing facial features	**Prosopagnosia** caused by damage to face recognition centers in the brain.
The client has difficulty reading the daily menu to select meals. She is given her food tray last because staff does not know what she ordered. Client settles for undesired food and does not consume sufficient calories for healing.	**Blurry vision** up close when reading caused by lack of accommodation of the lens (presbyopia)	**Dyslexia** or **dysphasia** can lead to problems deciphering written language.
When playing a game of Bingo, client reads the number 25 on the card as a 5 and misses the first numeral. He misses opportunities to win. He also has trouble writing checks and leaves a large space at the left margin of the line. He gives up financial management and hands control of financial matters to his neighbor, because he has no relatives in the state.	**Reduced visual acuity** caused by a retinal disease (e.g., macular degeneration) leading to a central blind spot slightly displaced to the left of fixation A left homonymous **visual field defect** caused by damage to the optic pathways on the right side of the brain (e.g., stroke)	**Hemi-inattention** caused by dysfunction of the attentional system of the brain (may exist with or without a visual field defect) leading to missed information on the left side.
Client reaches for her beverage on the right side of the placemat but misses, despite looking at it. She knocks the drink over and spills red wine on her friend's white blouse. She is so embarrassed that she bursts out crying.	**Constricted visual fields** caused by damage of the optic nerve (e.g., glaucoma) leading to tunnel vision	**Eye–hand coordination deficits** caused by dysfunction of coordination centers in the brain
Client cannot find a grapefruit spoon in a drawer full of cutlery. She fumbles for the spoon and accidentally cuts herself on a knife that she did not notice.	**Reduced contrast sensitivity** from swelling of the retina caused by a systemic disease (e.g., diabetes)	**Figure-ground separation difficulties** caused by inability to inhibit competing or distracting visual information

Assessment Table 5-1 | Summary of Assessments of Vision and Visual Processing

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths & Weaknesses
Brain Injury Visual Assessment Battery for Adults (BiVABA) (Warren, 1998)	A collection of instruments to screen for visual processing impairments following brain injury. The intention of the battery is to find out whether and how visual processing impairments prevent or hinder participation in occupations; items are selected based on the visual perceptual hierarchy (Fig. 5-1). Norms and cutoff scores are not relevant because the intention is to identify deficiencies in primary visual functions.	Entire battery may take upward of 1 hour; some subtests may take as little as 3–5 minutes.	Not reported	Not reported	Not reported	Strength: Comprehensive assessment battery for foundational visual skills; detailed instructions for setup and testing, extensive interpretation guidelines. Weaknesses: No psychometric data available. Requires practice in administration and interpretation before working with clients.
The Self-Report Assessment of Functional Visual Performance (SRAFVP) (Warren et al., 2008). Available in Warren (2011). *Occupational Therapy Interventions for Adults with Low Vision.* Bethesda, MD: American Occupational Therapy Association.	A 45-item activities of daily living (ADL) performance measure that combines a self-report assessment of 38 items and optional observations of seven ADL tasks. Both sections are scored using a three-point ordinal scale. Tasks are ordered by level of visual difficulty with the most visually demanding items listed first; scores yield a "recovery profile" showing tasks that client is unable to complete, tasks that are difficult, and tasks for which client is mostly independent.	Self-report may take up to 40 minutes.	Differentiated between individuals with complete homonymous hemianopsia and those with macular sparing for reading tasks ($p = 0.03$) and eye coordination ($p = 0.047$) but not with navigation ($p = 0.787$)	Internal consistency: Cronbach's α for the 38 items = 0.96 (Mennem, Warren, & Yuen, 2012).	Not reported	Strength: Developed for clients with low vision. Weaknesses: May not be appropriate for clients with oculomotor dysfunction; no psychometric data available. Copyrighted, requires explicit permission by the authors.
National Eye Institute Visual Function Questionnaire, 25-item version (NEI VFQ-25) (Mangione, 2000).	This quality-of-life questionnaire can be administered by an interviewer or completed as a self-report. Twenty-five statements specific to the impact of vision loss on general health, well-being, and ADL are scored on a 5-point ordinal scale. Higher scores = higher quality of life	Interview may take up to 60 minutes.	Statistically significant correlation between the 25-item NEI VFQ and clinical indicators of visual function (Pearson correlations ranged from .11–.70, $p<.05$)	Good internal consistency among NEI VFQ-25 subscales (Cronbach's $\alpha = 0.73$–0.87; driving $\alpha = 0.45$; overall $\alpha = 0.93$)	Not reported	Strengths: Available in the public domain for clients with low vision. May be self-administered or administered via interview by the practitioner.

(continued)

Assessment Table 5-1 | Summary of Assessments of Vision and Visual Processing (*continued*)

Instrument & Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths & Weaknesses
Melbourne Low-Vision Activities of Daily Living Index (MLVAI) (Haymes, Johnston, & Heyes, 2001b).	A 25-item ADL performance measure combining a questionnaire and observations of performance in structured, standardized tasks. Both sections are scored using 4-point ordinal scales. Higher scores = lower disability	May take up to 60 minutes	Moderately high correlation with vision impairment ($r = -0.68$, $p = 0.001$).	Good internal consistency (Cronbach's $\alpha = 0.96$) Strong test–retest reliability (Spearman's correlation coefficient = 0.94; $p = 0.001$), and the interpractitioner reliability for five different pairs of practitioners was 0.90 or higher ($p = 0.001$).	Not reported	Strength: For clients with low vision; measure of functional performance related to visual functioning. Weaknesses: Observation portion is culturally specific (Australian). Available on request from the author.
Catherine Bergego Scale (CBS) (Azouvi et al., 2003)	Assesses behavioral neglect. Ten items from everyday life situations (e.g., grooming left side of face, collisions with people or objects on the left). Unilateral neglect (UN) scored on 4-point scale, where 0 indicates no neglect observed and 3 indicates severe neglect: Client only able to access right hemispace	Unknown, but would be observed during the occupational therapist's evaluation of ADL	CBS score correlated significantly with performance on five paper and pencil tests (Spearman's ρ = 0.50–0.74). Significant correlation between CBS and Barthel Index Spearman's ($\rho = -0.63$) Correlated with line-bisection subtest of the Behavioral Inattention Test (Spearman correlation = .56) (Luukkainen-Markkula et al., 2011).	Internal consistency: Spearman's rho ranged from 0.58 to 0.88. Strong inter-rater reliability (Spearman rank order correlation coefficient = .96, $p<.0001$)	Authors found it more sensitive than conventional paper and pencil tests.	Strengths: Direct observations of clients' function during everyday activities; provides the client with insight into their deficits. Several items of the CBS and the line-bisection test of Behavioral Inattention Test (BIT) were found to be especially sensitive in identifying the combination of visual neglect and visual field deficits in stroke patients (Luukkainen-Markkula et al., 2011). Weaknesses: Training recommended for inexperienced therapists unfamiliar with unilateral neglect (UN). Difficulty differentiating sensory and motor neglect.
Behavioral Inattention Test (Wilson et al., 1987)	Assesses visual neglect. Fifteen-item standardized test battery: six pen and paper tests (such as line bisection, letter cancellation, and star cancellation) and nine behavioral tasks. Cutoff scores are used to indicate neglect.	Approximately 30 minutes	Correlation between BIT and Barthel Index: $r = 0.642$ (Cassidy et al., 1999) Correlation between BIT behavior subtests and items on an ADL checklist: $r = 0.77$ (Hartman-Maier & Katz, 1995)	Test–retest: $r = 0.99$ Interrater reliability: $r = 0.99$	Behavioral subtests were found to differentiate between groups: neglect and no neglect (Hartman-Maier & Katz, 1995)	Strength: Includes functional as well as conventional tests Weakness: Two subtests (map navigation and picture scanning) were found not to correlate with a functional ADL (Hartman-Maier & Katz, 1995). Measures neglect in peripersonal space only and cannot distinguish between sensory and motor neglect.

Visually guided actions and interactions with one's surroundings are dependent on a mental model of the environment, discussed earlier in the chapter (Colenbrander, 2009). In the past, therapists often evaluated visual perception without a good understanding of the optical system and how it provides the foundation for vision (Cate & Richards, 2000; Hunt & Bassi, 2010; Warren, 1999;). What may be thought of as a deficit in visual perception, such as the ability to differentiate a figure from its background, may be the result of a problem in the sensory or motor components of vision. Warren (1993b) recommended that therapists' limited time was best spent evaluating the foundations for visual function rather than higher level visual cognitive skills.

Screening the Foundations of Visual Function

Visual acuity, visual fields, and oculomotor control form the foundations for visual function. Although deficits in any of these visual functions can affect client performance, clients may not complain of any problems, or they may make complaints that appear unrelated to vision. Therefore, it is important to screen the foundations of visual function even if the client denies visual difficulties. However, prior to screening visual functions, all clients should be screened for refractive errors.

Refractive Errors

Clients should use their best available vision when participating in visual screens. This is particularly true when screening visual acuity. Without adequate correction, clients may demonstrate greater visual acuity impairment, leading the occupational therapist to presume that visual acuity is hindering occupational performance. Refractive errors are easily correctable. Correctable vision impairments that go

untreated are associated with poorer quality of life, reduced participation in daily occupations, and increased risk of injury (Vitale, Cotch, & Sperduto, 2006). If glasses are not available, the client can view the acuity chart through a small pinhole punched into an index card (Scheiman, Scheiman, & Whittaker, 2007). The pinhole method is a quick screen to determine whether visual acuity can be improved with eyeglasses or contact lenses, which can only be prescribed by an ophthalmologist or optometrist.

Visual Acuity

Visual acuity testing demonstrates the sharpness of vision at the part of the retina with which the person fixates on the target—the fovea. Visual acuity is not constant throughout the retina: it rapidly decreases from the fovea (the area of greatest acuity) outward to the periphery. Therefore, visual acuity describes only the small area of sharpest vision, known as central visual acuity, or central vision. There are many measurements of visual acuity. "Best-corrected visual acuity" reflects the client's potential visual acuity using prescriptive lenses. "Presenting visual acuity" denotes the client's visual acuity at initial testing. "Pin hole visual acuity" indicates that the measurement was taken with the client viewing the visual acuity chart through a tiny aperture.

Traditionally, visual acuity is measured for distance (e.g., driving) at 6 meters (20 feet) and for near tasks (e.g., reading) at 40 centimeters (16 inches). The notation of visual acuity as a fraction (e.g., 20/20) describes the magnification required by the observer. The numerator denotes the distance at which the client recognizes the stimulus (measured in meters or feet), and the denominator is the size of the letter or symbol on the chart (measured by a unit called an M-size). A person with 6/6 (20/20) vision requires no magnification, because the value of the fraction is 1. However, a person with 6/60 (20/200) requires $10\times$ magnification; it also means that this person is only able to recognize at 6 meters (20 feet) a stimulus that a person with "standard" vision could recognize at 60 meters (200 feet) (see Procedures for Practice 5-1).

Visual acuity is screened using a standardized logarithmic letter or symbol chart, such as the Early Treatment of Diabetic Retinopathy Study (ETDRS) chart, which is considered the gold standard for visual acuity measurement (International Council of Ophthalmology, 2002). Other charts, such as LEA Symbols, LEA Numbers, or Sloan Letters are also appropriate for screening visual acuity (Chaplin & Bradford, 2011). Regardless of the chart being used, it is essential that the examiner position the client at the testing distance for which the chart is intended. Most charts are designed in the metric system but provide a corresponding measure in feet (Snellen equivalent). Visual acuity screening should be carried out with the best correction available; in other words, clients should wear their glasses or corrective lenses. If the glasses/lenses are not available, have the client look through a pinhole in a piece of paper, as described earlier (International Council of Ophthalmology, 2002).

Procedures for Practice 5-1

Screening for Distance Visual Acuity

Equipment: ETDRS-type chart

Setup

- Client must wear contact lenses or glasses for distance (single vision for distance or multifocals) if typically worn. If the client wears bifocals, trifocals, or progressive multifocals, ensure that the client views the chart through the upper segment of the glasses.
- Client is seated directly opposite the chart, which is positioned at eye level. A common testing distance is 4 meters. Most ETDRS-type charts are calibrated to be used at distances of 4, 2, and 1 meters.
- The room should have standard illumination.

Procedure

- Patch the client's left eye.
- Instruct the client to name the letters on the chart, starting at the top row. If using a symbol chart, instruct the client to name the symbols or match them to a handheld symbol key. If using a "tumbling C" chart (e.g., for illiterate or dysphasic clients), instruct the client to point to the direction of the opening in the "C" (i.e., the direction of the gap in the letter).
- If the client is reluctant to name the letters, encourage guessing.

- If the client cannot name the letters, encourage the client to draw the letters in the air or on a piece of paper.
- If the client cannot identify any characters on the top line, bring the chart to a closer distance as specified in chart instructions. If the client cannot identify any characters at the shortest distance for which the chart is designed (e.g., 1 meter), note this in the client's record and proceed to screen the other eye.
- Record the last line in which the client was able to identify three or more characters on the line. The size of the characters is noted as an M-size (e.g., 16M). When noting visual acuity as a fraction, write the distance of the client from the chart in meters as the numerator (e.g., 4 meters) and the M-size of the characters on the last line in which 3 or more characters were read as the denominator (e.g., 4/16).
- Return the chart to the furthest testing distance and repeat with the left eye, followed by both eyes together.
- Record score separately in the following order: right eye, left eye, both eyes.
- Fractions can be converted from meters to feet using 20 as the numerator, e,g, 4/16 to 20/80.
- Visual acuity worse than 4/8 (20/40) with prescriptive lenses is an indication for a referral to an eye physician.

Adapted from International Council of Ophthalmology. (2002). Visual standards: Aspects and ranges of vision loss with emphasis on population surveys. Retrieved from http://www.icoph.org/downloads/visual-standardsreport.pdf.

Cataract is an example of a disease of the crystalline lens that can cause a disruption in the optical stage of image formation, leading to decreased visual acuity. Macular degeneration is an example of an age-related disease that causes a disruption in the retinal stage of image formation, in which the image is converted into neural impulses. People with loss of central visual acuity commonly refer to their vision as being blurry or veiled; common complaints include reading difficulties and inability to distinguish facial features. People with central vision loss may be observed tilting or shaking their heads or gazing in different directions when attempting to identify the target. Because visual targets are not distinct, clients may try to get closer to the target, enlarge the target, or view the target from an angle.

Contrast Sensitivity

Contrast sensitivity is the ability to detect a visual target against a background of similar tone or hue and more accurately reflects conditions of the visual environment, such as sidewalk curbs, or facial features. Contrast sensitivity is also referred to as "low contrast acuity" and is closely related to problems experienced in everyday activities, particularly falls (American Academy of Ophthalmology

Vision Rehabilitation Committee, 2007). Various charts are available to measure contrast sensitivity. The salient feature in all of them is that the size of the stimulus is constant, whereas the contrast of the stimulus fades.

Diabetes is a systemic disease that can damage the blood vessels of the eye and is the leading cause of new cases of blindness in American adults older than age 20 years (Centers for Disease Control and Prevention, 2011). Despite having good visual acuity, many people with diabetic retinopathy have reduced contrast sensitivity related to vascular damage (Arend et al., 1997).

Visual Field

The visual field is defined as the boundary of what is seen while looking straight ahead. It is commonly described monocularly as extending approximately 50° superiorly, 70° inferiorly, 90° temporally, and 60° nasally. However, the visual fields of both eyes overlap, and the horizontal binocular field is increased by 30° from 150° monocularly to 180° binocularly (Scheiman, Scheiman, & Whittaker, 2007) as shown in Figure 5-2. Defects can affect all areas of the peripheral visual fields, only one side of the visual field in each eye, only the center of the visual field, or only the upper or lower portion of the visual field.

Overlapping
binocular field
Figure 5-2 Visual fields. The illustration shows the limits of the visual fields in each eye, including the area where the visual fields of each eye overlap. The overlapping field is the binocular visual field, where visual targets appear to have solidity and depth. In clients with double vision, objects within the overlapping area appear duplicated when both eyes are open.

Peripheral Visual Field. Confrontation testing is typically used to screen for gross visual field defects. Confrontation testing has been found to be relatively unreliable and should therefore be used in conjunction with functional observations (Warren, 1998). Typically, visual fields are measured in each eye separately, and the client's visual fields are compared to the examiner's visual fields when sitting juxtaposed to the client. More recently, Scheiman (2011) recommended testing both eyes together rather than one at a time, insofar as the purpose of the occupational therapy screen is to determine whether a bilateral visual field defect is hindering the client's occupational performance (see Procedures for Practice 5-2).

Damage to the optic nerves or the visual pathways may result in visual field losses. Glaucoma is a constellation of diseases that causes degeneration of the cells that form the optic nerve. Glaucoma is known as "the silent thief." Visual field loss often goes unnoticed by clients until it is too late, because, in general, they pay less attention to the edges of their sight. Glaucoma is the second leading cause of blindness in the United States, after macular degeneration (Prevent Blindness America, 2008). Damage to the optic nerve leads to contraction or constriction of the visual fields in one or both eyes, commonly referred to as "tunnel vision," yet central visual acuity may remain intact. A person with constricted visual fields may have difficulty finding his or her way in unfamiliar or dark areas, bump into people or obstacles, and have difficulty reaching for objects. Because they do not see the entire picture, clients commonly move away from visual targets in order to get a wider view of the scene.

Hemianopic Visual Field. Hemianopic visual field defects are caused by damage to the visual pathways beyond the

Procedures for Practice 5-2

Screening for Peripheral Visual Field Defect Using the Binocular Confrontation Method

Equipment: Interesting Target Mounted on a Wand

Setup

- Client should not wear glasses (as they may obscure the visual targets).
- Client is seated directly opposite examiner, approximately 20 inches away.
- Background behind examiner should be dark and distraction free.

Procedure

- Instruct client to look at your finger, which you hold between your own eyes. Let the client know you will be moving a target from the side, and the client should tell you when it is first seen while looking at your finger.
- Move target in from all angles, starting at 12 o'clock and moving clockwise to the 2, 4, 6, 8, 10 o'clock positions.
- Compare the client's response with yours.
- A problem is indicated if the client cannot see the target when you do.

From Scheiman, M. (2011). *Understanding and managing vision deficits: A guide for occupational therapists* (3rd ed.). Thorofare, NJ: Slack.

organ of the eye. The most common ones seen by occupational therapy practitioners are hemianopia and quadrantanopia: visual field defects on the same side in each eye. Clients frequently refer to a field loss in one eye and sometimes lack awareness that, in fact, the field loss is bilateral. Some clients with brain damage may not be aware of their visual field defects or may present with lack of attention to the affected side. Take care to differentiate between this (hemi-inattention) and a true visual field defect, keeping in mind that they can coexist in the same client.

Central Visual Field. A scotoma is an area of reduced central vision commonly described as a "blind spot," surrounded by intact visual fields. The client may or may not be aware of the presence of one or more scotomas because of "perceptual completion." Perceptual completion occurs when the mental model of the visual target or the environment is perceived as complete, despite missing visual input. Scotomas vary in amount, size, location, and density (Fletcher & Schuchard, 1997). Testing methods require a high degree of accuracy in order to detect the presence of small or relative blind spots; this is called "macular perimetry." Careful observations during reading tasks can also detect the presence of scotomas (see Reading Assessment).

Oculomotor Functions

Control of eye movements depends on a complex interaction at cortical and subcortical levels. Colenbrander (2009) suggested that eye movements used to search for or follow moving visual targets are made in direct response to the mental model of the environment. Because detailed vision is restricted to a small portion of the central retina—the fovea—eye movements are necessary in order to position and maintain the fovea on visual targets of interest, particularly during motion (Purves et al., 2004; Warren 1998). Foveation refers to positioning of the object of interest on the area of clearest vision. Gaze stabilizing movements are reflexive reactions to head and body motions. These compensatory eye movements are generated by the vestibular/ocular/cervical response system. The vestibular-ocular reflex is initiated when the vestibular system detects a change in head position during a visual task. Feedback is provided to the oculomotor system to produce compensatory eye movements in order to maintain a steady visual image (Purves et al., 2004; Warren, 1998). Gaze shifting movements, saccades and pursuits, are made for the purpose of directing the eyes toward visual targets of interest or maintaining targets of interest on the area of clearest vision. Vergence eye movements help keep the visual target on the fovea of each eye as the target moves closer (convergence) or further away (divergence) from the viewer.

Oculomotor control can be assessed in each eye separately or with both eyes together. However, for the purposes of the occupational therapy screen, the tests should be conducted binocularly because deficits are more readily observed this way (Warren, 1998).

Saccades. Scanning is the ability to shift the area of clearest vision back and forth in order to find or identify visual targets. In order to scan the visual environment, for example when looking for a particular person in a crowded room, the observer makes quick eye movements called saccades (see Procedures for Practice 5-3).

Smooth Pursuits. When tracking and following moving targets, the eyes must keep the object of regard in the area of clearest vision, the fovea. The eyes make smooth pursuits in order to maintain continued fixation on the moving target, as when watching an airplane take off (see Procedures for Practice 5-4).

Procedures for Practice 5-3

Screening of Saccades

Equipment: Two interesting targets (e.g., two tongue depressors, one with a green circle on the end and the other with a red circle on the end)

Setup

- Client must wear contact lenses or glasses for distance (single vision for distance or multifocals) if typically worn. If the client wears bifocals, trifocals, or progressive multifocals, ensure that the client views through the upper segment of the glasses.
- Client is seated directly in front of and facing the examiner.

Procedure

- Hold wands approximately 16 inches from the face, separated by approximately 8 inches.
- Give no instructions regarding head movement.
- Tell the client, "Look at the red dot when I say red. Look at the green when I say green, and remember to wait until I say to look."
- Tell the client to look from one target to the other for a total of 10 fixations, five round trips.
- Observe
  - Ability to complete five round trips
  - Accuracy of eye movements (overshooting or undershooting target)
  - Movement of head or body

Adapted from Maples, W., Atchley, J., & Ficklin, T. (1992). Northeastern State University College of Optometry's oculomotor norms. *Journal of Behavioral Optometry, 3*, 143–150.

Procedures for Practice 5-4

Screening of Smooth Pursuits

Equipment: Interesting target mounted on a wand

Setup

- Client is seated directly in front of and facing the examiner.
- Client must wear contact lenses or glasses for distance (single vision for distance or multifocals) if typically worn.
- Hold target approximately 16 inches from the client's face.

Procedure

- Give no instructions regarding head movement.
- Tell the client, "Watch the target, and don't take your eyes off of it."
- Move target clockwise two rotations and counterclockwise for two rotations.
- Observe
  - Number of rotations the client is able to complete
  - Ability to maintain fixation, that is, the number of times the client has to refixate
  - Movement of the head or body

Adapted from Maples, W., Atchley, J., & Ficklin, T. (1992). Northeastern State University College of Optometry's oculomotor norms. *Journal of Behavioral Optometry, 3*, 143–150.

Convergence. Convergence is a reflexive response elicited when the viewer attends to a visual target moving closer to the viewer (see Procedures for Practice 5-5). A break in fixation normally occurs when the target is within 2–4 inches of the face, and recovery of a single image takes place at 4–6 inches. The client may not report seeing a double or blurry image because of suppression of vision from one eye. Therefore, it is important to observe the eyes and note when one eye drifts out or in during convergence and pulls back in or out with fusion.

Binocular Vision

Binocular vision allows us to blend the two slightly different images from each eye into a singular image containing volume and depth. Binocular vision depends on good eye alignment and the ability of the eyes to work as a team. In screening binocular vision, the therapist checks objective eye alignment and accommodation.

Eye Alignment. Eye alignment is objectively measured by observation of the light reflected off of the corneas with both eyes at the same time. The client should wear glasses or corrective lenses if typically worn. The therapist asks the seated client to gaze at a target at least
Normal

Figure 5-3 Eye alignment showing how a single light source reflects on both corneas in reference to the pupils. In normally aligned eyes, the reflections are located in the center of the pupil of each eye. In eyes that are out of alignment, the light reflections are different from each other.

20 feet away, so that the eyes are in the position of primary gaze. The therapist holds a penlight centered approximately 16 inches away from the client's eyes. The therapist observes the light reflection in each eye; the reflection should be in the same position in both eyes (Fig. 5-3). Discrepancies in positions of the reflections are noted (Warren, 1998).

Accommodation. Accommodation describes the ability of the lens to strengthen its optical power so that close objects are seen clearly. Decline in accommodation becomes functionally significant around age 40 years. If the client is older than age 40 years, expect accommodation to be decreased, necessitating reading glasses.

Visual Processing Deficit Screening

The ability to use vision for completing daily tasks depends not only on the solid foundations of acuity, field, and oculomotor control but also on the ability to engage vision with other sensory input as well as with motion and cognition (International Council of Ophthalmology, 2008). The client's ability to use vision to interact with the environment may be diminished if the information cannot adequately be processed.

Procedures for Practice 5-5

Screening for Convergence Deficits

Equipment: Penlight or target; ruler

Setup

- Client is seated directly opposite the therapist.
- Client must wear contact lenses or glasses for distance (single vision for distance or multifocals) if typically worn.
- Client's head should be vertically erect.

Procedure

- Slowly move the penlight or target toward client at eye level (do not shine light directly into the client's eyes; direct it at the brow slightly above eye level).
- Ask the client to keep his or her eyes on the light and to report when the light appears blurred or when two lights are seen. Note the distance at which this occurs. Observe for a break in fusion.
- When the break in fusion occurs, move the target in another inch or so and begin to move it away from the client.
- Ask the client to let you know when he or she can see one light again. Note the distance at which fusion is reported.

Adapted from Warren, M. (1998). *Brain Injury Assessment Battery for adults: Test manual*. Birmingham, AL: visABILITIES Rehab Services, Inc.

Visual Attention and Visual Search

Visual attention is a prerequisite for higher visual processing; *visual search* is a response to the desire to selectively find and attend to targets of interest (Warren, 2011). Two visual processes seamlessly coexist: the central process, which attends to visual detail for analysis and identification of visual targets, and the peripheral process, which provides background information about the viewer's whereabouts in space. The former requires selective attention, whereas the latter requires global awareness of the environment. The amount of attention devoted to each process depends on the task, and attention may be apportioned or divided accordingly. Warren (2011) illustrates this point: "When crossing a crowded room to talk to a friend, one must monitor the movement in the room to avoid collisions while at the same time focus on the friend" (p. 409).

Visual search (or scanning) is the motor response to the desire to shift visual attention from one visual target to another. In order to take in new visual information from the environment, the viewer must first disengage from the current visual target and redirect gaze toward the new visual target. Visual search is accomplished using saccadic eye movements, which can originate reflexively (as a response to an unexpected visual target in the environment that is perceived as a threat) or voluntarily (as a response to the deliberate desire to search the environment for specific visual targets).

Screening for visual attention and visual search deficits occurs at the same time and cannot be separated into components, because visual search is the expression of the client's ability to selectively attend to, disengage from, and shift visual attention to find new targets (Warren, 2011). A good visual search includes the following features (Warren, 2011):

- Initiation of a horizontal or vertical pattern
- An organized and efficient strategy
- Symmetrical search of both sides of the scene
- Sustained engagement in the visual search without drifting off
- Successful identification of targets
- Ability to search increasingly complex environments

Hemi-Inattention. Hemi-inattention is a disorder characterized by the loss of ability to attend, respond, or react to sensory stimuli on the side contralateral to the brain lesion. Three main features of hemi-inattention are generalized difficulty with alertness and attention, spatial bias (preference for initiating and confining visual search to the ipsilateral side), and difficulty forming a mental representation of space that includes the involved side (Warren, 2011). The disorder occurs most commonly in lesions of the right hemisphere with hemi-inattention involving the left side. The severity of the disorder ranges from mild to severe, with the terms visual neglect and hemispatial neglect reserved to describe the most severe condition, which may

be accompanied by a left hemianopsia (Warren, 2011). Unilateral neglect and visual neglect are terms often used interchangeably, but they are not the same (see below).

Unilateral Neglect. Unilateral neglect (UN) is a category of disorders that broadly refers to the failure to detect, report, or respond to stimuli (people or objects) presented to the side that is opposite of a brain lesion (Hillis, 2006; Plummer, Morris, & Dunai, 2003). UN can involve sensory, motor, and representational modalities that may not be detected in assessment of vision (Goff, 2010). In severe cases of neglect, evidence suggests that in addition to the features of hemi-inattention described above, attention to visual stimuli on the extreme ipsilateral side is diminished as well, leading to the characterization of neglect as "a bilateral, asymmetrical compression of experienced space" (Ellis, Jordan, & Sullivan, 2006, p. 861). For example, a client with a right-brain stroke may appear to not see a person sitting on the left side of his body or fail to shave the left side of his face. Clients with UN are often not aware that they are missing information and believe they are seeing things as complete (Toglia & Cermak, 2009). Although it is typically associated with right parietal lobe damage, UN can occur after unilateral lesion of a diverse range of brain structures (Cumming et al., 2009).

There are two main classification systems for the many types and clinical presentations of UN (Pierce & Buxbaum, 2002). One system is based on the modality in which the neglect is elicited (i.e., sensory, motor, representational), and the other is based on the distribution of abnormal behavior (i.e., personal or spatial) (Plummer, Morris, & Dunai, 2003) (see Definition 5-2). This chapter addresses aspects of sensory neglect (specifically visual neglect), personal neglect, and spatial neglect (motor neglect is described further in Chapter 8).

Although, to onlookers, it may appear that clients with UN do not see stimuli on the contralateral side of their brain lesion, UN is generally believed to be an attention-based processing impairment, not an impairment of the eyes or visual system (Gillen, 2009). Occupational therapists attempt to discern between possible symptoms of visual field deficits and UN during the assessment process (see Table 5-3) and administer specific assessments of UN if it is suspected (see options in Assessment Table 5-1) so that the most appropriate intervention plan may be developed.

When screening for visual attention and visual search deficits, the occupational therapist must consider the context in which the search occurs. A visual search of the area immediately surrounding the body—the peripersonal space—requires a different search strategy than a visual search of the larger environment—the extrapersonal space. (Also see Figure 24-4 for depiction of extrapersonal versus peripersonal space.)

Peripersonal Space Visual Search. A visual search of peripersonal space requires high amounts of selective attention, because visual targets at close range can be inspected

Definition 5-2

Categories of Unilateral Neglect

- **Sensory neglect** (also called "input neglect and perceptual neglect") refers to a condition in which the client is not aware of the visual, auditory, or tactile stimuli on the part of the body contralateral to the lesion.
- **Motor neglect** (also called "output neglect") presents as impaired initiation or execution of movement in response to a stimulus even when the person is aware of the stimulus that cannot be explained by a motor deficit or weakness.
- **Representational neglect** pertains to disregard of the contralesional half of mental visualizations of a task, action, or environment. For example, the client with right-brain stroke is asked to imagine and then describe her bedroom as if she were standing in the doorway, but she omits the left-sided details in her description.
- **Personal neglect** refers to lack of awareness of the side of the body opposite the brain damage, such as failing to comb one side of the head.
- **Spatial neglect** refers to the failure to respond to stimuli on the contralateral side of space, further characterized as peripersonal neglect (failure to eat food on half of the plate) or extrapersonal neglect (bumping into a doorway).

Adapted from Plummer, P., Morris, M. E., & Dunai, J. (2003). Assessment of unilateral neglect. *Physical Therapy*, 83, 732–740.

for greater detail than those in the distant environment. Assessments conducted at close range are commonly given in the form of pen-and-paper tests administered at a desk. Examples of tests include line bisection, single-letter cancellation, design copy, and draw a clock (Goff, 2010; Rengachary et al., 2009; Warren, 2011). A computerized

Table 5-3 Scanning: Visual Field Defect Versus Hemi-Inattention

Visual Field Defect	Hemi-Inattention
Abbreviated scanning pattern	Disorganized, random scanning pattern
Scanning pattern is organized	Asymmetrical search pattern in hemispace
Rescanning is observed	Scanning pattern is carried out with reduced effort and little or no rescanning
Length of time/effort are appropriate for the task	Task is completed swiftly, or if client is aware of deficit, will take an inordinate amount of time in an attempt to compensate

Reprinted with permission from Warren, M. (1998). *Brain Injury Assessment Battery for adults: Test manual.* Birmingham, AL: visABILITIES Rehab Services, Inc.

reaction time test—the Posner Cueing Paradigm—was shown to have the greatest sensitivity to detecting left-sided visual neglect when compared with some of the aforementioned tests in clients in the acute and chronic phases of stroke recovery (Rengachary et al., 2009).

Extrapersonal Space Visual Search. The area that extends beyond arm's reach is extrapersonal space and represents the larger environment through which an individual moves. Global awareness of the environment must be balanced with selective attention to the visual details of targets. Wider eye and head movements are required to effectively perform visual searches of the environment; searches can be conducted when the client/viewer is stationary or while the client performs a mobility task.

Three visual search strategies are used by people with normal visual attention: clockwise, counterclockwise, or rectilinear (Warren, 1998). The ScanBoard was developed to assess visual search of extrapersonal space when the client is stationary (Warren, 1998). The client is required to point out 10 numbers as he or she sees them without cueing. The therapist records the order of the numbers read. The ScanBoard tells if the client used an organized, sequential search strategy or whether the search was disorganized, random, or abbreviated (Warren, 1998). Visual search of extrapersonal space during ambulation can be observed by asking the client to identify features of the environment while walking through it. Warren (1998) recommended placing ten 1-inch letters or numbers along each side of a hallway at various heights and distances from one another and then asking the client to point out and read each letter or number during ambulation (Warren, 1998, 2011).

Reading Assessment

Reading difficulty is the most frequently cited complaint in clients with vision impairments (Watson, 1999). Reading is a complex task that involves many cognitive processes other than vision. Assessments were developed to examine the impact of central vision loss on particular aspects of reading: acuity, size, speed, accuracy, and comprehension. In low vision reading assessments, the size of print is calibrated using the same unit of measure, M-size, as the characters on visual acuity charts. Newsprint positioned at 40 centimeters (16 inches) from the reader roughly corresponds to a print size of 1.0M, also considered the size of standard print.

The Minnesota Reading Acuity Charts (MNRead) were designed to measure the effect of print size on reading speed. The client reads the sentences out loud while the examiner records the time taken to read each sentence. The smallest print size that is read fluently and without errors in the fastest time is called the "critical print size." The smallest print size read, regardless of reading speed, is termed "reading acuity" (Legge et al., 1989). The critical print size is used to determine the amount of magnification the client needs in order to read "standard" print.
Visual recognition of words, eye movement control during reading, and the interference of central scotomas are measured using the Pepper Visual Skills for Reading Test (VSRT). The client is required to read aloud unrelated letters and words in rows with varied spacing while the examiner records errors and the time to complete the test (Fig. 5-4). The test reveals reading rate, line mastery, and prevalent errors in reading for the print size in which the test is presented (Watson, Baldesare, & Whittaker, 1990).

A client's reading grade level can be calculated using the Morgan Low Vision Reading Comprehension Assessment. The test uses the "cloze" method, in which a word is omitted from a sentence, and the client is required to provide the missing word after reading it only once (Watson et al., 1996).

Formal Vision-Related Questionnaires

The National Eye Institute 25-Item Visual Function Questionnaire (VFQ-25) Version 2000 (Mangione et al., 2001) is a standardized vision-specific quality of life outcome measure designed to evaluate the impact of visual symptoms on visual tasks (e.g., reading medication labels and driving) and general health (e.g., emotional well-being and social functioning). It has been extensively used in research and is available in the public domain.

The Melbourne Low-Vision Activities of Daily Living Index (MLVAI) is a standardized test of basic and instrumental activities of daily living (ADL) for clients with low vision. The therapist conducts an interview and observes structured tasks that are scored according to descriptive criteria (Haymes, Johnston, & Heyes, 2001b). The Weighted Melbourne Low-Vision ADL Index (MLVAI$_w$) uses the same criteria from the MLVAI but includes the client's rating of the importance of the ADL items. The ranking of importance allows the therapist to measure the impact of low vision on the client's perception of disability (Haymes, Johnston, & Heyes, 2001a).

case example

Mrs. F.: Low Vision in a Client with a Hip Fracture

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	**Examples of Internal Dialogue**
Client Information Mrs. F. is a 78-year-old woman who was admitted for inpatient rehabilitation following repair to the right femoral neck. Other chronic health conditions include osteoarthritis, hypertension, and macular degeneration. Her expected length of stay in the rehabilitation unit is 8 days.	Understand the client's diagnosis or condition	"Mrs. F. broke her leg at the hip—I wonder if she tripped over something she did not see? The macular degeneration is likely to make it difficult for her to recognize the people on the unit and read postsurgical instructions. I wonder what her vision is like now compared to what it used to be before her eye disease. It is important for me to know her level of vision impairment so that I can modify instructions accordingly."
Mrs. F. was a homemaker who did not learn to drive until she turned age 55 years. Prior to getting her driver's license, her hobbies included cross-stitching and reading romance novels. Once she got her license, she and her husband would plan weekend excursions to visit family and friends across state borders.	Know the person	"She does not strike me as someone who takes care of herself—she seems like someone who always takes care of others. I wonder if she has been to see her eye doctor lately to get a dilated eye exam."

Mrs. F. lost her husband of 58 years 6 months ago. Of her four children, one lives locally, one lives several states away, and one lives overseas. Her second child committed suicide at age 30 years. Her relationships with her children are strained, and they rarely come to visit.	Appreciate the context	"I imagine it has been very difficult keeping up with housework, paying bills, cleaning, and driving—not only because of her vision loss but also coping with the recent loss of her husband."
	Develop provisional hypotheses	"Even though Mrs. F. is here for a broken hip, I imagine that one of the greatest barriers to her successful rehabilitation will be her vision loss, particularly in tasks requiring appreciation of details. I am predicting that she has poor visual acuity, contrast sensitivity loss, and a scotoma that makes reading very difficult. She might also be depressed because she has suffered so many losses in such a short time. She is going to be spending a lot of time in one place, so she will likely desire to engage in activities within her peripersonal space—requiring greater attention to visual details."
Assessment Process In addition to completing an occupational profile and observations of performance in activities of daily living (ADL), the therapist chose the Canadian Occupational Performance Measure (COPM) to obtain information about Mrs. F.'s perceived problems and priorities. The therapist also screened visual acuity using an Early Treatment of Diabetic Retinopathy Study (ETDRS) chart at 4 meters with glasses, the Minnesota Reading Acuity (MNRead) chart (to obtain information about reading acuity and critical print size), the Pepper Visual Skills for Reading Test (VSRT) (to obtain information on reading accuracy), and the Morgan Low Vision Reading Comprehension Assessment (LVRCA) (to estimate current grade-level reading ability).	Consider evaluation approach and methods	"I already know that she will not be able to do certain ADL tasks because of her postsurgical non–weight-bearing status. I need to evaluate her vision to give me a better understanding of how her loss of vision impacts her ability to engage in other daily activities."
Assessment Results The COPM revealed that although her highest priority was to do everything possible to allow her hip to heal and be a "good patient," Mrs. F. was very concerned about her ability to cope with the demands of the therapists and nursing staff. She disclosed that she was more worried about potential embarrassing situations caused by her "hidden disability" (like difficulty recognizing faces or reading therapy instructions) than those caused by her temporary dependence on others for mobility assistance. She was dissatisfied with her ability to read instructions, sign her name on admission forms, and distinguish the faces of the therapists and nursing staff. Best corrected visual acuity at 4 meters using both eyes was 4/16 (equivalent to 20/80), indicating moderate vision impairment displaced to the left of fixation. The MNRead, which Mrs. F. held at 33 centimeters, revealed a reading acuity of 1.3M and a critical print size of 2.5M. Reading speed was not calculated. The VSRT was administered at 3.2M. Mrs. F. demonstrated frequent misidentification of word beginnings, indicating a possible central scotoma. The LVRCA was administered at 3.0M, and Mrs. F.'s reading grade level was equivalent to that of a fifth grader.	Interpret observations	"Mrs. F. is highly motivated to participate in her own therapeutic process but is concerned about the disabling impact her vision loss has on her ability to meet the challenges that the clinical staff might present to her. She seems willing to accept help for limitations caused by her hip fracture—look at her bossing her visitor to go fetch her a box of tissues from the bathroom or a drink from the vending machine. Yet she is clearly concerned that she will embarrass herself when she is asked to read something, such as the breakfast menu, and it is revealed that she cannot see. She is worried that everyone will think she is illiterate. The reading tests were really difficult for her to complete and made a huge emotional impact on her. She broke down and cried. She said she felt like a complete idiot. I guess this was the first time that she could not "fudge" it—she is not used to being alone now, and when her husband was alive he did all of the reading."

Occupational Therapy Problem List

1. At risk for poor adherence to rehabilitation efforts related to hip fracture because of vision limitations. Difficulty acknowledging vision loss to others.
2. Decreased awareness of how her vision loss can potentially interfere with the therapy process.
3. Difficulty recognizing faces of staff on the unit.
4. Difficulty reading print size smaller than the equivalent of subheadings in a newspaper.
5. Decreased comprehension of reading materials.

Synthesize results

"She is putting up a good front and is managing to hold herself together for the most part. I would like to screen for depression in the following days, once we establish a good therapeutic relationship. I think that doing the reading tests really opened the floodgates and touched a deep sorrow for all the losses she has had to face in the past year and might be facing in the near future—losing her husband, her eyesight, her driver's license, and possibly her ability to take care of her house. She was not expecting me to address her vision loss, because she came here for her hip. I would also like to involve her eye-care provider and find out when she is due for an appointment and what tools might be available to help her. I wonder if since her husband's passing, her home has gotten so disorganized that she tripped and fell over something that was not put away, causing the hip fracture. She will benefit from a home assessment prior to discharge."

Clinical Reasoning in Occupational Therapy Practice

Effects of an Old Stroke on Visual Function

During her inpatient rehabilitation, Mrs. F. was observed to eat only the food on the right side of her plate. Her medical history revealed an old stroke on the right side of her brain.

What might you suspect to find in the occupational therapy vision screen?

Summary Review Questions

1. What is the difference between visual function and functional vision?
2. How do you understand the Occupational Therapy Practice Framework, 2nd edition, in the context of visual function and functional vision?
3. What are the foundations for visual function?
4. Your client with brain injury did poorly on a test of figure-ground administered by another therapist. List two possible reasons why.
5. Why is it important to assess contrast sensitivity?

6. Name four vision-related professions. Where would you be most likely to interact with workers in those professions? What information would you exchange?
7. What is the difference between low vision and visual dysfunction?
8. Name three age-related eye diseases and describe their impact on visual function.
9. What are three distinguishing features of hemi-inattention, and how does it differ from a visual field defect?
10. Why is it important to screen vision as early as possible?

Glossary

Contrast sensitivity—The ability to distinguish the edges of objects against backgrounds of similar color or hue.

Hemi-inattention—A disorder of attention resulting in decreased visual search to one side.

Pursuits—Slow movements of the eyes allowing the moving object of regard to remain in the area of clearest vision.

Saccades—Quick movements of the eyes from one target to another while positioning the visual targets in the area of clearest vision.

Scanning—The act of visually searching the environment.

Tracking—The act of visually following a moving target.

Unilateral neglect (UN)—A category of disorders that broadly refers to the failure to detect, report, or respond to stimuli (people or objects) presented to the side that is opposite of a brain lesion (Hillis, 2006; Plummer, Morris, & Dunai, 2003).

Visual acuity—Sharpness of vision.

Visual field—The span of vision; what one sees all around while looking straight ahead.

Visual perception—The visual and cognitive processes required to adapt to the environment.

Assessing Abilities and Capacities: Cognition

Mary Vining Radomski and M. Tracy Morrison

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Appreciate the role of cognition in occupational performance.
2. Describe specific cognitive capacities and abilities and analyze their influence on occupational function.
3. Select cognitive assessment methods and tools based on individual clients' characteristics, properties of various measures, and requirements of the setting or episode of care.
4. Anticipate and describe factors that should be considered in interpreting the results of cognitive assessment.
5. Distinguish occupational therapy's contribution to multidisciplinary cognitive assessment from that of other rehabilitation disciplines.
Cognition refers to the integrated functions of the human mind that together result in thought and goal-directed action. Cognition underlies being and doing and is evidenced in how people interact with others and perform both simple and complex activities of daily life. Perhaps the central role of cognition in occupational performance is best illustrated as one imagines what it must be like to suddenly lose the ability to concentrate, remember, and problem solve. Survivors of traumatic brain injury (TBI) describe how their once-familiar routines and environments become chaotic, confusing, and frightening, which devastates their sense of identity and competence (Erikson et al., 2007).

Occupational therapists assess cognition because many people seeking occupational therapy services are likely to have some degree of cognitive impairment that influences their ability to participate in rehabilitation and achieve rehabilitation outcomes (Skidmore et al., 2010). Cognitive changes can be temporary, relatively static, or progressive. As above, many survivors of TBI experience deficits in information processing speed, attention, memory, and executive functions that persist for months or years postinjury (Skandsen et al., 2010). A significant number of persons who sustain a spinal cord injury also have a concurrent TBI with similar implications for cognition (Macciocchi et al., 2008). Individuals with chronic conditions may also experience cognitive changes including those with multiple sclerosis (Rogers & Panegyres, 2007), Parkinson's disease (Caviness et al., 2007), cancer (Boykoff, Moieni, & Subramanian, 2009), epilepsy (Helmstaedter et al., 2003), systemic lupus erythematosus (McLaurin et al., 2005), and human immunodeficiency virus/acquired immunodeficiency syndrome (Heaton et al., 2004). Even individuals with mild stroke who are independent in activities of daily living (ADL) may have executive dysfunction that impacts their ability to work, drive, and engage in recreational activities (Edwards et al., 2006; Wolf, Barbee, & White, 2011).

This chapter begins with descriptions of specific cognitive domains and processes. We then review clinical reasoning considerations pertinent to cognitive assessment and describe specific methods and tools based on three complementary approaches to cognitive assessment. We conclude with considerations for interpreting the results of cognitive assessment.

DEFINING COGNITIVE CAPACITIES AND ABILITIES

The term cognition generally refers to the product of many integrated processes carried out by the brain that allow humans to be aware, think, learn, judge, plan, and execute behavior (National Institutes of Health [NIH], n.d.). These domains and processes include orientation, perception, attention, memory and learning, judgment, reasoning, language, and executive functions (NIH, n.d.). How these processes and domains precisely interact to enable being,

Table 6-1	Possible Observable Manifestations of Cognitive Dysfunction
Cognitive Domain	**Examples of Patient Performance That Suggest Cognitive Dysfunction**
Orientation	Mr. K. is asked to report the correct date, time, or location. Sometimes during morning sessions he responds correctly but later in the day provides illogical or far-fetched answers.
Attention	Mrs. G. sorts a basket of laundry into two piles based on color. She stops and looks around every time she hears an overhead page, requiring cues to restart the task.
Memory	Mr. B. takes his medication right before breakfast. Two hours later, Mr. B. reports that he cannot recall whether or not he took his morning pills (episodic memory failure).

thinking, and doing is unclear, but it appears that executive functions may control and coordinate the other cognitive operations in the service of goal-directed action (Salthouse, 2005). Consider the working definitions that follow and how dysfunction might be observed in everyday activities (see Table 6-1).

Primary Cognitive Operations

Primary cognitive operations such as orientation, attention, and memory are thought to be prerequisite to higher level thinking abilities such as executive functions and metacognition. That is, people must have a sense of place or time and some ability to focus their attention and remember information in order to reason, problem solve, plan, and execute complex activities.

Orientation

Orientation refers to the awareness of self in relation to person, place, time, and circumstance (Sohlberg & Mateer, 1989). Orientation deficits are typically symptoms of brain dysfunction, with disorientation to time and place being most common (Lezak, 1995).

Attention

The term attention was famously defined by William James as "the taking possession by the mind, in a clear and vivid form, of one out of what seem several simultaneously present objects or trains of thought" (James, 1890, pp. 403–404). Attentional abilities are dependent on multiple brain regions including the cingulate cortex, limbic system, prefrontal cortices, and sensorimotor regions (Posner, 1980). Each person is thought to have a limited capacity for consciously attending to information—a hard-wired upper limit that dictates how many inputs

Definition 6-1

Components of Attention and Influence on Performance

Component of Attention	Definition	Implications: Performance during Meal Preparation
Focused attention	Basic response to stimuli as in turning head to sound of bell (Sohlberg & Mateer, 2001)	None. This level of attention is considered low level and often recovered as individuals emerge from coma and gain conscious awareness.
Sustained attention	Vigilance; maintaining attention over time during continuous activity (Sohlberg & Mateer, 2001)	To peel several potatoes, an individual must stay focused for the duration of the task.
Selective attention	Freedom from distractibility; occurs when an individual concentrates on one set of stimuli while ignoring competing stimuli (Sohlberg & Mateer, 2001)	The cook ignores the noise from the television while measuring or counting ingredients.
Alternating attention	Capacity for mental flexibility; occurs as one flexibly shifts attention between multiple operations (Sohlberg & Mateer, 2001)	The cook interrupts meal preparation to answer the telephone and then quickly resumes setting the table while monitoring the status of food simmering on the stove.
Divided attention	Ability to respond to two tasks simultaneously (Sohlberg & Mateer, 2001)	The cook browns the meat while talking with a family member.

can be simultaneously processed (Lezak, 1995). Deficits in attention are common following brain injury as numerous and diffuse neural regions work to support the individual's attentional abilities. Deficits can also be experienced because of a lack of sleep or decreased nutrition (Groeger et al., 2011).

Learning is dependent on attention as individuals cannot encode into memory stimuli or content they do not attend to. Definition 6-1 describes five components of attention (Sohlberg & Mateer, 2001) and their implications for task performance.

Memory

Memory broadly refers to information storage and retrieval (Lezak, 1995). Rather than a unitary process or construct, there are many types of neural processes that support an individual's memory capacity (Sohlberg & Turkstra, 2011). Experts still debate about what transpires during the process of remembering (Cowan, 2008). Atkinson and Shiffrin's (1971) Information-Processing Model, which highlights stages of acquiring and employing new knowledge and skills, is one of many conceptions as to how this process occurs (Fig. 6-1). We use this model to introduce
Figure 6-1 Human information-processing diagram that incorporates concepts proposed by Atkinson and Shiffrin (1971) and Levy (2011).

memory-related concepts, acknowledging the continued debate regarding precise terms and their meanings in this realm. (Also see Dubuc [2011] and Levy [2011] for more in-depth information on the following discussion.)

Sensory Registers. Information from the environment is briefly (milliseconds) held in registers (or stores) specific to the human senses (Lezak, 1995). This registration stage has been called the intake valve for determining what data from the environment are ultimately stored. This phase is influenced by acuity of the senses (such as hearing and vision), affective set, and perception.

Short-Term Memory/Working Memory. The short-term phase of information processing reflects "faculties of the human mind that can hold a limited amount of information in a very accessible state temporarily" (Cowan, 2008, p. 324). It has many labels: primary memory, immediate memory, short-term memory, and working memory. The term *primary memory* pertains to a pattern of neural firing associated with a given idea, about which the person may or may not be aware (Cowan, 2008). This includes data just transferred from the sensory registers related to one's focus of attention (Levy, 2011). The term *working memory* pertains to the attention-related processes that are involved in managing incoming information and manipulating stored information for planning and problem solving (Cowan, 2008). It can be thought of as the seat of conscious thought; it connotes the effortful deployment of cognitive resources during this stage as well as the manipulation of information involved in active thinking (Sohlberg & Turkstra, 2011). Many experts believe that for input from sensory registers to proceed to storage in long-term memory, the input must

be the subject of deliberate concentration in working memory for approximately 30 seconds (Lezak, 1995). Without this focused attention, the memory trace decays, and the memory is not retained (Lezak, 1995). Unlike long-term memory, which is thought to have an infinite capacity, working memory has a restricted holding capacity of seven plus or minus two chunks of information (Miller, 1956). In addition to its role in information processing, working memory is the foundation of concentration and problem solving (Baddeley, 1990). Based on electrochemical activity in the brain, working memory reflects the contribution of attention to the memory process (Lezak, 1995).

Long-Term Memory. Whereas data in working memory have a short shelf life, information in long-term memory can be stored for minutes to a lifetime (Lezak, 1995). When we remember information (an event that occurred an hour ago or a year ago), we have located and retrieved data from long-term memory and are holding it for conscious attention and thought in limited-capacity working memory. Storage in long-term memory is based on relatively permanent changes in brain cell structure (Glover, Ronning, & Bruning, 1990), although there does not appear to be a single local storage site for stored memories (Lezak, 1995).

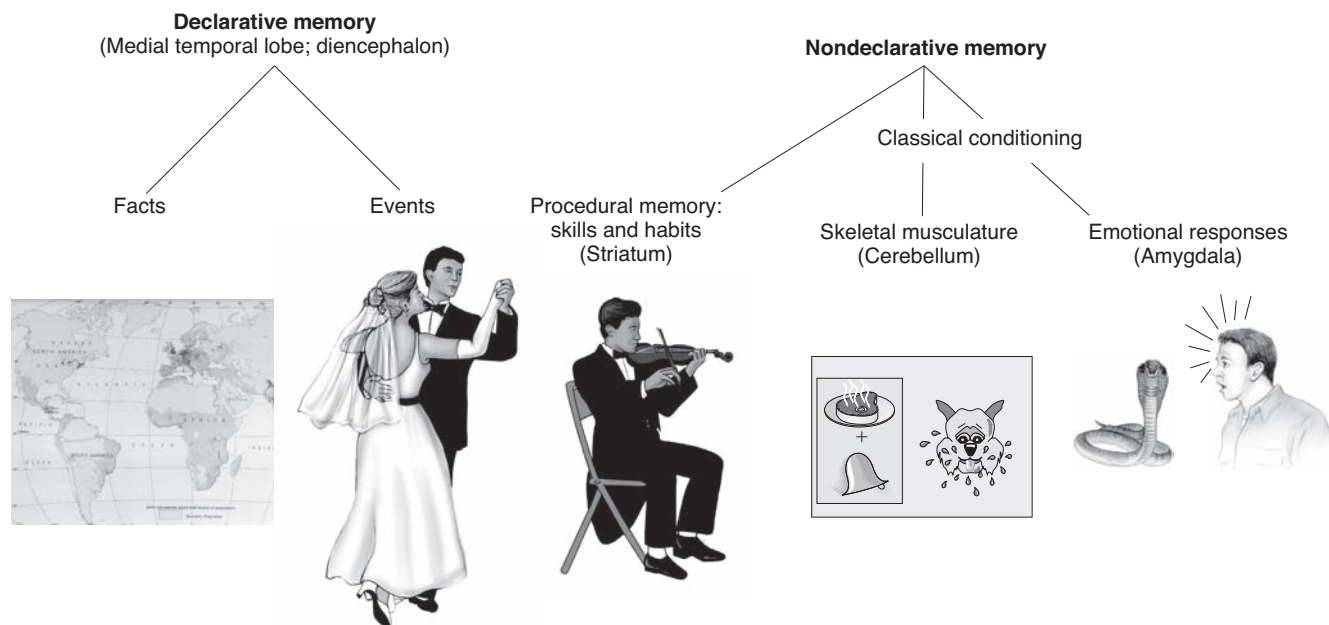
Long-term memory is thought to consist of two subsystems, explicit (or declarative) memory and implicit (or nondeclarative) memory (Fig. 6-2). Declarative memory pertains to factual information and includes episodic memory (knowledge of personal information and events such as what you ate for breakfast) and semantic memory (knowledge of facts about the world such as that horses are big and ants are small) (Eysenck & Keane, 1990). Prospective memory is another form of declarative


Figure 6-2 Two subsystems of long-term memory.

memory, having to do with remembering to do tasks that one intends (Fish, Wilson, & Manly, 2010). Implicit or nondeclarative memory differs from explicit memory because it does not involve conscious awareness of learning (Sohlberg & Turkstra, 2011). This includes procedural memory, which pertains to knowing how to do things; it allows us to learn and perform skilled motor actions (Eysenck & Keane, 1990).

Memory impairments are typically characterized as mild, moderate, or severe based on the results of cognitive assessment. The term *neurologic amnesia* is reserved to describe losses of broad categories or segments of memory resulting from brain trauma, stroke, or tumor (Dubuc, 2011) (see Definition 6-2).

Executive Abilities

The term *executive abilities* (also called executive functions) refers to a group of higher order thinking processes that enable individuals to achieve self-determined goals and engage independently and purposefully in complex everyday tasks, such as work and academic life (Lezak, 1995). As outlined in Table 6-2, the domains and functions that comprise executive processing underlie the personalized methods through which individuals begin, accomplish, and complete tasks. As such, executive abilities are critical to occupational performance.

Definition 6-2

Types of Amnesia

Retrograde	Loss of ability to recall events that occurred before the trauma
Anterograde	Decreased memory of events occurring after trauma
Posttraumatic amnesia (PTA)	Period following trauma during which the patient is confused and disoriented and seems to lack the ability to store and retrieve new information

Executive Functions in Everyday Life

Executive abilities determine our ability to problem solve, plan, establish goals, monitor our work, and initiate and terminate tasks. Individuals with executive deficits commonly experience significant disability when they encounter novelty and complexity such as when discharged from clinical environments to return home (Baum et al., 2008).

Table 6-2 **Possible Observable Manifestations of Problems with Executive Processing**

Domain	Examples of Performance That Suggest Executive Dysfunction
Initiation	Mrs. M. wants to create a photo album for her son. She has an empty photo album and a large bag of photographs on a table and a free afternoon but cannot get herself to begin.
Inhibition	Mr. G. finds himself lost while driving in a new city. Two hours later he notices a shopping center he continually passes by and realizes he has circled the same one-half mile block the entire time.
Task persistence	Mr. J. selects a 60-piece model of an antique car to assemble for his nephew. He dumps the pieces on the table top and tries to fit together the two pieces that are within easiest reach. When that does not work, he quits the task.
Organization	Ms. C. has missed her therapy session again. The occupational therapist notices that Ms. C. showed up 4 hours late for her last therapy session and arrived on the wrong day for preceding session. When telephoned, Ms. C. exclaims, "I thought the appointment was tomorrow! I am so upset. I need this therapy to help me get my life back together!"
Generative thinking	Mr. F. is a member of a support group for individuals with brain injury. An occupational therapist leads the group and makes a suggestion to move a future meeting time to a new day because of upcoming holidays. Mr. F. rarely participates in group dialogue, but becomes very agitated by the change and states, "I cannot have any changes in my schedule! I want us to keep the meeting time the same!"
	As assigned, Ms. D. brings ingredients to her outpatient therapy session so that she can prepare a familiar, favorite recipe. The recipe involves making a graham cracker crust, to be prepared during the session. Ms. D. puts large graham crackers in a bowl and starts the electric mixer. After giving Ms. D. sufficient time to self-correct, the therapist stops the task as cracker pieces fly out of the bowl and around the kitchen.
Awareness	When Ms. S. arrives to her outpatient therapy, the therapist observes her disheveled appearance. She is wearing flip-flops despite the cold winter conditions, and she smells of body odor. When asked her about her plans for the day, she reports that she is going to a job interview immediately after the therapy session.

From Sohlberg, M. M., & Mateer, C. A. (2001). *Cognitive rehabilitation*. New York: Guilford Press.

Simple daily tasks (such as ADL) that were premorbidly performed through habit, or procedural memory, become novel and layered in complexity following a disabling injury or condition. Many individuals with executive deficits describe feelings of mental fatigue and a decreased mood when they return home from a hospital setting. They may experience deterioration in personal grooming and cleanliness, an inability to manage household tasks (such as managing personal finances), and/or difficulties returning to work. To help prevent excess disability, it is critically important that occupational therapists accurately assess patients' executive abilities before they have returned to their homes or at other significant transitions in recovery.

Executive Abilities and Brain Function

Neuroscientists use a variety of measurement methods to link brain functions to brain structures. One commonly used method is magnetic resonance imaging (MRI), which provides three-dimensional reconstructed images of the brain and skull. Advances from the field of cognitive neuroscience have enabled scientists to link executive abilities to prefrontal and subcortical brain regions (Alexander, Delong, & Strick, 1986). In addition, clinicians now realize that individuals with basal ganglia disorders associated with Parkinson's disease, for example, often experience executive dysfunction and cognitive impairment prior to experiencing severe motor impairments (Goldman & Litvan, 2011). Depending on what area of the brain is affected, people may have difficulties in some domains of executive functioning and not others. During the assessment process, clinicians try to determine which, if any, aspects of executive processing are impaired to focus intervention on specific areas of concern.

Self-Awareness and Metacognition

Self-awareness is an executive ability that pertains to the ability to process information about the self and compare it with a long-standing self-evaluation (Dougherty & Radomski, 1993). Some consider self-awareness to be the highest of all integrated activities of the brain (Prigatano & Schacter, 1991). It has two primary dimensions: (1) appreciation of personal attributes, such as physical and cognitive strengths and weaknesses, and (2) initiation of compensatory strategies in response to known personal attributes. In general, persons with TBI tend to be more aware of physical deficits than cognitive or emotional changes (Anderson & Tranel, 1989), and typically, the more severe the brain injury, the more problems the individual has with self-awareness (Sherer et al., 2005). Interestingly, some family members view unawareness as a blessing in persons with dementia (Fleming, Strong, & Ashton, 1996), whereas for other caregivers, it is associated with higher levels of subjective distress (Prigatano et al., 2005).

Crosson et al. (1989) proposed a three-level self-awareness hierarchy consisting of intellectual awareness, emergent awareness, and anticipatory awareness. This hierarchy helps clinicians specify awareness problems and is a useful structure for characterizing progress in this realm (e.g., a patient who previously endorses his wife's report of his memory failures [intellectual awareness] now writes himself an errand list before leaving the house [anticipatory awareness]).

1. Intellectual awareness is a person's ability to understand at some level that a particular function is impaired. Severe deficits in memory impede intellectual awareness because such awareness requires recall of the past.
2. Emergent awareness is the ability of a person to recognize a problem when it is actually happening.
3. Anticipatory awareness, which depends on the existence of intellectual and emergent awareness, is the ability to anticipate a challenge or problem resulting from physical or cognitive impairments.

Self-awareness is fundamental to metacognition, which is defined as "thinking about thinking" (Flavell, 1979, p. 906) and intimately linked to executive processing (Fernandez-Duque, Baird, & Posner, 2000). As in the previous example, to initiate note-taking in response to prospective memory demands (a metacognitive strategy), a person must appreciate vulnerability from memory deficits and anticipate the challenge the activity represents (intellectual and anticipatory awareness). Scientific evidence suggests executive processes work in a supervisory fashion over other cognitive domains, whereas metacognition involves both knowledge of one's cognitive abilities and regulation to coordinate cognitive processes through monitoring (e.g., error detection) and control (e.g., error correction or prevention) (Fernandez-Duque, Baird, & Posner, 2000). Although executive processing and metacognition are behaviorally interrelated, patients may have problems in one area but not the other. For example, patients can experience difficulty in organizing and planning tasks while maintaining good metacognitive knowledge about these deficits (Lysaker et al., 2011). This enables them to anticipate their cognitive vulnerabilities and initiate strategies to circumvent potential problems.

The importance of executive functions and metacognition to satisfying and productive role performance cannot be overstated. Impairments in executive functions are major factors associated with the loss of everyday competence (Goverover, 2004) and social autonomy and with the inability to return to work long after TBI (Mazaux et al., 1997). Decreased metacognition after TBI may prevent survivors from recognizing their deficits, which limits performance and diminishes motivation to participate in rehabilitation therapies. Executive functions reciprocally influence metacognition. Metacognition informs the selection of reasonable goals for a given undertaking as well as strategies that best facilitate performance. Ongoing monitoring of task performance with adjustment of strategies and incorporation of feedback can in turn affect self-awareness, altering percepts of personal strengths and weaknesses.

In summary, cognition is understood as an array of domains and processes. Occupational therapists must

understand these constructs in order to assess cognition. For clarity and convenience, in this section we have described various cognitive domains and processes as separate and discrete entities. However, doing so belies the reality of their inseparability, as evidenced in the concept of **dual-task performance**. Based on an experimental dual-task paradigm from cognitive psychology, older adults and clinical populations demonstrate greater decrements in performance of a relatively simple primary task (such as walking) when a secondary (cognitive) task is added (McCulloch, 2007; McDowell, Whyte, & D'Esposito, 1997; Sosnoff et al., 2011) than do healthy controls. These dual-task conditions appear to be sensitive to frontal brain damage (McDowell, Whyte, & D'Esposito, 1997) and illustrate how attention, memory, and executive functions intersect in function. Dual-task performance involves divided attention, challenges the resource limitations of working memory, and requires flexible allocation of attention, which is thought to represent an executive ability (McCulloch, 2007; McDowell, Whyte, & D'Esposito, 1997). Although dual-task assessment methods have not yet been formalized in occupational therapy practice, dual-task performance is clearly relevant to the complexities of real-world occupational performance.

THE PROCESS OF COGNITIVE ASSESSMENT

Occupational therapists assess cognition for many reasons: (1) to measure baseline, progress, and/or outcome status; (2) to understand the patient's cognitive strengths, weaknesses, and capacity for strategy use in order to plan intervention; and (3) to estimate the patient's ability to safely perform every day activities (Baum & Katz, 2010). The purpose and methods will vary by patient, setting, competence of the therapist, roles of neuropsychology and/or speech language pathology personnel, and the point in the continuum of care at which the patient is assessed. However, one aspect of occupational therapy cognitive assessment is consistent: the focus on occupational performance. Occupational therapists have the potential to contribute a critical and unique perspective to the cognitive assessment process by combining their understanding of cognitive domains and operations and task analysis with keen observation and interpretation skills.

Procedures for Practice 6-1 describes the general process for assessing cognition, which represents a segment of a comprehensive occupational therapy evaluation. A cognitive assessment should incorporate patient/family self-report, measures of specific cognitive domains or processes, and observations of functional performance; occupational therapists may conduct part or all of the assessments, depending on setting. Examples of these assessment approaches are included in Assessment Table 6-1. In-depth and more extensive analyses of cognitive assessments can be found in the work of Katz (2011) and Gillen (2009).

Procedures for Practice 6-1

Procedures for Assessing Cognition

Prepare	Review the patient's medical record to learn about diagnosis, background, results of procedures and other diagnostics, other disciplines involved in care. Look for information about possible language-communication problems, literacy, or medical issues (e.g., pain or fatigue) that may confound cognitive assessment.
	Obtain information from patient and/or family about perceptions of current status and priorities. Informally observe functional performance to establish hypotheses regarding possible areas of cognitive dysfunction.
	If information is not available in the medical record, perform a vision screen to assure that the patient has adequate visual skills to participate in a valid cognitive assessment.
	Coordinate with members of the interdisciplinary team so that elements of cognitive assessment are complementary and not duplicative.
Select	Decide what approach and/or measure(s) to use to assess cognition. Consider factors described above (e.g., diagnosis, patient priorities, and contributions of other team members), purpose of cognitive assessment, and psychometric properties of assessment options relative to patient characteristics.
Administer	If using standardized measures or methods, follow published setup and administration procedures. Observe and note behaviors during assessment; record assessment scores.
Interpret	Use scoring guidelines, if available, to interpret score. Consider the extent to which other variables (such as pain, fatigue, and stress) may have influenced performance.
Report	Document results in medical record; discuss results with patient, family, and/or team members.

Assessment Table 6-1 | Summary of Assessments of Cognition

Selected Measures Involving Self-Report

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Self-Awareness of Deficits Interview (SADI) (Fleming, Strong, & Ashton, 1996)	Tool designed to obtain both qualitative and quantitative data on status of self-awareness. The patient is asked about self-awareness of deficits, self-awareness of functional limitations because of deficits, and ability to set realistic goals. A therapist familiar with the patient's level of functioning assigns a score in each realm (0–3, with 0 representing full awareness).	10 minutes	SADI moderately correlated with the Dysexecutive Questionnaire (DEX) ($r = 0.40$, $p < 0.05$). Regression analyses indicated that SADI scores were significantly predicted by a set of executive functioning measures ($p < 0.01$, $R^2 = 0.31$) (Bogod, Mateer, & MacDonald, 2003).	Strong interrater reliability (Intraclass correlation coefficient [ICC] = 0.82). Strong test–retest reliability (ICC = 0.94) (Simmond & Fleming, 2003).	No information	Strength: Brief semistructured interview with questions that are relevant to treatment planning Weakness: Potential for bias because clinician judges the extent to which patient responses reflect level of self-awareness disorder
Behavioral Rating Inventory of Executive Function–Adult version (BRIEF-A) (Roth, Isquith, & Gioia, 2005)	A standardized self-report and informant report questionnaire that measures an adult's appraisal of his or her executive functioning in everyday life. The BRIEF-A measures the following domains: inhibit, self-monitor, plan and organize, initiate, task monitor, emotional control, working memory, and organization of materials. The BRIEF-A is composed of 75 items with composite scores falling into two broad indexes: behavioral regulation and metacognition. An overall summary score results in a global executive composite. Higher values reflect greater difficulty experienced by the individual.	35 minutes	Convergent validity has been established through correlations with other self-reports and informant reports of frontal dysfunction. There appears to be a significant relationship between frontal lobe volumes and self-reported deficits measured by the BRIEF-A (Garlinghouse et al., 2010).	Moderate to high internal consistency ($\alpha = 0.73$–0.90 for clinical scales; 0.93–0.96 for index and global scores). High internal consistency for both the self-report ($\alpha = 0.80$–0.94 for clinical scales; 0.96–0.98 for index and global scales) and informant form (α range = 0.85–0.95 for clinical scales; 0.96–0.98 for index and global scales). Good test–retest reliability ($r = 0.82$–0.94) for self-report forms and high ($r = 0.91$–0.94) for informant reports (Roth, Isquith, & Gioia, 2005)	A study by Rabin et al. (2006) found the BRIEF-A to be sensitive to mild cognitive impairments among a group of 28 individuals with mild cognitive impairment and cognitive complaints when compared with controls.	Strengths: Good to excellent reliability; user-friendly; provides specific information on patient perceptions of executive functioning in daily life Weaknesses: The majority of validity studies have been conducted by the creators of the BRIEF-A; more studies are needed to further validate this tool.

Selected Measures of Functional Cognitive Performance

Measure	Description	Time	Validity	Reliability	Sensitivity	Strengths/Weaknesses
Observed Tasks of Daily Living–Revised (OTDL-R) (Diehl et al., 2005)	An assessment of everyday problem solving in which the patient performs nine tasks related to medication use, telephone use, and financial management.	25–30 minutes	OTDL-R scores were associated with measures of executive functioning (moderate correlation with the Toglia Category Assessment, $r = 0.506$, and moderately strong correlation with the Deductive Reasoning Test, $r = 0.796$) (Goverover & Hinojosa, 2002). OTDL-R scores were significantly different among four groups (community-dwelling older adults, older adults living in nursing homes, individuals with schizophrenia, and individuals with brain injury) ($p < 0.001$) (Goverover & Josman, 2004).	Internal consistency for the total measure (Cronbach's $\alpha = 0.82$)	Not established	Strength: Measure of everyday cognition that can be administered at bedside Weakness: Does not provide a comprehensive picture of cognitive function, especially related to unstructured situations
Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE) (Arnadottir, 1990)	There are two parts to the instrument. Part 1 involves observing ADL performance and completing the (1) Functional Independence Scale and (2) Neurobehavioral Specific Impairment Subscale. Part 2 is optional, enabling the clinician to cross-link the neurobehavioral impairment to the most likely lesion site.	25 minutes	Content validity established through expert input. Discriminant validity: compared scores of 50 persons with stroke and 79 healthy controls. Significant Mann-Whitney U test suggests A-ONE discriminates between groups for all items of the Functional Independence Scale and all but six items of the Neurobehavioral Subscale.	Interrater reliability: Functional Independence Scale, $\kappa = 0.83$; Neurobehavioral Specific Impairment Subscale ($\kappa = 0.86$). Test-retest reliability within 1 week ($r_s = 0.85$)	No information	Strength: Standardized methods for combining assessment of ADL with assessment of some areas of cognition so that therapists can assess both areas at the same time Weakness: Neurobehavioral subscale does not include assessment in key cognitive capacities such as memory and attention.
Executive Function Performance Test (EFPT) (Baum et al., 2003)	A standardized top-down performance-based measure of executive functioning. The EFPT examines the execution of four basic tasks associated with self-maintenance: simple cooking, telephone use, medication management, and bill paying. The EFPT uses an ordinal scoring system that highlights individuals' ability levels through measurement of the cues provided by the clinician.	60 minutes	Concurrent validity was established ($\rho = 0.61$) with the Assessment of Motor and Process Skills (AMPS) (Cederfeldt et al., 2011). Construct validity was established by Baum et al. (2008) with control EFPT total scores significantly ($p \leq .05$) lower (better) than mild stroke scores and moderate stroke scores ($p \leq 0.0001$). Mild stroke scores were also significantly lower than moderate stroke scores ($p \leq 0.0001$).	Excellent interrater reliability of the overall EFPT (ICC = 0.91). Internal consistency is excellent for total sample scores ($\alpha = .94$) (Baum et al., 2008). Test-retest reliability has not been evaluated.	Performance-based measures are not diagnostic tests and thus difficult to determine sensitivity or specificity. As such, sensitivity has not been investigated for the EFPT.	Strengths: One of few standardized performance-based measures and the only performance-based measure that provides clinicians with guidance on the level of cues needed to support clients' functional abilities; excellent reliability and validity. Weaknesses: Requires a full hour; cannot be used as an outcome tool without test–retest reliability established

Assessment Table 6-1 | Summary of Assessments of Cognition *(continued)*

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
The Multiple Errands Test (MET) (Shallice & Burgess, 1991)	A naturalistic performance-based measure of executive functioning deficits. The MET is set up much like a scavenger hunt. Participants are given a task list (typically 12 tasks); tasks with rules (typically 9 rules); and a map of the test environment. Participants are told to begin the test and to complete the test as they wish. Patients are successful only with careful planning with test goals and rules in mind.	60 minutes	Dawson et al. (2009) established ecological validity with good to strong correlations ($\rho \geq 0.51$) when the MET was compared to the Dysexecutive Questionnaire, AMPS and Stroke Impact Scale. Among participants with stroke, rule adherence and time to complete task showed the most robust correlations with measures of daily life function. Among the people with TBI, robust correlations were also seen between rule adherence and the process score of the AMPS, as well as between total errors and weighted errors with the DEX.	Moderate interrater reliability based on two studies: ICCs ≥ 0.70 (Alderman et al., 2003) and ICC ≥ 0.60 (Dawson et. al., 2009).	The MET has not been tested for sensitivity.	Strengths: Complex performance-based test that measures individuals' performance deficits as they navigate dynamic real-world environments, possibly sensitive to otherwise undetectable high-level problems Weaknesses: Site specific, requiring careful preparation prior to each test session; questionable clinical use given the complexity of the test for both participants during test execution and administrators during test setup and evaluation; does not have a standardized test manual or scoring system. The MET requires a significant amount of time for test setup and high rater skill. Morrison et al. (2005) suggested scoring focus only on quantifiable performance deficits versus behavioral lapses identified during the test session.

Selected Tools for Assessing Cognitive Capacities and Abilities

Tool	Description	Time	Validity	Reliability	Strengths/Weaknesses
Galveston Orientation and Amnesia Test (GOAT) (Levin, O'Donnell, & Grossman, 1979)	A widely used measure of orientation to person, place, time, and memory for events preceding and following injury. Ten questions with weighted error points deducted from a total of 100 points.	10–15 minutes	Performance on the GOAT strongly related to aspects of the Glasgow Coma Scale (for eye opening, $\chi^2 = 21.09$, $p < 0.00001$; for verbal responding, $\chi^2 = 19.53$, $p < 0.000001$).	Good interrater reliability (Kendall τ coefficient = 0.99, $p < 0.001$)	Well suited to track fluctuations in confusional period after traumatic brain injury	Strength: Brief test that evaluates PTA and RA (see Definition 6–1) Weakness: Designed for use after TBI; may be difficult to use with other populations of rehabilitation patients
Test of Everyday Attention (TEA) (Robertson et al., 1996)	Test of sustained, selective, and divided attention based on eight ecologically plausible subtests such as map and telephone search (selective attention), elevator counting and lottery (sustained attention), and telephone dual task (divided attention).	45–60 minutes	Concurrent validity: moderate to moderately strong correlation between TEA subtests and other measures of attention ($r = 0.42$–0.63). Discriminant validity: statistically significant differences between older healthy controls and older stroke patients on all subtests ($p < 0.001$) and on five of eight subtests with younger paired subjects.	Test-retest reliability (across parallel forms of the test) is strong across subtests of the parallel versions ($r = 0.66$–0.90).		Strengths: Development of TEA was based on investigations for functional-neuroanatomical specialization of attention. Subtests have ecological validity for clients. There are three parallel forms of the TEA to prevent patients from learning the test with repeated administration. Weaknesses: Not appropriate for patients with significant visual problems; rather lengthy assessment of one dimension of cognitive function
Rivermead Behavioral Memory Test (RBMT) (Wilson, Cockburn, & Baddeley, 1985)	Assesses memory skills necessary for everyday life including remembering names, faces, routes, and appointments.	30–45 minutes	Discriminant validity: Wilson et al. (1989) found statistically significant differences between persons with brain injury and healthy controls on all RBMT subtests ($p < 0.001$).	Interrater reliability: 100% agreement when 40 subjects with brain injury were scored separately but simultaneously by two raters (Wilson et al., 1989)		Strengths: Subtests are similar to everyday tasks; useful in the characterization of memory disorders for a wide range of diagnostic groups (Lezak et al., 2004). There are four parallel forms of the RBMT to prevent patients from learning the test with repeated administration. Weakness: Requires intact visual and verbal skills
Contextual Memory Test (Toglia, 1993)	Dynamic assessment of recall, awareness of memory capacity, and memory strategy use, in which client tries to remember 20 objects related to one of two themes (ADL routine or restaurant).	30–40 minutes	Concurrent validity: strongly correlated with the RBMT ($r = 0.80$–0.84).	Reliability for parallel forms of test ($r = 0.73$–0.81). Test-retest reliability for persons with brain injury ($r = 0.85$–0.94)	Not established	Strength: One assessment that provides information about memory and information about metamemory Weakness: Potential for cultural bias–associated pictures (Josman & Hartman-Maeir, 2000)

Assessment Table 6-1 | Summary of Assessments of Cognition (continued)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Selected Cognitive Screens and Microbatteries						
Mini-Mental State Examination (MMSE) (Folstein, Folstein, & McHugh, 1975).	Screening tool involving a therapist-administered interview composed of 11 questions related to orientation, attention, learning, calculation, abstraction, information, construction, and delayed recall. Scores of 0–30, with scores of 24 or below suggestive of possible cognitive disorder (Tombaugh & McIntyre, 1992).	5–10 minutes	Concurrent validity: MMSE score is highly correlated with Weschler Adult Intelligence Scale (for verbal IQ, Pearson $r = 0.776$, $p < 0.0001$; for performance IQ, Pearson $r = 0.660$, $p < 0.001$).	24-hour test–retest reliability, Pearson $r = 0.887$. Interrater reliability, Pearson $r = 0.827$	Concerns about sensitivity of MMSE with scores <24 (Kukull et al., 1994). Improved sensitivity when the MMSE (Teng & Chui, 1987) is used in combination with draw a clock (Suhr & Grace, 1999; Watson, Arfken, & Birge, 1993).	Strengths: Widely used and understood by many rehabilitation and medical disciplines; brief screen that is helpful in determining need for more in-depth cognitive assessment (Zwecker et al., 2002) Weaknesses: Bias toward verbal items and, therefore, insensitive to damage in right hemisphere; poor sensitivity to mild cognitive deficits
The Montreal Cognitive Assessment (MoCA) (Nasreddine et al., 2005)	A screening tool developed to measure mild cognitive impairment. The MoCA screens attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation. The MoCA has been validated on a range of patients, including those with stroke, Parkinson's disease, and dementia (Dalrymple-Alford et al., 2010; Dong et al., 2010; Nasreddine et al., 2005) but can be used on any patient experiencing memory difficulties who scores within the normal ranges on the MMSE (Nasreddine et al., 2005).	10–15 minutes	Excellent concurrent validity among patients with mild Alzheimer's disease ($r = 0.87$) (Nasreddine et al., 2005). Also discriminant validity established on a variety of diagnostic groups with neurological impairments (see Nasreddine, 2013).	Excellent internal consistency ($\alpha = 0.83$); excellent test–retest reliability ($r = 0.92$) (Nasreddine et al., 2005)	Using a cutoff of a raw value of 26 to identify mild cognitive impairment; sensitivity is good (0.97) but specificity is poor (Nasreddine et al., 2003)	Strengths: Highly sensitive to mild cognitive impairment in many populations; user friendly with normative values; best used as a screening tool; found to be more sensitive to cognitive impairment after mild stroke than the MMSE and a better predictor of outcome of acute rehabilitation (Toglia et al., 2011) Weaknesses: May be overly sensitive with current published cutoff values (potentially suggesting impairment where this is none). Therapists should be cautious in determining mild cognitive impairment based only on the MoCA as an evaluation tool.

	Description	Time	Validity	Reliability	Sensitivity	Strengths/Weaknesses
Loewenstein Occupational Therapy Cognitive Assessment (LOTCA) (Katz et al., 1989)	Microbattery consisting of 20 subtests in four areas: orientation, perception, visuomotor operations, and thinking operations.	30–45 minutes	Discriminant validity: All subtests, except identification of objects, differentiated between patients with craniocerebral injury and healthy controls and stroke patients and healthy controls using Wilcoxon two-sample tests (*p* < 0.0001).	Strong interrater reliability (Spearman's rank correlation coefficient ranged from 0.82 to 0.97 for various subtests)	Katz et al. (1989) observed improved test scores between test scores at admission and after 2 months for TBI and stroke patients.	Strength: Provides a snapshot of a number of cognitive capacities in a relatively short amount of time Weaknesses: Does not pick up subtle cognitive deficiencies on persons with mild injuries; does not include measure of memory
Cognistat (Neurobehavioral Cognitive Status Examination) (Kiernan et al., 1987)	Microbattery comprised of 10 subtests in the areas of orientation*, attention, comprehension*, repetition*, naming*, construction, memory, calculation, similarities, and judgment.	20–25 minutes	Discriminant analysis: Wilcoxon analysis suggested that four of the subtests (see areas marked with asterisks in column to the left) discriminated between elderly persons with stroke and healthy independent elderly (Katz, Elazar, & Itzkovich, 1996); statistically significant differences in mean scores for healthy controls, persons with Alzheimer's type dementia, and neurosurgical patients on 9 of 10 subtests (Katz et al., 1997).	No information	Found to be more sensitive than MMSE with neurosurgical patients (Schwamm et al., 1987)	Strengths: Scores as average, mild, moderate, or severe impairment and presented in a profile of performance in each domain; normative data available for healthy elderly persons (Eisenstein et al., 2002). Weaknesses: Some test items (construction subtest) may be too difficult for both stroke patients and healthy elderly persons (Osmon et al., 1992); not appropriate for geriatric or psychiatric patients (Engelhart, Eisenstein, & Meininger, 1994).

Self-Report Measures

Self-reports measures consist of standardized interviews and questionnaires in which the patient rates his or her performance in various aspects of cognitive functioning. Keep in mind that individuals with impaired self-awareness may minimize problems on self-reports. Discrepancies between the patient's self-report and that of significant others may be used as indicators of inaccurate perceptions of competency (O'Keeffe et al., 2007).

Measures of Functional Cognitive Performance

Occupational therapists' education and expertise lend themselves especially well to this aspect of cognitive assessment. There are three themes in the realm of assessing cognitive functional performance: dynamic assessment, informal observations of function, and performance-based assessments.

Dynamic Assessment

Unlike static assessments, which identify and quantify impairment at a specific point in time, dynamic assessment refers to an approach in which the clinician uses cues and feedback to understand how to elicit the patient's best performance (Toglia & Cermak, 2009). Dynamic Interactional Assessment (DIA) (Toglia, 1998) is an example of a dynamic assessment approach. DIA consists of awareness questioning, cueing and task grading, and strategy investigation (Toglia, 1998). Patients predict their performance before beginning the assessment task. Graded verbal cues are offered as needed once the patient begins work, and parameters of the task are changed, if necessary, to buoy the patient's performance. The therapist also asks questions about what strategies or approaches the patient uses. Toglia (1993) incorporated DIA into a number of the standardized assessment tools she developed, including the Contextual Memory Test. In addition to these specific measures, therapists can convert any task (such as organizing the messy cupboard in Fig. 6-3) into a dynamic assessment by deliberately manipulating task and environment variables and offering strategies and cues to determine in what conditions the patient performs at his or her best (Dougherty & Radomski, 1993).

Informal Observation

Informal observation of task performance enables the therapist to make hypotheses about cognitive strengths and weaknesses and identify domains warranting further evaluation. For example, during an ADL or homemaking evaluation, occupational therapists observe attention to task by counting episodes of distraction in a specific

Figure 6-3 Example of informal observation of performance: the patient is asked to organize an array of items in a storage cupboard.

time period or environment, memory for instructions, performance accuracy, and evidence of organization and planning. Of course, informal observations are highly subjective and easily influenced by the clinician's definition of "normal" and his or her acumen in using the observable (behavior) to make inferences about internal cognitive processes. Informal observations may be preferable for patients who cannot understand verbal or written instructions, as with communication deficits or speaking another language.

Performance-Based Assessment

In general, performance-based assessment involves patient performance of a task (or tasks) that simulate an everyday activity, "under the observation of the examiner, who utilizes behaviorally based measures to quantify different aspects of functional capacity" (Loewenstein & Acevedo, 2010, p. 98). Many disciplines and fields (e.g., occupational therapy, educational psychology, and neuropsychology) use this approach to characterize what a person does under standardized, directed conditions (Moore et al., 2007). Performance-based assessments vary widely in their structure, complexity, and assessment objectives as

exemplified by standardized functional assessments and measures of executive functioning.

Standardized Functional Assessment. Whereas informal observations yield hypotheses that inform continued evaluation and intervention, standardized, semistructured functional assessments provide information about what a patient can or cannot do in ADL or instrumental activities of daily living (IADL). As exemplified by the Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE) (Arnadottir, 1990), this approach allows the therapist to examine cognition in the context of functional tasks.

The A-ONE evaluates performance of ADL and examines the effect of neurobehavioral dysfunction on task performance. There are two parts to the instrument; part 2 is considered optional. During part 1, the occupational therapist observes the patient performing dressing, hygiene, transfer and mobility, feeding, and communication tasks and completes the Functional Independence Scale by assigning a numerical score (0–4) for each aspect of the various tasks. For example, a score is assigned to each of the activities of dressing (donning shirt, pants, socks, and shoes; fastening clothing). While observing the patient's performance of each component, the therapist also rates the patient in terms of presence of neurobehavioral impairments, again using a 0–4 scale. For example, the patient is scored on each of the following possible neurobehavioral impairments specified for the task of dressing: motor apraxia, ideational apraxia, unilateral body neglect, somatoagnosia, spatial relations, unilateral spatial neglect, abnormal tone, perseveration, and organization and sequencing. The scores on the Functional Independence Scale and Neurobehavioral Scale are not additive but used to establish patterns of performance and impairment. Occupational therapists may use the results of part 1 to localize cerebral dysfunction based on functional performance (part 2). Part 1 of the A-ONE, which takes approximately 25 minutes to administer, was standardized on patients with cortical central nervous system dysfunction. Its author recommends that therapists attend a training seminar before using the tool (Arnadottir, 1990).

Performance-Based Measures of Executive Functioning. Deficits in executive abilities can be difficult to assess in clinical environments (Baum et al., 2008). Formal, standardized measures of specific cognitive domains and function often fail to detect existing deficiencies in executive abilities and complex task performance (Tranel, Hathaway-Nepple, & Anderson, 2007). This is because the inherent structures of these assessments typically do not adequately challenge executive processes, commonly resulting in a false negative in the detection of executive impairments. To identify executive impairments,

Lezak (1995) suggested that clinicians ask "how" or "whether" patients perform complex tasks. Inefficiencies during task performance are common hallmarks among individuals with executive deficits (Levine et al., 2011). The valid assessment of executive abilities depends on adequate task complexity, novelty, and challenge (Alderman et al., 2003).

Performance-based assessments are designed to incorporate the cognitive complexity that people typically encounter in IADL, work, school, and community life. Performance-based assessments typically require the patient to problem solve, manage distractions, and incorporate some degree of multitasking—all elements of executive abilities. We describe two performance-based assessments as examples: the Executive Function Performance Test (EFPT) (Baum et al., 2008) and the Multiple Errands Test (MET) (Alderman et al., 2003; Shallice & Burgess, 1991).

The EFPT was developed by Baum et al. (2008) to measure individuals' functional abilities through the performance of four test tasks identified as supportive of independent everyday living: preparing a light meal, managing medications, using the telephone, and paying bills. The EFPT examines three primary executive abilities—task initiation, task execution, and task completion—and measures the level of therapist assistance required to support patients during each task performance. Examiners use a 0–5 ordinal scoring system based on the level of cue they provide. For example, the level of cue advances after two cues of each type have been administered. Advancement in cues is reflected through a scoring paradigm where a score of 0 equals complete independence, 1 equals verbal guidance, 2 equals gestural guidance, 3 equals direct verbal instruction, 4 equals physical assistance, and 5 equals total assistance from the therapist. The EFPT has a detailed administration manual that includes details of test setup, the examiner's script, and specific criteria for timing, circumstances of cue provision. On average, the test for the EFPT takes 30 minutes and can be reliably administered once therapists have studied the test manual. However, novice therapists should practice administering the EFPT on nonpatients with special attention to the cueing system. Following test completion, test scores result in executive function component scores ranging from 0 to 20; task scores ranging from 0 to 25, and the overall total score ranging from 0 to 100 with 0 equaling a perfect performance on all functional tasks. The EFPT is one of few performance-based measures with psychometric rigor (Baum et al., 2008; Cederfeldt et al., 2011). This tool has been used with multiple patient populations with several ongoing studies investigating the validity of separating EFPT tasks to shorten test time.

The MET was created to capture the everyday performance failures reported by patients with high-level executive dysfunction (Shallice & Burgess, 1991). The MET is

a naturalistic measure of executive performance designed to present ongoing and dynamic challenges throughout test performance. Patients are presented with a list of 12 everyday tasks and 9 rules. Test initiation and task execution is left to the participant without interference or cueing from the examiner. The MET is site specific, which means the test tasks are dependent on the test location. To date, a standardized manual with scoring system that is site neutral does not exist. The MET does not have an easily replicated scoring system, which creates significant challenge to clinicians attempting to administer the test in clinical settings. Questions about the clinical utility of the MET remain as this test is extremely challenging for patients with TBI and requires significant skill and time to administer. Since the first publication, alternative versions of the MET have been published in effort to simplify the administration and to meet site-specific needs (Alderman et al., 2003; Dawson et al., 2009; Knight, Alderman, & Burgess, 2002; Morrison et al., 2005; Rand et al., 2009).

Measures of Specific Cognitive Domains and Processes

While performance-based assessments are designed to have relevance to performance in real-world contexts (Connor & Maier, 2011), tools and methods that assess specific cognitive capacities and abilities are generally composed of desktop activities with standardized administration and scoring procedures. Cognitive screens and microbatteries allow the clinician to assess a number of cognitive domains using a single tool. A cognitive screen takes less than 15 minutes to administer and provides the clinician with a general sense of a patient's cognitive status but little information about what specific areas may be impaired. A microbattery may take up to 45 minutes to administer and consists of a number of subtests, typically associated with an array of cognitive capacities and abilities. Many instruments have demonstrated reliability and validity and standardized scoring criteria that greatly reduce therapist bias.

INTERPRETING RESULTS OF PERFORMANCE ON COGNITIVE ASSESSMENT

An individual's cognitive performance at any point in time is determined by many interacting variables, including neurobiological, affective, cultural, task, and environmental influences. Changes in any of these domains improve or detract from a person's cognitive status and thereby his or her occupational functioning. Therefore, to effectively assess cognition and interpret findings, occupational therapists must appreciate how variables can affect performance during cognitive assessment. What follows is a brief summary of each influence, supported with specific examples from the literature.

Neurobiological Influence on Cognition

Throughout this chapter, we have alluded to the neurobiological influence on cognition; that is, the ways in which changes to the anatomy and physiology of the brain impact cognition. Persons with stroke have local damage to brain tissue that often results in predictable and specific cognitive deficits, such as frontal lobe damage leading to executive dysfunction and temporal lobe damage affecting memory. Neurobiological changes that accompany aging also seem to affect thinking abilities and memory. Crystallized intelligence (well practiced, overlearned skills and knowledge) is reportedly maintained or strengthened into the eighth decade of life, whereas fluid intelligence, which entails reasoning and problem solving for unfamiliar challenges, begins a slow decline in the sixth decade of life (Lezak, 1995). Normal age-related cognitive changes underscore the importance of using age-normed cognitive assessments whenever possible.

Changes or deterioration of other functions of the human body have secondary neurobiological influences on cognition. For example, visual-perceptual impairments alter the inputs into the memory process, limiting what a person can accurately remember. Diminished visual acuity in and of itself is associated with significantly reduced performance on neuropsychological evaluations (Hunt & Bassi, 2010). Dehydration and anemia may also negatively impact cognition (Denny, Kuchibhatla, & Cohen, 2006; Lieberman, 2007), as do some medications. Researchers suggest a link between adjuvant chemotherapy for operative primary breast cancer and cognition (Schilling et al., 2005).

Affective Influences on Cognition

A person's emotional state has a pervasive influence on cognition (Chepenik, Cornew, & Farah, 2007). For example, anxious people differ from others in several aspects of attentional functioning. Anxious people are more likely to attend to threat-related stimuli and use limited-capacity working memory for worry, self-concern, and other task-irrelevant distractions (Beaudreau & O'Hara, 2009). Persons with depression also frequently complain about poor memory but often do not demonstrate memory deficits on neuropsychological testing (Lezak, 1995). Depressed individuals are thought to show passive disengagement with the environment in that their attentional focus is on internal concerns rather than environmental events (Eysenck & Keane, 1990). Depressed people also demonstrate a negative recall bias (a tendency to recall more negative information about

themselves than others do) (Baddeley, 1990). Memory problems associated with depression seem to have a secondary effect on executive processes, possibly because of distractions by dysfunctional negative thoughts that occupy limited-capacity working memory during problem solving and task performance (Channon & Green, 1999). As discussed in Chapter 3, patients who are anxious or depressed must be referred to specialized psychological or medical services.

Transient mental distractions can also impair cognition. Pain and fatigue (especially mental fatigue) are thought to be irrelevant inputs that interfere with memory trace formation and diminish the function of limited-capacity working memory by occupying attention that is therefore unavailable to incoming data (Denburg, Carbotte, & Denburg, 1997; Dick & Rashiq, 2007; Seminowicz & Davis, 2007). Therefore, clients who are tired or in pain may be unable to demonstrate their cognitive capabilities during assessment (Bryant, Chiaravalloti, & DeLuca, 2004). Under such circumstances, the occupational therapist may defer cognitive assessment to another time or, at a minimum, consider the influence of these factors when interpreting the assessment results.

Sociocultural Influences on Cognition

Experts suggest that basic processes of perception and cognition are influenced by cultural and social factors, such as education. Nisbett and Masuda (2003) summarized a series of studies that illustrate information-processing differences in East Asian and Western cultures. They suggested that Americans tended to focus their attention on objects and object attributes, but Japanese subjects tended to focus on the field, background, relationship, or context of the objects. Culture may also influence displays of self-awareness. Prigatano, Ogano, and Amakusa (1997) suggested that, because incompetence in personal care is a sign of disgrace in Japan, Japanese patients with TBI tended to overestimate their abilities in this realm. On the other hand, Japanese people generally believe it is impolite to report high estimations of social and interpersonal skills. Therefore, Japanese patients with TBI tended to underestimate their abilities in this realm. Beyond cultural background, performance on cognitive tests appears to be shaped by years of education. In a study involving a random sample of age stratified healthy older adults, younger age and higher education were associated with better performance on cognitive testing (Ganguli et al., 2010). This suggests a possible education-related bias in cognitive assessments: persons with higher education may score within normal limits on cognitive tests even with decrements in their functioning and/or persons with lower education who perform poorly on cognitive assessments may, in fact, be cognitively intact.

Task and Environment as Contextual Mediators of Cognition

People bring their neurobiological, emotional, and sociocultural predispositions to all information processing, but performance at a given moment is mediated by characteristics of the task and environmental contexts. Here is an example of task-cognition interplay. When a task is familiar, the thinker requires relatively little attention to recognize a problem type and determine a hypothesis and plan of action (Mayer, 1992). A familiar task or problem prompts the individual to retrieve a large number of interconnected units of knowledge, both related facts and previous solutions (Mayer, 1992). This suggests that patients who are expert cooks may outperform those who rarely cook on functional cognitive assessments that involve meal preparation. The environment similarly affects cognition. Contextual cues in the environment enhance recall of similar tasks or previously effective techniques or solutions. The stimulus-arousal properties of the environment also influence cognitive function. Lighting and noise can focus attention or, as is often the case for persons with brain injury, provide distractions that derail thinking.

In summary, cognition consists of specific but interrelated capacities and abilities that are influenced by neurobiological, affective, sociocultural variables, and task and environmental contexts. This discussion, although not exhaustive, highlights the complexity, if not the mystery, of cognitive function, which is an appreciation necessary for assessing cognitive capacities and abilities in occupational therapy. This discussion also evidences the importance of knowing something about the patient (i.e., diagnosis, education and cultural background, psychological and medical status, literacy, and communication abilities) before assessing his or her cognitive status. In judging the cognitive status of another person, teasing out performance confounders is as important as selecting and correctly administering the assessment tool. Whereas assigning and summing scores on standardized instruments requires the attentiveness of a trained technician, observing and interpreting performance during assessment requires the insight of a professional.

case example
D.B.: Assessing Cognitive Function

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information	Understand the patient's diagnosis or condition	"D.B. had a severe brain injury and will likely have significant, long-term cognitive impairments. He sounds like someone who is used to being active, and mobility restrictions may be confusing and frustrating. I wonder how he is getting around now that he is 3 months post-injury."
D.B. is a 26-year-old single male who sustained a TBI as a result of a pedestrian–auto accident. Upon admission to the emergency department, he had a Glasgow Coma Scale score of 6, and records indicate that he was in a coma for approximately 10 days. In addition to the brain injury, D.B. sustained fractures in both legs, a tibia-fibula fracture on the right and fracture of the femur on the left. D.B. participated in inpatient rehabilitation for 3 weeks. D.B. graduated from college with a degree in law enforcement and worked in a rural community as a police officer at the time of his injury. His former girlfriend broke off the relationship approximately 1 month ago. Unable to return to his own apartment because of concerns about safety, D.B. was discharged from the inpatient rehabilitation unit to his brother's home.	Know the person	"I know that I have certain stereotyped expectations of cops. I expect him to be sort of rigid and reluctant to take instructions from women. I wonder if D.B.'s girlfriend could not handle the changes related to the TBI or if there were long-standing issues that led to the recent breakup. Either way, D.B. must feel sad and isolated."
At approximately 3 months post-TBI, D.B. was referred to outpatient occupational therapy to assess readiness for independent living. The occupational therapist focuses the assessment on D.B.'s ability to assume self-maintenance roles and identification of cognitive deficits interfering with role and task performance.	Appreciate the context	"I wonder what transpired during the past 2 months at the brother's home. How much of a role is the brother willing to play in this transition?"
	Develop provisional hypotheses	"Given his diagnosis and history, I presume that D.B.'s cognitive impairments are the biggest barriers to independent living."
Assessment Process	Consider evaluation approach and methods	"Because he has not been assessed in occupational therapy for over 2 months and he has not had a neuropsychological evaluation, I want to get a full picture of his occupational functioning. The COPM will tell me about his priorities and give me a snapshot of his awareness of deficits. The EFPT will provide me with information about his ability to safely perform tasks at home. With this test, I can observe his ability to begin and complete activities of daily living. I will gain insight into his ability to sequence and problem solve through task steps, which will help identify the level of support he needs to live independently. Cognistat will give me a sense of his cognitive strengths and weaknesses and be useful in benchmarking cognitive change. His response to homework will help me observe his use of compensatory cognitive strategies."
The therapist selected the following evaluation tools: Canadian Occupational Performance Measure (COPM) to obtain information about the client's perceived problems and priorities, Executive Function Performance Test (EFPT) to evaluate D.B.'s executive functioning, Cognistat to obtain a general picture of cognitive capabilities, and systematic observation of the client's response to the presentation of homework.		

Assessment Results

COPM: D.B. indicated that his ability to function independently was limited because of lower extremity fractures. He was dissatisfied with his inability to drive, the slowness with which he donned lower extremity clothing, his low stamina when walking outside the home, and lack of avocational outlets because of mobility limitations. When queried about known dependence on family members to take medications and his lack of initiation of self-maintenance tasks, D.B. quickly dismissed these reports as awkwardness associated with being a guest in their home.

EFPT: When the therapist administered the EFPT, she noted D.B. answered all pretest questions as if he experienced no difficulties living independently, which conflicted with the information provided by his brother. When the therapist observed D.B.'s performance, she noted he experienced no difficulty with the hand-washing task, which indicated he would be able to perform the rest of the EFPT tasks. D.B. had the following scores for the rest of the EFPT tasks:

1 = hand washing
0 = telephone use
3 = taking medication
5 = paying bills

Cognistat: D.B.'s cognitive status profile indicated the following: performance within the average range for orientation, comprehension, naming, construction; and mild impairment in similarities, judgment, calculations, repetition; mild to moderate impairment in attention and memory.

   Informal observation: During each of his two outpatient evaluation sessions, the therapist gave D.B. oral instructions specific to three homework assignments to complete at home, all of which he agreed to do but did not make note of. He completed none of them. He seemed motivated throughout the assessment and did not appear distracted by pain or emotional distress during his sessions.

Occupational Therapy Problem List

1. Decreased initiation of ADL and IADL
2. Decreased productivity because of poor stamina and limited repertoire of appropriate avocational outlets
3. Memory inefficiency and inadequate repertoire of memory compensation strategies
4. Decreased awareness of cognitive deficits interfering with compensatory strategy use

Interpret observations

"D.B. seems to be quite aware of concrete changes in his mobility but less aware of possible cognitive changes related to initiation and memory of medications. I wonder how much family members are helping to prevent any errors in daily life that might otherwise give him feedback about his cognitive changes."

"Based on D.B.'s performance on the EFPT tasks, I am concerned he is having difficulty performing tasks on his own because he is having problems with higher order thinking abilities, like problem solving and working memory. I noticed he had to be cued to remember to turn off the stove after cooking. He also needed specific verbal direction in figuring out when to take the medications. He could not do the mathematics required for bill paying and did not catch the balance difference in the available money and bill sums. If he has problems like this on the EFPT, it is likely he is going to have problems living alone and functioning independently without support."

"D.B.'s performance on the Cognistat does not surprise me all that much given the severity of his TBI. He seems to have a number of cognitive strengths that I think will really help him participate in the therapy process."

"I'm guessing that D.B. has not had to take responsibility for keeping track of information in recent months; no doubt his brother has done that for him. I bet D.B. has not had much experience with his memory changes and does not appreciate that he needs to compensate for these changes. He seems to be a really good candidate for outpatient rehabilitation at this point."

Synthesize results

"Overall, D.B. seems to have rather superficial awareness of his limitations; he acknowledges physical but not cognitive changes. His brother's report of D.B.'s need for supervision with medications and prompts for ADL and IADL seem consistent with what I saw on his performance of the EFPT. I will want to incorporate opportunities for dynamic assessment into the treatment plan. I need to talk a little more with D.B.'s brother about the role he would like to play in the therapy program. Maybe he needs a break and wants the team to take a more dominant role for a while."

Clinical Reasoning in Occupational Therapy Practice

Effects of Environment on Cognitive Function

During his inpatient rehabilitation, D.B. was observed to have decreased attentional capacities, especially with complex tasks. How might this problem be evident during the occupational therapy homemaking assessment? What factors in the environment might exaggerate these problems? What factors might minimize them?

Summary Review Questions

1. Analyze bill paying and grocery shopping in terms of the specific cognitive capacities and abilities required.
2. Compare the advantages and disadvantages of the three approaches to cognitive assessment described in this chapter.
3. Describe each variable that influences a person's ability to think. How would you expect these variables to affect cognitive assessment of an elderly illiterate client? How would you expect these variables to affect cognitive assessment of a college student?
4. Explain the occupational therapist's contribution to the rehabilitation team in the realm of cognitive assessment. Specifically, outline the ways in which occupational therapy complements the assessments of other professionals and the unique elements of occupational therapy.

Glossary

Attention—The ability to deploy limited mental resources for purposes of concentration. Human activities have various attentional demands, including sustained attention (length of time), selective attention (competing stimuli), divided attention (multiple simultaneous stimuli), and alternating attention (shifts back and forth between various stimuli).

Cognition—The general term that reflects the mental enterprises related to absorbing information, thinking, and goal-directed action.

Dual-task performance—Conditions in which performance of a single task is compared to performance of the single task performed simultaneously with a secondary task. *Dual-task cost* refers to the decrement in performance of a relatively simple primary task when a secondary (cognitive) task is added (McCulloch, 2007).

Executive function—Metaprocesses that enable a person to initiate, plan, self-monitor, and correct his or her approach to goal-directed tasks. Executive disorders often result from frontal lobe damage and are evidenced by problems with self-control, self-direction, and organization (Lezak, 1995).

Memory—The result of interactive cognitive systems that receive, code, store, and retrieve information.

Neuropsychological evaluation—A long battery of standardized tests for purposes of diagnosis, patient care and planning, rehabilitation evaluation, and research (Lezak, 1995). Typically, the examiner is a doctor of psychology with specialized training in cognitive processes and brain–behavior relationships.

Orientation—Awareness of self in relation to person, place, time, and circumstance (Sohlberg & Mateer, 1989).

Self-awareness—The capacity to objectively perceive the self (Prigatano & Schacter, 1991) and (with a reasonable degree of accuracy) to compare that conception to a premorbid standard.

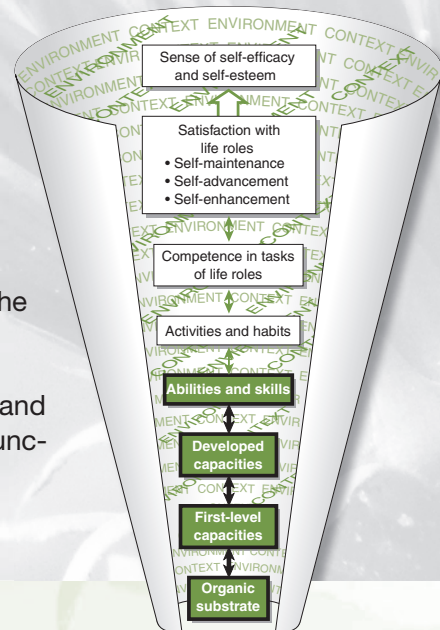
Assessing Abilities and Capacities: Range of Motion, Strength, and Endurance

Lynsay R. Whelan

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Determine when evaluation of motion, strength, and endurance is appropriate and the best methods for obtaining such data.
2. Evaluate range of motion of the upper extremity using a goniometer.
3. Evaluate underlying causes of decreased motion and strength including edema, scar tissue, and pain.
4. Perform a manual muscle test to evaluate strength of the upper extremity.
5. Determine functional endurance level.
6. Interpret the findings of the evaluations in this chapter and incorporate the results into intervention planning in a functional manner.


INTRODUCTION

The assessments presented in this chapter are appropriate for patients who are unable to do or are restricted in doing the occupational tasks and activities important to them because of range of joint motion, strength, or endurance impairments. Being able to move (mobility, or range of motion [ROM]) and use the extremities against resistance (strength) for an extended period (endurance) is essential for the completion of most occupational tasks. For example, a person who cannot fully flex the elbow, is too weak to lift a spoon to the mouth, or is too fatigued to lift the utensil repeatedly cannot eat a meal independently. Because deficits in these abilities and capacities may lead to impaired occupational functioning, it is within the realm of occupational therapy to assess them. Keep in mind that occupational therapy assessments of mobility, strength, and endurance focus on how deficits in these areas impact occupational functioning. Occupational therapists also consider other variables in the overall evaluation, including environmental and contextual constraints that contribute to performance ability. The majority of this chapter will focus on evaluating limitations that impact upper extremity (UE) function and occupational performance.

Use of the assessments described in this chapter allows for the establishment of the patient's baseline abilities. Reassessment produces documentation of progress or lack thereof as well as return to function within normal limits (WNL). With the demands for efficiency in health care delivery, it is essential that occupational therapists be skilled in their evaluations of patients to justify continuation or discharge of therapy services.

The Occupational Therapy Practice Framework (OTPF) (American Occupational Therapy Association [AOTA], 2008) recognizes that client factors impacting mobility, muscle power, and endurance (such as neuromusculoskeletal and movement-related body functions and structures) can impact occupational functioning. The OTPF also recognizes that activity demands and contextual factors contribute to an individual's success in performing various tasks (AOTA, 2008). Similarly, the Occupational Functioning Model recognizes the sensorimotor abilities, motor skills, cardiorespiratory (CR) skills, and contextual influences that impact function in life roles. Although this chapter will focus on the assessment of occupational performance and intervention planning portions of the occupational therapy process, it is important to also remember that the occupational profile or subjective portion of the evaluation influences the therapists' decisions regarding what objective measures to analyze in determining the factors impacting performance (AOTA, 2008).

FUNCTIONAL UPPER EXTREMITY ASSESSMENT

Depending on the reason for the referral to occupational therapy services, a screening (or preliminary assessment to determine whether more in-depth evaluation is needed) of motion and functional strength may be more appropriate than individual measurement of motion and strength at each joint and muscle. It is often appropriate to screen some areas while taking formal measurements of others, which is why therapists will often begin with the functional screen. For example, a patient may be referred to therapy following a distal radius fracture. When individuals have a cast on their wrist, they may lose motion at the shoulder and elbow as well because of nonuse and protective posturing. It would be appropriate to screen the shoulder and elbow and compare bilaterally to ensure motion there is WNL and then do specific ROM measurements at the wrist and hand. If deficits are noted on the screen at the shoulder or elbow, then it would also be appropriate to complete specific measurements where the limitation was noted.

Similarly, a gross screening of UE strength may be more appropriate than testing individual muscles. This screening is often appropriate in inpatient and rehabilitation settings in which the patient may be experiencing more gross weakness from debilitation. During the screening, if the therapist determines any patterns such as weakness in one specific nerve distribution, he or she may wish to then do more specific manual muscle testing (MMT) of muscles innervated by that nerve (for more information on functional screening of the UE, see Procedures for Practice 7-1). Note that, depending on the practice setting, the terms upper limb or upper quadrant may be used rather than upper extremity.

FUNCTIONAL LOWER EXTREMITY ASSESSMENT

Physical therapists typically complete any needed formal measurements of ROM and strength of the lower extremities (LE). However, there is a role for occupational therapists in the functional assessment of the lower extremities insofar as they are commonly consulted regarding return to independence in activities of daily living (ADL) and instrumental activities of daily living (IADL) for patients with, for example, various orthopedic, neurological, and other debilitating chronic conditions. In these cases, evaluation of LE function is typically done with the demonstration of ADL/IADL tasks and functional transfers. Occupational therapists are not interested in the exact degree of motion at the hip, knee, or ankle as much as they are interested in whether that motion, for example, allows

Procedures for Practice 7-1

Functional Active Range of Motion and Strength Screen

- The patient should be seated if possible.
- The patient should perform the motions bilaterally, if possible. If not, the unimpaired or least impaired side should move first to set a baseline for normal for this person.
- Observe for complete movements, symmetry of movements, and timing of movements.
- Demonstrate the movements if the patient has a language barrier or cognitive deficits.
- To estimate the amount of active movement in the following motions, give instructions such as these to the patient:

Motion/Resisted Motion	Examples of Instruction
Shoulder flexion	Lift your arms straight up in front of you and reach toward the ceiling. Now, with your arms straight in front of you, do not let me push you down.
Shoulder abduction	Move your arms out to the side. Now reach over your head. With your arms straight out, do not let me push you down.
Shoulder horizontal abduction and adduction	Raise your arms forward to shoulder height. Move each arm out to the side, then back again while keeping your arm level. Push against me this time.
External rotation	Touch the back of your head with your hand, like you are washing your hair. Now push against me, like you were going to throw a ball overhand.
Internal rotation	Touch the small of your back with your hand like you are tucking in your shirt. Now push against my hand.
Elbow flexion and extension	Start with your arms straight down by your sides. Now bend your elbows so your hands touch your shoulders. Push and pull against me starting with your arm flexed like you are making a muscle.
Forearm supination and pronation	With your arms at your side and your elbows flexed to 90°, rotate your forearms so the palms of your hands face the floor and then the ceiling. Now, like we are shaking hands, resist my motion.
Wrist flexion and extension	Move your wrists up and down. Now, resist my pressure.
Finger flexion and extension	Make a fist, then open your fingers. Squeeze my hands (ensure your hand is interlocked in the web space to avoid injury of your own hand).
Finger opposition	Touch your thumb to the tip of each finger one at a time. Now, try to hold your thumb to your index finger and small finger without letting me break the circle.

the individual to transfer to and from a toilet or complete dressing independently and safely.

For example, an occupational therapist is consulted to evaluate and treat a patient following a hip replacement. The therapist evaluates the patient's LE motion and strength as it relates to the patient's ability to perform bed mobility; functional transfers; and ADL/IADL tasks, such as dressing, bathing, and meal preparation, while following any precautions the surgeon has prescribed. Patients may be asked to demonstrate how they would put on their socks or retrieve an item from the bottom shelf of the refrigerator while following their hip precautions. The therapist may develop a treatment plan after evaluation that provides or recommends adaptive equipment

and educates the patient on compensatory techniques for completing ADL/IADL tasks with modified independence (see Procedures for Practice 7-2 and Figs. 7-1 to 7-3 for additional information regarding functional LE assessment).

If the physical therapy evaluation is not available for review prior to the occupational therapy evaluation, the occupational therapist should screen motion and strength to ensure safety when engaging in functional tasks as long as it is not contraindicated by the physician's orders, the condition, or the weight-bearing status of the patient. The therapist should have the client demonstrate ankle, knee, and hip motion either lying in bed or at the edge of the bed with resistance if it is not contraindicated.

Procedures for Practice 7-2

Motion	Example Instructions
Hip	Show me how you would move from lying down to sitting on the edge of the bed.
	How would you get on and off the commode?
	Show me how you would get in and out of the tub.
	How would you get something from a bottom shelf?
Knee	Show me how you would put on your socks.
	How would you get on and off the commode?
	How would you get something from a bottom shelf?
Ankle	Show me how you will wash your feet.
	Show me how you would put on your socks.
Functional transfers	Show me how you would get in and out of bed (assess bed mobility, supine to sit, sit to stand, stand to sit, and sit to supine).
	Show me how you would sit on the commode (assess stand to sit and sit to stand with toilet or bedside commode transfers).
	Show me how you will get in and out of the shower (assess shower bench or transfer bench or safety in getting in and out of tub or walk-in shower as appropriate to patient).
	Show me how you will get in and out of the car (use real or simulated car).
	Show me how you will get up from this chair (cushioned seating versus solid chair).

Figure 7-1 Functional lower extremity assessment with patient at edge of bed. Note the motion required to sit in this position.

Figure 7-2 Functional lower extremity assessment with patient donning socks. Note the hip, knee, and ankle position. How could this task be modified?
Figure 7-3 Functional lower extremity assessment with patient reaching for bottom shelf item. What adaptive equipment could assist in this task? How would you educate the patient?

If weakness is noted, the therapist should take extra precautions during the functional screening and ensure a gait belt is used. The occupational therapist should also ensure that the appropriate mobility device is being used during the functional screening.

RANGE OF MOTION MEASUREMENT

Normally, each joint can move in certain directions and to certain limits of motion based on the joint itself as well as the integrity of surrounding tissues. Trauma or disease that affects joint structures or the surrounding tissues can decrease motion at the joint and limit occupational functioning.

Measurement of joint range may be done actively or passively. Passive range of motion (PROM) is the amount of motion at a given joint when the joint is moved by an outside force. Typically, the outside force comes from the therapist or therapeutic equipment. Active range of motion (AROM) is the amount of motion at a given joint achieved when the patient contracts the muscles that control the desired motion. Additional types of ROM include self range of motion (SROM), where the client performs ROM on the affected side by using the nonaffected side, and active assistive range of motion (AAROM) where the therapist, the client, or another caregiver may provide support during active motion to allow the client to move beyond their current AROM limits. These are not typically measured in an evaluation but may be used in treatment to improve deficits in ROM. It is normal to have slightly more PROM than AROM; however, if AROM is

significantly less than PROM, there is a problem with how the underlying structures are functioning. Examples of this include the following:

- If the tendon is not intact, including lacerations or avulsions to the tendon, the result is that the tendon cannot pull along its anatomical path to produce AROM, but the joint can still be moved passively.
- Muscle weakness or loss of strength can prevent full contraction and, therefore, full motion.
- Pain may be caused by edema in or injury to surrounding tissue. The individual may be able to move further passively because he or she is not actively using the injured tissue and therefore has less pain.
- Scar tissue can adhere to underlying structures and impede motion.

If both AROM and PROM are limited, underlying causes could include a bony block to motion, capsular tightness around the joint, tightness of the muscle–tendon unit, edema, contractures, or more extensive scar tissue such as from burns.

If limitations in AROM are observed, they are formally measured and documented. If there are no contraindications (see Safety Note 7-1), the therapist then attempts to move the joint through its full PROM. If the joint is free to move to the end range, the problem is with active motion.

Safety Note 7-1

Precautions in the Evaluation of Active and Passive Range of Motion

- Carefully review consult/referral to therapy and note any contraindications to motion or restrictions in motion by the referring provider.
- Limited motion protocols may require that motion only be tested within the limits prescribed even if the patient feels they can move beyond these limits. For example, following tendon repair, the surgeon may prescribe a limited arc of motion to avoid overstressing the repair during the healing process.
- Avoid pushing passive range of motion when the underlying cause of the limitation is unknown, particularly with trauma.
- Avoid increasing edema or pain for the sake of a measurement. For example, immediately following casting the therapist would expect tightness of the tissues that have been immobilized, and active range of motion (AROM) measurements may be all that is needed to set baseline goals. It may be appropriate to try a heat modality (if edema does not contraindicate this) and then remeasure AROM to see whether increasing the extensibility of the soft tissues helps to improve ROM.

If the end range cannot be attained when the therapist moves the limb, the problem is with passive motion, and the PROM limitation is measured and recorded.

When recording PROM, the therapist should also note any abnormal end-feel. End-feel is the descriptive term used to describe what the therapist feels at the end range of passive limits of motion. Cyriax, Kaltenborn, and Paris are three different classification systems of end-feel (Petersen & Hayes, 2000). All three require more research into the interrater reliability of the classifications (Petersen & Hayes, 2000; van de Pol, van Trijffel, & Lucas, 2010). Commonly used terms for end-feel, mostly based on the Cyriax and Kaltenborn systems include:

- bony, hard, or bone-to-bone end-feel, where movement stops as the bony surfaces meet such as elbow extension
- capsular end-feel, which is somewhat firm or leathery but has some give, such as end range of shoulder external rotation
- soft end-feel or tissue approximation, which is when soft tissue stops the movement, such as elbow flexion
- spasm end-feel, where the tissue responds with a harsh movement in the opposite direction
- empty end-feel, where there is no "feel," but rather the patient asks to stop because of pain
- springy end-feel, where there is some rebound at the end range of motion (Petersen & Hayes, 2000; van de Pol, van Trijffel, & Lucas, 2010)

Although some of these may be a normal end-feel, it is important to note when they are abnormal. For example, a bony end-feel prior to full wrist extension may indicate underlying pathology or a capsular end-feel during elbow extension when the elbow is at 30° may be the result of capsular tightness from immobilization.

A goniometer is the most common tool used for measuring joint motion of the UE. Every goniometer has a protractor, an axis, and two arms. The stationary arm extends from the protractor, on which the degrees are marked. The movable arm has a center line or pointer to indicate angle measurement. The axis is the point at which these two arms are riveted together. A full-circle goniometer, which measures 360°, or 0°–180° in each direction, permits motion measurement in both directions, such as flexion and extension, without repositioning the tool. When using a half-circle goniometer, the protractor must be positioned opposite to the direction of motion so that the indicator remains on the face of the protractor. A finger goniometer is designed with a shorter movable arm and flat surfaces to fit comfortably over the finger joints. Figure 7-4 shows examples of these types of goniometers.

Some clinics use a manual or electronic inclinometer rather than a goniometer to measure ROM. These devices use gravity rather than the therapist's visual skills to determine the starting position for measurement and therefore can improve accuracy, particularly in more complex motions
Figure 7-4 Types of goniometers. The small half-circle goniometer and modified half-circle (*top*) is used to measure small joints, such as the wrist. The small finger goniometer (*middle left*) has flat arms that fit over the fingers. The small and large full-circle goniometers (*middle right and bottom*) are used to measure with the 360° method and for larger joints.

such as compound spine motions (Gerhardt, Cocchiarella, & Lea, 2002). It is important to note that the position of the individual being measured may need to change with the use of an inclinometer because gravity is used to obtain the starting position. Another potential tool is the electrogoniometer. This tool can offer continuous measurement of ROM once positioned and calibrated (Yen & Radwin, 2000). This may be particularly helpful in work and industry type settings where repetitive work tasks and ergonomic impact are being assessed. When using the electrogoniometer, the therapist should calibrate the instrument for the task being performed to decrease errors often seen at angles greater than 45° (Yen & Radwin, 2000). Because the goniometer is most commonly used in occupational therapy practice and the general principles apply to the alignment of other instruments, the figures depicting ROM measurement in this chapter include standard goniometers.

Reliability

The therapist must place the axis and arms appropriately to ensure accuracy and reliability. See Procedures for Practice 7-3 for general principles to follow when using the goniometer. The specific placement of the goniometer for each joint is described and demonstrated in this chapter.

In addition to goniometer placement, multiple patient-related and environmental factors can affect accuracy and reliability of ROM measurements. Patient-related factors include pain, fear of pain, fatigue, and feelings of stress or tension. For the most accurate and reliable results, every effort should be made to make the patient physically and emotionally comfortable, including talking to the patient and describing the procedure that is to follow.

Procedures for Practice 7-3

Principles of Goniometer Placement

- Place the axis of the goniometer over the axis of motion. The axis of motion for some joints coincides with bony landmarks, but for others it must be found by observing movement and finding the point around which the movement occurs. In that case, the axis of motion can change position during movement, so it is acceptable for the goniometer to be repositioned at the end of range. When the two arms of the goniometer are placed correctly, they intersect at the axis of motion (Triffitt, Wildin, & Hajioff, 1999), so it is more important to have the arms line up correctly. The axis placement then automatically falls in line.
- Position the stationary arm parallel to the longitudinal axis of the body segment proximal to the joint being measured, although there are some exceptions.
- Position the movable arm parallel to the longitudinal axis of the body segment distal to the joint being measured, with some exceptions.

Environmental factors include time of day, temperature of the room, type of goniometer used, and training and experience of the tester. For the most reliable pretest–posttest information, the same tester should use the same goniometer at approximately the same time of day.

Intrarater reliability is consistently higher than interrater reliability for ROM testing using a universal goniometer. Intrarater reliability refers to *one* therapist consistently measuring the same joint angle over multiple trials, whereas interrater reliability concerns *multiple* therapists consistently measuring the same joint angle. In one study of shoulder internal and external rotation measured in the supine position, intrarater reliability was good ($r = 0.58$–0.71), and interrater reliability was fair to good ($r = 0.41$–0.66) (Awan, Smith, & Boon, 2002). A second study found that combined finger flexion measured with a ruler was a reliable measure when taken by different therapists, but that goniometric measures of the finger joints were more reliable when a single therapist was involved (Ellis & Bruton, 2002).

Active motion measurements are more reliable than passive ones. In one study by Sabari et al. (1998), 30 adults were measured for both active and passive ROM for shoulder flexion and abduction in two positions, sitting and supine. The AROM measurements were more reliable than the PROM measurements for both positions. Furthermore, the researchers found only a moderate range of agreement ($r = 0.64$–0.81) between goniometric measurements of shoulder movements with the patient sitting and supine. The authors concluded that the position of the patient can affect ROM. Therefore, therapists should record the testing position, and the same position should be used each time the patient is retested (Sabari et al., 1998). This chapter demonstrates measurement of shoulder ROM in a sitting patient because it measures shoulder mobility in the position more frequently used for functional task performance.

A multicenter study looked at the reliability of three goniometric techniques for measuring passive wrist flexion and extension: radial, ulnar, and volar-dorsal approaches. The study found the volar-dorsal approach to be slightly more reliable. The interclass correlation coefficient (ICC) was 0.93 for flexion and 0.84 for extension with the volar-dorsal approach, whereas the corresponding values were 0.88 and 0.80 for the radial approach and 0.89 and 0.80 for the ulnar approach (LaStayo & Wheeler, 1994). All three approaches are reliable, but they are not interchangeable. The therapist must be sure to document which approach is being used and use the same approach consistently to document progress.

It is commonly believed that experience plays a major role in the reliability of ROM measurements. A study of how therapist experience influences reliability of goniometric measurements found no dramatic difference in reliability between experienced physical therapists and inexperienced therapy students measuring ankle joint angle. All of the inexperienced therapists were uniformly trained on specific testing procedures (Somers et al., 1997). Thus, interrater reliability may be more dependent on training than experience.

Recording Range of Motion

Depending on the facility, ROM may be documented electronically or on paper, making it a part of the medical record and a legal document. This form should include the date that the measurements were taken, whether the measurements represent AROM or PROM, the starting and ending position for each movement, whether the right versus the left side was tested, and the physical or electronic signature of the therapist performing the measurements. A sample form is provided in Figure 7-5. When reading the goniometer, always state your results as a range using two numbers. The first number is the starting position of the extremity, and the second number is the limit of motion at end range. At reevaluation, compare the initial evaluation measurements to evaluate progress.

The most common method of determining ROM is the Neutral Zero Method recommended by the Committee on Joint Motion of the American Academy of Orthopaedic Surgeons (AAOS) (Greene & Heckman, 1994). The ROM normative data presented in this chapter is also from the AAOS, although it is important to note that other sources, such as the American Medical Association (AMA), have documented these averages differently, and these sources may be seen in practice as well. In the Neutral Zero Method, the anatomical position is considered to be 0, or if a given starting position is different from anatomical position, it is defined

Figure 7-5 Sample range of motion recording form.

as 0. Measurement is taken from the stated starting position to the stated end position. If the patient cannot achieve the stated starting and end positions, the actual starting and end positions are recorded to indicate limitations in movement. An example using elbow flexion, is as follows:

0°–150°: No limitation
20°–150°: A limitation in extension (problem with the start position)
0°–120°: A limitation in flexion (problem with the end position)
20°–120°: Limitations in flexion and extension (problems with start and end positions)

To record hyperextension of a joint, which may be occasionally seen in metacarpophalangeal (MP) and elbow joints, the AAOS recommends a separate measurement to describe the available ROM without confusion. For example, if 20° of elbow hyperextension (an unnatural movement) is noted, it should be recorded as follows:

0°–150° of flexion
0° of extension
0°–20° of hyperextension

If a joint is fused, the starting and end positions are the same, with no ROM. This is recorded as "fused at X°." If a joint that normally moves in two directions cannot move in one direction, the ROM-limited motion is recorded. For example, if wrist flexion is 15°–80° with a 15° flexion contracture, the wrist cannot be positioned at zero or be moved into extension; therefore, wrist extension is −15° or a 15° extension lag.

Because there are various systems of notations, each having its own meaning, it is important to clarify the intended meaning to ensure consistency among therapists and physicians within the same facility.

RANGE OF MOTION MEASUREMENT OF THE UPPER EXTREMITY

This chapter addresses ROM of the UE, because most functional activities require UE use and manipulation skills. For the measurements given here, unless otherwise noted, the patient is seated with trunk erect against the back of an armless straight chair, although the measurements can be taken with the patient standing or supine, if necessary. This procedure can be done actively or passively. For active movement, take special care to ensure that there are no substitutions of movement.

A substitution or compensatory movement is the use of an alternate muscle or position to complete a motion, possibly preventing measurement of the true limits of motion. In order to avoid this error, the therapist should watch the individual as the motion is completed rather than focusing too intently on the goniometer. For PROM, the tester supports both the body part and the goniometer proximal and distal to the joint, leaving the joint free to move. Comfortable handling of the goniometer together with the movable body segment may require practice.

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of UE ROM. The narrative descriptions frequently use the sagittal, transverse, and frontal planes of motion to describe the motion being measured (see Fig. 7-6 for pictorial clarification of these planes of motion).

Body Planes
Figure 7-6 Planes of motion of the body.

Shoulder Flexion

Movement of the humerus anteriorly in the sagittal plane (0°–180°), which represents both glenohumeral and axioscapular motion (Figs. 7-7 and 7-8): starting position deviates from the anatomical position to allow the palm of the hand to face the body.

Goniometer Placement

Axis. A point around which motion occurs through the lateral aspect of the glenohumeral joint; at the start of motion, it lies approximately 1 inch below the acromion process with arm in neutral rotation. At the end position, the axis has moved, and the goniometer must be repositioned.

Stationary Arm. Parallel to the lateral midline of the trunk.

Movable Arm. Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

Trunk extension/rotation, shoulder abduction. Having the patient place the arm not actively being tested against a wall or chair in front of the patient may prevent excessive trunk motion used as a substitution method (Gerhardt, Cocchiarella, & Lea, 2002).

Figure 7-7 Shoulder flexion, start position.

Figure 7-8 Shoulder flexion, end position.

Shoulder Extension

Movement of the humerus posteriorly in the sagittal plane with the arm in neutral rotation (0°–60°) (Figs. 7-9 and 7-10): some natural internal rotation occurs at the end range and is permitted (Greene & Heckman, 1994).

Goniometer Placement

Axis. A point around which motion occurs; it lies approximately 1 inch below the acromion process through the lateral aspect of the glenohumeral joint.

Stationary Arm. Parallel to the lateral midline of the trunk.

Movable Arm. Parallel to the longitudinal axis of the humerus on the lateral aspect.

Possible Substitutions

Trunk flexion/rotation, excessive scapular elevation and downward rotation, shoulder abduction.
Figure 7-9 Shoulder extension, start position.

Figure 7-10 Shoulder extension, end position.

Shoulder Abduction

Movement of the humerus laterally in the frontal plane (0°–180°), which represents both glenohumeral and axioscapular motion (Figs. 7-11 and 7-12).

Goniometer Placement

Axis. A point through the anterior or posterior aspect of the glenohumeral joint.

Stationary Arm. Along the trunk, parallel to the spine.

Movable Arm. Parallel to the longitudinal axis of the humerus.

Possible Substitutions

Lateral flexion of trunk, scapular elevation, shoulder flexion or extension. If excessive lateral flexion of the trunk is noted, the arm not being actively tested may be stabilized at 90° of abduction against a wall or other stable object to prevent trunk motion (Gerhardt, Cocchiarella, & Lea, 2002).
Figure 7-11 Shoulder abduction, start position.

Figure 7-12 Shoulder abduction, end position.

Horizontal Abduction

Movement of the humerus on a horizontal (transverse) plane from 90° of shoulder abduction (0°–45°) (Figs. 7-13 and 7-14).

Goniometer Placement

Axis. On top of the acromion process.

Stationary Arm. Across the shoulder, anterior or posterior to the neck and in line with the opposite acromion process.

Movable Arm. Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitutions

Trunk rotation or trunk flexion, scapular motion, shoulder flexion (can be avoided by stabilizing the arm in 90° abduction).

Figure 7-13 Shoulder horizontal abduction, start position.

Figure 7-14 Shoulder horizontal abduction, end position.

Horizontal Adduction

Movement of the humerus on a horizontal (transverse) plane from 90° of shoulder abduction through 90° of shoulder flexion, across the trunk to the limit of motion (0°–140°) (Figs. 7-15 and 7-16).

Goniometer Placement

Axis. On top of the acromion process.

Stationary Arm. Across the shoulder, anterior to the neck and in line with the opposite acromion process.

Movable Arm. Parallel to the longitudinal axis of the humerus on the superior aspect.

Possible Substitution

Trunk rotation, scapular motion, shoulder flexion/extension (can be avoided by stabilizing the arm in 90° abduction).

Figure 7-15 Shoulder horizontal adduction, start position.

Figure 7-16 Shoulder horizontal adduction, end position.

Internal Rotation

Rotation of the humerus internally around the longitudinal axis of the humerus (0°–70°) (Figs. 7-17 and 7-18). Preferably the zero start position is with the arm abducted to 90° and elbow flexed at 90° with the forearm moving toward the floor from this starting position.

Goniometer Placement

Axis. Olecranon process of the ulna.

Stationary Arm. Perpendicular to the floor, which will be parallel to the lateral trunk if the patient is sitting up straight with hips at 90°. The goniometer reads 90° at the start, and this score must be adjusted from the final score when recording ROM. *Note:* If the patient is supine with the shoulder abducted to 90° and the elbow flexed to 90°, the stationary arm is perpendicular to the floor, with the movable arm along the ulna. The goniometer reads 0° at the start (Boone & Smith, 2000).

Movable Arm. Parallel to the longitudinal axis of the ulna.

Possible Substitutions

Scapular elevation and downward rotation, trunk flexion, elbow extension.

Figure 7-17 Shoulder internal rotation, start position.

Figure 7-18 Shoulder internal rotation, end position.

External Rotation

Movement of the humerus laterally or upward from the ground in the 90° abducted start position around the longitudinal axis of the humerus (0°–90°) (Figs. 7-19 and 7-20).

Goniometer Placement

Axis. Olecranon process of the ulna.

Stationary Arm. Perpendicular to the floor. The goniometer will read 90° at the start, and this must be considered when recording the ROM score.

Movable Arm. Parallel to the longitudinal axis of the ulna.

Possible Substitutions

Scapular depression and upward rotation, trunk extension, elbow extension.

Figure 7-19 Shoulder external rotation, start position.

Figure 7-20 Shoulder external rotation, end position.

Internal and External Rotation: Alternative Method

If shoulder limitation prevents positioning for the previously described method, the patient may be seated with the humerus adducted to the side and elbow flexed to 90° with forearm in neutral (Figs. 7-21 and 7-22). This method is inaccurate in internal rotation if the patient has a large abdomen (internal rotation, 0°–90°; external rotation, 0°–60°).

Figure 7-21 Shoulder internal and external rotation, alternative method, start position.

Figure 7-22 Shoulder external rotation, alternative method, end position.

Elbow Flexion–Extension

Movement of the supinated forearm anteriorly in the sagittal plane (0°–150°) (Figs. 7-23 and 7-24). Significant elbow extension is not typically seen in the adult population, but children and some hypermobile adults may demonstrate 10°–15° of hyperextension at the elbow, although most functional tasks are completed in the 30°–130° arc of flexion (Greene & Heckman, 1994).

Goniometer Placement

Axis.   Lateral epicondyle of the humerus.

Stationary Arm.   Parallel to the longitudinal axis of the humerus on the lateral aspect.

Movable Arm.   Parallel to the longitudinal axis of the radius.

Figure 7-23   Elbow flexion, start position (elbow extension).

Figure 7-24   Elbow flexion, end position.

Forearm Supination

Rotation of the forearm laterally around its longitudinal axis from midposition so that the palm of the hand faces up (0°–80°) (Figs. 7-25 and 7-26). Starting position is with the forearm in neutral, and the humerus stabilized against the body.

Goniometer Placement

Axis. Longitudinal axis of the forearm displaced toward the ulnar side.

Stationary Arm. Perpendicular to the floor, which should also be parallel with the humerus if no substitution movements are allowed.

Movable Arm. Across the distal radius and ulna on the volar surface.

Possible Substitutions

Adduction and external rotation of the shoulder.

Figure 7-25 Supination, start position.

Figure 7-26 Supination, end position.

Forearm Pronation

Rotation of the forearm medially around its longitudinal axis from neutral so that the palm of the hand faces down (0°–80°) (Figs. 7-27 and 7-28). Functional forearm rotation is 50° of both pronation and supination (Greene & Heckman, 1994).

Goniometer Placement

Axis. Longitudinal axis of forearm displaced toward the ulnar side.

Stationary Arm. Perpendicular to the floor, which should also be parallel with the humerus if no substitution movements are allowed.

Movable Arm. Across the distal radius and ulna on the dorsal surface.

Possible Substitutions

Abduction and internal rotation of the shoulder.

   Although the distal forearm method described here for supination and pronation has been the gold standard, two additional methods (the handheld pencil and plumbline goniometer methods) have shown high interrater and intrarater reliability in a more functional measure of supination and pronation. The handheld pencil method can be easily used in the clinic to determine functional forearm rotation. The standardized method is to have the client seated with hips and knees at 90°, feet flat on the ground, arms adducted to the sides with elbow flexed to 90°, forearm unsupported in neutral. The client holds a standard 15-cm pencil in a tight fist, with the pencil extending from the radial aspect of the hand. The goniometer is aligned with the axis at the head of the third metacarpal, stationary arm perpendicular to the floor, and moveable arm parallel to the pencil (Karagiannopoulos, Sitler, & Michlovitz, 2003).

Figure 7-27 Pronation, start position.

Figure 7-28 Pronation, end position.

Wrist Flexion (Volar Flexion)

Movement of the hand volarly in the sagittal plane (0°–80°) (Figs. 7-29 and 7-30). Starting with the forearm pronated and digits in a relaxed position will prevent any negative impact of the tenodesis effect on demonstrating the limits of motion.

Goniometer Placement

Axis. On the dorsal aspect of the wrist joint in line with the base of the third metacarpal in the proximal capitate region. (*Note:* The lunate protrudes as the wrist is flexed forward, and the capitate is located distal to the lunate and proximal to the base of the third metacarpal.)

Stationary Arm. Along the midline of the dorsal surface of the forearm.

Movable Arm. Parallel to the longitudinal axis of the third metacarpal.

Figure 7-29 Wrist flexion, start position.

Figure 7-30 Wrist flexion, end position.

Wrist Extension (Dorsiflexion)

Movement of the hand dorsally in the sagittal plane (0°–70°) (Figs. 7-31 and 7-32). Again, prevent the tenodesis effect by reminding the patient to relax the fingers rather than trying to maintain them in full extension while measuring wrist motion.

Goniometer Placement

Axis. Same position as wrist flexion or, if the goniometer does not accommodate this position, on the volar surface of the wrist in line with the palmaris longus tendon in line with the third metacarpal at the level of the carpal bones.

Stationary Arm. Along the midline of the volar surface of the forearm.

Movable Arm. Parallel to the longitudinal axis of the third metacarpal. The movable arm may need to rest between the third and fourth digits if the digits prevent correct alignment.

Figure 7-31 Wrist extension, start position.

Figure 7-32 Wrist extension, end position.

Wrist Ulnar Deviation

Movement of the hand toward the ulnar side in a frontal plane (0°–30°) (Figs. 7-33 and 7-34). The AAOS recommends a starting position with the forearm pronated, whereas the AMA recommends neutral forearm rotation. Proper alignment of the goniometer is easier in pronation.

Goniometer Placement

Axis. On the dorsal aspect of the wrist joint in line with the base of the third metacarpal over the capitate where the motion is observed.

Stationary Arm. Along the midline of the forearm on the dorsal surface. After positioning the patient, stabilizing the forearm can assist in isolating motion to the wrist.

Movable Arm. Along the midline of the third metacarpal. (*Note:* Do not be distracted by additional abduction of the third digit, and palpate the third metacarpal to ensure alignment.)

Possible Substitutions

Wrist extension, wrist flexion.

Figure 7-33 Wrist ulnar deviation, start position.

Figure 7-34 Wrist ulnar deviation, end position.

Wrist Radial Deviation

Movement of the hand toward the radial side in a frontal plane (0°–20°) (Figs. 7-35 and 7-36).

Goniometer Placement

Axis. On the dorsal aspect of the wrist joint in line with the base of the third metacarpal over the capitate.

Stationary Arm. Along the midline of the forearm on the dorsal surface. After positioning the patient, stabilizing the forearm can assist in isolating motion to the wrist.

Movable Arm. Along the midline of the third metacarpal.

Possible Substitution

Wrist extension.

Figure 7-35 Wrist radial deviation, start position.

Figure 7-36 Wrist radial deviation, end position.

Thumb Carpometacarpal Flexion

Movement of the thumb across the palm in the frontal plane (0°–15°) (Figs. 7-37 and 7-38).

Goniometer Placement

Axis. On the radial side of the wrist at the junction of the base of the first metacarpal and the trapezium.

Stationary Arm. Parallel to the longitudinal axis of the radius.

Movable Arm. Parallel to the longitudinal axis of the first metacarpal. For accuracy, the arms of the goniometer must remain in full contact with skin surface over the bones. (*Note:* Avoid excessive pressure with the edge of a half-circle goniometer.) The axis of the goniometer may lift off the skin at greater degrees of motion in order to keep the arms in contact. These statements apply to all flexion–extension measurements of the thumb and fingers.
Figure 7-37 Thumb carpometacarpal flexion, start position.
Figure 7-38 Thumb carpometacarpal flexion, end position.

Thumb Carpometacarpal Extension

Movement of the thumb away from the palm in the frontal plane (0°–20°) (Figs. 7-39 and 7-40).

Goniometer Placement

Axis. On the volar side of the wrist at the junction of the base of the first metacarpal and the trapezium.

Stationary Arm. Parallel to the longitudinal axis of the radius.

Moveable Arm. Parallel to the longitudinal axis of the first metacarpal.

Figure 7-39 Thumb carpometacarpal extension, start position.

Figure 7-40 Thumb carpometacarpal extension, end position.

Thumb Metacarpophalangeal Flexion–Extension

Movement of the thumb across the palm in the frontal plane (0°–50°) (Figs. 7-41 and 7-42).

Goniometer Placement

Axis. On the dorsal aspect of the MP joint.

Stationary Arm. On the dorsal surface along the midline of the first metacarpal.

Movable Arm. On the dorsal surface along the midline of the proximal phalanx of the thumb.

Figure 7-41 Thumb metacarpophalangeal flexion, start position (extension).

Figure 7-42 Thumb metacarpophalangeal flexion and extension, end position.

Thumb Interphalangeal Flexion–Extension

Movement of the distal phalanx of the thumb toward the volar surface of the proximal phalanx of the thumb (0°–80°) (Figs. 7-43 and 7-44).

Goniometer Placement

Axis. On the dorsal aspect of the interphalangeal (IP) joint.

Stationary Arm. On the dorsal surface along the proximal phalanx.

Movable Arm. On the dorsal surface along the distal phalanx. (*Note:* If the thumbnail prevents full goniometer contact, shift the movable arm laterally to increase accuracy. Also, thumb MP and IP flexion and extension can be measured on the lateral aspect of the thumb using lateral aspects of the same landmarks.)

Figure 7-43 Thumb interphalangeal flexion, start position (extension).

Figure 7-44 Thumb interphalangeal flexion, end position.

Thumb Palmar Abduction

Movement of the thumb perpendicular to the palm (0°–70°) (Figs. 7-45 and 7-46).

Goniometer Placement

Axis. Over the trapezium on the dorsal aspect of the hand.

Stationary Arm. On the dorsal surface parallel to the second metacarpal.

Movable Arm. Parallel to the first metacarpal.
Figure 7-45 Thumb palmar abduction, start position.

Figure 7-46 Thumb palmar abduction, end position.

Thumb Radial Abduction

Movement of the thumb radially and in line with the plane of the palm (0°–80°) (Figs. 7-47 and 7-48).

Goniometer Placement

Axis. Over the trapezium on the dorsal aspect of the hand.

Stationary Arm. On the dorsal surface parallel to the second metacarpal.

Movable Arm. Parallel to the first metacarpal.

Figure 7-47 Thumb radial abduction, start position.

Figure 7-48 Thumb radial abduction, end position.

Opposition: Ruler Measurements

The pad of the thumb rotates to meet the pad of each finger. The little finger rotates to better meet the pad of the thumb. As a summary measure of opposition, record the distance from the tip of the thumb pad (not the thumbnail) to the tip end of the little finger or base of little finger (Fig. 7-49).

Figure 7-49 Measurement of opposition to the little finger using a centimeter ruler.

Finger Metacarpophalangeal Flexion–Extension

Movement of the finger at the MP joint (0°–90°) (Figs. 7-50 and 7-51). Hyperextension is normal at this joint.

Goniometer Placement

Axis. On the dorsal aspect of the MP joint of the finger being measured.

Stationary Arm. On the dorsal surface along the midline of the metacarpal of the finger being measured.

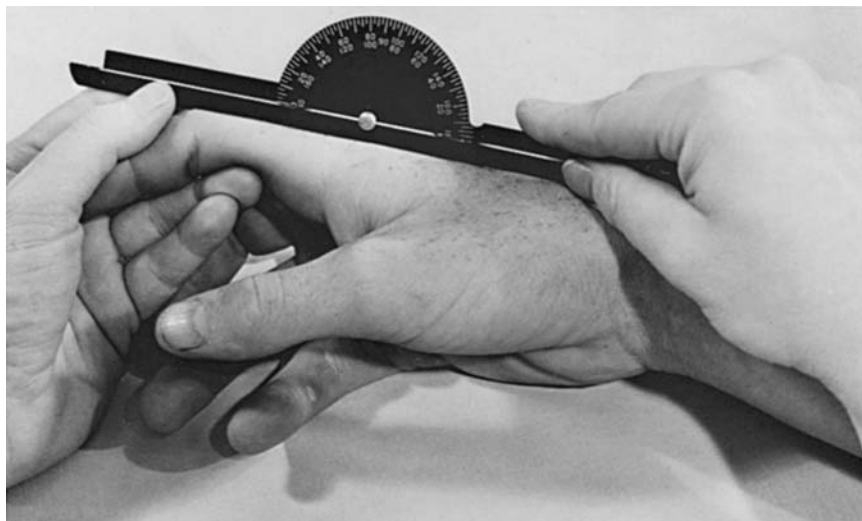
Movable Arm. On the dorsal surface along the midline of the proximal phalanx of the finger being measured.


Figure 7-50 Finger metacarpophalangeal flexion, start position (extension).
Figure 7-51 Finger metacarpophalangeal flexion, end position.

Finger Proximal Interphalangeal Flexion–Extension

Movement of the middle phalanx toward the palmar surface of the proximal phalanx (0°–100°) (Figs. 7-52 and 7-53).

Goniometer Placement

Axis. On the dorsal aspect of the proximal interphalangeal (PIP) joint of the finger being measured.

Stationary Arm. On the dorsal surface along the midline of the proximal phalanx of the finger being measured.

Movable Arm. On the dorsal surface along the midline of the middle phalanx of the finger being measured.
Figure 7-52 Proximal interphalangeal flexion, start position (extension).
Figure 7-53 Proximal interphalangeal flexion, end position.

Finger Distal Interphalangeal Flexion–Extension

Movement of the distal phalanx toward the palmar surface of the middle phalanx (0°–90°) (Figs. 7-54 and 7-55).

Goniometer Placement

Axis. On the dorsal aspect of the distal interphalangeal (DIP) joint of the finger being measured.

Stationary Arm. On the dorsal surface along the midline of the middle phalanx of the finger being measured.

Movable Arm. On the dorsal surface along the midline of the distal phalanx of the finger being measured. (*Note:* If the fingernail prevents full goniometer contact, shift the arms laterally to increase accuracy. If contact with the palm impacts goniometer alignment, a hooked-fist position may improve accuracy of measurement. Also, finger PIP and DIP flexion and extension can be measured from the lateral aspect of each finger using the lateral aspect of the same landmarks. This method may be more accurate when joints are enlarged or when there is diffuse edema noted along the digit.)

Figure 7-54 Distal interphalangeal flexion, start position (extension).
Figure 7-55 Distal interphalangeal flexion, end position.

Composite Measurement and Recording of Total Finger Flexion

A method of recording composite digital motion used by hand therapists is to sum the values for the degrees of flexion motion of the MP, PIP, and DIP joints, taking into consideration extension deficits (Ellis & Bruton, 2002). Total active motion (TAM) or total passive motion (TPM) can then be expressed by a single number. The formula for calculating these values is as follows: (MP + PIP + DIP flexion) − (MP + PIP + DIP extension deficits) = TAM or TPM.

Another method for measuring combined flexion of the PIP and DIP joints or combined flexion of the MP, PIP, and DIP joints using a centimeter ruler is illustrated in Figures 7-56 and 7-57.

Figure 7-56 Proximal and distal interphalangeal combined finger flexion; ruler measurement.

Figure 7-57 Metacarpophalangeal and proximal and distal interphalangeal combined finger flexion; ruler measurement.

Finger Abduction

Movement of the index, ring, and little fingers away from the midline of the hand in a frontal plane. The middle finger, which is the midline of the hand, abducts in both radial and ulnar directions (Figs. 7-58 and 7-59).

Goniometer Placement

Axis. On the dorsal aspect of the MP joint of the finger being measured.

Stationary Arm. Along the dorsal surface of the metacarpal of the finger being measured.

Movable Arm. Along the dorsal surface of the proximal phalanx of the finger being measured.

Figure 7-58 Finger abduction, start position.

Figure 7-59 Finger abduction, end position.

Finger Adduction

Movement of the index, ring, and little fingers toward the midline of the hand in a frontal plane. Note that the middle finger cannot adduct as it is already in midline (Figs. 7-60 and 7-61).

Goniometer Placement

Axis. On the dorsal aspect of the MP joint of the finger being measured.

Stationary Arm. Along the dorsal surface of the metacarpal of the finger being measured. The middle finger is not measured.

Movable Arm. Along the dorsal surface of the proximal phalanx of the finger being measured.

Figure 7-60 Finger adduction, start position.

Figure 7-61 Finger adduction, end position.

Metacarpophalangeal Deviation Correction Measurement

When there is ulnar deviation deformity of the MP joints, often seen in rheumatoid arthritis, this additional measurement is taken (Figs. 7-62 and 7-63).

The active range is compared with the passive range to determine whether muscle weakness is present. PROM is compared with the norm of 0° deviation to determine whether a fixed deformity exists.

Goniometer Placement

Axis. Over the MP joint of the finger being measured.

Stationary Arm. Placed along the dorsal midline of the metacarpal.

Movable Arm. Placed along the dorsal midline of the proximal phalanx.

Figure 7-62 Metacarpophalangeal deviation correction, start position.

Figure 7-63 Metacarpophalangeal deviation correction, end position.

Interpreting the Results

The initial evaluation is interpreted by reviewing the recording form to identify which joints have significant limitation. A significant limitation is one that decreases occupational functioning or may lead to deformity. Limits of motion scores can be used in several ways. First, the therapist can compare the scores of the involved to the uninvolved extremity. A study of more than 1,000 healthy male subjects, however, found a significant difference in ROM between the dominant and nondominant sides. The nondominant side had greater range in many of the UE joints tested (Gunal et al., 1996). This information should be kept in mind when comparing the two sides. The patient's scores can be compared with the average limits (norms) expected for each motion. The average limits stated by the Committee on Joint Motion of the American Academy of Orthopaedic Surgeons (Greene & Heckman, 1994) are commonly used and are included here. However, patients may be functional with less ROM than is noted in the norms for particular joints. The emphasis in occupational therapy is to enable occupational functioning.

With the significant limitations and probable cause in mind, treatment goals that reflect the identified problem can be developed. For example, if skin, joint, and/or muscle tissues have shortened as a result of immobilization, the goal is to increase range by stretching these tissues. If the limitation is caused by edema, pain, spasticity, or muscle weakness, the primary goal is to reduce or correct the underlying problem, and the secondary goal is to prevent loss of ROM caused by the immobility imposed by the primary condition. If the cause is bony ankylosis or long-standing contracture, the goal is to teach the patient methods of compensation, because these conditions do not respond to nonsurgical treatment.

Comparing initial evaluation scores to mid- and post-treatment scores is important to assess the outcome and redirect treatment, if necessary. Interpretation of a re-evaluation that shows improvement following treatment must be tempered with the realization that changes may occur simply as a result of remeasurement. For ROM measurements to reflect actual change, the amount of change must exceed measurement error, which was found to be 5° for both the upper and lower extremities (Groth et al., 2001). For example, an increase of 10° in shoulder flexion is considered an improvement, but 5° may be accounted for by measurement error.

EDEMA

Edema, one cause of limited ROM, is quantified using circumferential or volumetric measurements. A millimeter tape is used to measure the circumference of a body part not easily submerged (as required by volumetric measurement) or when the edema is very localized (such

Figure 7-64 Measuring edema using circumferential method.

as to a single digit, making measurement of the entire hand unnecessary). With circumferential measurements, it is essential to measure at exactly the same place from test to test. Using anatomic landmarks can assist in the placement, such as over the third digit PIP joint or 5 cm proximal to the ulnar styloid (see Fig. 7-64 for an example of circumferential measurement).

Volumetric measures document changes in the mass of a body part by use of water displacement and is most often used to measure hand edema. A water vessel that is large enough to allow submersion of the whole hand is used as shown in Figure 7-65. When the hand is placed in the vessel, water is displaced and spills out into a collection beaker via the spout near the top and is then measured with a graduated cylinder. An edematous hand displaces more water

Figure 7-65 Measuring edema of the hand using a volumeter. Note the water being displaced into the graduated beaker as the hand is submerged.

Safety Note 7-2

Precautions for Edema Measurements

Immersing the hand in water is sometimes contraindicated, such as with open wounds or skin conditions, immediately postoperatively, with percutaneous pinning and external fixation devices, healing skin grafts, and suspicion of infection. It is also inappropriate if having the extremity in the dependent position during testing significantly increases pain and edema or if spasticity or paralysis impacts the measurement (Dewey et al., 2007; Maihafer et al., 2003).

than does a nonswollen hand, so a lower reading is considered an improvement. The therapist should not expect the hand volume to be the same bilaterally, because the dominant hand typically has more muscle mass. Precautions with using this method are listed in Safety Note 7-2.

Dodds et al. (2004) examined therapists' ability to orient the extremity consistently within the volumeter and to measure the displaced water accurately. Following this protocol in the clinic setting, the therapist should follow the steps below:

1. An adjustable table should be set at a height that allows the client to keep the shoulder in neutral position when placing the hand in the volumeter on the tabletop. The therapist should ensure that the volumeter is stable, and the table is level.
2. The volumeter should be filled with room temperature water to the point of overflow. Any excess water should be wiped out of the collection beaker.
3. The client should be positioned parallel to the volumeter with the volar forearm and palm of the hand facing his or her body. The client should stand to the side of the table that will allow his or her thumb to face the spout of the volumeter.
4. The client should be instructed to note the dowel in the volumeter and slowly lower his or her hand into the volumeter at a rate that allows the water to collect in the beaker below the spout until the web space between the third and fourth digits rests on the dowel and the water stops dripping. Tell the client to avoid touching the sides of the volumeter during the test.
5. The therapist should stand behind the client to support the trunk and prevent any rotation or leaning and can provide verbal cues to the client to prevent excess motion and ensure the hand is properly positioned. Instruct the client to remain silent until the test is complete to avoid motion from talking.
6. After the client removes his or her hand from the volumeter and dries it (provide a towel), the therapist uses

the 500-mL graduated cylinder to measure the amount of displaced water to the nearest 5 mL. The use of a 10-mL micropipette allows the therapist to measure the displaced water to the nearest 1 mL, thereby increasing accuracy. Occasionally, more than 500 mL will be displaced, and multiple graduated cylinders will be needed, or the water will be measured to 500 mL and then discarded, the graduated cylinder dried out, and the remaining water measured and added to the 500 mL already measured.

This protocol showed high reliability over two repeated tests on 50 hands, showing a test–retest reliability of 0.99 (Dodds et al., 2004). To interpret findings, compare the measurement of the affected part with that of its contralateral counterpart. If edema is present, the short-term goal of treatment may be to decrease edema more than 10 mL, which is more than the standard error of measurement of less than 3 mL (Dodds et al., 2004). However, it is important to remember the reasoning behind wanting the decrease in edema. For example, the entire short-term goal may be written as, "The patient will demonstrate a 10-mL decrease in volumeter measurement of edema of the right hand in order to increase hand function with dressing tasks."

A second method of measuring edema of the whole hand is the figure-of-eight technique (Pellecchia, 2004). This method is based on the understanding that edema of the hand tends to collect more dorsally. Using a ¼-inch wide tape measure with the wrist in neutral and fingers adducted, the tape is started at the medial aspect of the wrist just distal to the ulnar styloid. The tape is then run across the volar surface of the wrist to the most distal point of the radial styloid and then run diagonally across the dorsum of the hand to the fifth MP joint. The tape is then run across the heads of the metacarpals to the second MP joint and then back across the dorsum of the hand to the starting point. The measurement recorded is the distance measured by the tape in centimeters (Fig. 7-66). The interrater and the intrarater reliabilities for this method are high ($r = 0.98–0.99$) (Leard et al., 2004; Pellecchia, 2004). When the figure-of-eight measurement was compared to the submersion method in a normal population, the two methods were highly correlated ($r = 0.94–0.95$) (Maihafer et al., 2003). The figure-of-eight measurement technique may be especially appropriate when volumetry is contraindicated.

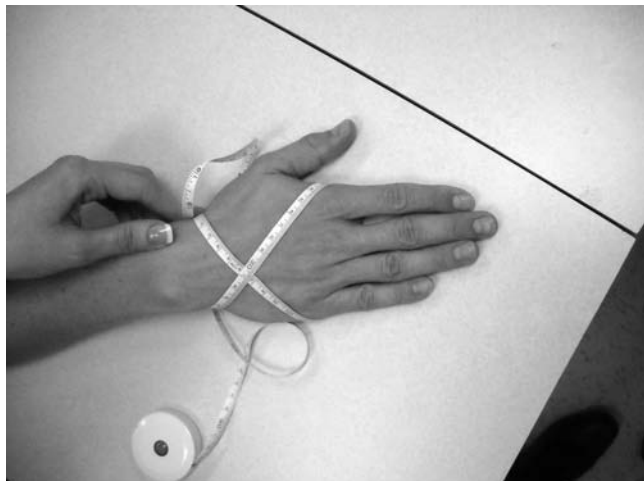
In a study by Dewey et al. (2007), this method has also been shown to be reliable and valid in the measurement of edema in patients with burns to the hands. Intrarater reliability in this population was ICC = 0.96–0.97, and interrater reliability was ICC = 0.94. Correlation between the figure-of-eight method and volumetry was also good ($r = 0.83–0.90$). This study emphasized the time efficiency and cost savings of the figure-of-eight method and the preference for this method, particularly in the intensive care unit setting. They identified a standard error of


Figure 7-66 Measuring edema of the hand using the figure-of-eight method.

measurement in the 33 hands measured of 1.16 cm and recommended that changes in this measurement must exceed this number in order to be clinically significant (Dewey et al., 2007).

PAIN

Pain is another possible cause of ROM limitations. Pain or fear of pain may affect a person's willingness to move. Pain is very subjective, and although therapists often assign a numerical value to the intensity of pain, that number is very individual and cannot be compared to any normative value or with any other patient (Farrar, Berlin, & Strom, 2003). Pain is also multidimensional, and by discussing the different components with the patient, the therapist can elicit a better understanding of how pain is impacting function. Components of pain include intensity, duration, location, description of type of pain, and the emotional impact of pain (Williamson & Hoggart, 2005). Because pain is subjective, self-report measures provide the most valid measure of the experience. Several self-report measures include the Visual Analog Scale (VAS), the Wong-Baker FACES® Pain-Rating Scale, the Numerical Rating Scale (NRS), and the Verbal Rating Scale (VRS) (Hockenberry & Wilson, 2009; Williamson & Hoggart, 2005).

The VAS consists of a 100-mm line with ends of the line designated with descriptions such as "no pain at all" and "the worst pain possible." The patient marks on the line the point that represents the intensity of the pain he or she feels. The score is obtained by measuring the line from the zero point to the patient's mark in cm. A review of data from two randomized controlled trials using the VAS suggests the following:

- 0–4 mm: no pain
- 5–44 mm: mild pain

- 45–74 mm: moderate pain
- 75–100 mm: severe pain

A 33% decrease in pain is needed on this scale in order for it to be significant (Jensen, Chen, & Brugger, 2003).

The NRS also has good sensitivity and is frequently used when evaluating pain. The 0–10 range is typical for the NRS, but this scale has also been used with 0–20 and 0–100 ranges. With the NRS, it has been suggested that a difference of 2 points on the 0–10 scale indicates a clinically significant difference (Farrar, Berlin, & Strom, 2003). This knowledge can be helpful in goal writing. For example, a patient with osteoarthritis of the carpometacarpal (CMC) joint of the right dominant hand may report a pain level of 7 out of 10 on initial evaluation. The therapist should ask in the discussion of pain with the client, "What would you like to be able to do if you had less pain in your hand?" The client may list several activities, such as completing housework, gardening, and caring for his or her pets. A short-term goal written to reflect this information could be, "The patient will report a decrease in pain of the right hand to 5 out of 10 or less with the use of joint protection techniques and clinical treatment in order to increase function for household and leisure tasks."

The verbal rating scale asks patients to describe their pain such as "none," "mild," "moderate," or "severe." Some therapists will turn this description into a 4-point scale. All of the pain-rating tools described have been researched for their reliability and sensitivity in detecting change in pain levels. Examples of the various pain scales can be found in Figures 7-67 and 7-68.

0	1	2	3	4	5
NO HURT	HURTS LITTLE BIT	HURTS LITTLE MORE	HURTS EVEN MORE	HURTS WHOLE LOT	HURTS WORST

Alternate coding   0   2   4   6   8   10
Brief word instructions: Point to each face using the words to describe the pain intensity. Ask the child to choose face that best describes their own pain and record the appropriate number.

Original instructions: Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain. Face 0 is very happy because he doesn't hurt at all. Face 1 hurts just a little bit. Face 2 hurts a little more. Face 3 hurts even more. Face 4 hurts a whole lot. Face 5 hurts as much as you can imagine, although you don't have to be crying to feel this bad. Ask the person to choose the face that best describes how he is feeling.

Rating scale is recommended for persons age 3 years and older.
Figure 7-67 FACES Pain Scale.

Figure 7-68 Example Pain Scales.

Often the therapist will ask the client about pain at the beginning of the evaluation, but it is also important to ask about increases in pain during the evaluation of ROM and strength. The report of pain should be documented along with the ROM limitations. By asking questions regarding where the pain is specifically located and the type and intensity of the pain, underlying conditions impacting motion and strength can sometimes be identified.

For example, a patient may present for evaluation following a distal radius fracture, but the pain he or she reports may be along the volar wrist and thenar aspect of the hand with a description of burning and pins and needles radiating into the radial digits. This pain may actually be from compression of the median nerve at the wrist level (i.e., carpal tunnel syndrome) from the initial injury or from the edema that resulted from the injury. The therapist may choose to do additional testing, and it may be appropriate to contact the referring orthopedic surgeon if this is a new finding.

It is important to know your patient population when selecting the most appropriate pain scale, and often one clinic will need more than one scale depending on the age, education, culture, and cognitive skills of the population being served. For example, the Wong-Baker FACES pain scale is more appropriate for the pediatric population than is asking children to rate their pain with the NRS (Hockenberry & Wilson, 2009). The clinician can also note any observations of pain, such as facial expressions (e.g., wincing) or physical motion (e.g., retraction of the extremity being tested).

SCAR TISSUE

Scar tissue, particularly scars that cross joints or run along tendons, can significantly impact motion. All wounds will heal with scar tissue, but not all scar tissue will impact motion. The size, color, and characteristics of any wounds or scars should be described during initial and subsequent evaluations. Typically, by manipulating the scar tissue with the fingers and pinching the skin around the scar, a therapist can determine whether any significant scar adhesions exist. Skin puckering around the scar with motion can also be a sign of adhesions (see additional information on wound healing and scar tissue in Chapters 19 and 37).

MUSCLE STRENGTH

Muscular strength, the "ability of the muscle to exert force," is a key component of muscular fitness (American College of Sports Medicine, 2010b, p. 86). Weakness is a lack or reduction of the power of a muscle or muscle group. When weakness limits or impairs the individual's occupational functioning, determining the degree and distribution of weakness to establish an appropriate intervention plan is necessary. Treatment can be focused on remediating the weakness, or it can focus on alternative ways of accomplishing the task. Weakness can manifest in several forms. It can be general, such as with Guillain-Barré syndrome, or it can be local, such as with a peripheral nerve lesion. In the former case, muscles throughout the body are assessed; in the latter case, just the muscles innervated by the involved nerve are tested. In both cases, the muscles to be tested are the ones contributing to the functional limitations on which treatment will focus.

A maximum voluntary contraction (MVC), the maximum amount of tension that can be produced under voluntary control, is commonly used to measure strength (Wilmore & Costill, 1999). Because muscle testing is a measurement of voluntary contraction of an isolated muscle or muscle group, strength testing is inappropriate for patients who lack the ability to contract a single muscle or a muscle group in isolation such as patients who exhibit patterned movement.

In this chapter, a technique called the "break test" is used. In the break test, the muscle to be tested is positioned at its greatest mechanical advantage. Once the extremity is positioned, the patient is asked to hold the position as the tester imparts external force (i.e., his or her hand and own strength) to overcome the contractile force of the muscle or muscle group. In other words, the therapist tries to break the patient's isometric contraction (Bohannon, 1988). *Safety Message: The therapist must ensure that providing resistance is not contraindicated by the diagnosis or the surgeon's orders for therapy. For example, putting resistance against a patient with a healing fracture, following various surgeries such as tendon or nerve repairs, after chest/heart/lung surgery, initially after myocardial infarction, where there is a history of bone metastasis, or after recent back/neck surgery is contraindicated. Precautions should also be taken with various neurodegenerative disorders so as not to stress fatigued or weakened muscles.*

The term *mechanical advantage* refers to the length–tension relationship of a muscle. The passive tension exerted by the elastic components in the lengthened muscle and surrounding tissue and the active tension generated by the contractile elements of the contracting muscle contribute to the total tension of a muscle (Hall & Brody, 1999). A muscle is able to generate its greatest total

tension or sustain the heaviest load when positioned at a length that gives it optimal mechanical advantage. This is usually slightly (10%) longer than resting length. Developed (active) tension, which is the total tension minus the elastic contribution, is greatest at resting length but decreases as the muscle shortens or lengthens. The length–tension principle is used to elicit the best response from prime movers during muscle testing. Furthermore, this principle is used to reduce the contribution of synergist muscles when testing the prime mover. Synergist muscles are placed at a mechanical disadvantage (either lengthened or shortened), whereas the prime mover is asked to resist the applied force (Hall & Brody, 1999). For muscles or muscle groups too weak to resist an external force, muscle strength is evaluated by isotonic contraction, in which the muscle is required to move the mass of the body part against gravity without applied resistance or with the effect of gravity decreased (Hislop & Montgomery, 1995; Kendall et al., 2005).

Gravity as resistance is considered an important variable and is used to test all motions when practical. Standard procedures for evaluation against gravity and with gravity eliminated are described in this chapter. Tests of the UE described here for the most part are motion tests for the purpose of evaluating strength in terms of functional ability. Tests of individual muscles in the wrist and hand are included because of the responsibility of the occupational therapist in the rehabilitation of hand injuries. The movements of the face, head, neck, and trunk, although important in the assessment of some patients,

have not been included in the interest of conserving space; however, this information can be found in references listed at the end of this chapter.

Prior to the start of MMT, an ROM scan should be done to determine what ROM is available at each joint. Although the available range is considered to be full ROM for the purposes of muscle testing, notation should be made of any limitation. The muscle or muscle group is assigned a grade according to the amount of resistance it can take. Two grading systems are presented here: Table 7-1 equates the Medical Research Council (1976) Oxford system to the descriptive grading system (Clarkson, 2000).

Procedures for Practice 7-4 shows the sequence of steps for testing every muscle or muscle group to ensure reliability and accuracy. There are additional considerations when performing an MMT. First, although fatigue differs for each person and each muscle, a rest of 2 minutes between maximum effort contractions of the same muscle is considered adequate (Milner-Brown, Mellenthin, & Miller, 1986). Second, for the comfort and convenience of the patient, all testing in one position is done before the patient changes to another position. Also, the positions of head, neck, and proximal parts are usually kept the same from test to test, although preliminary study results indicated that this does not affect tension development (Anderson & Bohannon, 1991; Bohannon, Warren, & Cogman, 1991).

Other methods of muscle testing can provide more specific data regarding strength, such as isokinetic testing done mostly in research and handheld dynamometry,

Table 7-1   Muscle Testing Grading System

Numerical Grade	Descriptive Grade	Definition
5	Normal	The part moves through full ROM against gravity and takes maximal resistance.
4	Good	The part moves through full ROM against gravity and takes moderate resistance.
4−	Good minus	The part moves through full ROM against gravity and takes less than moderate resistance.
3+	Fair plus	The part moves through full ROM against gravity and takes minimal resistance before it breaks.
3	Fair	The part moves through full ROM against gravity and is unable to take any added resistance.
3−	Fair minus	The part moves less than full range of motion against gravity.
2+	Poor plus	The part moves through full ROM in a gravity-eliminated plane, takes minimal resistance, and then breaks.
2	Poor	The part moves through full ROM in a gravity-eliminated plane with no added resistance.
2−	Poor minus	The part moves less than full ROM in a gravity-eliminated plane, no resistance.
1	Trace	Tension is palpated in the muscle or tendon, but no motion occurs at the joint.
0	Zero	No tension is palpated in the muscle or tendon, and no motion occurs.

Procedures for Practice 7-4

Muscle Testing Procedures

1. Explain the procedure and demonstrate the desired movement.
2. Position the patient so that the direction of movement will be against gravity.
3. Stabilize proximal to the joint that will move to prevent substitutions.
4. Instruct the patient to move actively to the end position. If the patient cannot move actively against gravity, place the patient in a gravity-eliminated position, and ask him or her to move actively in this position.
5. If the patient can move actively against gravity, tell the patient to hold the contraction at the end position.
6. Apply resistance:
   - to the distal end of the segment into which the muscle inserts
   - in the direction the movement came from
   - by starting with light resistance and increasing to maximal resistance over a 2- to 3-second period
7. Palpate over the prime mover to determine whether the muscle is contracting or whether gravity and/or synergistic muscles are substituting.
8. Record the appropriate grade according to the resistance tolerated before the muscle broke or by the amount of movement achieved without resistance in an against-gravity or gravity-eliminated position.

which uses MMT set up with the dynamometer directly against the body part being tested to register specific muscle strength when resistance is applied. The majority of the research shows moderate to good reliability and validity with the use of the handheld dynamometer, and the limitations seem to be a lack of standardized testing procedures and the inability of the therapist to resist against the body part being tested (Stark et al., 2011). The joint is placed in a gravity-eliminated position, and the handheld dynamometer is placed perpendicular to the limb segment. The patient is asked to build a maximum contraction against the dynamometer for a 1- to 2-second period and then to hold that contraction against the dynamometer for 4–5 seconds. The recorded measure is the maximum isometric value that was achieved by the patient. This type of measurement is particularly helpful for quantifying antigravity strength, grades 3+ to 5 (Hayes et al., 2002).

Reliability

Reliability is essential for meaningful evaluation. Most important to the reliability of the scores of repeated tests is strict adherence to the exact procedures of testing. In addition, reliability of muscle testing scores is affected by the interest and cooperation of the patient and by the experience and tone of voice of the tester, with higher volume eliciting greater muscle contractions (Johannson, Kent, & Shepard, 1983). The most suitable environment is free of distractions, is at a comfortable temperature, and has proper lighting. Other factors known to affect outcome are posture, fatigue, the patient's ability to understand directions, the therapist's operational definitions of various grades, and test positions (Kendall et al., 2005). For reliability, these variables must be controlled from test to test and among therapists at the same facility. It is necessary for the inexperienced therapist to develop a kinesthetic sense of minimal, moderate, and maximal resistances by working with experienced therapists, each testing the same patient and discussing the grade to be assigned.

MMT is a valid and reliable procedure to measure muscle strength (Herbison et al., 1996; Schwartz et al., 1992). A study of reliability for testing intrinsic hand muscles found the correlation for intrarater reliability to range from 0.71 to 0.96 and from 0.72 to 0.93 for interrater reliability (Brandsma et al., 1995). Florence et al. (1992) performed MMT on patients with Duchenne muscular dystrophy and, using a standard method of testing and the modified Medical Research Council grading scale (Table 7-1), found that reliability for muscle grades 0–5 ranged from 0.80 to 0.99. The most reliable grades were 3 and below, with the least reliable grades being 3+ (0.80), 4− (0.83), and 5− (0.83), those that involve a developed kinesthetic sense of minimal, moderate, and maximal resistance.

Recording Muscle Strength Scores

Muscle strength must be accurately documented in the medical record, identifying muscle tested, grades assigned to the right and left sides, date of testing, and electronic or physical signature of the therapist performing the evaluation. A sample form is presented in Figure 7-69. On that form, the peripheral nerve and spinal segmental levels are listed beside each muscle to assist the therapist in interpreting the results of the muscle test.

On the pages that follow, the reader will find narrative and pictorial descriptions to help in understanding and practicing measurement of UE strength.

Figure 7-69 *(continued)*

PROXIMAL UPPER EXTREMITY MEASUREMENT

Scapular Elevation

Prime Movers

Upper trapezius and levator scapulae.

Against-Gravity Position (Fig. 7-70)

Start Position. Patient sitting erect with arms at side.

Stabilize. Trunk is stabilized against the chair back.

Instruction. "Lift your shoulders toward your ears like you are shrugging. Do not let me push them down."

Resistance. The therapist places his or her hands over each acromion and pushes down toward scapular depression. A normal adult trapezius cannot be broken.

Substitution. It could appear that the patient's shoulders elevated if he or she placed the hands on the legs to push the shoulders into elevation.

Gravity-Eliminated Position (Fig. 7-71)

Start Position. Prone with arms at side and therapist supporting under the shoulder.

Stabilize. The trunk is stabilized against the mat or plinth.

Instruction. "Lift your shoulder toward your ear."

Palpation. The upper trapezius is palpated on the shoulder at the curve of the neck. The levator scapulae is palpated posterior to the sternocleidomastoideus on the lateral side of the neck.

Figure 7-70 Scapular elevation against gravity.
Figure 7-71 Scapular elevation, gravity eliminated.

Scapular Depression

Prime Movers

Lower trapezius and latissimus dorsi.

Resistance Test (Fig. 7-72)

Start Position. This movement is tested in a gravity-eliminated position because the patient cannot be positioned to move against gravity. The patient lies prone with arms by the sides.

Stabilize. The trunk is stabilized by the mat or plinth.

Instruction. "Reach your hand down toward your feet."

Resistance. The therapist's hand cups the inferior angle of the scapula; the therapist pushes up toward scapular elevation. When the inferior angle is not easily accessible because of tissue bulk, apply resistance at the distal humerus if the shoulder joint is stable and pain free.

Palpation. Palpate the lower trapezius lateral to the vertebral column as it passes diagonally from the lower thoracic vertebrae to the spine of the scapula. Palpate the latissimus dorsi along the posterior rib cage or in the posterior axilla as it attaches to the humerus.

Figure 7-72 Scapular depression.

Scapular Adduction: Retraction

Prime Movers

Middle trapezius and rhomboids.

Against-Gravity Position for the Middle Trapezius (Fig. 7-73)

Start Position. Prone on a mat with the shoulder abducted to 90° and the elbow flexed to 90°.

Stabilize. The trunk is stabilized against the mat or plinth. Additional stabilization over the contralateral scapula provides counterpressure during action and resistance.

Instruction. "Raise your elbow toward the ceiling. Do not let me push it down."

Resistance. Apply resistance laterally at the vertebral border of the scapula or, if the shoulder is stable and pain free, downward at the distal humerus.

Palpation. With your hand over the vertebral border of the scapula, feel to determine whether the scapula stays adducted during resistance. Palpate the middle trapezius between the vertebral column and vertebral border of the scapula at the level of the spine of the scapula.

Against-Gravity Position for the Rhomboids (Fig. 7-74)

Start Position. Prone on the mat with the shoulder internally rotated and with the back of the hand resting on the lumbar region.

Stabilize. The trunk is stabilized against the mat or plinth. Additional stabilization over the contralateral scapula will provide counterpressure during action and resistance.

Instruction. "Lift your hand off of your back. Do not let me push it down."

Resistance. Apply downward resistance against the distal humerus or, if the shoulder is unstable or painful, against the vertebral border of the scapula in the direction of scapular abduction.

Palpation. Palpate the rhomboids along the vertebral border of the scapula near the inferior angle. The rhomboids are located deep to the trapezius, and the positioning of the hand in the small of the back allows the trapezius to remain relaxed so the rhomboids can be palpated.

Figure 7-73 Scapular adduction, test for middle trapezius.

Figure 7-74 Scapular adduction, test for rhomboids.

Gravity-Eliminated Position for the Middle Trapezius and Rhomboids (Fig. 7-75)

Start Position. Sitting erect with the humerus abducted to 90° and supported.

Stabilize. The trunk is stabilized by the chair. Note a table or the therapist's arm can be used to support the arm of the individual being tested.

Instruction. "Try to move your arm backward."

Grading. If the scapula moves toward the spine, give a grade of 2. If no movement is noted, palpate the scapular adductors.

Palpation. Same as previously described.

Figure 7-75 Scapular adduction, gravity eliminated. The therapist is pointing to the middle trapezius.

Scapular Abduction: Protraction

Prime Mover

Serratus anterior.

Against-Gravity Position (Fig. 7-76)

Start Position. Supine with the humerus flexed to 90°. The elbow may be flexed or extended.

Stabilize. The trunk is stabilized on the mat or plinth.

Instruction. "Reach your arm toward the ceiling."

Resistance. According to the rule, resistance should be applied along the axillary border of the scapula. Because it is difficult to apply resistance there, therapists often resist this motion either by grasping the distal humerus or by cupping the hand over the patient's elbow and pushing down or back toward scapular adduction. (*Note:* This method is not used if the glenohumeral joint is unstable or painful.)

Gravity-Eliminated Position (Fig. 7-77)

Start Position. Sitting erect with the humerus flexed to 90° and supported.

Stabilize. The trunk is stabilized against the chair.

Instruction. "Try to reach your arm forward."

Grading. Movement of the scapula into abduction receives a grade of 2. If no movement occurs, palpate the serratus anterior.

Palpation. Palpate the serratus anterior on the lateral ribs just lateral to the inferior angle of the scapula.

Substitution. In the gravity-eliminated position, this motion can be achieved by inching the arm forward on a supportive surface using the finger flexors.

Figure 7-76 Scapular abduction against gravity.

Figure 7-77 Scapular abduction, gravity eliminated.

Shoulder Flexion

Prime Movers

Anterior deltoid; coracobrachialis; and pectoralis major, clavicular head; biceps, both heads.

Against-Gravity Position (Fig. 7-78)

Start Position. Sitting in a chair with the arm down at the side in midposition.

Stabilize. Over the clavicle and the scapula.

Instruction. "Lift your arm in front of you to shoulder height. Do not let me push it down."

Resistance. The therapist's hand, placed over the distal end of the humerus, pushes down toward extension. Movement above 90° involves scapular rotation; these motions are separated for muscle testing, although they are not separated for ROM measurement.

Substitutions. Shoulder abductors, scapular elevation, or trunk extension.

Gravity-Eliminated Position (Fig. 7-79)

Start Position. Lying on the side with the arm along the side of the body in midposition; therapist supports the arm under the elbow.

Instruction. "Try to move your arm so your hand is at the level of your shoulder."

Palpation. Palpate the anterior deltoid immediately anterior to the glenohumeral joint. The coracobrachialis may be palpated medially to the tendon of the long head of the biceps, which is palpated on the anterior aspect of the humerus. The clavicular head of the pectoralis major may be palpated below the clavicle on its way to insert on the humerus below the anterior deltoid.

Figure 7-78 Shoulder flexion against gravity.

Figure 7-79 Shoulder flexion, gravity eliminated.

Shoulder Extension

Prime Movers

Latissimus dorsi; teres major; posterior deltoid; and triceps, long head.

Against-Gravity Position (Fig. 7-80)

Start Position. Sitting with the arm by the side and the humerus internally rotated.

Stabilize. Over the clavicle and scapula; make sure the patient remains upright.

Instruction. "Move your arm straight back as far as it will go. Keep your palm facing the back wall."

Resistance. The therapist's hand, placed over the distal end of the humerus, pushes forward toward flexion.

Substitutions. Shoulder abductors, tipping the shoulder forward, bending the trunk forward.

Gravity-Eliminated Position (Fig. 7-81)

Start Position. Lying on the side with the arm along the side of the body and in internal rotation. Therapist supports the elbow during the motion.

Instruction. "Try to move your arm backward."

Palpation. The latissimus dorsi and teres major form the posterior border of the axilla. The latissimus dorsi is inferior to the teres major. The posterior deltoid is immediately posterior to the glenohumeral joint. The triceps are palpated on the posterior aspect of the humerus.

Figure 7-80 Shoulder extension against gravity.

Figure 7-81 Shoulder extension, gravity eliminated.

Shoulder Abduction

Prime Movers

Supraspinatus and middle deltoid.

Against-Gravity Position (Fig. 7-82)

Start Position. Sitting erect with the arm down at the side and in midposition.

Stabilize. Over the clavicle and the scapula.

Instruction. "Raise your arm out to the side to shoulder level. Do not let me push it down."

Resistance. The therapist's hand, placed over the distal end of the humerus, pushes the humerus down toward the body. Movement above 90° involves scapular rotation and is not measured.

Substitutions. The long head of the biceps can substitute if the humerus is allowed to move into external rotation; trunk lateral flexion.

Gravity-Eliminated Position (Fig. 7-83)

Start Position. Supine with the arm supported at the side in midposition. The therapist supports the elbow during the motion.

Instruction. "Try to move your arm out to the side."

Palpation. The supraspinatus lies too deep for easy palpation. Palpate the middle deltoid below the acromion and lateral to the glenohumeral joint.

Figure 7-82 Shoulder abduction against gravity.

Figure 7-83 Shoulder abduction, gravity eliminated.

Shoulder Adduction

Prime Movers

Pectoralis major, teres major, and latissimus dorsi.

Gravity-Eliminated Position (Fig. 7-84)

The patient cannot be positioned for this motion against gravity.

Start Position. Supine with the humerus abducted to 90° and the forearm in midposition.

Stabilize. The trunk is stabilized by the mat.

Instruction. "Bring your arm down to your side, and do not let me pull it away."

Resistance. The therapist's hand, placed on the medial side of the distal end of the humerus, attempts to pull the humerus away from the patient's body.

Palpation. The pectoralis major forms the anterior border of the axilla, where it may be easily palpated. Palpation of the teres major and the latissimus dorsi is described earlier in the chapter.

Grading. Antigravity grades can only be estimated; a question mark should be entered beside the grade on the form. With experience, the therapist develops the skill to estimate reliably.

Substitutions. On a supporting surface, the arm can be inched down using the finger flexors.

Figure 7-84 Shoulder adduction.

Shoulder Horizontal Abduction

Prime Mover

Posterior deltoid.

Against-Gravity Position (Fig. 7-85).

Start Position. Prone with the arm over the edge of the mat. The shoulder is abducted to 90°, and the elbow is flexed to 90°.

Stabilize. The scapula and trunk are stabilized by the mat. Counterpressure over the contralateral scapula is helpful during action and resistance.

Instruction. "Raise your elbow toward the ceiling."

Resistance. The therapist's hand, placed on the posterior surface of the distal end of the humerus, pushes the arm down toward horizontal adduction.

Gravity-Eliminated Position (Fig. 7-86)

Start Position. Sitting in a chair with the humerus supported in 90° of flexion and the elbow straight. The therapist supports the elbow.

Stabilize. The trunk is stabilized against the back of the chair.

Instruction. "Try to move your arm out to the side."

Palpation. Palpate the posterior deltoid immediately posterior to the glenohumeral joint.

Substitution. Trunk rotation.

Figure 7-85 Shoulder horizontal abduction against gravity.

Figure 7-86 Shoulder horizontal abduction, gravity eliminated.

Shoulder Horizontal Adduction

Prime Movers

Pectoralis major and anterior deltoid.

Against-Gravity Position (Fig. 7-87)

Start Position. Supine with the humerus abducted to 90° in neutral rotation and the elbow extended.

Stabilize. The table stabilizes the scapula and trunk. If the elbow extensors are weak, be sure to support the distal end of the forearm so the hand does not fall into the patient's face during horizontal adduction.

Instruction. "Move your arm in front of you and across your chest."

Resistance. The therapist's hand, placed on the anterior surface of the distal end of the humerus, pulls the arm out toward horizontal abduction.

Gravity-Eliminated Position (Fig. 7-88)

Start Position. Sitting in a chair with the arm abducted to 90°.

Stabilize. The trunk is stabilized against the back of the chair. The therapist supports the arm under the elbow.

Instruction. "Try to bring your arm across your chest."

Palpation. Palpate the pectoralis major along the anterior border of the axilla. The anterior deltoid is immediately anterior to the glenohumeral joint below the acromion process and superior to the pectoralis major.

Substitutions. Trunk rotation can substitute. The arm can be inched across a supporting surface using the finger flexors.

Figure 7-87 Shoulder horizontal adduction against gravity.

Figure 7-88 Shoulder horizontal adduction, gravity eliminated.

Shoulder External Rotation

Prime Movers

Infraspinatus, teres minor, and posterior deltoid.

Against-Gravity Position (Fig. 7-89)

Start Position. Prone with the humerus abducted to 90° and supported by the mat. The elbow is flexed to 90° and is hanging over the edge of the table.

Stabilize. The humerus is held just proximal to the elbow to allow only rotation.

Instruction. "Lift the back of your hand toward the ceiling."

Resistance. The therapist's hand, placed on the dorsal surface of the distal end of the forearm, pushes toward the floor. The therapist's other hand keeps the patient's elbow supported and flexed to 90° to prevent supination.

Substitutions. Scapula adduction combined with downward rotation can substitute. The triceps may substitute when resistance is applied.

Gravity-Eliminated Position (Fig. 7-90)

Start Position. Prone with the entire arm hanging over the edge of the mat. The arm is in internal rotation.

Stabilize. The trunk and scapula are stabilized on the mat.

Instruction. "Try to turn your palm outward."

Palpation. Palpate the infraspinatus inferior to the spine of the scapula. Palpate the teres minor between the posterior deltoid and the axillary border of the scapula; it is superior to the teres major. Palpation of the posterior deltoid was described earlier.

Substitution. Supination may be mistaken for external rotation in a gravity-eliminated position.

Figure 7-89 Shoulder external rotation against gravity.

Figure 7-90 Shoulder external rotation, gravity eliminated.

Alternative Gravity-Eliminated Position (Fig. 7-91)

Start Position. Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.

Stabilize. The distal end of the humerus is held against the body to allow only rotation.

Instruction. "Try to move the back of your hand out to the side."

Palpation. Same as previously described.

Figure 7-91 Shoulder external rotation, alternative position with gravity eliminated.

Shoulder Internal Rotation

Prime Movers

Subscapularis, teres major, latissimus dorsi, pectoralis major, and anterior deltoid.

Against-Gravity Position (Fig. 7-92)

Start Position. Prone with the humerus abducted to 90° and supported by the mat. The elbow is flexed to 90° and hangs over the edge of the mat.

Stabilize. The humerus is held just proximal to the elbow to allow only rotation.

Instruction. "Lift the palm of your hand toward the ceiling."

Resistance. The therapist's hand, placed on the volar surface of the distal end of the forearm, pushes toward the floor. The therapist's other hand keeps the patient's elbow supported and flexed to 90° to prevent supination.

Substitutions. Scapular abduction combined with upward rotation can substitute. The triceps can substitute as in external rotation.

Gravity-Eliminated Position (Fig. 7-93)

Start Position. Prone with the entire arm hanging over the edge of the mat. The arm is in external rotation.

Stabilize. The trunk and scapula are stabilized by the mat.

Instruction. "Try to turn your palm inward."

Palpation. The subscapularis is not easily palpated but may be found in the posterior axilla. Palpate the teres major, latissimus dorsi, pectoralis major, and anterior deltoid as previously described.

Substitutions. Scapular abduction combined with upward rotation can substitute. Pronation may be mistaken for internal rotation in a gravity-eliminated position.

Figure 7-92 Shoulder internal rotation against gravity.

Figure 7-93 Shoulder internal rotation, gravity eliminated.

Alternative Gravity-Eliminated Position (Fig. 7-94)

Start Position. Sitting in a chair with the humerus adducted to the side and the elbow flexed to 90°.

Stabilize. The distal end of the humerus is held against the body to allow only rotation.

Instruction. "Try to move the palm of your hand in toward your stomach."

Palpation. Same as previously described.

Figure 7-94 Shoulder internal rotation, alternative position with gravity eliminated.

Elbow Flexion

Prime Movers

Biceps, brachialis, and brachioradialis.

Against-Gravity Position (Fig. 7-95)

Start Position. Sitting in a chair with the arm at the side. The position of the forearm determines which muscle is working primarily: forearm in supination, biceps brachii; forearm in pronation, brachialis; forearm in midposition, brachioradialis.

Stabilize. Stabilize the distal end of the humerus during the action. While applying resistance, provide counter-pressure at the front of the shoulder.

Instruction. While the patient is in each of the three forearm positions, say, "Bend your elbow to touch your shoulder, and do not let me pull it back down."

Resistance. For each of the three positions, the therapist's hand is placed on the distal end of the forearm and pulls out toward extension.

Gravity-Eliminated Position (Fig. 7-96)

Start Position. Sitting with the arm supported by the therapist in 90° of abduction and elbow extension. The position of the forearm determines which muscle is working, as described earlier.

Stabilize. Distal humerus.

Instruction. "Try to move your hand toward your shoulder."

Palpation. The biceps is easily palpated on the anterior surface of the humerus. With the biceps relaxed and the forearm pronated, palpate the brachialis just medial to the distal biceps tendon. With the forearm in midposition, palpate the brachioradialis along the radial side of the proximal forearm.

Substitution. In a gravity-eliminated plane, the wrist flexors may substitute.

Figure 7-95 Elbow flexion against gravity.

Figure 7-96 Elbow flexion, gravity eliminated.

Elbow Extension

Prime Mover

Triceps.

Against-Gravity Position (Fig. 7-97)

Start Position. Prone with humerus abducted to 90° and supported on the table. The elbow is flexed, and the forearm is hanging over the edge of the table.

Stabilize. Support the arm under the anterior surface of the distal humerus.

Instruction. "Straighten your arm, and do not let me push it back down."

Resistance. Apply resistance with the elbow at 10°–15° less than full extension so that the elbow does not lock into position, which may indicate greater strength than the patient actually has. The therapist's hand, placed on the dorsal surface of the patient's forearm, pushes toward flexion.

Gravity-Eliminated Position (Fig. 7-98)

Start Position. Sitting, with the humerus supported by the therapist in 90° of abduction. The elbow is fully flexed.

Stabilize. The humerus is supported and stabilized.

Instruction. "Try to straighten your elbow."

Palpation. The triceps are easily palpated on the posterior surface of the humerus.

Substitutions. In the gravity-eliminated position, no external rotation of the shoulder is permitted, so as to avoid letting the assistance of gravity produce extension. On a supporting surface, finger flexion may be used to inch the forearm across the surface.

Figure 7-97 Elbow extension against gravity.

Figure 7-98 Elbow extension, gravity eliminated.

Pronation

Prime Movers

Pronator teres and pronator quadratus.

Against-Gravity Position (Fig. 7-99)

Start Position. Sitting with the humerus adducted, elbow flexed to 90°, and forearm supinated. The wrist and fingers are relaxed.

Stabilize. The distal humerus is stabilized to keep it adducted to the body.

Instruction. "Turn your palm to the floor, and do not let me turn it back over."

Resistance. The therapist's hand encircles the patient's volar wrist with the therapist's index finger extended along the forearm. The therapist applies resistance in the direction of supination.

Substitutions. Shoulder abduction or wrist and finger flexion may substitute.

Gravity-Eliminated Position (Fig. 7-100)

Start Position. Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90°, and the forearm is in full supination. The wrist and fingers are relaxed.

Stabilize. The humerus is stabilized.

Instruction. "Try to turn your palm away from your face."

Palpation. The pronator teres is palpated medial to the distal attachment of the biceps tendon on the volar surface of the proximal forearm. Pronator quadratus is too deep to palpate.

Figure 7-99 Pronation against gravity.

Figure 7-100 Pronation, gravity eliminated.

Supination

Prime Movers

Supinator and biceps.

Against-Gravity Position (Fig. 7-101)

Start Position. Sitting, with the humerus adducted, elbow flexed to 90°, and forearm pronated. The wrist and fingers are relaxed. To differentiate the supinator from the supination function of the biceps, isolate the supinator by extending the elbow. The biceps does not supinate the extended arm unless resisted (Kendall et al., 2005).

Stabilize. The distal humerus is stabilized.

Instruction. "Turn your palm up toward the ceiling, and do not let me turn it back over."

Resistance. Same as for pronation except that resistance is in the direction of pronation.

Substitutions. The wrist and finger extensors may substitute.

Gravity-Eliminated Position (Fig. 7-102)

Start Position. Sitting with the humerus flexed to 90° and supported. The elbow is flexed to 90°, and the forearm is in full pronation. The wrist and fingers are relaxed.

Stabilize. The humerus is stabilized and supported.

Instruction. "Try to turn your palm toward your face."

Palpation. The supinator is palpated on the dorsal surface of the proximal forearm just distal to the head of the radius. Palpation of the biceps was described earlier.

Figure 7-101 Supination against gravity.

Figure 7-102 Supination, gravity eliminated.

WRIST AND HAND MEASUREMENT

Because many tendons of the wrist and hand cross more than one joint, test positions for individual muscles must include ways to minimize the effect of other muscles crossing the joint. As a general rule, to minimize the effect of a muscle, place it opposite the prime action. For example, to minimize the effect of the extensor pollicis longus (EPL) on extension of the proximal joint of the thumb, flex the distal joint.

Wrist Extension

Prime Movers

Extensor carpi radialis longus (ECRL), extensor carpi radialis brevis (ECRB), and extensor carpi ulnaris (ECU).

Against-Gravity Position (Figs. 7-103 and 7-104)

Start Position. The forearm is supported on a table in full pronation with fingers and thumb relaxed or slightly flexed.

Stabilize. The forearm is stabilized on the table.

Instruction. "Lift your wrist as far as you can, and do not let me push it down."

Resistance. To test the ECRL, which extends and radially deviates, apply resistance to the dorsum of the hand on the radial side in the direction of flexion and ulnar deviation (Fig. 7-103). To test the ECRB, apply resistance on the dorsum of the hand and push into flexion. To test the ECU, which extends and ulnarly deviates, apply resistance to the dorsum of the hand on the ulnar side and push in the direction of flexion and radial deviation (Fig. 7-104).

Substitutions. EPL and extensor digitorum (ED).

Gravity-Eliminated Position

Start Position. The forearm is supported on the table in midposition with the wrist in a slightly flexed position.

Instruction. "Try to bend your wrist backward."

Palpation. Palpate the tendon of the ECRL on the dorsal surface of the wrist at the base of the second metacarpal. The muscle belly is on the dorsal proximal forearm adjacent to the brachioradialis. Palpate the tendon of the ECRB on the dorsal surface of the wrist at the base of the third metacarpal adjacent to the ECRL. The muscle belly of the ECRB is distal to the belly of the ECRL on the dorsal surface of the proximal forearm. Palpate the ECU on the dorsal surface of the wrist between the head of the ulna and the base of the fifth metacarpal. The muscle belly is approximately 2 inches distal to the lateral epicondyle of the humerus (Rybski, 2004).

Figure 7-103 Wrist extension. Resistance is being given to the extensor carpi radialis.

Figure 7-104 Wrist extension. Resistance is being given to the extensor carpi ulnaris.

Wrist Flexion

Prime Movers

Flexor carpi radialis (FCR), palmaris longus, and flexor carpi ulnaris (FCU).

Against-Gravity Position (Figs. 7-105 and 7-106)

Start Position. The forearm is supinated, the wrist is extended, and the fingers and thumb are relaxed.

Stabilize. The forearm is stabilized on the table with the back of the hand raised off the table to allow the wrist to go into slight extension.

Instruction. "Bend your wrist all the way forward, and do not let me push it back."

Resistance. To test the FCR and palmaris longus, the therapist applies resistance over the heads of the metacarpals on the volar surface of the hand toward extension. To test for the FCU, the therapist applies resistance over the head of the fifth metacarpal on the volar surface of the hand toward wrist extension and radial deviation.

Substitutions. Abductor pollicis longus, flexor pollicis longus, flexor digitorum superficialis (FDS), and flexor digitorum profundus (FDP).

Gravity-Eliminated Position

Start Position. Forearm in midposition, wrist extended, and fingers and thumb relaxed.

Figure 7-106 Wrist flexion. The therapist is resisting the flexor capri ulnaris.

Stabilize. The forearm rests on the table.

Instruction. "Try to bend your wrist forward."

Palpation. Palpate the FCR (Figure 7-105) on the volar surface of the wrist in line with the second metacarpal and radial to the palmaris longus (if present). Palpate the FCU (Figure 7-106) on the volar surface of the wrist just proximal to the pisiform bone. The palmaris longus is a weak wrist flexor. The tendon crosses the center of the volar surface of the wrist (Figure 7-107). It is not tested for strength and may not even be present; if it is present, it will stand out prominently in the middle of the wrist when wrist flexion is resisted or the palm is cupped with the thumb and fifth digit opposed to one another.

Figure 7-105 Wrist flexion. The therapist is pointing to the flexor carpi radialis longus tendon as she gives resistance.

Figure 7-107 The therapist is pointing to the tendon of the palmaris longus as the patient cups her hand in an effort to make his tendon stand out.

Finger Metacarpophalangeal Extension

Prime Movers

ED, extensor indicis proprius, and extensor digiti minimi.

Against-Gravity Position (Fig. 7-108)

Start Position. The forearm is pronated and supported on the table. The wrist is supported in neutral position, and the finger MP and IP joints are in a relaxed flexed posture.

Stabilize. Wrist and metacarpals.

Instruction. "Lift this knuckle straight as far as it will go [touch the finger that is to be tested]. Keep the rest of your fingers bent. Do not let me push your knuckle down." (*Note:* Be sure to demonstrate this action.)

Resistance. Using one finger, the therapist pushes the head of each proximal phalanx toward flexion, one at a time.

Substitution. Apparent extension of the fingers can result from the rebound effect of relaxation following finger flexion. Flexion of the wrist can cause finger extension through tenodesis action.

Gravity-Eliminated Position

Start Position. Forearm supported in midposition, wrist in neutral position, and fingers flexed.

Stabilize. Wrist and metacarpals.

Instruction. "Try to move your knuckles back as far as they will go, one at a time. Keep the rest of your fingers bent."

Palpation. Palpate the muscle belly of the ED on the dorsal–ulnar surface of the proximal forearm. Often the separate muscle bellies are discernible. The tendons of this muscle are readily seen and palpated on the dorsum of the hand. The extensor indicis proprius tendon is ulnar to the ED tendon. Palpate the belly of this muscle on the mid- to distal dorsal forearm between the radius and ulna. Palpate the extensor digiti minimi tendon ulnar to the ED. Actually, it is the tendon that looks as if it were the ED tendon to the little finger because the ED to the little finger is only a slip from the ED tendon to the ring finger.

Figure 7-108 Finger metacarpophalangeal extension. The tendons of the extensor digitorum can be seen on the back of the patient's hand.

Finger Interphalangeal Extension

Prime Movers

Lumbricals, interossei, ED, extensor indicis proprius, and extensor digiti minimi.

According to electromyographic evidence, the intrinsics, especially the lumbricals, are the primary extensors of the IP joints (Long, 1968; Long & Brown, 1962). Except for the lumbricals and interossei, the other muscles have been discussed. The interossei are discussed under their alternative action of finger abduction and adduction. The lumbricals, arising as they do from the flexor profundus and inserting on the ED, have a unique action in regard to finger extension. Contracting against the noncontracting flexor profundus, the lumbricals pull the tendons of the profundus toward the fingertips. This slackens the profundus tendons distal to the insertion of the lumbricals, allowing the ED to extend the IP joints fully, regardless of the position of the MP joints (Long, 1968). The interossei flex the MP joints while extending the IP joints and, in fact, operate to extend only when the MP joints are flexed or flexing (Long, 1968).

Against-Gravity Position for the Lumbricals

There is no reliable test for lumbrical function. Test 1 is traditional. Test 2 is suggested in accordance with electromyographic evidence.

Start Position. The forearm is supinated and supported. The wrist is in neutral position. Test 1: MPs are extended with the IPs flexed. Test 2: MPs are flexed with the IPs extended.

Stabilize. Metacarpals and wrist.

Instruction. Test 1: "Bend your knuckles and straighten your fingers at the same time." (*Note:* Be sure to demonstrate this movement.) Test 2: "Straighten your knuckles and keep your fingers straight at the same time."

Resistance. Test 1: The therapist holds the tip of the finger being tested and pushes it toward the starting position. Test 2: The therapist places one finger on the patient's fingernail and pushes toward flexion (Fig. 7-109).

Substitution. Nothing substitutes for DIP extension in the event of the loss of lumbrical function when the MP joint is extended. Other muscles of the dorsal expansion can substitute for DIP extension when the MP joint is flexed.

Palpation. Lumbrical muscles lie too deep to be palpated.

Figure 7-109 Finger interphalangeal extension. Resistance is given to the lumbricals as described for test 2.

Finger Distal Interphalangeal Flexion

Prime Mover

FDP.

Against-Gravity Position (Fig. 7-110)

Start Position. Forearm supinated and supported on a table; wrist and IP joints relaxed.

Stabilize. Firmly support the middle phalanx of each finger as it is tested to prevent flexion of the proximal IP joint; the wrist should remain in neutral position.

Figure 7-110 Finger distal interphalangeal flexion. The other joints of the finger are prevented from flexing.

Instruction. "Bend the last joint on your finger as far as you can."

Resistance. The therapist places one finger on the pad of the patient's finger and applies resistance toward extension.

Substitutions. Rebound effect of apparent flexion following contraction of extensors. Wrist extension causes tenodesis action.

Gravity-Eliminated Position

Start Position. The forearm is in midposition, resting on the ulnar border on a table. The wrist and IP joints are relaxed in neutral position.

Stabilize. Same as previously described.

Instruction. Same as previously described.

Palpation. Palpate the belly of the FDP just volar to the ulna in the proximal third of the forearm. The tendons are sometimes palpable on the volar surface of the middle phalanges.

Finger Proximal Interphalangeal Flexion

Prime Movers

FDS and FDP.

Against-Gravity Position for the Flexor Digitorum Superficialis (Fig. 7-111)

Start Position. Forearm supinated and supported on the table; wrist and MP joints relaxed and in zero position. To rule out the influence of the FDP when testing the FDS, hold all IP joints of the fingers not being tested in full extension to slight hyperextension. Because the FDP is essentially one muscle with four tendons, preventing its action in three of the four fingers prevents it from working in the tested finger. In fact, the patient cannot flex the distal joint of the tested finger at all. In some people, the FDP slip to the index finger is such that this method cannot rule out its influence on the PIP joint of the index finger. This should be noted on the test form.

Stabilize. All IP joints of the other digits of the hand.

Instruction. Point to the PIP joint and say, "Bend just this joint."

Resistance. Using one finger, the therapist applies resistance to the head of the middle phalanx toward extension.

Substitutions. FDP. Wrist extension causes tenodesis action.

Gravity-Eliminated Position

Start Position. Forearm supported in midposition, with the wrist and MP joints relaxed in neutral position. Again, rule out the influence of the FDP by holding all the joints of the untested fingers in extension.

Stabilize. Proximal phalanx of the finger being tested as well as all IP joints of the other digits of the hand.

Figure 7-111 Finger proximal interphalangeal flexion. The flexor profundus is prevented from substituting because the therapist is holding in extension all fingers not being tested.

Instruction. Point to the PIP joint and say, "Try to bend just this joint."

Palpation. Palpate the FDS on the volar surface of the proximal forearm toward the ulnar side. Palpate the tendons at the wrist between the palmaris longus and the FCU.

Finger Metacarpophalangeal Flexion

Prime Movers

FDP, FDS, dorsal interossei (DI), volar (palmar) interossei, and flexor digiti minimi.

The tests for the first four muscles are discussed under their alternative actions. The flexor of the little finger has no other action and is described here.

Against-Gravity Position for the Flexor Digiti Minimi (Fig. 7-112)

Start Position. Forearm supported in supination.

Figure 7-112 Flexor digiti minimi. The therapist is pointing to the muscle belly.

Stabilize. Other fingers in extension.

Instruction. "Bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight."

Resistance. Using one finger, the therapist pushes the head of the proximal phalanx toward extension. The therapist must be sure the IP joints remain extended.

Substitutions. The FDP, FDS, or third volar interosseus may substitute.

Gravity-Eliminated Position

Start Position. Forearm supported in midposition.

Stabilize. Other fingers in extension.

Instruction. "Try to bend the knuckle of your little finger toward your palm while you keep the rest of the finger straight."

Palpation. The flexor digiti minimi is found on the volar surface of the hypothenar eminence.

Finger Abduction

Prime Movers

DI (4) and abductor digiti minimi.

Gravity-Eliminated Position (Fig. 7-113)

Start Position. The pronated forearm is supported with the wrist neutral. The fingers are extended and adducted. Be sure the MP joints are in neutral or slight flexion.

Stabilize. The wrist and metacarpals are gently supported.

Instruction. "Spread your fingers apart, and do not let me push them back together."

Action. Because the midline of the hand is the third finger and abduction is movement away from midline, the action of each finger is different. It is important to know which

Figure 7-113 Finger abduction.

DI you are testing. The first DI abducts the index finger toward the thumb. The second DI abducts the middle finger toward the thumb. The third DI abducts the middle finger toward the little finger. The fourth DI abducts the ring finger toward the little finger. The abductor digiti minimi abducts the little finger ulnarly.

Resistance. Using the thumb and index finger to form a pincer, the therapist applies resistance at the radial or ulnar side of the head of the proximal phalanx in an attempt to push the finger toward midline. Applying resistance to the radial side of the heads of the index and middle fingers tests the first and second DI. Applying resistance to the ulnar side of the middle, ring, and little fingers tests the third and fourth DI and the abductor digiti minimi.

Substitutions. ED.

Grading. Normal finger abductors do not tolerate much resistance. If the fingers give way to resistance but spring back when the resistance is removed, the grade is 5. The grade is 4 if the muscle takes some resistance. The grade is 3 when there is full AROM. The grade is 2 if there is partial AROM. The grade is 1 when contraction is felt with palpation. The grade is 0 when no contractile activity is palpable.

Palpation. The first DI fills the dorsal web space and is easy to palpate there. Palpate the abductor digiti minimi on the ulnar border of the fifth metacarpal. The other interossei lie between the metacarpals on the dorsal aspect of the hand, where they may be palpated; on some people, the tendons can be palpated as they enter the dorsal expansion near the heads of the metacarpals. When the DI are atrophied, the spaces between the metacarpals on the dorsal surface appear sunken.

Finger Adduction

Prime Movers

Volar (palmar) interossei (3).

Gravity-Eliminated Position (Fig. 7-114)

Start Position. The forearm is pronated, and the MPs are abducted and in extension.

Stabilize. Both of the therapist's hands are needed for resistance. The forearm and wrist can be supported on a table.

Instruction. "Bring your fingers together and hold them. Do not let me pull them apart."

Figure 7-114 Finger adduction.

Action. Because the midline of the hand is the third finger and adduction is movement toward midline, the action of each finger is different. The first palmar interosseus (PI) adducts the index finger toward the middle finger. The second adducts the ring finger toward the middle finger, and the third adducts the little finger toward the middle finger.

Resistance. The therapist holds the heads of the proximal phalanx of two adjoining fingers and applies resistance in the direction of abduction to pull the fingers apart. For the index and middle finger pair, the first PI is tested. For the middle and ring finger pair, the second PI is tested. For the ring and little finger pair, the third PI is tested.

Substitutions. Extrinsic finger flexors.

Grading. Same as with the finger abductors.

Palpation. The PI are usually too deep to palpate with certainty. When these muscles are atrophied, the areas between the metacarpals on the volar surface appear sunken.

Thumb Interphalangeal Extension

Prime Mover

EPL.

Against-Gravity Position (Fig. 7-115)

Start Position. Forearm supported in midposition, wrist flexion of 10°–20°, and thumb MP and IP flexion.

Instruction. "Straighten the end of your thumb."

Figure 7-115 The therapist is resisting the extensor pollicis longus, whose tendon is prominent.

Stabilize. Proximal phalanx into MP flexion.

Resistance. The therapist places one finger over the dorsum of the distal phalanx (thumbnail) and pushes only the DIP toward flexion.

Substitutions. Relaxation of the flexor pollicis longus produces apparent extensor movement as a result of rebound effect. Because the abductor pollicis brevis, adductor pollicis, and flexor pollicis brevis insert into the lateral aspects of the dorsal expansion, they may produce thumb IP extension when the EPL is paralyzed. To prevent this, the position of maximal flexion of CMC and MP joints, wrist flexion of 10°–20°, and full forearm supination are used to put these synergists in a shortened, disadvantaged position while testing the EPL (Howell et al., 1989).

Gravity-Eliminated Position

Start Position. Forearm supinated, thumb flexed.

Instruction. "Try to straighten the end of your thumb."

Palpation. The tendon of the EPL may be palpated on the ulnar border of the anatomical snuffbox and on the dorsal surface of the proximal phalanx of the thumb.

Thumb Metacarpophalangeal Extension

Prime Movers

Extensor pollicis brevis (EPB) and EPL.

Against-Gravity Position for the Extensor Pollicis Brevis (Fig. 7-116)

Start Position. Forearm supported in midposition, MP and IP joints flexed.

Figure 7-116 The therapist is resisting the extensor pollicis brevis, whose tendon can be seen.

Stabilize. Firmly support the first metacarpal in abduction.

Instruction. "Straighten the knuckle of your thumb while keeping the end joint bent." (*Note:* You may have to move the thumb passively a few times for the patient to get the kinesthetic input regarding the movement.)

Resistance. The therapist's index finger, placed on the dorsal surface of the head of the proximal phalanx, pushes toward flexion.

Substitution. EPL.

Gravity-Eliminated Position

Start Position. Forearm supinated, MP and IP joints flexed.

Stabilize. First metacarpal in abduction.

Instruction. "Try to straighten the knuckle of your thumb while keeping the end joint bent."

Palpation. Palpate the tendon of the EPB on the radial border of the anatomical snuffbox medial to the tendon of the abductor pollicis longus. The EPB may not be present.

Thumb Abduction

Prime Movers

Abductor pollicis longus and abductor pollicis brevis.

Against-Gravity Position for the Abductor Pollicis Longus (Fig. 7-117)

Start Position. Forearm supinated, wrist in neutral position, thumb adducted.

Stabilize. Support the wrist on the ulnar side and hold it in neutral position.

Instruction. "Bring your thumb away from your palm. Do not let me push it back in."

Action. Patient abducts the thumb halfway between thumb extension and palmar abduction. The therapist may have to demonstrate this action while giving the instructions.

Resistance. The therapist's finger presses the head of the first metacarpal toward adduction.

Substitutions. Abductor pollicis brevis and EPB.

Gravity-Eliminated Position

Start Position. Forearm in midposition, wrist in neutral position, thumb adducted.

Stabilize. Support the wrist on the ulnar side and hold it in neutral position.

Instruction. "Try to bring your thumb away from your palm."

Palpation. Palpate the tendon of the abductor pollicis longus at the wrist joint just distal to the radial styloid and lateral to the EPB.

Against-Gravity Position for the Abductor Pollicis Brevis (Fig. 7-118)

Start Position. Forearm is supported in supination, wrist in neutral position, and thumb adducted.

Stabilize. Support the wrist in neutral position by holding it on the dorsal and ulnar side.

Instruction. "Lift your thumb directly out of the palm of the hand. Do not let me push it back in."

Resistance. The therapist's finger presses the head of the first metacarpal toward adduction.

Substitution. Abductor pollicis longus.

Gravity-Eliminated Position

Start Position. Forearm is supported in midposition, wrist in neutral position, thumb adducted.

Stabilize. Support the wrist in neutral position by holding it on the dorsal and ulnar side.

Instruction. "Try to move your thumb away from the palm of your hand."

Palpation. Palpate the abductor pollicis brevis over the center of the thenar eminence.

Figure 7-117 The therapist is resisting the abductor pollicis longus, which moves the thumb away from the palm halfway between extension and palmar abduction.

Figure 7-118 The therapist is resisting the abductor pollicis brevis, which moves the thumb directly up from the palm of the hand (palmar abduction).

Thumb Interphalangeal Flexion

Prime Mover

Flexor pollicis longus.

Against-Gravity Position (Fig. 7-119)

Start Position. Elbow flexed and supported on a table. Forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb extended at the MP and IP joints.

Figure 7-119 The therapist is resisting the flexor pollicis longus.

Stabilize. Proximal phalanx, holding MP joint in extension.

Instruction. "Bend the tip of your thumb as far as you can, and do not let me straighten it."

Resistance. The therapist's finger pushes the head of the distal phalanx toward extension.

Substitution. Relaxation of the EPL causes apparent rebound movement.

Gravity-Eliminated Position

Start Position. Forearm supinated to 90° so that the thumb can flex across the palm.

Stabilize. Proximal phalanx, holding MP joint in extension.

Instruction. "Try to bend the tip of your thumb as far as you can."

Palpation. Palpate the flexor pollicis longus on the palmar surface of the proximal phalanx.

Thumb Metacarpophalangeal Flexion

Prime Movers

Flexor pollicis brevis and flexor pollicis longus.

Against-Gravity Position for the Flexor Pollicis Brevis (Fig. 7-120)

Start Position. Elbow flexed and supported on the table. Forearm supinated so that the palmar surface of the thumb faces the ceiling; thumb is extended at both the MP and IP joints.

Figure 7-120 The therapist is resisting the flexor pollicis brevis.

Stabilize. Firmly support the first metacarpal.

Instruction. "Bend your thumb across your palm, keeping the end joint of your thumb straight. Do not let me pull it back out."

Resistance. The therapist's finger pushes the head of the proximal phalanx toward extension.

Substitution. Flexor pollicis longus; the abductor pollicis brevis and the adductor pollicis through insertion into the extensor hood. To rule out the effect of the flexor pollicis longus when testing the flexor pollicis brevis, a test position of maximal elbow flexion, maximal pronation, and maximal wrist flexion has been recommended (Howell et al., 1989).

Gravity-Eliminated Position

Start Position. Forearm supinated to 90° so that the thumb can flex across the palm.

Stabilize. First metacarpal.

Instruction. "Try to bend your thumb into your palm, keeping the end joint of your thumb straight."

Palpation. Palpate the flexor pollicis brevis on the thenar eminence just proximal to the MP joint and medial to the abductor pollicis brevis.

Thumb Adduction

Prime Mover

Adductor pollicis.

Against-Gravity Position (Fig. 7-121)

Start Position. Forearm pronated, wrist and fingers in neutral position, thumb abducted, and MP and IP joints of the thumb in extension.

Figure 7-121 The therapist is resisting the adductor pollicis.

Stabilize. Metacarpals of fingers, keeping the MP joints in neutral.

Instruction. "Lift your thumb into the palm of your hand, and do not let me pull it out."

Resistance. The therapist grasps the head of the proximal phalanx and tries to pull it away from the palm toward abduction.

Substitutions. The EPL, flexor pollicis longus, or flexor pollicis brevis may substitute.

Gravity-Eliminated Position

Start Position. Same except forearm is in midposition.

Stabilize. Metacarpals of fingers, keeping the MP joints in neutral.

Instruction. "Try to bring your thumb into the palm of your hand."

Palpation. Palpate the adductor pollicis on the palmar surface of the thumb web space.

Opposition

Prime Movers

Opponens pollicis and opponens digiti minimi.

Against-Gravity Position (Fig. 7-122)

Start Position. Forearm supinated and supported, wrist in neutral position, thumb adducted and extended.

Stabilize. Hold the wrist in a neutral position.

Instruction. "Touch the pad of your thumb to the pad of your little finger. Do not let me pull them apart."

Resistance. The therapist holds along the first metacarpal and derotates the thumb or holds along the fifth metacarpal and derotates the little finger. These can be resisted simultaneously using both hands.

Substitutions. The abductor pollicis brevis, flexor pollicis brevis, or flexor pollicis longus may substitute.

Gravity-Eliminated Position

Start Position. Elbow resting on the table with forearm perpendicular to the table, wrist in neutral position, thumb adducted and extended.

Stabilize. Hold the wrist in a neutral position.

Instruction. "Try to touch the pad of your thumb to the pad of your little finger."

Palpation. Place fingertips along the lateral side of the shaft of the first metacarpal where the opponens pollicis may be palpated before it becomes deep to the abductor

Figure 7-122 The therapist is resisting both the opponens pollicis and the opponens digiti minimi.

pollicis brevis. The opponens digiti minimi can be palpated volarly along the shaft of the fifth metacarpal.

Interpreting the Muscle Test

After recording all muscle test scores, the therapist reviews the scores and looks for the weak muscles and the distribution and significance of the weakness. Any muscle that grades "good minus" (4−) or below is considered weak. "Good plus" (4+) muscles are functional and usually require no therapy. "Good" (4) muscles may or may not be functionally adequate for the patient, depending on his or her occupational task requirements. The pattern of muscle weakness is important. The pattern may indicate general weakness caused by disuse secondary to immobilization, or it may reflect the level of spinal innervation in a patient after spinal cord injury or the distribution of a peripheral nerve in the case of peripheral nerve injury. A pattern of imbalance of forces in agonist and antagonist muscles may be deforming; therefore, counterpositioning or splinting should be considered along with strengthening of the weak muscles.

The pattern of significant strength is also important. For example, a muscle test of a patient with an injured spinal cord that indicates some strength in a muscle innervated by a segment below the diagnosed level of injury is hopeful for more recovery. Or, because muscles are reinnervated proximally to distally after peripheral nerve injury, findings showing beginning return of strength in particular muscles help to track the progress of nerve regeneration.

Short-term goals move the patient from the level of strength determined by testing to the next higher level. For example, if a muscle grades 3, the short-term goal is to improve strength to 3+; if it grades 3+, the goal is to increase strength to 4−, and so on. However, the goal should not purely reflect the numerical increase in the muscle strength. Improved strength should instead be reflected in some sort of functional task. For example, the short-term goal may state, "The patient will demonstrate an increase in left elbow muscle strength to 3+, as needed for independent hygiene tasks of brushing the teeth and washing the face." The required strength for occupational functioning must always be kept in mind when establishing goals.

If the muscle is being reevaluated, the scores are compared with those of the previous test. The frequency of reevaluation depends on the nature of expected recovery. Expected rapid recovery requires frequent reevaluation. For example in a young, healthy individual recovering from a fracture that has been cleared by the surgeon to begin strengthening, it may be appropriate to reevaluate every 2 weeks until full strength is returned. However, in an individual recovering from a peripheral nerve injury when nerve healing is slow and expected to only

heal 1 inch every month, it may be more appropriate to wait 4 weeks between reevaluations. If significant gains are noted in therapy and the patient would benefit from a change in the treatment plan, then a reevaluation should be completed to document these gains and the change in treatment plan. If the repeated muscle test shows that the patient is making gains, the program is considered beneficial, and its demands are upgraded. If repeated muscle tests show no gains despite program adaptations, the patient is considered to have reached a plateau and to no longer benefit from remedial therapy. In that case, the focus of treatment shifts to teaching the patient compensatory strategies and the use of adaptive equipment to enable participation in desired tasks and activities.

There are, of course, exceptions to these standards. Patients with degenerative diseases are expected to get weaker; therefore, therapy is aimed at maintaining their strength and function for as long as possible, and efficacy is confirmed with repeat tests. A plateau for these patients is desirable; it indicates that the therapy is effective for maintaining strength and should be continued. Documentation of how this maintenance of strength impacts independence in ADL and IADL tasks should also be used to justify continued services. These patients often benefit from rehabilitation to maintain their current level of independence as well as compensatory techniques in order to conserve energy and maintain independence. For example, an individual may have the functional strength needed in order to shower standing and use basic techniques for all required steps including squeezing the shampoo bottle, lathering the body, bending and reaching to clean all body parts, and rotating in the shower to rinse. However, the person may be so tired following this routine that he or she does not have the energy to cook a meal or engage in a favorite hobby. In this case, activity analysis would aid in determining compensation techniques and equipment to conserve energy so the individual can both shower and have enough energy to also engage in additional ADL and IADL tasks. The individual may benefit from a shower bench, long-handled sponge, removable shower head, and pump bottles to aid in completing this task with modified independence.

GRASP AND PINCH STRENGTH MEASUREMENT

More specific measurements beyond MMT grading can demonstrate more discrete changes in grip and pinch strength. In a review of 42 studies of hand-grip strength, the methods, equipment, and metrics were evaluated to determine standardization of procedures (Roberts et al., 2011). Normative data for both grip and pinch strength has long been established (Mathiowetz et al., 1985). Abbreviated versions of the norms are listed in Tables 7-2 and 7-3. When individual scores are outside of these established norms, an individual with unilateral injury may also be compared to him- or herself by using the 10% rule. In right-handed individuals, the dominant side is typically 10% stronger than the nondominant side, although left-handed individuals typically demonstrate equal strength bilaterally (Roberts et al., 2011).

Definitions of handedness vary widely in the literature. In a literature review on how handedness impacts grip strength, the difference between a definitive preference for the right versus left hand and degree of preference are discussed (Clerke & Clerke, 2001). In a discussion with a client, the individual may state that he or she writes with the left hand but completes most sports and

household tasks with the right hand. This individual may demonstrate better scores on dexterity testing on the left, while demonstrating higher grip scores on the right. Clerke and Clerke (2001) suggest that more research be done regarding the effect of handedness with greater specificity of how handedness is defined. The literature they reviewed included variations in grip strength up to 40% between an individual's hands (Clerke & Clerke, 2001). The therapist should consider each person's unique situation when evaluating this area. A mechanic may appear to have good return of strength following a carpal tunnel release but continue to complain of difficulty with work tasks compared preoperatively. Further activity analysis of his or her work tasks and occupation-based treatment and goals should be the focus rather than purely a numerical goal.

Grip-strength norms were originally established using the Jamar dynamometer, which is most commonly used in research. However, interinstrument reliability, or the ability of multiple instruments to be used interchangeably, has been established between devices with various levels of confidence (see Table 7-4 for a listing of instruments used to measure grip strength). Although these instruments can be used with various levels of confidence against the norms,

Table 7-4 **Dynamometer Equipment: Dynamometer Interinstrument Reliability Compared to the Jamar Dynamometer**

Excellent	Moderate to Excellent	Low	Unclear

From Roberts, H. C., Denison, H. J., Martin, H. J., Patel, H. P., Syddall, H., Cooper, C., & Sayer, A. A. (2011). A review of the measurement of grip strength in clinical and epidemiological studies: Towards a standardised approach. *Age and Ageing*, 40, 423–429.

the selected instrument still must be calibrated every 4–12 months. It is recommended to use the same instrument at the same time of day using a standard protocol and instructions for body and instrument position when evaluating and reevaluating individual patients. In the use of the Jamar dynamometer, there are five grooves along the handle used to select the grip position. The second grip position from the gauge is the standard position used, although hand size and nail length may impact which position allows for maximum grip strength. It was also recommended that a change in score of at least 6 kg or 13 pounds is needed to be clinically significant (Roberts et al., 2011).

The pinch norms can be used with the B & L, JTech, and NK pinch meters because they have been found to be interchangeably reliable: for symptomatic subjects ($r > 0.90$) and for nonsymptomatic subjects ($r = 0.80$) (MacDermid, Evenhuis, & Louzon, 2001).

As with any tool of measurement, the instrument must be calibrated and set at 0 to start. Dynamometers and pinch meters can be calibrated by placing known weights on or suspending them from the compression part of the meter (Fess, 1987). With this procedure, the Jamar dynamometer was found to be accurate to within 7% (Shechtman, Gestewitz, & Kimble, 2005), and the B & L pinch meter was found to be accurate within 1% (Mathiowetz, Vizenor, & Melander, 2000).

The standard method of measurement used in the study from which the norms were established reflects the recommendations of the American Society of Hand Therapists (ASHT) (Fess, 1992). Test–retest reliability of this method using the Jamar hydraulic dynamometer was found to be 0.88; interrater reliability (two raters, same time) was 0.99. Interrater (two raters, same time) reliability of averaged B & L pinch meter scores was 0.98, and test–retest reliability was 0.81 (Mathiowetz et al., 1984).

A vigorimeter cannot be used interchangeably with a dynamometer. However, it is an acceptable alternative hand strength–measuring device for patients whose diagnoses contraindicate stress on joints and/or skin, because it requires the patient to squeeze a rubber bulb rather than a steel handle. The vigorimeter is a commercially available instrument for which norms have been published (Fike & Rousseau, 1982; Roberts et al., 2011).

Fong and Ng (2001) studied the effect of wrist position on grip strength in a normal population. Their review of the literature on this topic revealed many conflicting findings. However, the methods in many of these studies were highly varied as well. They followed the basic ASHT recommendations for test position but deviated by using a testing board to secure the wrist in the position they were testing and then rested this board on a table. They found the highest grip scores with the wrist in 15° or 30° of extension with no radial or ulnar deviation and did find significant differences in scores when the wrist was positioned in 15° of ulnar deviation. They did not test for positions with less ulnar deviation, and further research is needed in this area, as well as with populations with UE conditions (Fong & Ng, 2001).

With occupational therapy practice moving into the community and home, the need for valid tools that are quick, portable, and easy to use is increasing. Grip strength has been studied as a method to evaluate overall strength and function. Various studies have revealed a range of correlation, with moderate correlation in individuals under the age 55 years. In a study of women over age 75 years, standardized grip-strength measurements were compared with computerized strength measurements using an isokinetic dynamometer and functional evaluations including the Barthel Index (BI) self-report of ADL function and the Timed Get-Up-and-Go Test (TUG) (Tietjen-Smith et al., 2006). Limitations of the study included that it was conducted in a busy assisted-living facility with high traffic and a lack of isolated, quiet areas for testing as well as their very specific patient population. Moderate correlation was found between grip and overall strength ($r = 0.583$). However, the authors caution against using grip alone to determine function because the grip measurements did not correlate with the BI. Although strength is important for completing ADL tasks, it is important to remember with this aging population that many other factors impact their independence (Tietjen-Smith et al., 2006).

Grasp

The patient should be seated in a chair without arms with his or her shoulder adducted and neutrally rotated, the elbow flexed at 90°, the forearm neutral and wrist between 0° and 30° of extension and up to 15° of ulnar deviation. Feet should be flat on the floor (Fess, 1992; Lindstrom-Hazel, Krat, & Bix, 2009). The handle of the dynamometer is set at the second position. The task is demonstrated to the patient. After the dynamometer is positioned in the patient's hand, the therapist says, "Ready? Squeeze as hard as you can," and urges the patient on throughout the attempt saying "Harder! . . . Harder! . . . Relax" (Mathiowetz et al., 1985). The patient squeezes the dynamometer with as much force as he or she can three times, with a 1-minute rest between trials. The score is the average of the three trials. Note that research has suggested that a single trial is as reliable as multiple trials (Coldham, Lewis, & Lee, 2006). This may be appropriate for cases in which multiple trials would cause undue pain or stress (see Fig. 7-123 and Table 7-2 for normative data and standardized position for grip-strength testing).

Pinch

Three types of pinch are typically evaluated because they are involved in accomplishing occupational tasks and activities efficiently. The seating and positioning of the arm should be the same as with grip testing, with the addition

Figure 7-123 Measuring grasp using a dynamometer. The patient's upper arm is close to his body, and the elbow is flexed to 90°.

that the fingers should be allowed to flex. With both tip and three-jaw pinch, it is important to note that in order to keep the forearm in a neutral position, the pinch gauge must be held vertically, and the wrist will naturally extend to assume the best testing position (MacDermid, Evenhuis, & Louzon, 2001).

Tip Pinch (Fig. 7-124 and Table 7-3)

The patient pinches the ends of the pinch meter between the tips of the thumb and index finger (Mathiowetz et al.,

Figure 7-124 Measuring tip pinch with a pinch meter.

Figure 7-125 Measuring lateral pinch.

1985). The test is administered by first giving the patient instructions and a demonstration. Next, the therapist says, "Ready? Pinch as hard as you can." The patient is urged on as he or she attempts to pinch. Three trials, with a rest between each trial, are completed. The average of three trials is recorded. It is important to observe for any compensation techniques because some individuals will naturally try to use the middle finger to assist without recognizing their deviance from the instructed test position.

Lateral Pinch: Key Pinch (Fig. 7-125 and Table 7-3)

The patient pinches the meter between the pad of the thumb and the lateral surface of the index finger. The instructions and procedure are the same as for tip pinch, but the pinch gauge is held horizontally. Interestingly, in a study of key pinch in children ages 5–12 years, differences were found according to age, but no significant differences were found by hand or gender in this age range. Based on these findings, comparing the right to left side in this age range should be possible as long as the injury or condition is not bilateral (De Smet & Decramer, 2006).

Palmar Pinch: Three-Jaw Chuck (Fig. 7-126 and Table 7-3)

The patient pinches the meter between the pad of the thumb and the pads of the index and middle fingers. The instructions and procedure are the same as for tip pinch.

Interpretation of Grasp and Pinch Scores

The scores are compared with those of the other hand or to norms to ascertain whether the patient has a significant limitation. Lindstrom-Hazel, Krat, and Bix (2009) questioned the current normative data based on the fact that it is more than 20 years old, and the differences in individual's activities compared to when the data were

Figure 7-126 Measuring palmar pinch or three-jaw chuck pinch.

collected. They determined that students using standardized methods could demonstrate high levels of interrater reliability (ICC = 0.99 for grip strength; ICC = 0.95–0.99 for pinch strength), indicating that, with training, students could contribute to collecting new normative data (Lindstrom-Hazel, Krat, & Bix, 2009).

In a recent Australian study of grip strength, the researchers compared their normative data to other studies that have collected norms in various countries. The trends and variations in these data are interesting to acknowledge and have been included in Figures 7-127 and 7-128 (Massy-Westropp et al., 2011).

The accuracy of the Jamar dynamometer was found to be 7%, which means that, if the patient scored 50 pounds, the actual strength may range from 46.5 to 53.5 pounds (Shechtman, Gestewitz, & Kimble, 2005). Grasp and pinch scores are considered abnormal if they are associated with a

functional limitation and/or if they are three standard deviations (SD) from the mean. For example, suppose a 40-year-old man had a grasp score of 50 pounds after three trials for his dominant right hand are averaged. Table 7-2 shows that the average score for his age group is 117 pounds, so the patient's grasp score was 67 pounds less than the mean normal score on the table. When the difference in his score is divided by the SD given in the table (21), he is 3.2 SD below the mean. Because this is more than 3 SD below the mean, he is considered to have a significant limitation.

Expanding on this patient example, imagine that the patient is a carpenter and recovering from a metacarpal fracture and can now demonstrate a full composite fist. He has an average score of 50 pounds on the right dominant hand, and an average of 100 pounds on the left nondominant hand. Using the 10% rule, the therapist would anticipate that 110 pounds was the patient's right hand strength prior to injury. The therapist's assessment could be written as, "Patient is 7 weeks post–metacarpal fracture with good return of motion. He demonstrates 45.5% of right hand strength compared to the left and 42.7% compared to established norms for his age and gender. The patient would benefit from continued occupational therapy services to increase strength needed for work and daily tasks." Grasp and pinch measurements can be quickly and easily reevaluated over time to monitor the progress of the patient and the effectiveness of the treatment plan.

DEXTERITY MEASUREMENT

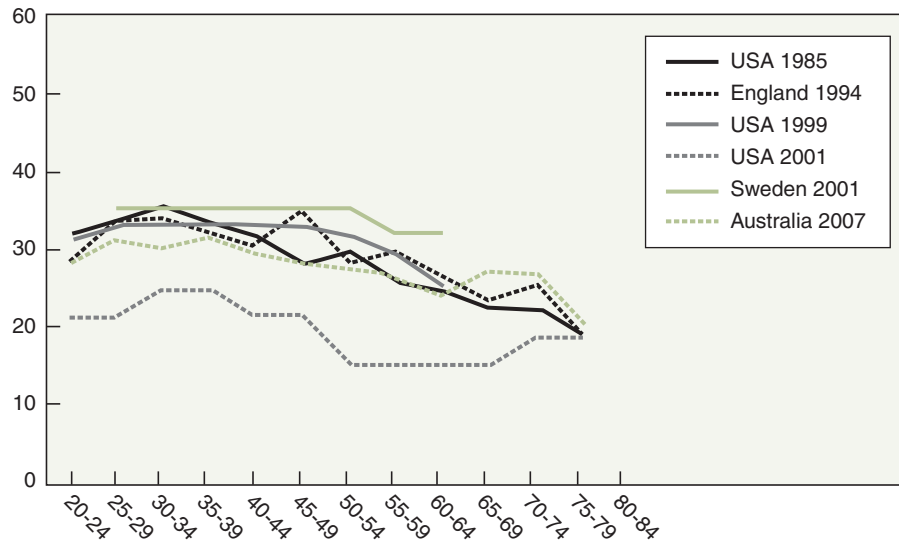
Dexterity requires hand ROM, hand strength, and sensation in order to manipulate objects. Individuals who lack full hand motion and function often complain about their inability to manipulate objects for writing, fastening clothing,
Figure 7-127 Comparison of male normative grip data across studies.


Figure 7-128 Comparison of female normative grip data across studies.

or turning a key in a car or door. The therapist may wish to further evaluate dexterity in these cases. Yancosek and Howell (2009) did a thorough review of common adult dexterity assessments and their psychometric properties. Further information on dexterity assessments can be found in Chapter 37.

ENDURANCE MEASUREMENT

Occupational therapists treat a variety of conditions that can impact an individual's endurance, including cardiac or pulmonary impairments, a major trauma or illness requiring bed rest, loss of significant muscle function, or the need to use a prosthesis or adaptive equipment. There are two components of endurance. The first is cardiovascular endurance, which is when during continuous physical activity both the circulatory and respiratory systems must supply adequate oxygen to continue the task (American College of Sports Medicine, 2010b). The second is muscular endurance, in which the muscles engaged during the task can continue to work without fatigue (American College of Sports Medicine, 2010b). Both of these aspects of endurance are vital to engagement in ADL and IADL tasks, which is why in some settings this is referred to as activity tolerance. The therapist may evaluate one aspect or both depending on the patient's symptoms.

Cardiovascular Aspects of Endurance

The role of the occupational therapist here is most clearly seen in the role of therapists in cardiac rehabilitation programs, although these same principles may apply to an individual receiving therapy after prolonged bed rest or to an individual in home health with decreased endurance. Once an individual is cleared to begin a cardiac rehabilitation program from his or her physician following

a cardiac event, the first activities that test CR fitness are typically self-care tasks (American College of Sports Medicine, 2010b). As the person progresses, household management tasks create a good challenge to the patient's endurance. Additionally, if the patient will be returning to work, the occupational therapist can assess the patient's workplace to gain a better understanding of the job demands and use task analysis to develop a program to return the patient to the endurance level needed to complete work tasks through a work-hardening program (American College of Sports Medicine, 2010b).

It is important for the therapist working with patients with decreased endurance to know the limitations and contraindications to pushing them in their progress to regain cardiovascular endurance. Additional information regarding safety during testing can be found in Safety Note 7-3. There are several measures of CR fitness that are beyond the scope of this chapter; however, the basic concepts will be explained to gain a better understanding of the contraindications. The criterion measure of CR fitness is maximal oxygen uptake (VO_{2max}) and is associated with heart functional capacity (American College of Sports Medicine, 2010b). It increases with physical training and decreases with bed rest and age. With physical training, the heart rate becomes lower for the same level of work, which is referred to as the "training effect." The training effect indicates improvement in circulatory system efficiency (American College of Sports Medicine, 2010a) (see further discussion of this topic in Chapter 42).

VO_{2max} is typically measured in a laboratory environment, which is not always available, but there is a linear relationship between oxygen uptake and heart rate for various intensities (i.e., light to moderately heavy exercise). Intensity of an activity is estimated in terms of light, moderate, or heavy work or metabolic equivalent (MET) level.

Safety Note 7-3

Precautions for Endurance Testing

- If the patient has recently experienced a cardiac event, he or she should first be cleared by the physician to engage in a rehabilitation program.
- If the patient exhibits significant dyspnea, weakness, changes in cognition, angina, decreased heart rate for increased workload, heart palpitations, significant changes in blood pressure, pallor, or cyanosis, his or her cardiopulmonary capacity has been exceeded (American College of Sports Medicine, 2010b).
- Endurance testing in occupational therapy should not reach this level, but if any of these symptoms are observed or reported by the patient, the intensity of work should be immediately reduced to a comfortable level or terminated, and the patient should be evaluated.

One MET equals basal metabolic rate (American College of Sports Medicine, 2010a). Basal metabolic rate is the amount of oxygen consumption necessary to maintain the metabolic processes (e.g., respiration, circulation, peristalsis, temperature regulation, and glandular function) of the body at rest and is quantified as 3.5 mL of oxygen per kilogram of body weight per minute. The energy cost of activities or exercise can be rated using multiples of METs. An exercise that is rated 4 METs requires four times the amount of oxygen per kilogram of body weight per minute than that of the basal rate. The oxygen consumption of daily living, recreational, and vocational tasks has been measured for normal subjects, and the METs required for each task have been calculated (see Table 42-1 for MET values of various activities). These costs are estimates that vary with environmental conditions, such as humidity and temperature, and personal conditions, such as anger or stress.

Because heart rate relates linearly to VO_{2max} except at the upper limits (80%–90%) of maximal capacity, if a person's heart rate is 70% of maximal heart rate (HR_{max}), he or she is using approximately 70% of VO_{2max} as long as there is no underlying pulmonary disorder. HR_{max} has traditionally been estimated by subtracting the person's age from 220; however, a more accurate formula is $HR_{max} = 206.9 - (0.67 \times age)$ (American College of Sports Medicine, 2010b). The pulse taken immediately after activity is then related to the person's HR_{max} as a percentage of maximum. A constant heart rate obtained during exercise indicates a steady state, that is, a balance of oxygen intake and consumption (Fletcher et al., 2001). Heart rate is measured by placing the index and middle fingers lightly but firmly over the radial artery at the wrist (lateral to the FCR) and counting the number of beats per minute (bpm). It is most accurate to count for a full minute, but an exercise heart rate can be counted for only 10–15 seconds, because the return to resting rate occurs quickly after stopping exercise. In that case, the obtained value is multiplied by 6 for 10 seconds or 4 for 15 seconds to arrive at the bpm (American College of Sports Medicine, 2010a).

Another way to assess endurance is to ascertain the individual's perception of how hard he or she is working. Scales of perceived exertion, such as the Rating of Perceived Exertion (RPE) (Borg, 1985), are based on psychophysics or the relating of a physical property to a subjective property via scaling procedures (Russell, 1997). The Borg (15-point) scale of Perceived Exertion ranges from 6 (no exertion at all) to 20 (maximal exertion) (American College of Sports Medicine, 2010b). This scale allows the person to assign one of a consecutive set of numbers with a corresponding descriptor of amount of exertion to the ongoing activity (e.g., 11, fairly light; or 17, very hard). For dynamic activities, the Borg scale has been found over the years to correlate validly with heart rate and oxygen uptake (Finucane, Fiddler, & Lindfield, 2005). Therapists should be aware that perceived exertion for a given level of oxygen uptake is higher for arm work than leg work (Russell, 1997). Lamb, Eston, and Corns (1999) looked at test–retest reliability and found it to differ by as much as 3 RPE when the level of agreement between trials was examined, and the scores of the two trials were not merely correlated. Nevertheless, these scales provide a good estimate when used repeatedly for the same patient and therefore may be used clinically during ongoing continuous activity, such as walking, bicycling, scrubbing floors, painting a wall, mowing the lawn, raking leaves, and calisthenic exercises. These scales do not apply to activities composed of sporadic variable movements.

The therapist should orient the person to the scale using the standardized instructions published by Borg (1985) prior to the start of the activity. The scale should be enlarged and posted so that it can be seen easily from where the person is engaging in activity. At appropriate intervals depending on the task, the therapist prompts the patient to rate exertion at that moment. The decision to continue depends on the goal and precautions for the particular patient.

Another measure easily used when engaging in functional tasks is the Talk Test. The client should be able to continue talking in full sentences during engagement in therapeutic tasks. This is correlated with the ventilator threshold, and when the client can no longer talk comfortably they have passed this threshold (American College of Sports Medicine, 2010a).

Muscular Aspects of Endurance

Muscular fitness is a combination of muscular strength and muscular endurance (American College of Sports Medicine, 2010b). This chapter has already explored the

evaluation of muscular strength with MMT, grip, and pinch strength testing. Muscular endurance is the ability of the muscle to perform multiple repetitions of a contraction without fatigue (American College of Sports Medicine, 2010b). Endurance may be decreased because of local trauma or reduction of innervation. In normal muscle contraction against low resistance, only a few of the available motor units are needed at any one time. The active and resting units take turns. Fatigue rarely occurs in conditions required for ADL tasks. However, if the person sustains a contraction that exceeds 15%–20% MVC for the muscle group involved, blood flow to the working muscle decreases, causing a shift to anaerobic metabolism, which limits duration of contraction. The limitation is signaled by symptoms of muscle fatigue (cramping, burning, and tremor, which are secondary to the accumulation of lactic acid) and slowed nerve conduction velocity to the muscle fibers, which reduce tension and eventually result in inability to hold the contraction (American College of Sports Medicine, 2010a). Strength and endurance are closely related. As muscle gains strength, its endurance for a given level of work also increases.

For neurologically disadvantaged muscle, such as after a spinal cord injury, peripheral nerve injury, or stroke, fewer motor units or muscle fibers may be available than are required for daily activity. Such muscles work at as much as 50%–75% MVC to do otherwise low-intensity work (Trombly & Quintana, 1985).

Endurance can be measured dynamically or statically. Dynamic assessments include the number of repetitions per unit of time. When evaluating both cardiovascular and muscular endurance, the percentage of maximal heart rate generated by the task or MET level can also be documented. Static assessment is the amount of time a contraction can be held (American College of Sports Medicine, 2010b; Fletcher et al., 2001).

Intensity, duration, and frequency of the activity are considerations in evaluation of endurance. Intensity is related to both resistance and speed. The heavier the resistance or the faster the pace is, the higher the intensity. The intensity of the test activity must be kept constant from test to test to gauge improvement.

The decision to measure dynamically or statically depends on the functional goal of the patient and his or her cardiopulmonary status. If the patient's self-advancement and self-enhancement roles require mostly isotonic activity, endurance should be evaluated dynamically. To measure endurance in terms of number of repetitions, use a light repetitive activity such as the Box and Block Test, which is described in Chapter 37. It can be adapted to measure UE endurance for light work by counting the number of blocks the patient can transfer before becoming fatigued.

For some individuals, engaging in a task as light as the Box and Block Test will not demonstrate the decreased endurance that may be impairing their ability to return to work. In these cases, a functional capacity evaluation may be appropriate or a test of endurance, using equipment such as the Baltimore Therapeutic Equipment (BTE) work simulator. This equipment can be set up to simulate a variety of work and daily tasks. A static trial can be completed to gain a numeric value for the individual's MVC for that task, and then to test endurance, the therapist can set the resistance level at 20%–30% of that maximum. The therapist can see on the equipment if the patient is decreasing in speed and showing fatigue. The time, repetitions, and weight can be documented for later comparison to show progress in the area of endurance. Although these numbers can be used clinically to demonstrate progress, the therapist should use caution when relating them to work capacity. Research suggests that endurance time, VO_2, heart rate, and RPE were all significantly different in lifting endurance on the BTE when compared to actual lifting (Ting et al., 2001). The discussion in this research suggests that the differences could result from the decreased metabolic and cardiovascular demands when using the BTE and the difference in the lifting task based on the design of the BTE, which changes both the dynamic and static aspects of the lift and allows for additional compensation by the individual lifting (Ting et al., 2001).

If the patient expects to return to a job or hobby that requires maintaining grasp or holding loads (isometric contractions), static endurance should be tested. To measure statically, the amount of time a person can hold an object or position requiring a certain level MVC is noted. Normally, a person can hold 25% MVC for 5–6 minutes, 50% MVC for 1–2 minutes, and 100% MVC only momentarily (Dehn & Mullins, 1977).

Isometric holding increases blood pressure and stresses the cardiopulmonary system (Pollock et al., 2000). This is true especially if the person holds his or her breath (Valsalva maneuver) while holding the contraction. Therefore, persons being tested should talk (e.g., count or sing) while doing an isometric contraction to preclude breath holding. Isometric testing can produce arrhythmias and, therefore, electrocardiogram and blood pressure should be monitored during isometric testing of patients with heart disease or abnormalities. The results of isometric testing cannot be extrapolated to gauge isotonic aerobic exercise capacity (Pollock et al., 2000).

In a review of the literature in the care of individuals following stroke, Ma and Trombly (2002) discuss the importance of meaningful and purposeful tasks in the evaluation and treatment of endurance. The studies they reviewed found that the number of repetitions and length of time a person was willing to engage in a task both increased when the task was meaningful or preferred (Ma & Trombly, 2002). Assessment Table 7-1 lists many of the tests used to measure ROM, strength, and endurance.

Assessment Table 7-1 | Abilities and Capacities: Range of Motion, Strength, and Endurance

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Measurement of range of motion	Interval scale. Range varies with joint being measured	Full evaluation of all joints in the UE, 45 minutes to an hour	Gold standard	Intrarater reliability for shoulder external rotation, interclass correlation coefficient (ICC) = 0.58–0.67, internal rotation ICC = 0.63–0.71. Interrater reliability external rotation = 0.41–0.66, internal rotation ICC = 0.41–0.66 (Awan, Smith, & Boon, 2002)	In the upper and lower extremities, measurement error is estimated at 5° (Groth et al., 2001).	Strengths: Relatively fast and inexpensive measure. Measurements are consistently more accurate when done by the same therapist with the patient in the same position from test to test. Weaknesses: Interrater reliability is consistently lower than intrarater reliability. Accuracy of measurement is dependent on the consistent placement of the goniometer.
Hand Volumetry (Dodds et al., 2004)	Interval scale because it is a direct measure of the volume of water displaced	10–20 minutes	Gold standard. Direct measurement of hand volume	Test–retest reliability ($r = 0.99$) (Dodds et al., 2004)	Variation of measurement 3–5 mL (Dodds et al., 2004)	Strength: Gold standard for edema measurement. Weakness: Hand must be immersed in water, so therapist must be aware of any contraindications. Takes considerable time.
Figure-of-eight technique to measure hand edema (Dewey et al., 2007; Pellecchia, 2004)	Interval scale	1–4 minutes	Correlation coefficient between figure-of-eight technique and hand volumetry ICC = 0.83–0.95 (Dewey et al., 2007; Maihafer et al., 2003)	Intratester ICC for figure-of-eight ICC = 0.96–0.99; intertester reliability ICC 0.94–0.99 (Dewey et al., 2007; Leard et al., 2004)	Recommend change of 1.16 cm to be clinically significant in patients with burns to the hands (Dewey et al., 2007)	Strengths: Fast measurement. Can be used with individuals with open wounds or skin conditions. Weakness: Larger studies of various patient populations needed.
Visual Analog Scale for pain measurement	Interval scale with scores measured along the 10-cm line	1 minute	Gold standard; however, still a subjective measure	Not established; in studies, a decrease in pain level resulted in less need for medication, showing clinical significance (Farrar, Berlin, & Strom, 2003).	Recommend 33% change for clinical significance (Farrar, Berlin, & Strom, 2003)	Strengths: Fast measurement. Can be used to monitor changes in pain in a single patient. Weakness: Cannot be used to compare pain levels between patients.

Assessment	Scale	Time	Purpose	Reliability/Validity	Norms/Sensitivity	Strengths/Weaknesses
Numerical pain-rating scale	0–10 scale of self-perceived pain level	1 minute	Subjective measure	In studies, a decrease in pain level resulted in less need for medication showing clinical significance (Farrar, Berlin, & Strom, 2003).	Recommend change in pain level by at least two levels to be significant (Farrar, Berlin, & Strom, 2003)	Strengths: Fast measurement. Can be used to monitor changes in pain in a single patient. Weakness: Cannot be used to compare pain levels between patients.
Manual muscle testing	Ordinal scale from 0 to 5	Depending on the number of muscles being tested, up to 1 hour	Gold standard	In a reliability test for intrinsic hand muscles, intrarater ($r = 0.71$–0.96) and interrater ($r = 0.72$–0.93) reliability (Brandsma et al., 1995). In an evaluation of reliability for the deltoid muscles, Pollard et al. (2005) found that two testers agreed exactly 82% of the time, ($\kappa = 0.62$).	Not established	Strength: No equipment needed. Weakness: Dependent on training and experience of the tester.
Handheld dynamometry	Interval scale; measurement is in kilograms	Depending on the number of muscles being tested, up to 1 hour	Direct measure of strength	Interrater reliability ICC = 0.79–0.96, and intrarater reliability ICC = 0.87–0.98 (Ottenbacher et al., 2002).	Norms established (Bohannon, 1988)	Strength: Reliable testing device. Weaknesses: Validity and sensitivity not established. Expense of device.
Grip strength test	Interval scale; measures resistance in pounds or kilograms	5 minutes	Recommended by American Society of Hand Therapists as a valid measure of hand strength (Fess, 1992)	Test–retest reliability Jamar dynamometer $r > 0.80$, and interrater reliability $r = 0.98$ (Roberts et al., 2011).	Norms established with gold standard Jamar dynamometer (Mathiowetz et al., 1985); recommend 13-pound change for clinical significance (Roberts et al., 2011)	Strengths: Quick and easy measure. Norms available. Weakness: Dynamometers need to be calibrated regularly in order to be accurate.
Pinch test	Interval scale; measures resistance in pounds or kilograms	5 minutes	Recommended by American Society of Hand Therapists as a valid measure of pinch strength (Fess, 1992)	Interrater reliability $r = 0.98$; test–retest reliability was $r = 0.81$ (Mathiowetz et al., 1984).	Norms established (Mathiowetz et al., 1985)	Strengths: Quick and easy measure. Norms available. Weakness: Pinch meters need to be calibrated regularly in order to be accurate.
Borg rating of perceived exertion scale	Ordinal scale, from 6 to 20	1 minute	Valid measure of exercise intensity (Chen, Fan, & Moe, 2002)	Not established	Not established	Strength: Good measure for individuals. Weakness: Not consistent between individuals.

case example
Mrs. A.: Upper Extremity Assessment Following Trauma

Clinical Reasoning Process

Occupational Therapy Assessment Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mrs. A. is a 42-year-old right-handed woman 8 weeks status post open reduction internal fixation (ORIF) of a right humerus fracture following a gunshot wound (GSW) during an assault in a parking lot in the city (about 45 minutes away). Her radial nerve (which is frequently injured during humerus fractures) was not lacerated, but she did have wrist drop for a week following the injury and surgery that has slowly been improving (neuropraxia). She complains of UE weakness, stiffness, and decreased motion. She also complains of pain and fatigue that are increasingly limiting her self-maintenance, self-advancement, and self-enhancement roles. She is a married dental hygienist, although her husband frequently travels for work. They live in a one-story house. She has two grown children and enjoys gardening, working out at the gym, and shopping. She was previously seen at another facility recommended by the injury lawyer but has decided to transfer to a new facility because it is closer to her home. She recently had a follow-up with her surgeon, who referred her to occupational therapy for evaluation and to begin strengthening training.	Understand the patient's diagnosis or condition Know the person Appreciate the context Develop provisional hypotheses	"Mrs. A. is very active and has not been able to fully return to work following this trauma. I wonder if her weakness is impacting her ability to engage in her work tasks?" "Mrs. A. is frequently home alone during the week. I wonder if she is having any problems with the trauma being so recent, and if this is impacting her engagement in tasks? I wonder if she has been avoiding any home maintenance or self-care tasks because of her fatigue?" "I bet being a dental hygienist requires good endurance of the muscles in both upper extremities to hold and manipulate the tools all day long. I wonder what she is currently doing at work?" "She has been working in therapy to regain her motion, but now that she is able to work toward improving her strength and endurance, I bet she will be motivated by the potential to fully return to work. I wonder how the trauma itself is impacting her engagement in activities?"
Assessment Process To determine Mrs. A.'s perception of her occupational dysfunction and her priorities, the therapist administered the Canadian Occupational Performance Measure (COPM). To determine to what extent motion, strength, and endurance problems affected Mrs. A.'s occupational functioning, a manual muscle test on selected muscle groups, grip- and pinch-strength assessments, numeric pain-rating scale, and engagement in 1 minute of wrist activity on the Baltimore Therapeutic Equipment (BTE) for endurance during work tasks were administered.	Consider evaluation approach and methods	"I need to get a picture of what occupations are important to her. I also need to know exactly how her arms are functioning in terms of motion, strength, and endurance. I would like to know how much pain she is having at rest and during activity."
Assessment Results The results of the COPM are as follows: Difficulty holding dental hygienist tools for prolonged periods (performance 3, satisfaction 2). Difficulty with morning activities of daily living, including showering and dressing. She has problems squeezing bottles, bathing the left side of the body such as her armpit and back, and putting on jewelry (performance 6, satisfaction 5). Difficulty engaging in shopping tasks because of the fear associated with it. She was on a shopping trip when the trauma occurred (performance 5, satisfaction 4).	Interpret observations	"Mrs. A. is involved in a number of gross and fine motor activities during the day and seems to be having problems with all of them."

Inability to do heavy meal preparation activities, including cutting vegetables and carrying dishes (performance 6, satisfaction 4).

Unable to garden as desired, specifically planting, digging with a trowel, and weeding (performance 3, satisfaction 2).

The results of Mrs. A.'s range of motion and manual muscle test are displayed below. Grip strength using a Jamar dynamometer was 18 pounds on the right and 58 pounds on the left. Tip pinch strength was 3 pounds on the right and 12 pounds on the left. Lateral pinch was 5 pounds on the right and 14 pounds on the left. Palmar pinch was 4 pounds on the right and 13 pounds on the left.

Active range of motion:
Shoulder, wrist, and hand AROM within normal limits.
Elbow extension–flexion right: 30°–120°
Elbow flexion left: 0°–150°
Elbow hyperextension left: 0°–5°
Supination right: 0°–60°
Supination left: 0°–90°
Pronation right: 0°–80°
Pronation left: 0°–90°

Mrs. A. has a 22-cm scar along the dorsal aspect of her arm that is red in appearance and flat. There is mild adhesion noted along the scar, and the scar does pucker with elbow motion.

Select manual muscle strength	Right	Left
Shoulder flexion	5	5
Shoulder abduction	4–	5
Elbow flexion	4	5
Elbow extension	4	5
Forearm supination	4	5
Forearm pronation	4	5
Wrist flexion	5	5
Wrist extension	3+	5
Digital extension	3+	5

Mrs. A. reported a 5 on the numeric pain-rating scale at rest and described it as burning pain, but stated that pain increases to 6 during morning activities of daily living, 6 during meal preparation, and 7 during work tasks. She describes this pain as sharp pain.

Using the BTE, Mrs. A. demonstrated only five repetitions of wrist motion during 1 minute when set at 70% of her maximum voluntary contraction, which was 3 pounds.

"Mrs. A. is weak in the muscles that have debilitated because of nonuse, as well as the muscles innervated by the radial nerve. The dynamometer test showed a significant decrease in grip strength for her right hand, which is her dominant hand, but grip strength was within normal limits for her left hand. Her right hand pinches were also significantly limited compared to the left or to the norms, whereas all three pinches of her left hand were within normal limits. The weakness in her right hand also contributes to her difficulty in many occupational tasks, such as work tasks, opening jars, and manipulating garden tools."

"Mrs. A.'s scores on the visual analog scale indicate increased pain in her hands and shoulders during many functional activities, with less, although still significant, pain at rest. She describes these pains differently, and burning pain can sometimes be attributed to the nerve trying to heal."

"The results of endurance testing on the BTE demonstrate decreased endurance with activities requiring wrist extension such as manipulating tools for work."

Occupational Therapy Problem List

Decreased ability to perform morning activities of daily living, including bathing and dressing, because of decreased motion, weakness, and low endurance.

Decreased ability to perform meal preparation tasks because of weak grasp and pinch on the dominant side.

Decreased ability to perform work-related tasks, including manipulating tools for prolonged periods of time because of weakness and decreased endurance of the muscles innervated by the radial nerve.

Decreased ability to garden because of weakness and pain.

Decreased engagement in shopping tasks based on psychosocial factors.

Synthesize results

"I wonder what adaptations she is already using in her activities of daily living and instrumental activities of daily living tasks and whether additional adaptations would be helpful until her strength and endurance are regained."

"Mrs. A. has problems with decreased motion, weakness, and endurance. She is motivated to return to work, and I should use activities for her therapy and goals to work on full return to work."

"I need to find out what all her works tasks involve and what sort of time she has between patients."

"I wonder if she is already seeking assistance for the psychosocial issues she is having following this trauma. I will ask her about this and make a referral if she is not."

Clinical Reasoning in Occupational Therapy Practice

Edema Assessment Selection

Expanding on Mrs. A.'s case example information, you are performing her initial evaluation 10 days postoperatively and note significant edema to the right wrist, hand, and digits. She has multiple open, sutured, and healing lacerations to her hands and arms from falling during her attack. What methods would you use to evaluate and specify the extent of her edema? Would you do anything differently at her reevaluation once the lacerations have fully healed?

Summary Review Questions

1. Where does the assessment of ROM, strength, and endurance fit within the role of occupational therapy and the OTPF?
2. What does it mean if AROM is less than PROM?
3. Describe a situation where a screening of motion and strength may be more appropriate than taking formal measurements at each joint and muscle group.
4. How is a break test used to determine strength?
5. An individual has decreased function with ADL, IADL, work, and leisure tasks 8 weeks post–wrist fusion operation with limited AROM at the MCP, PIP, and DIP joints of the dominant hand and decreased hand grip strength 70 pounds less than the contralateral side. The person specifically mentions decreased ability to complete meal preparation, dressing, office administrative work, and golfing. Write appropriate short- and long-term goals.
6. Describe the standardized procedures for testing muscle strength.
7. An individual demonstrates 4−/5 MMT for the right, dominant hand, wrist, and digital extension while recovering from a radial nerve entrapment. The client states that he cannot write for more than 10 minutes or type for more than 15 minutes, which is impacting his role as a college student. Describe appropriate intervention planning for this individual.
8. An individual demonstrates decreased endurance following amputation of the left leg below the knee with an extended period of immobility from surgical complications. She is now being fit with a prosthesis, but the surgeon is concerned with safety from the decreased cardiovascular and muscular endurance. The client enjoys cooking, puzzles, and baseball. What intervention planning would you recommend?
9. What is your maximum heart rate?
10. Select a diagnosis that would impact ROM, strength, or endurance. If you were impacted by that diagnosis, what would be your short- and long-term goals? What sort of intervention planning would help you accomplish those goals?

Glossary

Active range of motion (AROM)—The amount of movement possible at a joint when it is voluntarily moved by muscle contraction.

Anatomical position—Standing straight with feet together and flat on the floor, with arms by the sides and palms of the hands facing forward. The zero position for ROM measurement.

Calibrate—To set an instrument at a known value according to a standard.

Contracture—Inability to move a body part because of soft tissue shortening.

Limits of motion—The beginning and ending positions of movement at a joint.

Maximum voluntary contraction (MVC)—The greatest amount of tension a muscle can generate and hold only for a moment, such as in muscle testing.

Mechanical advantage—The position in which the muscle is able to generate the greatest tension, that is, when it is longer than the resting length of the muscle. In this position, the passive tension generated by the viscoelastic properties of the muscle and its tendon combine with the active tension generated by the contraction of the muscle fibers to produce a maximum voluntary contraction. When the muscle is fully lengthened or shortened, the viscoelastic, or passive, tension is reduced.

Metabolic equivalent (MET) level—One MET (the unit of measure) equals basal metabolic rate. Basal metabolic rate is the amount of oxygen consumption necessary to maintain the metabolic processes of the body at rest and is quantified as 3.5 mL of oxygen per kilogram of body weight per minute (American College of Sports Medicine, 2010a). The energy cost of activities or exercise can be rated using multiples of METs.

Passive range of motion (PROM)—The amount of movement possible at a joint when an outside force moves the limb.

Reliability—Characteristic of an instrument indicating that the instrument consistently produces the same results including stability (intrarater), internal consistency, and equivalence (interrater) when properly administered under similar circumstances (Yancosek & Howell, 2009). Reliability is usually defined by a correlation coefficient (r) or an interclass correlation coefficient (ICC). An r or ICC of 1 indicates a perfect linear relationship between one variable (e.g., rater A's scores) and another variable (e.g., rater B's scores). An r of 0.85 or ICC of 0.75 is considered acceptable for measuring instruments. Reliability can be increased by controlling all variables that affect the scores other than the one being measured (e.g., change in ROM). Control is gained by keeping everything the same or by deleting some variables.

Standard deviation (SD)—A measure of dispersion indicating the variability within a set of scores. Low variability within the scores of a set of therapists indicates that the therapists are following the same protocol and the phenomenon being measured is unchanging; high variability indicates that the phenomenon being measured is unstable or that the therapists should control their test administration better. To interpret a score, the therapist often compares it with norms (averages and SDs). The SD tells you where your patient's score falls in relation to the norm because you can relate it to the normal curve. In the bell-shaped normal curve, 1 SD is equal to approximately 68% of the area under the curve (34% on each side of the mean); 2 SD is equal to approximately 95% of the area under the curve; and 3 SD is equal to approximately 99% of the area under the curve. A score of 2–3 SD below the mean normative score indicates a limitation and need for treatment.

Tenodesis—The mechanical effect caused by the length of extrinsic finger flexors and extensors. When the wrist is flexed, the fingers tend to extend because the extensors are too short to allow full finger flexion and wrist flexion at the same time. Similarly, when the wrist is extended, the fingers tend to flex.

Assessing Abilities and Capacities: Motor Planning and Performance

Khader Almhdawi, Virgil Mathiowetz, and Julie D. Bass

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Contrast the reflex-hierarchical and systems models of motor control.
2. Describe various types of motor dysfunction seen in persons with central nervous system lesions.
3. Compare the neuromaturational and systems theories of motor development.
4. Contrast the assumptions of the neurophysiological and task-related approaches to treatment.
5. Describe the different evaluation strategies that are used by the neurophysiological and task-related approaches.
6. Describe some additional evaluation strategies that are not associated directly with either approach related to motor ability including balance, reach and manipulation, functional gait, apraxia, and motor neglect.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

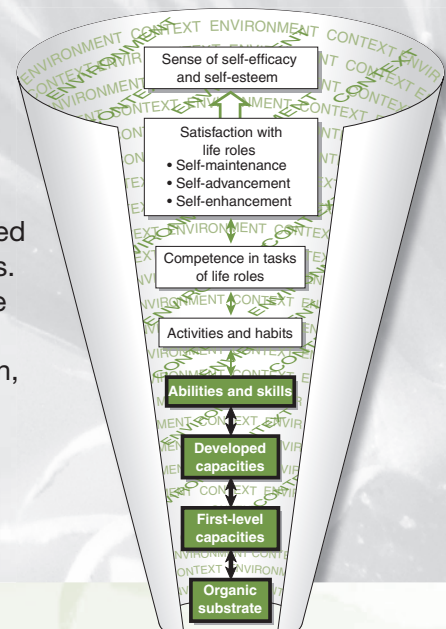
Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate


Our understanding of motor behavior and motor control, motor development, motor learning, and motor skill continues to evolve (Shumway-Cook & Woollacott, 2012). Sophisticated technology has led to an explosion of information about the control, development, and acquisition of movement (Fee & Long, 2011; Ingram & Wolpert, 2011). Human movement scientists, neurophysiologists, neuropsychologists, and others contribute to this effort. In an attempt to impose order on the many pieces of information, they deduce models and theories of motor behavior. As these models and theories change, therapeutic approaches and their evaluations also must change.

As a result of changes in the motor behavior literature, some (Rao, 2011; Shumway-Cook & Woollacott, 2012) have questioned the assumptions underlying the neurophysiological approaches, which include Rood's (1954) sensorimotor approach, Knott and Voss's (1968) proprioceptive neuromuscular facilitation, Brunnstrom's (1970) movement therapy, and Bobath's (1978, 1990) neurodevelopmental treatment. See web chapters A, B, C for further description of these approaches. Two task-related approaches, a task-oriented approach (Horak, 1991; Mathiowetz & Bass Haugen, 1994) and Carr and Shepherd's approach (1987, 2011), are proposed as alternatives to the neurophysiological approaches.

Definition 8-1 contrasts the assumptions of the neurophysiological and task-related approaches, the models and theories of motor behavior that they are based on, and the evaluation strategies associated with each approach. The evaluation strategies used by the neurophysiological approaches still continue to influence clinical practice as well. However, task-related evaluation strategies have an increasing influence on current practice.

When assessing motor behavior for clients recovering from neurological disorders, the therapist needs to consider both function and impairment. This evaluation should be applied individually, emphasizing each client's specific role performance and functional participation (Almhdawi, 2011). Following the World Health Organization definition of functioning, disability, and health (World Health Organization [WHO], 2001), the therapist can assess the body function or impairment, measuring the client's physical abilities such as range of motion and strength. Activity limitations or functional abilities are measured by examining the client's quality of movements and functional performance during real-life activities consistent with each client's specific roles and functional needs.

NEUROPHYSIOLOGICAL APPROACHES

Assumptions of the Neurophysiological Approaches

Definition 8-1 includes the assumptions of the four neurophysiological approaches as described by their original proponents. It is recognized that some of these approaches have evolved over time, adopting the assumptions of the task-related approaches (Howle, 2002). As a result, the theoretical differences between some of these approaches are much smaller today than they were 20 years ago. Unfortunately, clinical practice tends to lag behind changes in theory. To understand the neurophysiological approaches, one must understand the reflex-hierarchical model of motor control and neuromaturational theories of motor development from which these treatment approaches originated.

Reflex-Hierarchical Model of Motor Control

Figure 8-1 illustrates a reflex-hierarchical model (Trombly, 1989) that synthesizes the basic science literature of the 1970s and 1980s. This model evolved from earlier separate reflex and hierarchical models, both of which were unsuccessful in explaining the variety of movements available to human beings. This combined model assumes that the central nervous system (CNS) is hierarchically organized and that movement is controlled by central programs or elicited by sensory input.

As can be seen in Figure 8-1, the first step of purposeful movements is motivation by internal or external stimuli such as thirst (Marsden, 1982). Following this, a person utilizes his long-term memory to select a prestored generalized movement program that can enable reaching to a water bottle (Marsden, 1982). The person then adjusts the prestored motor programs to fit the context being faced (such as determining the specific muscles needed, the force of the contractions, and the overall duration of the movement) and then forwards these orders for execution (Marsden, 1982).

As the program for reaching a bottle of water is executed, the movements are monitored via cutaneous input, visual and auditory cues, and ongoing proprioceptive input (Brooks, 1986). The program being executed would be changed only if the movement was sensed to be wrong or in the case of an unexpected event. When the motor program is executed, the α- and γ-motor neurons are coactivated and excite the extrafusal and intrafusal muscle fibers according to the plan. A discrepancy in the length of these fibers would be sent to the higher centers when active movement is stopped unexpectedly. Stretch reflexes are activated in response to this discrepancy (Brooks, 1986). The outcome of the movement determines whether the motor plan needs to be adapted for future use through the use of knowledge of results feedback (Gazzaniga, Ivry, & Mangun, 2009; Wei & Körding, 2009). Finally, the successful movements whose sensory feedback matches the intended movements at the time of generating the motor program are stored in the long-term memory system for future use (Adkins et al., 2006; Gentile, 1972). The learned motor skill must be practiced to be retained at the same level of expertise (Halsband & Lange, 2006). Expertise is improved by practice with intention to improve (Cano-de-la-Cuerda et al., 2012; Latash et al., 2010).

Definition 8-1

Comparison of the Neurophysiological and System-Based Task-Related Approaches

Neurophysiological Approaches	Systems-Based Task-Related Approaches

Models of Motor Control

Reflex-Hierarchical Systems

- Movements are elicited by sensory input or controlled by central programs.
- Open-loop and closed-loop controls are used.
- Feedback and feed-forward influence movements
- Central nervous system (CNS) is hierarchically organized, with higher centers controlling lower centers.
- Reciprocal innervation is essential for coordinated movement.

Systems

- The movements are organized by the functional needs/goals.
- Movement emerges from the interaction of many systems.
- Systems are dynamical, self-organizing, and heterarchical.
- The proffered movement pattern is the most efficient to achieve the functional goal.
- Changes in one or more systems can alter behavior.

Theories of Motor Development/Redevelopment

Neuromaturational Systems

- Changes are due to CNS maturation.
- Development follows a predictable sequence (e.g., cephalocaudal, proximal-distal).
- CNS damage leads to regression to lower levels and more stereotypical behaviors.

Systems

- Changes are due to interaction of multiple systems.
- Progression varies because person and environmental contexts are unique.
- CNS damage leads to attempts to use remaining resources to achieve functional goals.

Assumptions of Therapeutic Approaches

- CNS is hierarchically organized.
- Sensory stimuli inhibit spasticity and abnormal movement and facilitate normal movement and postural responses.
- Repetition of movement results in positive permanent changes in CNS.
- Recovery from CNS damage follows a predictable sequence.
- Behavioral changes after CNS damage have a neurophysiological basis.

- Personal and environmental systems, including the CNS, are heterarchically organized.
- Intensive and variable functional task practice improves the motor behavior.
- The environment interacts with the individual influencing the occupational performance.
- Individuals' functional relearning strategies are not necessarily the same.
- Recovery is variable because personal characteristics and environmental contexts are unique.
- Behavioral changes reflect attempts to compensate and to achieve task performance.

Evaluation

Primary Focus on Performance Components

- Abnormal muscle tone.
- Abnormal reflexes and stereotypical movement patterns leading to incoordination.
- Postural control.
- Sensation and perception.
- Memory and judgment.
- Stage of recovery or developmental level.

Primary Focus on Occupational Performance Using a Client-Centered Perspective

- Task analysis to determine performance components and contexts that limit function and to identify preferred movement patterns for specific tasks in varied contexts.
- Variables that cause transitions to new patterns.

Secondary Focus: Occupational Performance

Secondary Focus: Selected Performance Components and Contexts That Limit Function

Reflex-Hierarchial Model of Motor Control

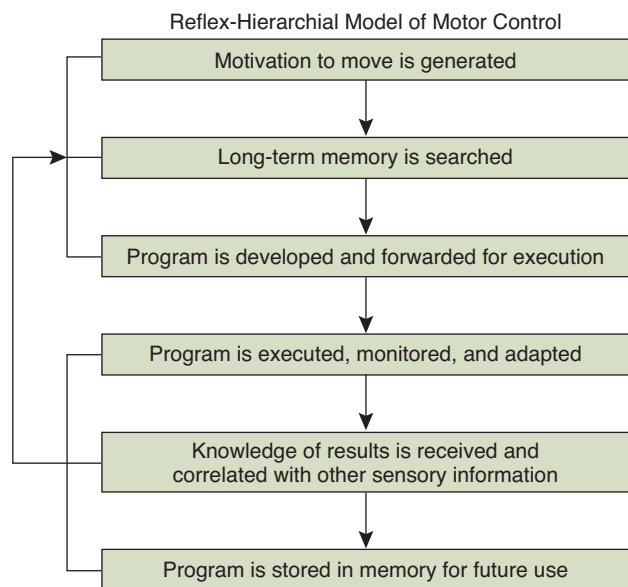
| Motivation to move is generated |
| Long-term memory is searched |
| Program is developed and forwarded for execution |
| Program is executed, monitored, and adapted |
| Knowledge of results is received and correlated with other sensory information |
| Program is stored in memory for future use |


Figure 8-1 Reflex-hierarchical model of motor control, includes both open-loop and closed-loop control. (Adapted from Trombly, C. A. [1989]. Motor control therapy. In C. Trombly [Ed.], *Occupational therapy for physical dysfunction* [3rd ed., pp. 72–95]. Baltimore: Williams & Wilkins.)

Reflex-hierarchical models of motor control have been challenged by three interrelated questions: (1) How can the CNS control the many degrees of freedom of each movement (i.e., the large number of joints, planes of motion within each joint, muscles that control each joint, and single motor units within each muscle) without specifying the details of the muscle activation pattern (Bernstein, 1967)? If the CNS does specify the details, each motor program would be extremely complex. (2) How many motor programs would be needed to perform the numerous tasks that humans perform in everyday life? It is likely that an extremely large number would be necessary, which creates a storage problem for the brain. (3) How many motor programs would be needed to perform a given task in varied contexts? Studies (Marteniuk, MacKenzie, & Jeannerod, 1987; Mathiowetz & Wade, 1995) have demonstrated that even small changes in environmental context can result in unique movement patterns during simple reaching tasks. Thus, the environment has a larger role in motor control than the reflex-hierarchical model would suggest, and it seems that an incomprehensible number of motor programs would be necessary to respond to various contexts (Newell, 2003). Does the brain have unlimited storage capacity to accommodate all of the motor programs that would be needed, even generalized motor programs? The answer is probably not, which indicates the need for an alternative explanation of motor behavior such as the task-related approaches.

Neuromaturational Theory of Motor Development

The neuromaturational theory of motor development (Gesell, 1954; McGraw, 1945) has influenced the neurophysiological approaches in various ways (Heriza, 1991).

It suggests that changes in motor development are due to maturation of the nervous system. In other words, changes in neural structures cause changes in motor function (McGraw, 1945). This implies that the environment plays a minimal role in motor development. Current research suggests the opposite—sensorimotor experiences in response to environmental opportunities or problems organize or reorganize the CNS (Kleim & Jones, 2008; Nudo, 2011).

Motor Dysfunction Caused by Central Nervous System Lesions

The view of the neurophysiological approaches is that motor dysfunctions that follow CNS damage (Definition 8-2) are understood best by knowing the site and extent of the lesions (Cheney, 1985). It is assumed that specific areas of the brain serve specific functions. Therefore, if a given area of the brain is damaged, its associated function is expected to be impaired.

View of Recovery after Central Nervous System Lesions

The view of the neurophysiological approaches is that motor recovery after CNS lesions is due to changes in the CNS. Recovery from cortical lesions is believed to follow a developmental sequence from reflex to voluntary control, from mass to discrete movements, and from proximal to distal control. After stroke, clients typically demonstrate synergistic movement patterns when attempting either an isolated single joint movement or a multijoint coordinated task. Brunnstrom (1970) referred to a stereotyped sequence of stages during motor recovery post stroke: (1) flaccidity (i.e., no voluntary movements), (2) basic components of synergies with some spasticity, (3) some voluntary control of synergies with increased spasticity, (4) movement out of synergies and decreased spasticity, (5) synergies no longer have dominance over motor acts and increased coordinated movement, and (6) movement coordination approaches normal.

A conservative definition suggests that motor recovery has been achieved when the person is able to perform functional tasks in a manner similar to before the injury. (Shumway-Cook & Woollacott, 2012). Traditionally, the neurophysiological approaches adopted this restricted view of recovery. Recovery, according to these approaches, can stop at any level along the continuum, and this is not totally predictable. The speed of early spontaneous recovery offers a clue to the ultimate level of function to be gained (Twitchell, 1951). This view of recovery is not supported by current neuroscience research (Kleim, 2011; Warraich & Kleim, 2010). The neurophysiological approaches have increasingly incorporated modern concepts of motor learning and control such as neuroplasticity and the specificity of motor learning; however, this has created some confusion in applying their treatment principles (Rao, 2011).

Definition 8-2

Motor Dysfunction Caused by Central Nervous System Lesions

Cortical Lesions

- *Hemiplegic posture or pattern of spasticity* includes retraction and depression of the scapula; internal rotation of the shoulder; flexion of the elbow, wrist, and fingers; pronation of the forearm; lateral flexion of the trunk toward the involved side; elevation and retraction of the pelvis; internal rotation of the hip; extension of the hip and knee; supination of the foot; and plantar flexion of the ankle and toes (Bobath, 1990).
- *Hypotonia* (decreased muscle tone or flaccidity) is less than normal resistance to passive elongation; the affected limb feels limp and heavy.
- *Hypertonia* (increased muscle tone) is more than normal resistance of a muscle to passive elongation. Both neural (spasticity) and mechanical (soft tissue stiffness) factors contribute to this.
- *Spasticity*, the neural component of hypertonus, is characterized by a velocity-dependent increase in tonic stretch reflexes and exaggerated tendon reflexes (Nagaoka & Kakuda, 2008). It is commonly accompanied by muscle clonus and the clasp knife reflex.
- *Clonus* is the oscillating contraction and relaxation of a limb segment caused by the alternating pattern of stretch reflex and inverse stretch reflex of a spastic muscle.
- *Clasp knife phenomenon or reflex* is resistance to passive stretch of a spastic muscle that suddenly gives way, like the blade of a jackknife.
- *Weakness* is the inability to generate the necessary force for effective motor action.
- *Loss of fractionation* is the inability to move a single joint without producing unnecessary movements in other joints resulting in stereotyped movement patterns instead of selective, flexible movement patterns.
- *Apraxia* is the inability to perform goal-directed motor activity in the absence of paresis, ataxia, sensory loss, or abnormal muscle tone. Apraxia is characterized by omissions, disturbed order of submovements within a sequence, clumsiness, perseveration, and inability to gesture or use common tools or utensils.
- *Lead pipe rigidity* is characterized by hypertonus in both agonist and antagonist muscles, with resistance to movement that is not velocity dependent and that is felt throughout the range of motion.

Cerebellar Lesions

- *Intention tremor* is the rhythmic oscillating movement that develops during precise intentional movements caused by involuntary alternating contractions of opposing muscles.
- *Dysmetria* is the inability to judge distances accurately; it results in overshooting or undershooting a specific target.
- *Decomposition of movement*, or *dyssynergia*, is characterized by movements that are broken up into a series of successive simple movements rather than one smooth movement involving multiple joints.
- *Dysdiadochokinesia* is impairment in the ability to perform repeated alternating movements, such as pronation and supination, rapidly and smoothly.
- *Adiadochokinesia* is the loss of ability to perform rapid alternating movements.
- *Ataxia* is unsteadiness, incoordination, or clumsiness of movement.
- *Ataxic gait* is a wide-based, unsteady, staggering gait with a tendency to veer from side to side.

Lesions of the Basal Ganglia

- *Tremors at rest* or *nonintention tremors* stop at the initiation of voluntary movement but resume during the holding phase of a motor task when attention wanes or is diverted to another task. Tremors at rest are fatiguing.
- *Cogwheel rigidity* is characterized by rhythmic interrupted resistance of the muscles being stretched when the wrist or elbow is flexed quickly.
- *Hypokinesia* is slowness or poverty of movement. It includes *akinesia*, difficulty initiating voluntary movements, and *bradykinesia*, slowness in carrying out movements. These symptoms are reflected in lack of facial expression, monotone speech, reduced eye movements, diminished arm swing during walking, and decreased balance and equilibrium responses seen in Parkinson's disease.
- *Festinating gait* is characterized by small, fast, shuffling steps that propel the body forward at an increasing rate and by difficulty stopping or changing directions.
- *Athetosis* is characterized by slow, writhing involuntary movements, particularly in the neck, face, and extremities. Muscle tone may be increased or decreased. Athetosis ceases during sleep.
- *Dystonia* is characterized by powerful, sustained contractions of muscles that cause twisting and writhing of a limb or of the whole body, often resulting in distorted postures of the trunk and proximal extremities.
- *Chorea* is characterized by sudden involuntary purposeless, rapid, jerky movements and/or grimacing, primarily in the distal extremities and face (e.g., Huntington's chorea).
- *Hemiballismus* is unilateral chorea in which there are violent, forceful, flinging movements of the extremities on one side of the body, particularly involving the proximal musculature.

From Fredericks, C. M., & Saladin, L. K. (Eds.). (1996). *Pathophysiology of the motor systems: Principles and clinical presentations*. Philadelphia: Davis.

Evaluations Used by Neurophysiological Approaches

Given the assumptions of the neurophysiological approaches (Definition 8-1), patient evaluation focuses primarily on abilities and capacities impaired by CNS damage. These include muscle tone, abnormal reflexes and movement patterns, postural control, sensation (see Chapter 9), perception (see Chapter 5), and cognition (see Chapter 6). In addition, it is important to determine the patient's stage of recovery or developmental level. Finally, occupational performance (see Chapter 4) is evaluated secondarily on the assumption that any deficits in these areas are due to impaired performance components. This bottom-up evaluation framework is not consistent with the Model of Occupational Functioning (see Chapter 1).

The evaluations used by the neurophysiological approaches still provide valuable information concerning the abilities and capacities of patients who have not recovered to the level required to engage in task-related approaches. For example, the constraint-induced movement therapy (CIMT), a task-related approach, requires voluntary, minimal range of motion abilities in the affected hand (Wolf et al., 2006). Evaluating muscle tone, strength, and sensation can help researchers assemble homogenous and specific research groups and helps clinicians to address their clients' specific motor behavior challenges to enhance treatment individualization.

Muscle Tone Assessment

Muscle Tone and Associated Factors. Muscle tone is defined as the resistance of a muscle to passive elongation or stretching (Shumway-Cook & Woollacott, 2012). Slight resistance in response to passive movement characterizes normal muscle tone. When the therapist moves the arm, it feels relatively light, and if the therapist lets go of it, it is able to maintain the position. Hypotonia is less than normal resistance to passive elongation. When the therapist moves the arm, it feels floppy and heavy. If the therapist lets go of it, it cannot maintain the position or resist the effects of gravity. Hypertonia, more than normal resistance of a muscle to passive elongation, is due to neural and mechanical factors. The neural factor (i.e., spasticity) is due to hyperactive stretch reflexes frequently seen after CNS damage. In a spastic muscle, there is a range of free movement, then a strong contraction of the muscle in response to stretch (i.e., stretch reflex), and free movement again when the muscle suddenly relaxes (i.e., clasp knife phenomenon or reflex) (Bellamy & Shen, 2007; Gillen, 2011). Thus, spasticity is not synonymous with hypertonus or muscle tone (Burridge et al., 2005). The mechanical factors of hypertonus are the elastic properties

of connective tissue and the viscoelastic properties of muscle. The mechanical factors change if a muscle is immobilized in a shortened or lengthened position (i.e., there is increased or decreased resistance to passive stretching) (Stolov, 1966). The neural changes after CNS damage—spasticity—contribute to abnormal positioning of limbs, which causes secondary changes in the mechanical factors. Together, the neural and mechanical factors account for increased resistance to passive elongation—hypertonus—that is seen after CNS damage (Burridge et al., 2005).

Muscle tone is measured clinically by observing the response of a muscle to passive stretch. A problem in measuring hypertonus, especially the neural factor, is the high variation in spasticity from day to day in the same patient. Furthermore, the reliability of a test is affected by the speed of the passive test movement because the tonic stretch reflexes are velocity dependent (Nagaoka & Kakuda, 2008). Reliability is also affected by effort, emotional stress, temperature, fatigue, changes in concurrent sensory stimulation, urinary tract infections, and posture. These factors make spasticity measurements context dependent. This could explain some reported instances of low levels of interrater reliability in clinical scores such as the Ashworth and the Modified Ashworth Scales even with well-trained therapists (Bhimani et al., 2011). Rigid standardization of the test procedure must be the rule; otherwise, the findings may be misleading (Burridge et al., 2005; Platz et al., 2005). Poor evaluation techniques that allow high test–retest variability may obscure therapeutic effectiveness. Although there are many assessments of muscle tone and spasticity described in the literature (Bhimani et al., 2011; Platz et al., 2005), most are not practical for clinical use, and the Modified Ashworth Scale (MAS) is the most widely used (van Wijck et al., 2001).

Modified Ashworth Scale. Ashworth (1964) proposed a qualitative scale for assessing the degree of spasticity as part of a drug study. The resistance encountered to passive movement through the full available range was rated on a 5-point scale (from 0 to 4). Although it was developed and described as a measure of spasticity, it is a measure of muscle tone or the resistance to passive movement (Burridge et al., 2005; Pandyan et al., 2002). Bohannon and Smith (1987) modified the Ashworth Scale (Procedures for Practice 8-1) by adding an additional level (1+), by incorporating the angle at which resistance first appeared, and by controlling the speed of the passive movement with a 1-second count. The examiner performs five to eight repetitions of the movement before assigning the rating. Assessment Table 8-1 describes the psychometric properties of the MAS, which has modest evidence of concurrent validity.

Procedures for Practice 8-1

Modified Ashworth Scale for Grading Spasticity

Grade	Description
0	No increase in muscle tone
1	Slight increase in muscle tone manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part or parts are moved in flexion or extension
1+	Slight increase in muscle tone manifested by a catch, followed by minimal resistance throughout the remainder (less than half) of the ROM
2	Marked increase in muscle tone through most of the ROM, but affected parts are easily moved
3	Considerable increase in muscle tone; passive movement difficult
4	Affected part or parts rigid in flexion or extension

Reprinted with permission from Bohannon, R. W., & Smith, M. B. (1987). Interrater reliability of a Modified Ashworth Scale of muscle spasticity. *Physical Therapy, 67,* 207. Copyright 1987 by American Physical Therapy Association.

Recently, the MAS was modified to be the Modified Modified Ashworth Scale (MMAS). This modification deleted the additional grade of 1+ between 1 and 2 from MAS and changed evaluation criteria (Ansari et al., 2006) to enhance the validity and reliability of the MAS. The MMAS has five categories scored 0–4 like the original Ashworth Scale. The scoring criteria for categories 1 and 2 reflect slight or marked increase in tone, but the MMAS includes additional stipulations about catch and resistance, which is similar to the MAS. The MMAS scoring criteria is as follows: 0 = no increase in muscle tone; 1 = slight increase in muscle tone, manifested by a catch and release or by minimal resistance at the end of the range of motion when the affected part(s) is moved in flexion or extension; 2 = marked increase in muscle tone, manifested by a catch in the middle range and resistance throughout the remainder of the range of motion, but affected part(s) easily moved; 3 = considerable increase in muscle tone, passive movement difficult; and 4 = affected part(s) rigid in flexion or extension. However, it seems that both MAS and MMAS have very good interrater reliability with no superiority for one over the other, as indicated in a study evaluating elbow flexor spasticity post stroke (Kaya et al., 2011).

SYSTEMS-BASED TASK-RELATED APPROACHES

The occupational therapy task-oriented approach (Almhdawi, 2011; Mathiowetz, 2011), the Carr and Shepherd Motor Learning Programme for Stroke (Carr & Shepherd, 2011), and CIMT (Wolf et al., 2006) are examples of the systems-based task-related approaches. The assumptions of these approaches are listed in Definition 8-1. They originate from a systems model of motor behavior, a systems view of motor development, an ecological view of action and perception, and motor learning theories related to the stages of learning, practice schedule, feedback, and learning transfer as discussed in Chapter 13. To understand the evaluation framework of the systems-based task-related approaches, it is important to understand the origins of their assumptions.

Systems Model of Motor Control

Over the past 35 years, a model of motor control has evolved from the ecological approach to perception and action (Gibson, 1979; Turvey, 1977) and from the study of complex dynamical systems in mathematics and the sciences (Gleick, 1987). The new model emphasizes the interaction between persons and environments and suggests that motor behavior emerges from persons' multiple systems interacting with unique task and environmental contexts (Newell, 1986). Thus, the systems model of motor control is more interactive or heterarchical and emphasizes the role of the environment more than the reflex-hierarchical model.

In this newer model, the nervous system is only one system among many that influence motor behavior. The nervous system itself is thought to be organized heterarchically so that higher centers interact with the lower centers but do not control them. Closed-loop and open-loop systems work cooperatively, and both feedback and feed-forward control are used to achieve task goals. The CNS interacts with multiple personal and environmental systems as a person attempts to achieve a goal.

Ecological Approach to Perception and Action. The ecological approach to perception and action emphasizes the study of interaction between the person and the environment during every day functional tasks and the close linkage between perception and action (i.e., purposeful movement). Gibson recognized the role of functional goals and the environment in the relationship between perception and action. He stated that direct perception entails the active search for *affordances* (Gibson, 1977), defined as the functional use of objects for persons and their unique characteristics (Warren, 1984). Thus, Gibson's concept of affordances explains the close relationship between perception and action in terms of what the information in the environment means to a specific person.

Assessment Table 8-1 | Psychometric Properties of Assessments of Muscle Tone or Resistance to Passive Movement.

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Modified Ashworth Scale (Bohannon & Smith, 1987)	Ordinal scale with score for each motion from 0 (normal muscle tone) to 4 (rigid in flexion or extension). Modification is the addition of one additional rating level (1+).	1–2 minutes per motion tested	Concurrent validity: $r_s = 0.39$–0.49 with quantitative spasticity measures (Allison & Abraham, 1995); $r = 0.50$ with motor and activity scores (Sommerfeld et al., 2004); $r_s = 0.51$ with resistance to passive movement (Pandyan et al., 2003); $r_s = 0.40$ with the H-reflex (Pizzi et al., 2005).	Interrater reliability: $K_w^1 = 0.49$–0.54 for shoulder, elbow, wrist, knee, and ankle joints (Mehrholz et al., 2005). Test–retest reliability: $K_w = 0.77$–0.94 for elbow, wrist, and knee flexors; $K_w = 0.59$–0.64 for ankle plantarflexors (Gregson et al., 2000) Interrater reliability: $K_w = 0.868$ for elbow flexor spasticity post stroke (Kaya et al., 2011) Both inter- and intrarater reliability $K_w > 0.8$ and ICC > 0.8) for subjects with developmental disabilities (Waninge et al., 2011).	Findings regarding sensitivity are mixed. One study found significant reduction in Modified Ashworth Scale scores after treatment with botulinum toxin (Bakheit et al., 2000, 2001) while another found nonsignificant reduction in Modified Ashworth Scale scores after treatment with botulinum toxin (Pandyan et al., 2002)	Strengths: It is a valid measure of muscle tone or resistance to passive movement (Pandyan et al., 2002); administration time is relatively brief; reliability is better for upper extremity than lower extremity joints. Moderate to good interrater reliability; moderate to very good test–retest reliability. Weakness: Only moderate concurrent validity with measures of spasticity; therefore, it is questioned as a measure of the neural component of muscle tone.

[1] Kw, weighted kappa.

Bernstein (1967) recognized the importance of the environment and personal characteristics (beyond the CNS) in motor behavior. He suggested that the role a particular muscle plays in a movement depends on the context or circumstances. Bernstein identified three possible sources of variability in muscle function. A first source is anatomical factors. For example, from kinesiology you know that the pectoralis major muscle will either flex or extend the shoulder, depending on the initial position of the arm. A second source of variability is mechanical factors. Many nonmuscular forces, such as gravity and inertia, determine the degree to which a muscle must contract. For example, a muscle must exert much more force to contract against gravity than in a gravity-eliminated plane. A third source of variability is physiological factors. When higher centers send down a command for a muscle to contract, middle and lower centers have the opportunity to modify the command. Lower and middle centers receive peripheral sensory feedback. Thus, the effect of the command on the muscle varies depending on the context and degree of influence of the middle and lower centers. As a result, the relationship between higher center or executive commands and muscle action is not one to one. The context can influence the movement patterns. Goal-directed, object-present activity has been shown to elicit different and more efficient movement patterns than non–goal-directed exercise (Lin et al., 2007; Trombly & Wu, 1999)

Thus, postures and movements are not triggered by external stimulation or central commands, as suggested by the reflex-hierarchical model, but are coordinative structures, capable of adapting to changing circumstances. Coordinative structures are groups of muscles, usually spanning several joints that are constrained to act as a single functional unit (Bockemühl, Troje, & Dürr, 2010; Magill, 2004). When learning a new task, a person tends to constrain or stiffen many joints to reduce the degrees of freedom to be controlled. This use of a coordinative structure enables the person to focus on controlling a limited number of joints. Natural tenodesis grasp and release is an example of a coordinative structure. The long flexor and extensor muscles of the forearm are constrained to work together for functional grasp and release. The coordinative structures can be modulated by sensory feedback in response to changes in the task context or demand (Safavynia & Ting, 2012; Ting et al., 2009)

Dynamical Systems Theory. The study of dynamical systems originated in mathematics, physics, biology, chemistry, psychology, and kinesiology, and it has been applied to OT, physical therapy, nursing, adapted physical education, and some areas of medicine (Burton & Davis, 1992; Lister, 1991). It has influenced the systems model of motor control as well. Dynamical systems theory proposes that behaviors emerge from the interaction of many systems. Because the behavior is not specified but emergent, it is considered to be self-organizing (Lewis, 2000). This concept of self-organization

is not compatible with the assumptions of the reflex-hierarchical model, which suggests that higher centers or motor programs prescribe movements. Evidence of self-organization is seen in the relatively stable patterns of motor behavior seen in many tasks in spite of the many degrees of freedom available to a person (Perry, 1998; Thelen & Ulrich, 1991). When we eat or write, we have many choices of ways to perform these tasks, yet we tend to use preferred patterns.

Behavior can change from stable to less stable as a result of aging or CNS damage. In fact, throughout life, behaviors shift between periods of stability and instability. It is during unstable periods, characterized by a high variability of performance, that new types of behaviors may emerge, either gradually or abruptly. These transitions in behavior, called phase shifts, are changes from one preferred pattern of coordinated behavior to another. An example of a gradual phase shift is when individuals with impaired gait post stroke change their stable inefficient gait pattern into more efficient ones in response to gait training. An example of an abrupt phase shift is when a person in a hurry walks faster and faster and suddenly changes to a running pattern.

In the dynamical systems view, control parameters are variables that shift behavior from one form to another. They do not control the change but act as agents for reorganization of the behavior to a new form (Perry, 1998). Control parameters are gradable in some way to simplify the motor tasks or to add some therapeutic challenge. This challenge should be appropriate to the client's level of motor performance, which is well known as the "just-right challenge." Therapists can influence motor behavior by manipulating the external control parameters, such as task variables (tools characteristics, success requirements, or time) or features in the environment (such as the physical space and the item setup). Internal control parameters also can be manipulated such as body alignment, muscle length, and muscle strength to influence the motor behavior. This change in motor behavior is described as a nonlinear system where the output is not proportional to the input (Harbourne & Stergiou, 2009).

Explanations of changes in motor behavior in the systems model of motor control are quite different from earlier neurophysiological models. Thelen (1989) stated that an important characteristic of a systems perspective is that the shift from one preferred movement pattern to another is marked by discrete, discontinuous transitions. These transitions in motor behavior are the result of changes in only one or a few personal or environmental systems (i.e., control parameters) (Davis & Burton, 1991). The dynamic systems theory also emphasizes the role of variability in controlling movements. Optimum movement variability is required to guarantee having flexible adaptive motor strategies that could accommodate for contextual change (Shumway-Cook & Woollacott, 2012). Thus, two important points are (1) systems themselves are

subject to change, and (2) there is no inherent ordering of systems in terms of their influence on motor behavior.

Systems Model of Motor Behavior

Figure 8-2 depicts the theoretical basis of the systems-based task-oriented approach. It illustrates the interaction between the systems of the *person* (cognitive, psychosocial, and sensorimotor) and the systems of the *environment* (physical, socioeconomic, and cultural). Ability to accomplish occupational tasks and activities of daily living (ADL), work, or play/leisure emerges from the interaction between the person and the environment. Changes in any one of these systems can affect occupational performance tasks and ultimately role performance. In some cases, only one primary factor may determine occupational performance. In most cases, occupational performance emerges from the interaction of many systems. The ongoing interactions among all components of the model reflect its heterarchical nature.

In addition, any occupational performance task affects the environment in which it occurs and the person acting. For example, a client with hemiplegia who has just become independent in making his own lunch may free his spouse from coming home from work during her lunch hour. It also may mean that certain objects in the kitchen must be kept in accessible places, and the kitchen may not be as orderly as the spouse is used to. Thus, the task of making lunch affects

people and objects in the environment. It also affects the person and the associated performance skills and patterns. The ability to be less dependent on his spouse may improve the client's self-esteem (i.e., psychosocial subsystem). The process of making lunch provides the client the opportunity to solve problems and to discover optimal strategies for performing tasks. This influences a client's cognitive and sensorimotor subsystems and the ability to perform other functional tasks. The various parts of the systems model of motor behavior can be related to the Occupational Therapy Practice Framework (OTPF) (American Occupational Therapy Association [AOTA], 2008) and the Occupational Functioning Model (OFM) (see Chapter 1).

View of Recovery after Central Nervous System Dysfunction

A client with a damaged CNS attempts to compensate for the lesion to achieve functional goals. Recovery from brain damage is a process of discovering what abilities and capacities remain to enable performance of activities and tasks. CNS damage affects each system differently relative to occupational performance. Therapists must consider all systems as potential variables to explain the behavior of each client at a specific time. For example, the flexor pattern commonly seen after a stroke is due to various factors in addition to spasticity, such as the inability to recruit appropriate

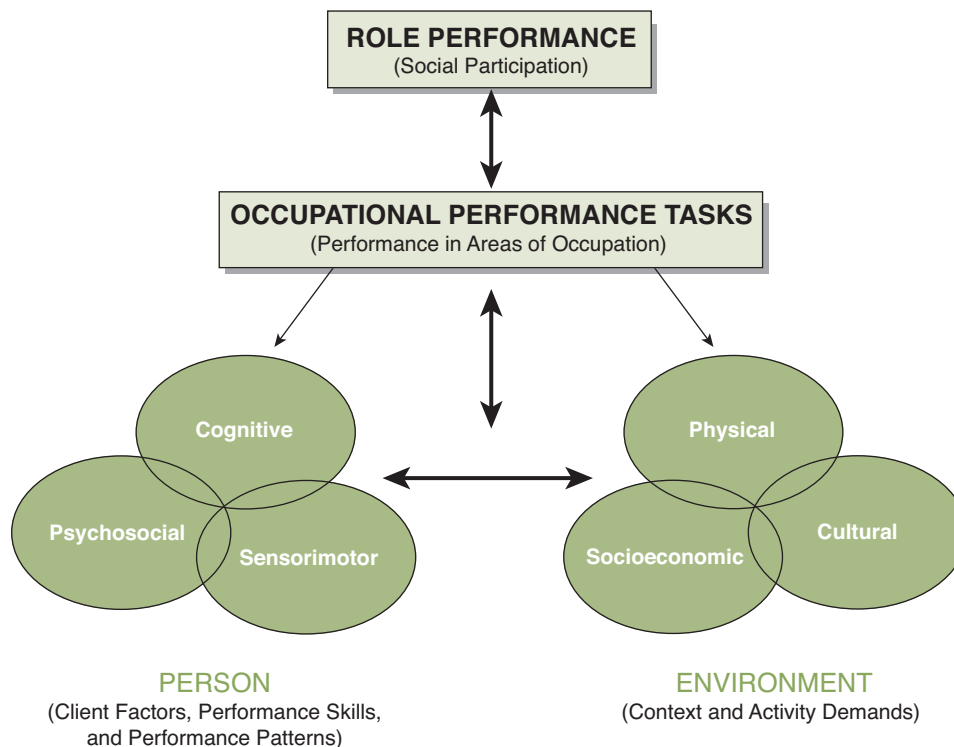

Figure 8-2 Systems model of motor behavior offer some of the theoretical bases of the task-related approaches. The occupational performance tasks and role performance emerge from an interaction of the person and environment. (Adapted with permission from Mathiowetz, V., & Bass Haugen, J. [2008]. Assessing abilities and capacities: Motor behavior. In M. V. Radomski & C. A. Trombly Latham [Eds.], *Occupational therapy for physical dysfunction* [6th ed., pp. 186–211]. Baltimore: Lippincott Williams & Wilkins.)

muscles, weakness, soft tissue tightness, and perceptual deficits (Bourbonnais & Vanden Noven, 1989; Shumway-Cook & Woollacott, 2012). This pattern may become obligatory because of abnormal positioning and decreased use in functional contexts. Because each client is a unique person and functions in a unique environment, therapists should expect recovery for each client to vary even if the CNS damage is similar (Almhdawi, 2011). In contrast with the neurophysiological approaches, the systems-based task-related approaches adopt a more flexible definition of recovery to include achieving tasks or goals using efficient and effective techniques or methods of performance not necessarily matching the ones used before the CNS injury (Shumway-Cook & Woollacott, 2012; Wittenberg, 2010).

There is increasing evidence that neural reorganization after a brain lesion reflects the functional demands on the CNS. For example, forced use of the involved limb has improved functional performance in persons more than a year post stroke (Gauthier et al., 2008; Liepert et al., 2000). These changes cannot be attributed to spontaneous recovery. Thus, providing appropriately challenging tasks and environments for those with CNS dysfunction, both in the hospital and at home, appears critical to the maximal rehabilitation of our clients (Bach-y-Rita, 1993; Nudo, 2011).

Evaluation Using the Systems-Based Task-Related Approaches

Evaluation is conducted using a top-down approach consistent with the Model of Occupational Functioning (see Chapter 1). A framework for evaluating motor behavior is described in Procedures for Practice 8-2 and illustrated in Figure 8-3.

First, evaluation focuses on role performance. A thorough understanding of the roles that a client wants, needs, or is expected to perform and of the tasks needed to fulfill those roles enables therapists to plan meaningful and motivating treatment programs. Although role definition and expectations can be assessed using a nonstandardized, semistructured interview, a standardized assessment tool such as the Role Checklist (Barris, Oakley, & Kielhofner, 1988; Hemphill-Pearson, 2007) is recommended. The Role Checklist is a written inventory designed for adolescents and adults with physical dysfunction. With clients undergoing major role

---

Procedures for Practice 8-2

Evaluation Framework for the Systems-Based Task-Related Approaches

1. Role Performance

- Determine interest in, and definition of, self-maintenance, self-advancement, and self-enhancement roles
- Identify past roles and whether they can be maintained or must be changed.
- Determine how future roles will be balanced: worker, student, volunteer, home maintainer, hobbyist, amateur, participant in organizations, friend, family member, caregiver, religious participant, other.

2. Occupational Performance Tasks: Areas of Occupation

Determine abilities in the following areas of occupation (AOTA, 2008).

- Activities of daily living (ADL): feeding, grooming, functional mobility, dressing, oral and toilet hygiene, bowel and bladder management, and bathing/showering.
- Instrumental ADL: care of others and/or pets, communication device use, community mobility, home management, meal preparation and clean-up, safety procedures, shopping, and others unique to the patient.
- Work-related tasks: employment seeking and acquisition; job performance; volunteer exploration and participation; and retirement preparation and adjustment.
- Play-leisure: exploration and participation.

3. Task Selection and Analysis

The therapist observes a functional task important to the client to identify which performance components and/or performance contexts limit or enhance occupational performance. The task setup should be as similar to the client's natural environment and tools as possible.

4. Person: Performance Components

- Cognitive: orientation, attention span, memory, problem solving, learning, and generalization.
- Psychosocial: values, interests, self-concept, interpersonal skills, self-expression, coping skills, time management, and self-control.
- Sensorimotor: strength, endurance, range of motion, coordination, sensory awareness and processing, perceptual processing, and postural control.

5. Environment: Performance Context

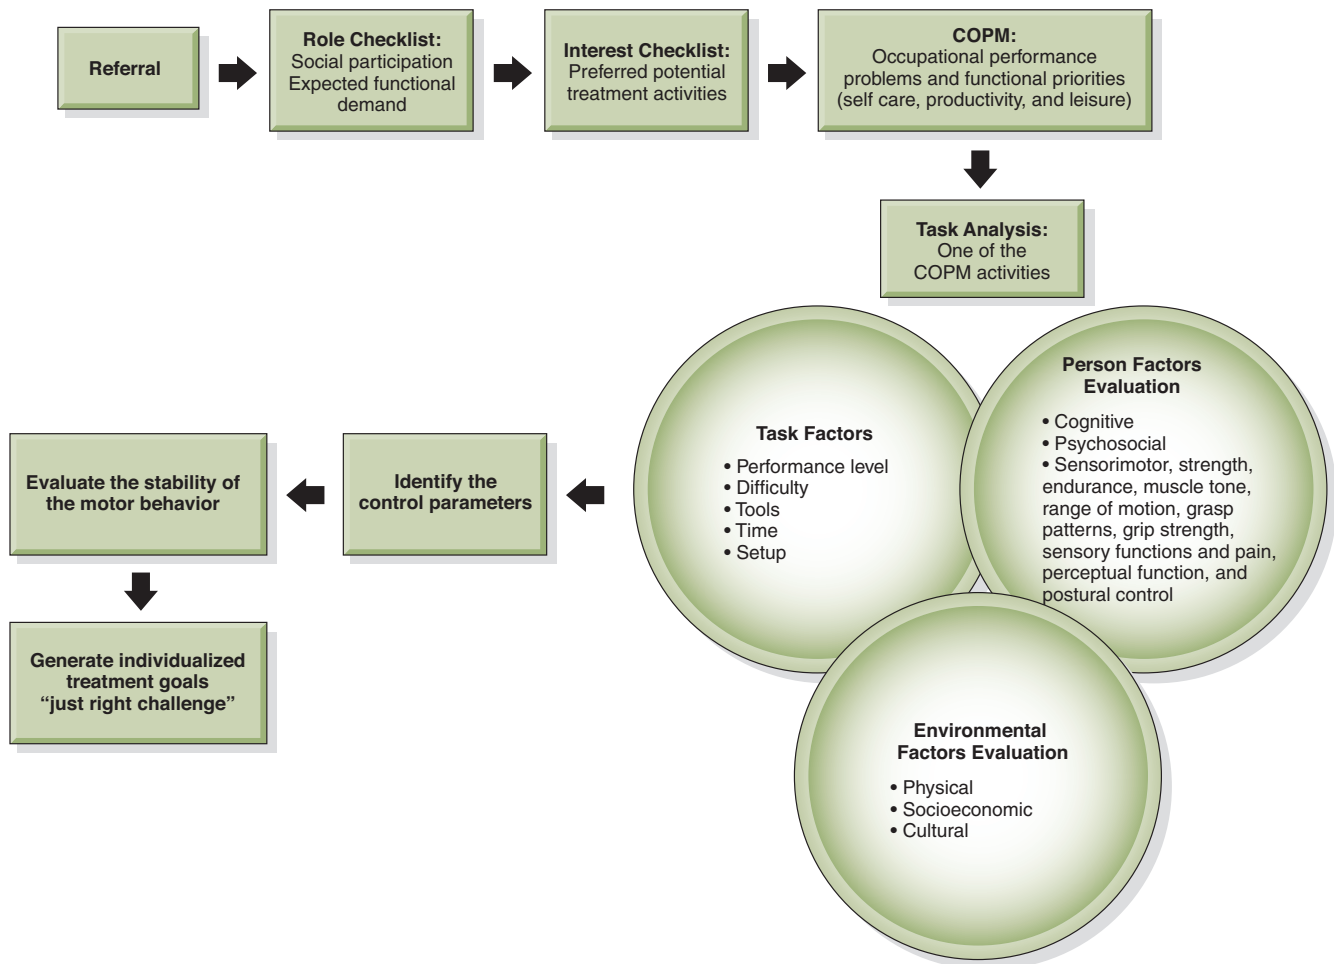
- Physical: objects, tools, devices, animals, and built and natural environments.
- Socioeconomic: social supports, including family, friends, caregivers, social groups, and community and financial resources.
- Cultural: ethnicity, family, attitudes, beliefs, values, customs, and societal expectations.


Figure 8-3 The occupational therapy task-oriented approach suggested evaluation flowchart. COPM, Canadian Occupational Performance Measure. (Adapted with permission from Almhdawi, K. A. [2011]. *Effects of occupational therapy task-oriented approach in upper extremity post-stroke rehabilitation* [Doctoral dissertation]. Retrieved from University of Minnesota Digital Conservancy.)

changes and when there is sufficient time for a comprehensive assessment, the Role Change Assessment for older adults (Rogers & Holm, 2007) or Client-Oriented Role Evaluation (CORE) (Toal-Sullivan & Henderson, 2004) are recommended.

Second, evaluation focuses on the assessment of occupational performance tasks: ADL, instrumental ADL, work, and play-leisure (Procedures for Practice 8-2). Because tasks, activities, and their contexts are unique to each role of each person, a client-centered assessment tool such as the Canadian Occupational Performance Measure (COPM) (Law et al., 1998) is recommended. It was designed to measure a client's perception of his or her occupational performance over time. A semistructured interview is used to administer the COPM. First, clients are asked to identify problem areas in self-care, productivity, and leisure. Second, the client rates the importance of each problem area. Third, clients rate their own performance and their satisfaction with the performance. The importance ratings assist therapists in setting treatment priorities. The information elicited by the COPM is unique to each client

and his or her environmental context, which is a critical facet of the systems-based task-related approaches.

While evaluating occupational performance tasks, therapists must observe both the outcome and the process (i.e., the preferred movement patterns, their stability or instability, the flexibility to use other patterns, efficiency of the patterns, and ability to learn new strategies) to understand the motor behaviors used to compensate and to achieve functional goals. It is important to determine the stability of the motor behavior, because it will help determine the feasibility of achieving behavioral change in treatment. Behaviors that are very stable require a great amount of time and effort to change. Behaviors that are unstable are in transition, the optimal time for eliciting behavioral change. Thus, a compensatory approach may be most appropriate when behaviors are stable, and a remediation approach may be more appropriate when behaviors are unstable.

Third is task selection and analysis (see Procedures for Practice 8-3). The tasks selected for observation should be ones that the client has identified as important but

Procedures for Practice 8-3

Assessment of Task Performance

During task observation, the therapist assesses performance for the following:

- Evidence of mobility impairments at specific joints
- Missing or limited components (e.g., lack of anterior pelvic tilt, hip flexion, ankle dorsiflexion when rising to stand)
- Incorrect timing of components within a movement pattern (e.g., inappropriate interplay among extrinsic and intrinsic finger muscles during attempts at grasp)
- Evidence of weakness or paralysis of specific muscles (e.g., weakness in quadriceps on attempts to stand up)
- Compensatory motor behavior (e.g., elevation of the entire shoulder girdle on attempts to reach forward)

difficult. Therapists use task or activity analysis (see Chapter 12) to determine whether there is a match between task requirements and personal characteristics that enables task performance within a relevant environment. If not, therapists attempt to determine which personal and/or environmental factors are interfering with occupational performance tasks. In dynamical systems theory, these personal or environmental factors are considered critical control parameters, or the variables that have the potential to shift behavior to a new level of task performance. Each person with CNS dysfunction has unique strengths, limitations, and environmental context. As a result, the critical control parameters that limit or support occupational performance tasks are also unique. Case studies by Flinn (1995) and Gillen (2000, 2002) illustrate the search for critical control parameters.

In its simplest form, this search consists of observing a functional task of high priority for the client via a task analysis process. The therapist hypothesizes reasons for poor motor behavior performance. When noticing an inefficient movement pattern (i.e., one that requires unaffordable energy or time), the therapist needs to list the reasons for that pattern. Poor grasp patterns (in poststroke rehabilitation, for example) are inefficient movement patterns that might be related to spasticity, tremor, learned nonuse, weakness, impaired sensations, and/or soft tissue tightness. Once the therapist accurately identifies the reasons for poor movement patterns, the therapy process can be much more focused, effective, and individualized (Almhdawi, 2011).

After identifying the variables that support or constrain occupational performance, the therapist must assess the interactions of these systems. For example, a carpenter whose occupation requires overhead nailing would be more affected by a small shoulder flexion limitation

than a secretary. This is a qualitative evaluation that depends on the therapist's clinical reasoning concerning the client's priorities and the feasibility of the therapeutic change attempt of the motor behavior patterns.

Fourth is to perform specific assessments of the personal and/or environmental factors that are hypothesized to be critical control parameters. The critical control variables are the only ones that must be specifically evaluated. This eliminates the need to evaluate variables that have little functional implication and saves therapists' time, which is critical for cost containment. Some assessments are designed to examine one or more environmental influences or personal factors within the context of occupational performance to detect possible control parameters. From a systems-based task-related perspective, these are preferred assessment tools because they closely link client factors to occupational performance. For example, the A-One Evaluation (Arnadottir, 1990) facilitates evaluation of perceptual and cognitive systems within the context of ADL. Assessments might also include the Unidimensional Fatigue Impact Scale (Meads et al., 2009). This scale was developed to evaluate the perceived effect of fatigue on the everyday lives of those with multiple sclerosis. The Assessment of Motor and Process Skills (AMPS) evaluates cognitive and motor processes underlying occupational performance (Gantschnig, Page, & Fisher, 2012; Merritt, 2011). This assessment requires extensive training and calibration on the part of the evaluator (Fisher, 2012). Personal factor assessments examine muscle strength, joint range of motion, edema, and endurance (Chapter 7); motor behavior (discussed below); sensation (Chapter 9); coordination (Chapter 37); and/or the cognitive and visual abilities discussed in Chapters 5 and 6, independent of occupational context.

Evaluation of a client's environment may include assessment of physical, social, cultural, personal, or temporal environments, which the AOTA (2008) practice framework acknowledges as important influences on occupational performance. Chapters 3 and 10 review assessments for these variables.

Assessments of Motor Behavior and Motor Function

Motor Assessment Scale.   Carr et al. (1985) developed the Motor Assessment Scale (MAS) as an easily administered and relatively brief (15–30 minutes) assessment relevant to everyday motor activities (Procedures for Practice 8-4). The original version of the MAS included a ninth subtest, muscle tone, which has been deleted because it had poor reliability and questionable validity. The psychometric properties of MAS are described in Assessment Table 8-2. Because reliability and validity data for individual subtests of the MAS are available, one or more subtests can be used independently with each client.

Procedures for Practice 8-4

Abridged Criteria for Scoring Motor Assessment Scale

The score assigned on each item is the highest criterion met on the best performance of three. A 0 score is assigned if the patient is unable to meet the criteria for a score of 1.

0 1 2 3 4 5 6

Supine to Side-Lying to Intact Side

1. Pulls self into side-lying with intact arm, moving affected leg with intact leg.
2. Moves leg across actively and lower half of body follows. Arm is left behind.
3. Lifts arm across body with other arm. Moves leg actively; body follows in a block.
4. Actively moves arm across body; rest of body follows in a block.
5. Rolls to side, moving arm and leg; overbalances. Shoulder protracts and arm flexes.
6. Rolls to side in 3 seconds. Must not use hands.

Supine to Sitting on Edge of Bed

1. After being assisted to side-lying, lifts head sideways; cannot sit up.
2. Side-lying to sitting on edge of bed with therapist assisting movement.
3. Side-lying to sitting on edge of bed with standby help assisting legs over side of bed.
4. Side-lying to sitting on edge of bed with no standby help.
5. Supine to sitting on edge of bed with no standby help.
6. Supine to sitting on edge of bed within 10 seconds with no standby help.

Balanced Sitting

1. Sits only with support after therapist assists.
2. Sits unsupported for 10 seconds.
3. Sits unsupported with weight well forward and evenly distributed.
4. Sits unsupported with hands resting on thighs; turns head and trunk to look behind.
5. Reaches forward to touch floor 4 inches in front of feet and returns to starting position.
6. Sitting on stool, reaches sideways to touch floor and returns to starting position.

Sitting to Standing

1. Gets to standing with help (any method).
2. Gets to standing with standby help.
3. Gets to standing with weight evenly distributed and with no help from hands.
4. Gets to standing; stands for 5 seconds, weight evenly distributed, hips and knees extended.
5. Stands up and sits down with no help; even weight distribution; full hip and knee extension.
6. Stands up and sits down with no help 3 times in 10 seconds; even weight distribution.

Walking

1. Stands on affected leg with hip extended; steps forward with other leg (standby help).
2. Walks with standby help from one person.
3. Walks 10 feet alone. Uses any walking aid but no standby help.
4. Walks 16 feet with no aid in 15 seconds.
5. Walks 33 feet, picks up small sandbag from floor, turns around, walks back in 25 seconds.
6. Walks up and down four steps with or without an aid three times in 35 seconds. May not hold rail.

Upper Arm Function

1. Supine, protracts shoulder girdle. Tester places arm in 90° flexion and supports elbow.
2. Supine, holds shoulder in 90° flexion for 2 seconds. (Maintains 45° external rotation and 20° elbow extension.)
3. From position in level 2, flexes and extends elbow to move palm to forehead and back.
4. Sitting, holds arm in 90° shoulder flexion with elbow extended, thumb pointing up, for 2 seconds. No excess shoulder elevation.
5. Achieves position in level 4; holds for 10 seconds; lowers arm. No pronation allowed.
6. Standing, arm abducted 90°, with palm flat against wall. Maintains hand position while turning body toward wall.

Hand Movements

1. Sitting, lifts cylindrical object off table by extending wrist. No elbow flexion allowed.
2. Sitting, forearm in midposition. Lifts hand off table by radially deviating wrist. No elbow flexion or forearm pronation allowed.
3. Sitting, elbow into side, pronates and supinates forearm through three-quarters of range.
4. Sitting, reaches forward to pick up 5-inch ball with both hands and puts ball down. Ball placement requires elbow extension. Palms stay in contact with ball.
5. Sitting, picks up plastic foam cup from table and puts it on table across other side of body.
6. Sitting, continuous opposition of thumb and each finger more than 14 times in 10 seconds.

Advanced Hand Activities

1. Reaches forward arm's length; picks up pen top; releases it on table close to body.
2. Picks up a jellybean from teacup with eight jellybeans and places it in another cup. Cups are at arm's length.
3. Draws horizontal lines to stop at a vertical line 10 times in 20 seconds.
4. Makes rapid consecutive dots with a pen on a sheet of paper. (Picks up and holds pen without assistance; at least 2 dots per second for 5 seconds; dots, not dashes).
5. Takes a dessert spoon of liquid to the mouth, without spilling. (Head cannot lower toward spoon).
6. Holds a comb and combs hair at back of head. (Shoulder is externally rotated, abducted at least 90°; head is erect.)

Assessment Table 8-2 | Psychometric Properties of Assessments of Motor Behavior and Function

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Motor Assessment Scale (MAS) (Carr et al., 1985)	Eight areas of motor function are rated on a 7-point hierarchical scale: 0 = easiest task and 6 = hardest task.	15–30 minutes for total MAS (Carr et al., 1985); 18–60 minutes for total MAS (Malouin et al., 1994).	Concurrent validity: $r_s = 0.88$ with the total FMA[1]; $r_s = 0.91$ for total upper extremity; $r_s = 0.28$ for balanced sitting (Poole & Whitney, 1988); $r_s = 0.96$ with the total FMA (Malouin et al., 1994). Predictive validity: arm function at 1 week ($r_s = .84$) and at 1 month ($r_s = .91$) are good predictors of arm function at discharge (Loewen & Anderson, 1990). Discriminates between different levels of motor recovery post stroke (Miller et al., 2010).	Interrater reliability: $r = 0.95$ and average of 87% agreement between raters (Carr et al. 1985); $r_s = 0.99$ between raters (Poole & Whitney, 1988). Test–retest reliability: $r = 0.96$ on clients post stroke (Miller et al., 2010).	Significant improvements for clients post stroke on all subtests as a result of clinical interventions (Ada & Westwood, 1992; Dean & Mackey, 1992).	Strengths: Items are functionally relevant; administration time is short. Evidence supports its reliability, validity, and sensitivity. Weaknesses: Sequence of the scoring hierarchy of the hand function and advanced hand activities scales is questioned (Dean & Mackey, 1992; Sabari et al., 2005)
Arm Motor Ability Test (AMAT) (Kopp et al., 1997)	Thirteen unilateral and bilateral functional tasks scored on performance time, functional ability, and quality of movement	30–45 minutes	Concurrent validity: $r_s = 0.92$–0.94 with FMA[1] (Chae, Labatia, & Yang, 2003); $r_s = 0.45$–0.61 with Motricity Index: arm score (Kopp et al., 1997). Appeared to be valid in a literature review (O'Dell et al., 2011)	Interrater reliability: $r_s = 0.97$–099; $K = 0.68$–0.77. Test–retest reliability: $r = 0.93$–0.99 Internal consistency: $K = 0.94$–0.99 (Kopp et al., 1997)	Significant improvement in scores after 1 or 2 weeks of intensive therapy (Kopp et al., 1997); significant improvement in scores after constraint-induced movement therapy (Kunkel et al., 1999)	Strengths: Use of functional tasks; excellent reliability; evidence of validity. Weaknesses: Ceiling and floor effects for performance time (Chae, Labatia, & Yang, 2003); less sensitive to change than the WMFT[2] (Morris et al., 2001)

Assessment	Description	Time	Reliability and Validity	Sensitivity to Change	Strengths and Weaknesses
Wolf Motor Function Test (WMFT) (Wolf et al., 2001; Morris et al., 2001)	Seventeen tasks: 2 measure strength; 15 are sequenced according to joints involved and level of difficulty (Edwards et al., 2012). Six timed upper extremity movements and nine timed functional tasks (Wolf et al., 2001). Functional Ability Scale (FAS) added (Morris et al., 2001). Yields three scores: speed of performance (seconds), quality of performance (6-point ordinal scale), and strength of grip (kilogram) (Edwards et al., 2012).	30–45 minutes	Discriminates between healthy persons and those post stroke (Wolf et al., 2001). Sensorimotor and kinematic measures of reach and grasp support the construct validity (Edwards et al., 2012). Concurrent validity with the Action Research Arm Test (ARAT): time ≥ 0.64, FAS ≥ 0.75 (Edwards et al., 2012)	Interrater reliability: r = 0.95–0.99 (Wolf et al., 2001). ICC ≥ 0.93 and agreement between raters ≥ 0.88 performance time and FAS (Morris et al., 2001). Test–retest reliability: r = 0.95 for FAS and 0.90 for performance time (Morris et al., 2001). Internal consistency: Cronbach's α=0.86–0.92 for performance time and functional ability (Morris et al., 2001); Cronbach's α ≥ 0.96 for both FAS and time scores (Edwards et al., 2012).	Significant improvement in scores after CIMT (Kunkel et al., 1999; Wolf et al., 2006). The FAS score is sensitive to clinical change in the acute stage of stroke recovery (Edwards et al., 2012) and in the chronic stage (Morris et al., 2001).	Strengths: Combination of simple and complex movements; excellent interrater and test–retest reliability for performance time; excellent internal consistency; more sensitive to change than the AMAT (Morris et al., 2001). First estimate of minimal clinically important differences were grip strength (5.0 and 6.2 kg) and FAS (1.0 and 1.2) for dominant and nondominant hands, respectively (Lang et al., 2008). Weakness: Nine individual items had less than adequate interrater reliability on the FAS (Morris et al., 2001).
Motor Activity Log (MAL) (Taub et al., 1993)	Thirty common daily life tasks tested for the affected post-stroke upper extremity. Two scales: amount of use (AOU) and quality of movement (QOM). It is a self-report instrument.	20–30 minutes	High concurrent validity of the QOM scale with an objective accelerometer-based measure of arm movement: r = 0.91; good internal consistency of both scales: Cronbach's α > 0.81 (Uswatte et al., 2005)	High (test–retest) reliability of the QOM scale: r > 0.91 (Uswatte et al., 2005)	Significant improvement in scores following CIMT (Kunkel et al., 1999; Wolf et al. 2006).	Strengths: Measures the actual use of the post-stroke affected upper extremity in real life situations; strong reliability and sensitivity. Minimal therapist time to score. Weaknesses: Subjective because it is a self-report measure. AOU not found reliable (Uswatte et al., 2005).
Fugl-Meyer Motor Assessment (FMA) (Fugl-Meyer et al., 1975)	Test of motor and sensory impairment after stroke. Most items are scored on a 3-point ordinal scale (0 = cannot be performed; 1 = performed partly; and 2 = performed faultlessly).	34–110 minutes for total FMA; 30–45 minutes for the upper and lower extremity subtests; 8–12 minutes for the upper extremity subtest alone	Actual motor recovery post stroke parallels the test items (Fugl-Meyer et al., 1975). Concurrent validity: r_s = 0.88 with total Motor Assessment Scale (Poole & Whitney, 1988) and r = 0.68–0.85 with the Barthel Index (Wood-Dauphinee, Williams, & Shapiro, 1990) and Spearman's rank correlation (ρ = 0.91–0.96) among FMA, Motor Status Scale, and ARAT (Wei, Tong, & Hu, 2011).	Interrater reliability: r = 0.79–0.99 for the upper and lower extremity subtests (Duncan, Propst, & Nelson, 1983). Interrater reliability for trainees versus an expert rater: ICC = 0.91–0.99 for motor scores and 0.87–0.96 for sensory scores (Sullivan et al., 2011) Intrarater (test–retest) reliability: r = .86 to .99 across three test times (Duncan, Propst, & Nelson, 1983). For an expert rater, over a 12-month time difference: ≥0.95 for motor and sensory scores (Sullivan et al., 2011).	Significantly greater improvement in experimental versus control group at 6- and 12-month follow-ups (Feys et al., 1998).	Strengths: Administration time for upper extremity is acceptable; evidence supports its reliability, validity, and sensitivity. Weaknesses: Administration time for total FMA is lengthy; items have little relevance to everyday activities; validity of balance subscale was questioned (Malouin et al., 1994) and is rarely used.

The Arm Motor Ability Test. The Arm Mobility Ability Test (AMAT) was developed as an assessment of functional ability and quality of movement as a result of CIMT (Kopp et al., 1997). Some of the 13 functional tasks are simulated (e.g., "cut meat" uses Play-Doh®) and thus are not as natural as most functional assessments. The psychometric properties are described in Assessment Table 8-2.

The Wolf Motor Function Test. The Wolf Motor Function Test (WMFT) "quantifies upper extremity movement ability through timed single- or multiple-joint motions and functional tasks" (Wolf et al., 2001, p. 1635). It was also developed to assess the effects of CIMT. Figure 8-4 shows an example of one of the WMFT 17 upper extremity tasks. The psychometric properties are described in Assessment Table 8-2.

The Motor Activity Log. The Motor Activity Log (MAL) is a structured interview that assesses the persons' post-stroke insight of how much they use the affected UE to perform 30 common functional activities (Taub et al., 1993). There are two other versions of the test, 1 with 14 tasks (Uswatte et al., 2005) and 1 with 28 (Uswatte et al., 2006). This test has two subscales: the Amount of Use Scale and the Quality of Movement Scale, where the average of 0–5 scale scores are computed for common upper extremity daily life tasks. Its psychometric properties are described in Assessment Table 8-2.

The Fugl-Meyer Motor Assessment. The Fugl-Meyer Assessment (FMA) was developed to evaluate motor function, balance, some aspects of sensation, and joint

function in persons post stroke (Fugl-Meyer et al., 1975). The items were based on earlier studies on the sequential stages of motor recovery post stroke (Brunnstrom, 1970; Twitchell, 1951). The maximum points are 66 for the upper extremity, 34 for lower extremity, 14 for balance, 24 for sensation, 24 for position sense, 44 for range of motion, and 44 for joint pain (total possible score, 250). Each section can be scored separately (see Fugl-Meyer et al. [1975] for test procedures and scoring criteria). The procedures for the upper extremity subtest are described in Table 8-1. Assessment Table 8-2 describes the psychometric properties of the FMA. The FMA is the second most frequently used assessment of motor deficits of persons with CNS impairments (van Wijck et al., 2001), is widely used in outcome studies, and was a recommended assessment of motor function in the Agency for Health Care Policy and Research clinical practice guidelines for post-stroke rehabilitation (Gresham et al., 1995).

Assessments of Balance

Balance is assessed through observational analysis as the person performs self-initiated movements in sitting and standing. These include the following:

- Looking in a variety of directions (e.g., up at the ceiling, behind oneself)
- Reaching forward, sideways, and down to the floor to pick up objects
- Walking in various conditions

Forward reach in sitting entails (1) anterior movement of the pelvis, (2) flexion of the trunk at the hips, and (3) active use of the legs to aid in balancing by creating an active base of support. Reaching sideways while sitting is more challenging than reaching forward, because the base of support is smaller. Reaching while standing requires (1) establishment of an appropriate base of support with one's feet and (2) shifting body weight and center of mass toward the direction of the goal object.

The Berg Balance Scale. The Berg Balance Scale (BBS) (Berg et al., 1992) evaluates a client's performance on 14 items common in everyday life. The items include "the subject's ability to maintain positions of increasing difficulty by diminishing the base of support from sitting, to comfortable stance, to standing with feet together, and finally tandem standing (i.e., one foot in front of the other) and single leg stance, the two most difficult items. Other items assess how well the subject is able to change positions from sitting to standing, transfer from chair to chair, turn, pick up an object from the floor, and sit down" (Berg et al., 1992, p. 1074). The psychometric properties of the

Table 8-1   **Fugl-Meyer Assessment of Motor Function: Upper Extremity Subtest**

Stage	Instruction	Response	Scoring Criteria
Shoulder/Elbow/Forearm: Subtotal Score (36 points)			
I & II: Reflex activity	Tap the biceps and finger flexor tendons Tap the triceps tendon	Stretch reflex at elbow and/or fingers Stretch reflex	0 = no reflex can be elicited 2 = reflex can be elicited
III: Voluntary movement within synergy	Flexor synergy "Turn your affected hand palm up and touch your ear." Extensor synergy "Turn your hand palm down and reach to touch your unaffected knee."	Shoulder retraction Shoulder elevation Shoulder abduction to 90° Shoulder external rotation Elbow flexion Forearm supination Shoulder adduction and internal rotation Elbow extension Forearm pronation	(For each of nine details) 0 = cannot perform 1 = can perform partly 2 = can perform faultlessly
IV: Voluntary movement mixing flexor and extensor synergies	"Show me how you would put a belt around you [or tie an apron]." "Reach forward to take [object held in front of patient]." "Put your arm to your side and bend your elbow. Turn your palm up and down."	Affected hand moves to lumbar spine area Reaches into 90° of shoulder flexion Pronates and supinates forearm with elbow at 90° and shoulder at 0°	0 = cannot perform 1 = hand must actively pass anterior-superior iliac spine 2 = faultless 0 = elbow flexes or shoulder abducts immediately 1 = if these occur later in motion 2 = faultless 0 = if cannot position arm or cannot pronate or supinate 1 = shoulder and elbow joints correctly positioned and supination seen 2 = faultless
V: Voluntary movement outside of synergies	"Turn your palm down and reach over here to touch [object held out to side]." "Reach as high as you can toward the ceiling." "Reach your arm directly forward and turn your palm up and down."	Abducts shoulder to 90° with elbow extended to 0° and forearm pronated Flexes shoulder from 90° to 180° with elbow in 0° Flexes shoulder to 30°–90°; extends elbow to 0°; and supinates and pronates	0 = initial elbow flexion or loss of pronation 1 = partial motion or elbow flexes and forearm supinates later in motion 2 = faultless 0 = elbow flexes or shoulder abducts immediately 1 = if these occur later in motion 2 = faultless 0 = if cannot position arm or cannot rotate 1 = correct position and beginning rotation 2 = faultless
VI: Normal reflex activity (tested if patient scores 6 in stage V tests)	Tap on biceps, triceps, and finger flexor tendons	Normal reflex response	0 = 2 reflexes are markedly hyperactive 1 = 1 reflex hyperactive or 2 reflexes lively 2 = no more than 1 reflex lively and none hyperactive

Table 8-1 **Fugl-Meyer Assessment of Motor Function: Upper Extremity Subtest** *(continued)*

Stage	Instruction	Response	Scoring Criteria
Wrist: Subtotal Score (10 points)			
Wrist stability with elbow flexed	Put the shoulder in 0° flexion and abduction, elbow in 90° flexion, and forearm pronated. "Lift your wrist and hold it there."	Patient extends wrist to 15°. Therapist can hold upper arm in position.	0 = cannot extend 1 = can extend, but not against resistance 2 = can maintain against slight resistance
Wrist stability with elbow extended	Put the elbow in 0°. "Lift your wrist and hold it there."	As above	As above
Active motion with elbow flexed and shoulder at 0°	"Move your wrist up and down a few times."	Patient moves smoothly from full flexion to full extension. Therapist can hold upper arm.	0 = no voluntary movement 1 = moves, but less than full range 2 = faultless
Active motion with elbow extended	"Move your wrist up and down a few times."	As above	As above
Circumduction	"Turn your wrist in a circle like this" [demonstrate].	Makes a full circle, combining flexion and extension with ulnar and radial deviation.	0 = cannot perform 1 = jerky or incomplete motion 2 = faultless
Hand: Subtotal Score (14 points)			
III: Mass flexion	"Make a fist."	Patient flexes fingers.	0 = no flexion 1 = less than full flexion as compared to other hand 2 = full active flexion
III: Hook grasp	"Hold this shopping bag by the handles."	Grasp involves MCP extension and PIP and DIP flexion.	0 = cannot perform 1 = active grasp, no resistance 2 = maintains grasp against great resistance
IIIB–VI: Finger extension	"Let go of the shopping bag." "Open your hand wide."	From full active or passive flexion, patient extends all fingers.	0 = no extension 1 = partial extension or able to release grasp 2 = full range of motion as compared to other hand
IV: Lateral prehension	"Take hold of this sheet of paper [or playing card]."	Patient grasps between thumb and index finger.	0 = cannot perform 1 = can hold paper but not against tug 2 = holds paper well against tug
V: Palmar prehension	"Take hold of this pencil as if you were going to write."	Therapist holds pencil upright and patient grasps it.	Scoring as above
V: Cylindrical grasp	"Take hold of this paper cup [or pill bottle]."	Therapist holds the object and patient grasps with first and second fingers together.	Scoring as above
VI: Spherical grasp	"Take hold of this tennis ball [or apple]."	Patient grasps with fingers abducted.	Scoring as above

Table 8-1	Fugl-Meyer Assessment of Motor Function: Upper Extremity Subtest *(continued)*		
Stage	**Instruction**	**Response**	**Scoring Criteria**
Coordination/Speed: Subtotal Score (6 points)			
VI: Normal movement	"Close your eyes. Now, touch your nose with your fingertip. Do that as fast as you can five times."	Patient does finger-to-nose test Tremor	*Tremor:* 0 = marked 1 = slight 2 = none
		Dysmetria	*Dysmetria:* 0 = pronounced or unsystematic 1 = slight and systematic 2 = none
		Speed (compare to unaffected side)	*Speed:* 0 = >6 seconds slower 1 = 2–5 seconds slower 2 = <2 seconds slower
TOTAL UPPER EXTREMITY SCORE (66 points)			

Adapted from Fugl-Meyer, A. R., Jäasko, L., Leyman, I., Olsson, S., & Steglind, S. (1975). The post-stroke hemiplegic patient: A method for evaluation of physical performance. *Scandinavian Journal of Rehabilitation Medicine, 7,* 13–31.

BBS are described in Assessment Table 8-3. The BBS was a recommended assessment of balance in the Agency for Health Care Policy and Research's clinical practice guidelines for post-stroke rehabilitation (Gresham et al., 1995).

Functional Reach Test. The Functional Reach Test (Duncan et al., 1990) was developed as a quick, clinical measure of dynamic balance that uses a continuous scoring system to assess the risk of falls in the elderly. It was intended to be an alternative to sophisticated laboratory-based assessments of falls, which are not feasible for clinical use. The psychometric properties are described in Assessment Table 8-3 (for a broader review of balance assessments, see Tyson and Connell [2009]).

Assessment of Gait

Walking, a critical component of daily task engagement, is a reasonable expectation for many individuals with CNS dysfunction. Occupational therapists work with patients who wish to improve their performance in kitchen and bathroom activities and in leisure or work pursuits. In each of these contexts, the occupational therapist must help patients reach their optimal walking potential. Physical therapists determine initial walking goals based on observation and comparison of each patient's performance against the critical kinematic features of walking that have been determined through descriptive research. Although observational gait analysis cannot provide information about the kinetics of a person's gait, spatiotemporal and kinematic variables provide clues about the underlying kinetic dynamics (such as information provided by force plates that record exact loading and unloading during stepping).

For purposes of description, the gait cycle for each leg is divided into a stance phase and a swing phase. Definition 8-3 shows the subdivision of these phases of the gait cycle. Basic knowledge about the motor requirements during each phase of the gait cycle guides therapists in their interventions for patients with CNS dysfunction.

Reach and Manipulation

The arm and hand function as a single unit in reach and manipulation, with the hand beginning to open for grasp at the start of a reaching action (Karok & Newport, 2010). In many activities, the upper body, or even the entire body, is an integral component of this single coordinated unit. Clearly, reach and grasp are not exclusively upper limb activities. All reaching actions from sitting or standing are preceded and accompanied by postural adjustments. When objects are beyond the arm's reach, shifts in total body alignment contribute to functional performance (Aimola et al., 2011).

Clinical assessment of reach and manipulation is achieved through detailed observation of each patient's attempts to perform selected functional tasks. Therapists use their knowledge about the kinetics and kinematics of upper limb function to develop hypotheses as to which deficits may be serving as control parameters in

Assessment Table 8-3	Psychometric Properties of Assessments of Balance

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Berg Balance Scale (Berg et al., 1992)	Fourteen items common in everyday life are "graded on a five-point scale, 0 to 4. Points are based on the time the position can be maintained, the distance the arm is able to reach forward, or the time to complete the task" (Berg et al., 1992, p. 1075)	About 15 minutes to administer and requires only a stopwatch and ruler	Concurrent validity: $r = 0.91$ with the Tinetti Balance Subscale (Tinetti, 1986); $r = -0.81$ with Timed Up-and-Go Test (TUG) (Podsiadlo & Richardson, 1991) or $r = -0.74$ with the TUG (Salavati et al., 2012). Discriminant validity: discriminates among persons using various types of walking aids (Berg et al., 1992).	Interrater reliability: ICC = 0.98 for total scale; ICC = 0.71–0.99 for individual items (Berg et al., 1992). For total scale: ICC = 0.97 (Blum & Korner-Bitensky, 2008) and 0.95 (Wirz, Müller, & Bastiaenen, 2010). Test–retest reliability: ICC = 0.99 for total scale (Berg et al., 1992). ICC for tests 1 week apart = 0.98 (Blum & Korner-Bitensky, 2008) and 0.96 (Learmonth et al., 2012). Internal consistency: Cronbach's $\alpha = 0.96$ (Berg et al., 1989) and 0.92–0.98 (Blum & Korner-Bitensky, 2008).	Significant changes in scores at 6 and 12 weeks post stroke (Wood-Dauphinee et al., 1997). Minimal detectable change value = 7 points (Learmonth et al., 2012)	Strengths: Measures many aspects of balance; consistent reports of excellent reliability; evidence of validity. Foreign versions have been studied and found psychometrically sound (Azad, Taghizadeh, & Khaneghini, 2011; Salavati et al., 2012; Scalzo et al., 2009). Weaknesses: Long administration time. Has floor and ceiling effects (Blum & Korner-Bitensky, 2008). Not predictive of falls (Blum & Korner-Bitensky, 2008; Wirz, Müller, & Bastiaenen, 2010).
Functional Reach Test (Duncan et al., 1990)	"The maximal distance one can reach forward beyond arm's length while maintaining a fixed base of support in the standing position" (Duncan et al., 1990, p. M192).	1–2 minutes to administer and requires a 48-inch leveled ruler, mounted on the wall at shoulder height (Weiner et al., 1993)	Concurrent validity: $r = 0.71$ with center of pressure excursion (Duncan et al., 1990). Discriminant validity: Significant difference between persons with high and low risk of falls. Predictive validity: score ≤ 6 inches predictive of falls in elderly (Duncan et al., 1992)	Interrater reliability: $r = 0.98$ Test–retest reliability: ICC = 0.92 (Duncan et al., 1990)	Marginal significant change ($p = 0.07$) after physical rehabilitation, responsiveness index = 0.97 (Weiner et al., 1993)	Strengths: Brief, functional test; excellent reliability, evidence of validity. Weakness: Sensitivity is borderline.

Definition 8-3

The Gait Cycle

Stance Phase

- Weight-load acceptance: from heel contact to foot flat on ground
- Midstance: from foot flat on ground to heel off of ground
- Push-off: weight moving forward onto toes and foot preparing to leave ground

Swing Phase

- Liftoff (early swing): leg swings forward with foot clearing the ground
- Reach (late swing): leg decelerates and prepares for heel contact

limiting the versatility or efficiency of motor strategies. Most motor dysfunction can be attributed to specific muscle weakness, muscle stiffness and length changes, and/or adaptive strategies developed to compensate for these impairments. Shoulder pain may also be a significant control parameter to efficient reach. Therapists test

their hypotheses through direct assessment of muscle strength and length and through patients' responses to interventions designed to modify adaptive strategies.

Assessment of Praxis

Apraxia is the inability to implement purposeful movement that cannot be explained by deficits in sensation, movement, or coordination (Gazzaniga, Ivry, & Mangun, 2009). We will discuss limb, constructional, and dressing types of apraxia. There are two additional apraxia types: verbal and buccofacial, which are usually evaluated by a speech and language pathologist and will not be discussed in this chapter.

Limb Apraxia. Limb apraxia is usually associated with left brain damage (LBD) in right-handed patients and right brain damage (RBD) in left-handed patients, although variations have been described (Marchetti & Della Sala, 1997). As can be seen in Table 8-2, there are many types of limb apraxia including ideomotor, ideational, dissociation, conduction, and conceptual (Heilman, Rothi, & Watson, 1997; Unsworth, 2007). Limb kinetic apraxia is characterized by a loss of ability to make finely graded precise finger movements and is thought to be a motor problem rather than a true apraxia (Heilman, Watson, & Rothi, 2003).

Psychometric properties of limb apraxia tests can be found in Assessment Table 8-4. This testing requires

Table 8-2   Types of Limb Apraxia

Type of Apraxia	Error Type	How Elicited	Functional Example
Ideomotor	Production errors	Most errors are made on pantomiming transitive tasks, improves with imitation and usually does best with the actual object.	Movements will be awkward but bear a resemblance to the intended movement. Able to use tools to complete tasks, but may appear clumsy or awkward.
Conceptual	Content errors: • Tool-action knowledge • Tool-association knowledge • Mechanical knowledge • Tool fabrication	Use of tools; actions associated with specific tools, association between tool and object.	Patient has obvious difficulty with tool use: may use a tube of toothpaste to brush teeth, comb hair with fork, etc.
Disassociation	Thought to be a disconnection between hemispheres; therefore, there is no recognizable movement on command.	Pantomime to command is impaired; imitation and use of object will be much better.	Unable to pantomime movements, but since able to imitate and use tools, minimal effect on functional activities.
Conduction	Difficulty decoding and understanding gestures	Impaired imitation of gestures; does better when asked to pantomime	A client with aphasia might have difficulty understanding and using gestures.
Ideational	Difficulty with a series of tasks	Tasks requiring a series of activities (e.g., clean pipe, put in tobacco, and light pipe)	Task may be completed more skillfully than with ideomotor apraxia, but client will have difficulty sequencing steps in the correct order (e.g., client might try to light the empty pipe, then put the tobacco in, and then clean it).

Adapted from Heilman, K. M., Watson, R. T., & Rothi, L. G. (2003). Disorders of skilled movements: Limb apraxia. In T. E. Fineberg & M. J. Farah (Eds.), *Behavioral neurology and neuropsychology* (2nd ed.). New York: McGraw-Hill.

Assessment Table 8-4 | Psychometric Properties of Assessments for Limb Apraxia

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Florida Apraxia Screening Test-Revised (FAST-R) (Rothi, Raymer, & Heilman, 1997)	Thirty items, gesture to verbal command test: 20 transitive, 10 intransitive pantomime; scored on multiple error types; normal cutoff score is 15 out of 30 correct.	Unknown; includes time to train and practice pantomime and then to complete a 30-item test	Not established	Not established Recommend that the responses are videotaped for later scoring	Not established	Strength: Can be completed with one hand only. Weakness: Psychometrics not established. Coexisting aphasia can be a problem because of verbal presentation. Relates to limb apraxia only. Scoring can be difficult and requires too much time for clinic use.
Screening for Apraxia (Almeida, Black, & Roy, 2002)	Five gestures (three transitive, two intransitive) five dimensions for each task is scored on a 3-point scale (see Roy et al., 1998 for scoring)	Authors feel that this can be used to detect apraxia and then a decision can be made to follow-up with a more comprehensive assessment battery	Not established	Not established on screen; κ coefficient for interrater reliability ranged from 0.71 to 0.78 on the full battery (Roy et al., 1998)	Not established	Strength: Short five-item screening test. Weakness: Scoring is unclear and requires knowledge and practice on the part of the examiner. Validity, test–retest reliability and sensitivity data are missing
Assessment of Apraxia (Van Heugten et al., 1999a)	Two subtests: demonstration of object use (three sets of objects presented under three different conditions) and imitation of gestures (six gestures to be imitated). Each is scored from 0 (movement not recognizable) to 3 (performance is correct and appropriate). Maximum subscore for object use is 54, for imitation of gestures is 36 with a total score of 90. Total score below 86 is considered to identify apraxia.	Unknown	Not established	Internal consistency good (Cronbach's α = 0.96; Mokken coefficient of reliability ρ = 0.96). Interrater reliability κ > 0.60 on all but three items (Zwinkels, et al., 2004)	A cutoff score of 86 (mean score – one standard deviation) sensitivity was 91%	Strength: Uses common gestures and objects Weaknesses: Validity and test–retest reliability data are missing. Includes items for ideational and ideomotor apraxia only.
Assessment of Disabilities in Stroke Patients with Apraxia (van Heugten et al., 1999b)	Set of standard activities of daily living (ADL) observations for assessment of disabilities caused by apraxia: personal hygiene, dressing, preparing food, and another of the therapist's choice. Scoring: four measures (independence, initiation, execution and control) scored from 0 (no observable problems) to 3 (therapist has to take over). Then they can be added together to get a total score.	Unknown, but could easily be observed during the occupational therapist's evaluation of ADL	Not established	Coefficient of reliability ρ = 0.94 Interrater reliability κ value highest for independence scores (0.81–0.97)	Not established	Strength: Can be easily incorporated into the therapist's ADL evaluation; task specifically related to the client can be addressed; allows therapist to determine where the breakdown is occurring (initiation, execution, or control) to develop treatment program. Weaknesses: Validity, test–retest reliability, and sensitivity data are missing. Training is recommended to improve reliability

Table 8-3	Apraxia Testing Methods

Method	Example
Gesture to command: should include both transitive movements (tool use) and intransitive movements (nonverbal communication).	Transitive: "Show me how you would open the door with a key" or "use a hammer." Intransitive: "Show me how you hitchhike, salute, wave good-bye."
Gesture to imitate	Examiner produces a gesture and asks the client to "do it the same way I do it; do not name the gesture and do not start until I'm finished"; can be familiar gestures or nonsense gestures (e.g., hand to the forehead).
Gesture in response to tool	Visual: Examiner shows the tool and says, "Show me how you use this." Tactile: Eyes closed or covered, client examines the tool by feeling and examiner says, "Show me how you use this."
Gesture in response to seeing object on which the tool acts: tool selection task	Examiner presents client with object representing an incomplete action (e.g., if the target is sawing, client is shown a partially cut piece of wood); client must choose the correct tool from a choice of three, one of which is the saw.
Actual tool use	Patient is given a tool (e.g., hammer) and asked, "Show me how you use this."
Gesture decision: discrimination between correctly and incorrectly pantomimed movements	Examiner makes a gesture and asks the client, "Is this the correct way to . . ." (e.g., use a pair of scissors).
Gesture comprehension	Examiner makes a gesture and asks the client, "Tell me what I am doing." "What tool am I using?" "Am I using a hammer or a saw?"
Serial acts	Examiner tells client, "Fold letter, put it in envelope, seal envelope, and place stamp on it."

Adapted from Rothi, L. J. G., Raymer, A. M., & Heilman, K. M. (1997). Limb praxis assessment. In L. J. G. Rothi & K. M. Heilman (Eds.), *Apraxia: The neuropsychology of action* (pp. 61–73). East Sussex, UK: Psychology Press Publishers.

gesture production where the client is asked to pantomime a task on command (e.g., "Show me how you wash your face"), to imitate the therapist, or to use an object. Transitive gestures are especially sensitive to apraxia (Enticott et al., 2010; Trojano, Labruna, & Grossi, 2007). Generally, clients with apraxia would have the least difficulty with proximal intransitive gestures away from the body (e.g., waving goodbye) and most difficulty with distal transitive gestures on the body (e.g., putting on makeup) (Helm-Estabrooks & Albert, 2004; Trojano, Labruna, & Grossi, 2007). Gesture comprehension and discrimination have been added to the list of apraxia testing methods (Table 8-3) (Heilman, Watson, & Rothi, 2003; York & Cermak, 1995).

Apraxia often occurs in conjunction with aphasia, and it is sometimes difficult to distinguish between the two (Unsal Delialioglu et al., 2008). Therefore, it is important when evaluating a client with aphasia to include (in addition to the regular commands, e.g., "show me how you would . . .") questions that can be answered by yes/no responses or by pointing at the correct answers. If the client performs poorly but can answer yes/no questions, he or she may be apraxic. Similarly, if the client is unable to respond to yes/no questions, failure to make the appropriate movement to command may be due to a language problem rather than apraxia.

There are few standardized tests available for limb apraxia (see Assessment Table 8-4). Rothi, Raymer, and Heilman (1997) have developed the Florida Apraxia Screening Test-Revised (FAST-R) for use in the research of neurologically impaired patients. This test consists of 30 items that are presented verbally (Table 8-4). The patient uses the dominant arm if possible. Prior to testing, patients practice pantomiming such that they pretend to hold the imagined tool and act on the imagined object. This rehearsal is important to discourage use of a body part as the imagined tool itself. Normal subjects may use a body part as tool, but with instruction, they correct their performance, whereas apraxic patients continue to do so even with the instruction (Raymer et al., 1997). Scoring for the FAST-R includes multiple error types based on content of the pantomime, timing and sequencing of the response, and spatial features (Table 8-5).

Table 8-4	Sample Items from the Florida Apraxia Screening Test (Revised)

Show me:
- how to salute
- how to use a saw to cut a piece of wood out in front of you
- how to hitchhike
- stop
- how to use a salt shaker to salt food on a table out in front of you
- how to use a spoon to stir coffee on a table out in front of you

From Rothi, L. J. G., Raymer, A. M., & Heilman, K. M. (1997). Limb praxis assessment. In L. J. G. Rothi & K. M. Heilman (Eds.), *Apraxia: The neuropsychology of action* (pp. 61–73). East Sussex, UK: Psychology Press Publishers.

Table 8-5	Apraxia Error Types
Error Type	**Description**
Content Errors	
Perseveration	Patient's response includes all or part of a previously produced pantomime.
Related	Pantomime is correctly produced but is only related to that requested (e.g., playing the trombone instead of playing a bugle as requested).
Nonrelated	Pantomime is accurately produced but unrelated to request (e.g., playing the trombone for shaving).
Hand	Performs the action without use of a real or imagined tool (e.g., turning a screw with the fingers rather than an imaginary screwdriver).
Temporal	
Sequencing	Addition, deletion, or transposition of the movement elements of a sequence.
Timing	Any alteration in the timing or speed of a pantomime: abnormally increased, decreased, or irregular rate of production.
Occurrence	Any multiplication of characteristically single-cycle movements (e.g., unlocking a door) or reduction of a characteristically repetitive cycle (e.g., screwing in a screw) to a single event.
Spatial	
Amplitude	Any increase, decrease, or irregularity of the characteristic movement.
Internal configuration	Any abnormality of the required finger/hand posture and its relationship to the target tool (e.g., when pretending to brush the teeth, the hand may be closed tightly into a fist with no space allowed for the imagined toothbrush handle).
Body part as tool	Patient uses finger, hand, or arm as the imagined tool even when requested to pretend they are holding the object (e.g., uses the finger to brush the teeth).
External configuration	Difficulties orienting the fingers/hand/arm to the object or in placing the object in space (e.g., brushing teeth with the hand so close to the mouth as to not allow room for the imagined toothbrush).
Movement	Any disturbance of the characteristic movement used when acting on an object (e.g., activates movement at incorrect joint; when pantomiming a screwdriver and rotation occurs at the shoulder rather than at the forearm).
Other	
Concretization	Patient performs pantomime not on an imagined object but instead on a real object not normally used in the task (e.g., instead of pretending to saw wood, they pantomime sawing on their leg).
No response	
Unrecognizable	Response shares no temporal or spatial features of the target, it is unrecognizable.

Adapted from Rothi, L. J. G., Raymer, A. M., & Heilman, K. M. (1997). Limb praxis assessment. In L. J. G. Rothi & K. M. Heilman (Eds.), *Apraxia: The neuropsychology of action* (pp. 61–73). East Sussex, UK: Psychology Press Publishers.

Some researchers suggest that there be more than one observer or even videotaping the response during testing. Butler (2002) advises not to rely on one test of apraxia, but rather to consider functional indices in ADL tasks as more clinically relevant. van Heugten et al. (1999b) developed an assessment of disability in stroke patients with apraxia that looks at an independence measure and three aspects (initiation, execution, and control) of four activities (personal hygiene, dressing, preparing food, and another activity that is chosen by the therapist). This allows the therapist to determine in what area the person is having difficulty and better focus treatment.

Constructional Apraxia. Constructional apraxia is a specific deficit in spatial-organizational performance (Chaikin, 2007) Patients with constructional apraxia have difficulty with copying, drawing, and constructing designs in two and three dimensions. Constructional apraxia was found to correlate with deficits of ADL (Neistadt, 1993; Poole, Sadek, & Haaland, 2009). It can be seen functionally as difficulty with such activities as setting a table, making a sandwich, and making a dress and with any mechanical activity in which parts are to be combined into a whole.

There are two types of constructional activities used in assessment: graphic tasks (e.g., copying line drawings and drawing to command) and assembly tasks (e.g., block and stick designs). Both types are included in an evaluation of constructional apraxia. The most common example of a graphic task is copying geometric shapes (from simple to complex)

Table 8-6	**Scoring for Drawing to Command**	
Shape	**Instruction**	**Scoring**
Clock	"Draw the face of a clock showing the numbers and the two hands."	0 to 3: 1 point each for approximately circular face, symmetry of number placement, and correctness of numbers
Daisy	"Draw a daisy."	0 to 2: 1 point each for general shape (center with petals around it) and symmetry of petal arrangement
Elephant	"Draw an elephant"	0 to 2: 1 point each for general shape (legs, trunk, head, body) and relative proportions correct
Cross	"You know what the Red Cross looks like? Draw an outline of it without taking your pencil off the paper."	0 to 2: 1 point each for basic configuration and ability to form all corners adequately with a continuous line
Cube	"Draw a cube-shaped block in perspective, as it would look if you could see the top and two sides."	0 to 2: 1 point each for grossly correct attempt and correctness of perspective
House	"Draw a house in perspective, so you can see the roof and two sides."	0 to 2: 1 point each for grossly correct features of house and accuracy of perspective

and drawing without a model (e.g., house, clock, or flower). It is best to use a simple task (e.g., simple geometric figures, three-dimensional block design), because a more complex task involves a greater number of skills, and interpretation becomes less specific (Cooke, McKenna, & Fleming, 2005). Goodglass and Kaplan (1983) described the test of drawing to command without a model. This test includes having the client draw a clock, daisy, elephant, cross, cube, and house; scoring criteria are given in Table 8-6. Assembly tasks include such activities as stick arrangement and three-dimensional block designs. Common errors on stick arrangement include selecting sticks of incorrect length; failing to reproduce parts of the model, especially lateral; making lines more oblique than the model indicates; tending to remove part of the model to make the copy; and crowding in (the client's copy rests on top of or touches the model) (Critchley, 1966). In general, assembly tasks are not standardized and rely on subjective judgment of the results. It is important to note the client's method of completing the task; the client's comments; any emotional display, hesitancy, indecision, and change of mind; and the type of errors made.

The Lowenstein Occupational Therapy Cognitive Assessment (LOTCA) battery was standardized on brain-injured adults and contains a section on visuomotor organization containing block design, copying, drawing, and pegboard design. The test has another updated version called the Dynamic Lowenstein Occupational Therapy Cognitive Assessment (DLOTCA) (Katz et al., 2012). See chapter 6 for more information about cognitive assessment in occupational therapy.

Dressing Apraxia. Dressing apraxia refers to an inability to dress oneself. It is usually due to RBD and secondary visuospatial disorganization. It is evaluated functionally by watching clients dress themselves. The underlying problem needs to be determined (e.g., visual deficits, unilateral neglect, apraxia, or constructional apraxia) rather than evaluating dressing apraxia per se.

Motor Neglect

Motor neglect presents as impaired initiation or execution of movement into contralateral hemispace by either limb (Bisiach et al., 1990; Tegner & Levander, 1991). Heilman, Watson, and Valenstein (2003) described several types of motor neglect (Definition 8-4). It is often difficult to differentiate between sensory and motor neglect because tests of motor neglect entail some form of sensory input. Consequently, therapists wonder whether clients fail to respond to a stimulus on the involved side because they do not see it or because they cannot initiate movement toward it. If motor neglect is suspected, one way to distinguish between the two entails contrasting a task that requires a hand response with one that has minimal motor response (e.g., naming letters on the involved side as opposed to pointing to the same letters). In other words, the stimulus (letters on the involved side) stays the same, and the motor response is varied (Arnadottir, 2011).

Definition 8-4

Motor Neglect

- Limb akinesia—Failure to move limb.
- Hypokinesia—Limb moves but only after a long delay and much encouragement.
- Hypometria—Movements are of decreased amplitude.
- Impersistence—Inability to maintain a movement or posture.
- Motor perseveration—Inability to disengage from a motor activity.
- Motor extinction—Delay or failure to move the contralesional limb when also required to move the ipsilateral limb.

Adapted from Heilman, K. M., Watson, R. T., & Valenstein, E. (2003). Neglect: Clinical and anatomic aspects. In T. E. Fineberg & M. J. Farah (Eds.), *Behavioral neurology and neuropsychology* (2nd ed.). new York; McGraw-Hill.

Although there are no standardized tests of motor neglect (Appelros et al., 2003), observations of clients and how they use the affected extremity can provide insight into the presence of motor neglect. One may note reluctance to move the arm or movement only after a delay (hypokinesia) or movement only with strong encouragement (akinesia), a tendency to undershoot a target when asked to move along a given line (hypometria), or inability to sustain a posture (impersistence) (Heilman, Watson, & Valenstein, 2003). Different limbs can be observed, as can the direction of the movement required (ipsilateral versus contralateral) and the hemispace in which the movement is to occur (ipsilateral versus contralateral).

SUMMARY

All therapeutic approaches evolve over time. Clinical practice and research will continue to test the assumptions and treatment principles of each approach. Evaluating motor behavior and performance will keep evolving as the therapeutic approaches evolve. The task-related approaches are more supported in current literature than the older neurophysiological approaches. The task-related approaches have their unique evaluative procedures that emphasize the roles of the environmental, task, and individual factors on motor behavior. However, many of the neurophysiological assessments are used when using the task-related approaches, particularly when assessing the individual's factors related to motor behavior such as strength and muscle tone. Development of more evaluation tools and measures of change (with better clinical usefulness and stronger psychometric properties) is critical, particularly for individuals with poor motor abilities (Connell & Tyson, 2012). Identification of critical factors influencing occupational performance and measures of motor behavior will lead to more effective and client-centered treatment strategies. Further testing of the assumptions and treatment principles for persons having CNS dysfunction and other motor behavior problems will provide additional support for use of the systems and task-related approaches in practice. When using a clinical measure that captures a change in motor behavior, it is fundamental to make sure that this change is clinically meaningful for the clients. A clinically meaningful change is one that exceeds the minimal requirements for real life occupational performance (Lang et al., 2008).

case example
Mr. B.: Assessment of Motor Behavior in a Patient with Left Cerebrovascular Accident

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information	Understand the patient's diagnosis or condition	"Mr. B. has right hemiparesis and moderate disability 1 week post stroke. Because his right arm is not flaccid and he is able to do some self-care already, his prognosis for recovery of functional ability appears to be good."
Mr. B. is a 55-year-old man who worked as an administrator at a junior college until a week ago, when he had a left cerebral vascular accident with resultant right hemiparesis. His medical history includes insulin-dependent diabetes mellitus and two heart attacks in the past 5 years. He lives with his wife in a ranch-style house. She works as a middle manager at an electronics firm. They have two adult children who do not live nearby.	Know the person	"Given his age and type of job, I expect that he will be motivated to return to work, but I cannot assume that."
The acute-care occupational therapist reported that he is independent in feeding, grooming, oral hygiene, and wheelchair mobility for short distances. He needs assistance with bathing, toilet hygiene, and dressing. Other occupational performance tasks were not assessed in acute care. He has weakness throughout his dominant right arm, with grade 2 muscle tone on the Modified Ashworth Scale for scapular depression, shoulder internal rotation, and elbow, wrist, and finger flexors. Passive range of motion (PROM) is within normal limits except for a 20° limitation in shoulder external rotation and elbow extension.		"I wonder how his wife is reacting to his various health problems. Will she support his return to work or will she try to protect him? I wonder about the accessibility of his home and work environment."
	Develop provisional hypotheses	"Given his diagnosis and history, I presume that sensorimotor, psychosocial, and cognitive client factors and the physical environment at home and/or work might limit his ability to perform occupational performance tasks and to resume his usual roles. Given his early recovery, he should be able to benefit from an intensive rehabilitation program."

Assessment Process

The Role Checklist was used to identify which roles were most important to him and to identify the tasks and activities that are associated with those roles. The Canadian Occupational Performance Measure (COPM) was used to determine the occupational performance tasks he wanted or needed to do and to determine his perception of his ability. Task analysis was used with specific tasks he perceived as difficult or impossible. The therapist observed him for client factors that might be limiting function and explored environmental factors that could support or limit his performance.

Consider evaluation approach and methods

"The primary aim of the assessment in the rehabilitation unit was to determine which roles and occupational performance tasks were most important to Mr. B. and to determine his ability on those tasks. The secondary aim was to determine whether specific client or environmental factors were supporting or limiting his functional performance."

Assessment Results

It was clear from the Role Checklist that Mr. B.'s work role was important to him. His concerns about returning to work included problems with writing, word processing, and removing heavy manuals from shelves above his desk. His wife, however, was pushing him to consider early retirement because of his increasing health problems. He and his wife enjoyed entertaining friends at home, for which he was the primary chef. This was an important activity for both of them. Although he was responsible for many home and yard maintenance tasks, they were not important to him. He thought friends would help them or they could hire help. On the COPM, return to work was ranked as most important, followed by cooking, toilet hygiene, dressing, and driving. He rated his performance and satisfaction for all of these tasks as very low.

His performance on several work-related, cooking, and self-care tasks were observed. He had difficulty holding a regular pen. However, a trial with an enlarged pen with a rubber grip enabled him to hold a pen for about 3 minutes and write with very poor legibility. He was unable to use his right hand for keyboarding because he could not isolate individual fingers. He became frustrated while performing a simple cooking task (i.e., making pudding) because he could not walk and had difficulty using his right hand for bilateral tasks. He was able to toilet himself with verbal cueing and standby assistance. During dressing, he had difficulty raising his right arm, reaching down to put on his socks (concerned appropriately about balance), and difficulty performing bilateral tasks (e.g., tying his shoelaces). He complained about the time and energy needed to complete functional tasks. He used his right hand in half of the bilateral tasks he attempted. Thus, it appeared that sensorimotor client factors might be the cause of the difficulty performing occupational performance tasks, so these were evaluated further.

There was no evidence of unilateral visual neglect on a line bisection test (see Chapter 5). Sensory testing indicated loss of protective sensation and diminished light touch in the right hand (Semmes-Weinstein monofilaments) and impaired proprioception in the wrist and fingers only (see Chapter 9). Selective muscle testing indicated grade 3+ in scapular elevation, elbow flexion, and extension; 3− in shoulder flexion, abduction, and external rotation; and wrist flexion and extension. Grip strength was 5 pounds in the right hand and 80 pounds in the left hand; key pinch was 3 pounds on the right and 19 pounds on the left (see Chapter 7). He was able to reach forward 9 inches on the Functional Reach Test.

Interpret observations

"It is clear that work and cooking tasks are priorities for this client, followed by self-care tasks. It is not yet clear whether he will be able to return to work. Decreased strength and impaired sensation are limiting the function of the right hand. Decreased PROM of the shoulder external rotation is a concern because it is often associated with development of a painful shoulder. There is no evidence of cognitive or perceptual deficits. He has a mild deficit in balance. I chose the Functional Reach Test instead of the Berg Balance Scale to assess balance because it was specific to the balance problems observed and administration time is brief. Selected subscales of the MAS were considered because they are more functional than the other motor function assessments. However, the two subscales—Hand Movements and Advanced Hand Activities—that would have provided the most useful information on Mr. B. have questionable validity. Therefore, I chose not to use the MAS with this client."

Occupational Therapy Problem List

1. Decreased ability to perform work, cooking, and self-care tasks because of sensorimotor impairments
2. Decreased strength, PROM, sensibility, and dexterity in his right upper extremity; decreased endurance for activity; mild impairment of sitting balance
3. Insufficient information on home environments to prepare adequately for discharge

Synthesize results

"Although I have sufficient information to begin treatment with Mr. B., I will need additional information from him and his employer about job requirements and work environment. In addition, more details about the home environment, home management roles and responsibilities, and other leisure interests are necessary."

Clinical Reasoning in Occupational Therapy Practice

The Use of Neurophysiological Assessments While Implementing the Task-Related Approaches

You are evaluating Mr. J. in an outpatient facility for subacute post-stroke rehabilitation. Mr. J. was excited about constraint-induced movement therapy and asked you whether you could apply its principle in his treatment. What types of neurophysiological assessments would help you to determine whether Mr. J. is eligible for CIMT? How would other neurophysiological assessments help you in customizing Mr. J.'s therapy in general?

Clinical Reasoning in Occupational Therapy Practice

Identifying the Control Parameters

You are using the occupational therapy task-oriented approach with Mr. J. for subacute post-stroke rehabilitation. Mr. J.'s COPM score indicated that he wants to play cards with his friends (importance score = 9 out of 10, performance score = 2 out of 10, and satisfaction score = 3 out of 10). How would you analyze the card playing task to identify the activity control parameters? How would you customize the treatment to offer the "just-right challenge"?

Summary Review Questions

1. How do the reflex-hierarchical and systems models of motor control differ?
2. How do neuromaturational and systems theories of motor development differ?
3. What types of motor dysfunction are associated with cortical, cerebellar, and basal ganglia lesions of the CNS?
4. What might account for the recovery seen after CNS damage?
5. What are at least four assumptions of the neurophysiological approaches?
6. How would you evaluate abnormal muscle tone and movement patterns?
7. What are at least four assumptions of the task-oriented approach?
8. How do evaluations used by the neurophysiological and task-related approaches differ?
9. Your client has LBD with resultant right hemiparesis and nonfluent aphasia. Why and how would you evaluate for the presence of apraxia?
10. When should you include evaluation of apraxia in a client?
11. How would you differentiate between motor and sensory neglect?

Glossary

Apraxia—The inability to carry out skilled movement in the presence of intact sensation, movement, and coordination.

Closed-loop system—A control system that uses feedback to correct movement errors in order to achieve the planned movement (Schmidt & Wrisberg, 2008).

Control parameter—A variable that changes behavior from one pattern of behavior to another. It does not control the change but acts as an agent for the shift in behavior (Perry, 1998).

Coordinative structures—Groups of muscles, usually spanning several joints, that are constrained to act as a single functional unit (Magill, 2004).

Degrees of freedom—Elements of a control system that are free to vary.

Heterarchical system or model—A system in which control is distributed among many systems; control emerges from the interaction of various subsystems; there is no strict order of command; subsystems in charge vary with task requirements.

Hierarchical system or model—A system with several levels of control, each level subordinate to the one above it.

Intransitive gestures—Movements expressing an idea not associated with a particular object such as waving good-bye (Enticott et al., 2010).

Knowledge of results—Awareness of the outcome of movement in relation to the goal.

Muscle tone—Resistance of a muscle to passive elongation or stretching.

Open-loop system—A control system that uses preprogrammed instructions (i.e., anticipatory, or feed-forward, control) to an effector; does not use feedback or error-detection processes (Schmidt & Wrisberg, 2008).

Phase shift—Change, which is often nonlinear, from one preferred coordinated pattern to another (Heriza, 1991).

Self-organization—The idea that a system composed of a number of subsystems can organize itself through the dynamic interaction of the subsystems (i.e., no higher level control or motor program is required) (Perry, 1998).

Transitive gestures—Goal-directed movements expressing an idea that entail object use, such as grasping a cup (Enticott et al., 2010).

Assessing Abilities and Capacities: Sensation

Jennifer L. Theis

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the effects of sensory loss on occupational function.
2. Predict the pattern of sensory loss based on diagnosis or described lesion in the somatosensory system.
3. Demonstrate appropriate sensory testing techniques for tactile sensation when provided with appropriate tools or equipment.
4. Differentiate standardized and nonstandardized tactile tests.
5. Choose appropriate sensory testing techniques for a given patient or situation.
6. Correctly interpret the results of sensory testing for treatment planning.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate
The American Occupational Therapy Association (AOTA) (2008, p. 675) defines sensory-perceptual skills as "actions or behaviors a client uses to locate, identify, and respond to sensations, interpret, organize, and remember sensory events via sensations that include visual, auditory, proprioceptive, tactile, olfactory, gustatory, and vestibular sensations." In this chapter, tactile, thermal, and proprioceptive sensations will be discussed, and methods of evaluating these senses will be described. The tactile sense throughout the body is necessary for competent occupational functioning, but tactile sensation is especially important in the hands. Moberg described hands without sensation as being like eyes without vision (Dellon, 1988).

Immediately after birth, an infant is bombarded with tactile sensations that are different from those in utero. Within a few weeks, the infant learns to interpret a multitude of tactile stimuli, such as soothing touch from a parent that brings comfort and contentment. This developed capacity supports further development of abilities and skills as the infant uses touch to grasp an object, bring two hands together at midline, and reach out to stroke a parent's face. These abilities are necessary for self-maintenance, self-enhancement, and self-advancement roles in childhood and throughout adulthood.

ROLE OF SENSATION IN OCCUPATIONAL FUNCTIONING

The role of sensation in occupational functioning is dramatically described in Cole's (1991) account of Ian Waterman, who at 19 years of age acquired a rare neurological illness that resulted in the loss of all sensation of touch in his body from the neck down. He had no awareness of the positions of his arms, legs, or body. Although his muscles were not affected, any attempt at movement was wildly uncontrolled. Ian's initial attempt at standing up resulted in him falling "in a heap . . . like a pile of wet clothes" (Cole, 1991, p. 11). He was unable to feed himself, get dressed, or do any functional activity requiring control of movement. Over several years, Waterman learned how to complete functional activities by substituting vision for his lost sensation. Every movement had to be carefully watched and consciously controlled. The high level of concentration required and the energy expended to complete daily self-care and work activities led Cole to name the account of Waterman's life, *Pride and a Daily Marathon*.

Although a loss of sensation like Waterman's without any motor loss is unusual, it exemplifies the close connection between the motor and sensory systems. With sensory loss in the hand, fine motor coordination is impaired, and manipulative ability is decreased (Carr & Shepherd, 2010). The amount of force needed to maintain grasp on an object also depends on sensory feedback. Usually, we use force that is just sufficient to overcome the pull of gravity, taking into account the amount of friction afforded by the surface texture. Without adequate tactile sensation, the force used to grip an object is either lower or higher than the force needed, resulting in objects slipping from grasp, delicate objects (such as a plastic foam cup) being crushed by excessive grip force, or muscles developing fatigue from overactivity (Johansson, 1996).

Some activities require sensory feedback because they are totally dependent on the sense of touch, such as determining the temperature of a bowl taken from the microwave. Tactile sensations let us know whether the food is warm and whether the bowl is too hot to carry to the table. Haptic perception, active touch, helps to determine the three-dimensional characteristics of objects (Norman et al., 2011). Finding coins or other objects in a pocket and fastening a necklace or closing a back zipper are examples of activities for which vision is not used; therefore, we rely entirely on sensory feedback. It is the tactile sense that tells us when our new shoes are a bit too tight and we had better remove them or we will get a blister. Impairment in the somatosensory system not only hinders movement but also increases the risk of injury.

PURPOSES OF SENSORY EVALUATION

The purposes of sensory testing, as defined by Cooke (1991), are as follows:

- Assess the type and extent of sensory loss
- Evaluate and document sensory recovery
- Assist in diagnosis
- Determine impairment and functional limitation
- Provide direction for occupational therapy intervention
- Determine time to begin sensory re-education
- Determine need for education to prevent injury during occupational functioning
- Determine need for desensitization

Before considering sensory evaluation, therapists need a good understanding of the neural structures responsible for tactile sensation.

NEUROPHYSIOLOGICAL FOUNDATIONS OF TACTILE SENSATION

Receptors for tactile sensation are present within skin, muscles, and joints. Each tactile receptor is usually specialized for a single type of sensory stimulation such as touch, temperature, or pain (Ropper & Samuels, 2009). The types of sensation, specific kinds of receptors, and corresponding neurons that connect the sensory receptors with the spinal cord and ultimately with the cerebral cortex appear in Table 9-1. Neural impulses follow the described pathways to the brain, where the sensations are perceived and interpreted.

Table 9-1	Neural Pathways of Sensory Stimuli			
Type of Sensation	**Sensory Receptor**	**Type of Afferent Neuron**	**Pathway**	**Termination of Pathway**
Constant touch or pressure Moving touch or vibration	Merkel's cell Ruffini's end organ Meissner's corpuscles Pacinian corpuscles Hair follicles	Type A-beta slowly adapting I and II myelinated neurons Type A-beta rapidly adapting I and II myelinated neurons	Ascend in dorsal column and medial lemniscus of spinal cord in posterior pyramidal tract, cross to opposite side in medulla	Thalamus and somatosensory cortex
Proprioception and kinesthesia	Same as both moving and constant touch or vibration plus touch receptors found in skin and joint structures Muscle spindles Golgi tendon organs	Same as for moving touch or vibration plus A-alpha myelinated neurons	Same as for moving touch or vibration plus spinocerebellar tract	Same as for moving touch or vibration plus cerebellum
Pain (pinprick) Pain (chronic) Temperature	Free nerve endings Free nerve endings Free nerve endings Warm receptors Cold receptors	Type A-delta myelinated neurons Type C unmyelinated fibers Type A-delta myelinated neurons and type C unmyelinated fibers	Immediately cross to opposite side and pass upward in anterior spinothalamic tracts of spinal cord	Brainstem, thalamus, and somatosensory cortex

Based on information in Dellon, A. L. (2000). *Somatosensory testing and rehabilitation*. Baltimore, MD: The Institute for Peripheral Nerve Surgery; Chapman, C. E., Tremblay, F., & Ageranioti-Bélanger, A. (1996). Role of primary somatosensory cortex in active and passive touch. In A. M. Wing, P. Haggard, & J. R. Flanagan (Eds.), *Hand and brain: The neurophysiology and psychology of hand movements* (pp. 329–347). San Diego: Academic; Fredericks, C. M. (1996a). Basic sensory mechanisms and the somatosensory system. In C. M. Fredericks & L. K. Saladin (Eds.), *Pathophysiology of the motor systems: Principles and clinical presentations* (pp. 78–106). Philadelphia: F. A. Davis; Fredericks, C. M. (1996c). Disorders of the spinal cord. In C. M. Fredericks & L. K. Saladin (Eds.), *Pathophysiology of the motor systems: Principles and clinical presentations* (pp. 394–423). Philadelphia: F. A. Davis.

Each sensory neuron and its distal and proximal terminations can be considered a sensory unit. Each sensory unit serves an area of skin that encompasses its defined receptive field. A stimulus anywhere in the field may evoke a response, but stimuli applied to the center of the receptive field produce sensations more easily. In other words, the center of a receptive field has a lower threshold than the periphery. Adjacent receptive fields overlap; therefore, a single stimulus evokes a profile of responses from overlapping sensory units.

The variation in the number of sensory units in a given area of skin is called innervation density. The face, hand, and fingers have high innervation densities. Areas with high innervation density are highly sensitive and have a proportionately large representation area within the somatosensory area of the cortex, the postcentral gyrus of the parietal lobe (Bear, Connors, & Paradiso, 2007; Ropper & Samuels, 2009). Figure 9-1 shows the organization within the cortex of sensory receptors from various regions of the body.

Table 9-1 and the description of sensory pathways simplify a complex process. For example, tactile stimuli of sufficient strength elicit responses from both constant and moving touch receptors and perhaps also from the pain receptors (Fredericks, 1996a). Extremes of hot and cold stimuli activate the pain receptors rather than the temperature receptors (Lindblom, 1994). Perception of joint motion (kinesthesia) and joint position (proprioception) appear to be a result of information from multiple kinds of receptors. Researchers disagree about the relative contributions of joint, muscle, and skin receptors to proprioception and kinesthesia (Fredericks, 1996a; Jones, 1996).

Therapists use a solid understanding of the neurophysiology of the tactile system to choose evaluation and treatment techniques for sensory deficits. They combine this understanding with knowledge of typical patterns of impairment from injury and illness prior to implementing assessment of sensation.

SOMATOSENSORY DEFICIT PATTERNS

Any interruption along the ascending sensory pathway or in the sensory areas of the cortex can lead to a decrease or loss of sensation. The extent and severity of the sensory deficit can generally be predicted in accordance with the mechanism and location of the lesion or injury. Patterns of sensory impairment are directly related to the involved neuroanatomical structures, which could be anywhere in the central or peripheral nervous system. Somatosensory and perceptual impairments contribute to poor motor control and may have an impact on participation in rehabilitation (Carr & Shepherd, 2010).

Cortical Injury

Patients with brain lesions caused by stroke or acquired brain injury demonstrate sensory losses related to loss of
Figure 9-1 The areas responsible for sensation of body parts within the postcentral gyrus of the cerebral cortex. (Reprinted with permission from Bear, M. F., Connors, B. W., & Paradiso, M. A. [2007]. *Neuroscience: Exploring the brain* [3rd ed.]. Baltimore: Lippincott Williams & Wilkins.)

functioning of specific neurons within the central nervous system. One study found that tactile sensory loss is more common than loss of proprioception (Tyson et al., 2008), whereas another found that loss of both proprioception and stereognosis were more prevalent than loss of tactile sense (Connell, Lincoln, & Radford, 2008). The discrepancy between the two studies may be accounted for in the methods chosen to test sensory abilities, or it may simply be that one study reported ranges of sensory capacities affected, whereas the other reported the averages of those same sensory capacities. This means that the discrepancy between the two studies may actually not be a true discrepancy because Connell's ranges encompass Tyson's reported averages of type of sensory loss. In another study, approximately half of those patients presenting for rehabilitation after stroke experienced decreased discriminatory sensation (both touch discrimination and proprioception) in both the contralesional and ipsilesional hands (Carey & Matyas, 2011). For patients with either stroke or brain injury, perception of fine touch and proprioception are most affected, temperature sensation is affected less, and pain sensibility is affected least (Fredericks, 1996a). Effects of stroke on sensation depend on specific disruption of blood supply. For instance, occlusion of the middle cerebral artery (the most common site of stroke) is often associated with contralateral impairment of all sensory modalities on the face, arm, and leg. Massive infarction in the distribution of the anterior and middle cerebral arteries may present with dense sensory deficits (Stein & Brandstater, 2010). Occlusion of the anterior cerebral artery tends to cause more loss of sensation in the contralateral leg than in the face and arm because of this artery's supply to the medial aspect of the cerebral cortex (Fig. 9-1) (Stein & Brandstater, 2010). Lesions to the posterior thalamus tend to result in loss or impaired cold sensation and central pain response (Kim et al., 2007). Patterns of sensory loss following head trauma are less predictable because of the more diffuse areas of brain damage associated with this condition (Saladin, 1996).

Sterzi et al. (1993) compared patients with left and right stroke and found that loss of proprioception and pain perception were more common following right stroke than left stroke. Patients with stroke also demonstrated decreased performance with visual deprivation (Scalha et al., 2011). Left neglect, an inability to recognize and use perceptions from the left side of the body and environment, was proposed as a factor underlying this difference. A study by Beschin et al. (1996) provides evidence to support the existence of tactile neglect; patients with right brain damage tend to ignore left space during active tactile exploration. Movement time is positively correlated with tactile sensitivity, $r = 0.604$, $p < 0.05$ (Gao et al., 2010).

Partial recovery of sensation following cortical injury is attributed to decreased edema, improved vascular flow, cortical plasticity (adaptability of neurons to assume new functions), and relearning (Carr & Shepherd, 2010). Recovery of pain and temperature perception usually precedes recovery of proprioception and light touch (Fredericks, 1996a).

Use the following guidelines in planning assessments for patients with cortical injury:

- Quickly screen those areas of the body where sensation is likely to be intact, followed by a more thorough evaluation only if a deficit is found during screening.
- Assess more thoroughly those areas most likely to be affected, usually the side contralateral to the injury.
- If tactile sensation and proprioception are intact, assessment of temperature and pain is not necessary, because these protective sensations will also be intact. For patients with mild cortical impairment, begin the sensory assessment with light touch and/or proprioception.
- If pain and temperature are absent, assessment of light touch and proprioception is not necessary because these sensations will also be absent. For patients with severe cortical impairment, begin with assessment of pain and temperature for greatest efficiency.
- During reassessment to document recovery, remember that pain and temperature sensation recover before light touch and proprioception.

Spinal Cord Injury

Patients with complete lesions of the spinal cord demonstrate a total absence of sensation in the dermatomes (Fig. 9-2) below the level of the lesion. The level of the lesion determines the extent of the sensory loss, with the greatest loss occurring in patients with lesions in the highest cervical regions of the spinal cord. Paresthesia (tingling or pins and needles sensation) may occur in the dermatome associated with the level of the lesion (Burns & Ditunno, 2001; Fredericks, 1996c).

Incomplete spinal cord lesions result in sensory losses that are related to damage within specific spinal tracts. For instance, damage to the anterior part of the spinal cord usually results in loss of pain and temperature sensation below the level of the lesion, whereas touch, vibration, and proprioception remain intact. Conversely, patients who have damaged the posterior portion of the spinal cord cannot feel light touch and vibration but can feel differences in temperature and painful stimuli. Patients with damage to one side of the spinal cord (Brown-Sequard syndrome) display loss of touch, vibration, and proprioception on the side of the lesion and loss of temperature and pain sensation on the side opposite the lesion. This occurs because of the differences in the

pathways of the ascending sensory fibers; neurons carrying temperature and pain sensations cross to the opposite side of the spinal cord immediately after entering it, whereas neurons carrying touch sensations ascend to the medulla before crossing to the opposite side (Fredericks, 1996c). Damage to the central spinal cord often results in bilateral loss of pain and temperature sensation below the level of the lesion because the neurons cross to the opposite side through the central portion of the cord. Mild to moderate compression of the spinal cord may result in decreased or absent sensation in the single dermatome at the level of the compression or could also involve dermatomes below the compressed area (Fredericks, 1996c).

Any sensory recovery following traumatic spinal cord injury usually occurs within the first year, with the greatest recovery in the first 3–6 months, especially in incomplete injuries (Burns & Ditunno, 2001; Kirshblum et al., 2004). Recovery of sensation is thought to occur because of resolution of ischemia and edema within the spinal cord.

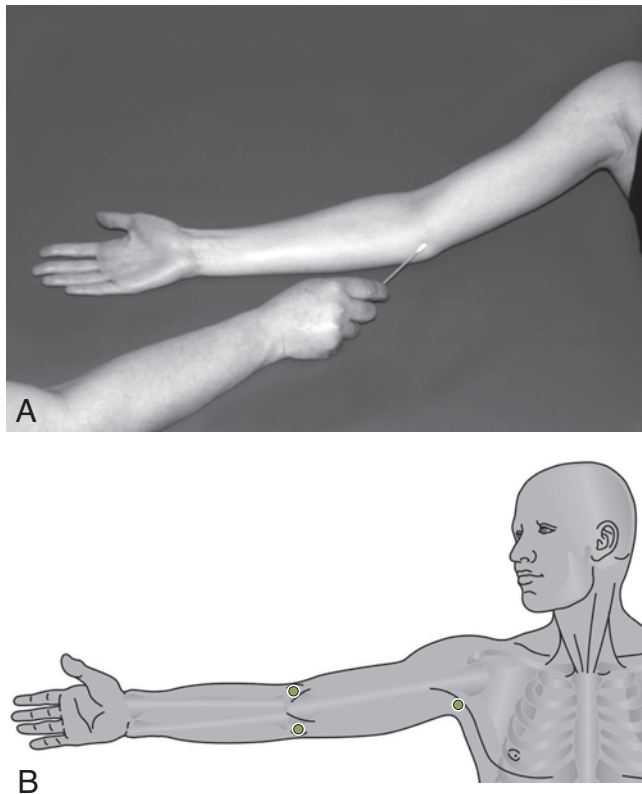
Use the following guidelines in planning assessments for patients with spinal cord injury:

- Use a test with both pain and light touch stimuli (pinprick and cotton ball, respectively) to determine level of injury. The gold standard for neurological classification of spinal cord injury is the American Spinal Injury Association's (ASIA) Impairment Scale (Consortium for Spinal Cord Medicine, 2008).
- Apply stimuli to key sensory points within each dermatome when assessing neurological level in a rostral to caudal direction (Fig. 9-3) (Consortium for Spinal Cord Medicine, 2008). The full neurological classification also involves muscle strength testing at key motor points (see Chapter 38 on Spinal Cord Injury for further details).
- Test bilaterally because results may differ from side to side.
- Do complete testing of pinprick and light touch for patients with complete lesions where sacral sparing is absent to determine the zone of partial preservation, which provides more comprehensive information to the therapist regarding the intervention and education needed regarding sensory concerns after spinal cord injury.
- Test for multiple sensory modalities, including at least one pain or temperature assessment and at least one measure of touch, vibration, or proprioception in patients with incomplete or unknown lesions. To determine spinothalamic function, select a thermal threshold test (Savic et al., 2007). To determine posterior column involvement, select a vibration threshold test (Savic et al., 2007). Finally, to test both spinothalamic and posterior column function, the electrical threshold Quantitative Sensory Test (QST) may be used (Savic et al., 2007). However, quantitative sensory testing is typically used in research settings rather than clinical
Figure 9-2 Typical dermatome distribution. (Reprinted with permission from Bear, M. F., Connors, B. W., & Paradiso, M. A. [2007]. *Neuroscience: Exploring the brain* [3rd ed.]. Baltimore: Lippincott Williams & Wilkins.)

therapy settings because of the cost of the instrument and the time required to administer the test.

Peripheral Nerve Injury

Patterns of sensory loss following peripheral nerve injury vary with the nerve or nerves involved. Damage to a single nerve root as it exits the spinal cord affects sensation on one side of the body within a single dermatome (Fig. 9-2). Damage to a peripheral nerve distal to the brachial plexus affects sensation within the appropriate peripheral nerve

distribution (Fig. 9-4) (Ropper & Samuels, 2009). For instance, in carpal tunnel syndrome, compression of the median nerve at the wrist produces sensory symptoms in the thumb, index, middle, and half of the ring finger on the affected side with the greatest changes in two-point discrimination being found in the middle finger (Comtet, 2005; Elfar, Stern, & Kiefhaber, 2010). Furthermore, compression of peripheral nerves in the upper limb can be characterized by the following: (1) pathology is observed primarily at anatomical locations where compression is more likely, (2) pathology may involve one or several specific nerves and


locations within the course of the nerves, (3) pathology has a smaller or larger extension along the nerve versus being limited to a small focal point, and (4) pathology is likely to spread and extend over time and involve several and/or larger nerve segments (Comtet, 2005; Jepsen et al., 2009).

The severity of the sensory loss can vary widely. A complete transection of a peripheral nerve results in a total loss of tactile sensation within the region, especially loss of two-point discrimination and cutaneous pain sensibility (Karabeg, Jakirlic, & Dujso, 2009). A mild nerve compression, such as in early stages of carpal tunnel syndrome, produces a slightly elevated threshold for sensing light touch or vibration (O'Conaire, Rushton, & Wright, 2011). As the compression persists or increases in severity, further loss of sensation will occur, the threshold of light touch and vibration sensation will be further elevated (Tucker et al., 2007), and the patient will begin to report symptoms such as frequently dropping items from the hand. Eventually, if the compression is not relieved, numbness and loss of protective sensation will develop, and furthermore, prolonged loss of peripheral sensation results in cortical reorganization of the body part (Lundborg & Rosén, 2007), further disrupting sensory interpretation.

Recovery of sensation following release of a nerve from compression is very likely if the compression is brief and mild. Significant recovery following prolonged compression is common, but sensory perception does not always reach normal levels. Recovery of sensation following total transection of a nerve is possible only with surgical intervention and adequate regrowth of neurons (Smith, 2011). The prognosis of sensory recovery for the transected peripheral nerve appears most correlated with length of graft and length of time before grafting (Karabeg, Jakirlic, & Dujso, 2009). Sensation of temperature and pain generally (but not always) recovers first, followed by touch sensation, because regrowth of pain fibers averages 1.08 mm per day, and regrowth of touch fibers averages 0.78 mm per day (Waylett-Rendall, 1988). Moving touch recovers before light touch. Accurate touch localization recovers last (Callahan, 2002/2011).

The pattern of sensory loss occurring as a result of peripheral polyneuropathies, which are associated with chronic conditions such as diabetes mellitus, alcoholism, and acquired immunodeficiency syndrome (AIDS), is typically bilateral and symmetrical, usually beginning in the feet and hands (glove-and-stocking distribution) and spreading proximally (MedicineNet.com, 2012). Paresthesia and pain may accompany peripheral neuropathy. Because of the chronic conditions associated with peripheral neuropathy, full recovery of sensation is generally not expected (Fredericks, 1996b). When examining diabetic neuropathy, it has been found that tactile direction discrimination is more accurate than vibration threshold testing (Loken et al., 2010). Tactile direction discrimination refers to the ability to determine the direction of movement of touch across the skin, whereas vibratory threshold testing refers to the ability to detect vibration of the skin, typically using a tuning fork. People diagnosed with complex regional pain syndrome tested using QST according to the standards of the German Research Network on Neuropathic Pain revealed a distinct pattern of generalized bilateral sensory loss and hyperalgesia (Huge et al., 2011).

Sensory loss can also be found in persons with burn injuries at a rate of about 10% (Gabriel, Kowalske, & Holavanahalli, 2009). Furthermore, this neuropathy is characterized similarly to that found in conditions such as diabetes, systemic lupus erythematosus, and rheumatoid arthritis; however, sensory loss in burn patients may show better spontaneous recovery, as documented by a pilot study of nerve conduction testing (Gabriel, Kowalske, & Holavanahalli, 2009).

Sensory loss can also be found with amputation injuries involving the peripheral nerves. Haas et al. (2011) found that tactile sensation, as tested by Semmes-Weinstein monofilaments, was decreased in crush/avulsion injuries to the thumb compared with clean cut injuries. Finally, sensory loss in the peripheral nerves can be found in people with cancer as a result of neurotoxicity to various chemotherapy interventions (Cavaletti & Marmiroli, 2012).

Posterior (dorsal)
Figure 9-4 Typical sensory distribution of peripheral nerves within the upper extremity. (Reprinted with permission from Sieg, K. W., & Adams, S. P. [2009]. *Illustrated essentials of musculoskeletal anatomy* [5th ed.]. Gainesville, FL: Megabooks Inc.)

Use the following guidelines in planning assessments for patients with peripheral nerve injury:

- The purpose of evaluation in clients with peripheral polyneuropathy is to establish the impact of disease on protective sensation, so choose an assessment of protective sensation.
- The desired outcome of sensory evaluation in clients with involvement of a single peripheral nerve is an accurate map of both the body area and severity of sensory loss.
- Evaluation of nerve compression and subsequent recovery requires measures that are highly sensitive to show small changes in sensory function.
- Because functional tests of sensation requiring object or texture identification are completed with the thumb, index, and middle fingers, these assessments provide information about the functioning of the C6, C7, and C8 nerve roots and the median nerve.

- In documenting recovery of peripheral nerve function, keep in mind the recovery sequence of pain → moving touch → light touch → touch localization.

EVALUATION TECHNIQUES

There are numerous methods of testing sensation. Some are intended to evaluate a specific type of sensory receptor, such as the test for vibration awareness using a tuning fork that is believed to be specific to the Meissner's and Pacinian corpuscles (Dellon, 2000). Some are intended to evaluate the use of sensation in skills that support occupational functioning, such as the use of the hand to identify objects by touch in the test of **stereognosis**. Some are designed to detect very small changes in sensory perception, such as the touch threshold test using **monofilaments** (fine nylon strands). The locognosia test, described by Jerosch-Herold, Rosen, and Shepstone (2006) can be used after peripheral

nerve injuries to determine touch localization. The test uses a grid superimposed on the hand or map of the hand divided into zones. The patient or subject is asked to identify the zone in which a stimulus such as an aesthesiometer is perceived. Some tests, such as the QST of the German Research Network on Neuropathic Pain that quantifies sensory responses to vibratory, pain (sharp/dull), and thermal stimuli are currently only used in research versus rehabilitation clinics (Blumenstiel et al., 2011).

The principles of sensory testing optimize the reliability of the testing results. These principles are listed in Procedures for Practice 9-1. The purpose of these principles

Procedures for Practice 9-1

Principles of Sensory Testing

- Choose an environment with minimal distractions.
- Ensure that the patient is comfortable and relaxed.
- Ensure that the patient can understand and produce spoken language. If the patient cannot, modify testing procedures to ensure reliable communication.
- Determine areas of the body to be tested.
- Stabilize the limb or body part being tested (Fig. 9-5).
- Note any differences in skin thickness, calluses, and so on. Expect sensation to be decreased in these areas.
- State the instructions for the test.
- Demonstrate the test stimulus on an area of skin with intact sensation while the patient observes.
- Ensure that the patient understands the instructions by eliciting the correct response to the demonstration.
- Occlude the patient's vision for administration of the test. Place a screen or a file folder between the patient's face and area being tested (Fig 9-6), blindfold the patient, or ask the patient to close his or her eyes.
- Apply stimuli at irregular intervals or insert catch trials in which no stimulus is given.
- Avoid giving inadvertent cues, such as auditory cues or facial expressions, during stimulus application.
- Carefully observe the correctness, confidence, and promptness of the responses.
- Observe the patient for any discomfort relating to the stimuli that may signal hypersensitivity (exaggerated or unpleasant sensation).
- Ensure that the therapist who does the initial testing does any reassessment.

From Brand, P. W., & Hollister, A. (1999). *Clinical mechanics of the hand* (3rd ed.). St. Louis: Mosby; Callahan, A. D. (2002/2011). Sensibility assessment for nerve lesions-in-continuity and nerve lacerations. In E. J. Mackin, A. D. Callahan, T. M. Skirven, L. H. Schneider, A. L. Osterman, & J. M. Hunter (Eds.), *Rehabilitation of the hand and upper extremity* (5th ed., pp. 214–239). St. Louis: Mosby. Archived online in T. M. Skirven, A. L. Osterman, J. M. Fedorczyk, & P. C. Amadio (Eds.). (2011). *Rehabilitation of the hand and upper extremity* (6th ed.). Philadelphia: Mosby, Inc./Elsevier; Reese, N. B. (2011). *Muscle and sensory testing* (3rd ed.). Philadelphia: Saunders/Elsevier Health Sciences Division.
Figure 9-5 Hand support during testing. **A.** Fingers must be carefully stabilized and supported during testing so that motion is prevented, avoiding inadvertent cues to the patient. **B.** A cushion of therapy putty can be used to provide the stabilization.

is to eliminate nontactile cues and to ensure that the responses from the patient accurately reflect actual sensation. Because many of the tests require subjective reports from the patient, results can be either deliberately or unconsciously manipulated by the patient to make the deficit appear better or worse. Careful attention to test administration and patient responses can minimize the possibility of test manipulation by patients. For cases where the patient's responses are questionable and a determination of testing manipulation must be made, therapists may use a forced-choice testing methodology and statistical analysis described by Greve, Bianchini, and Ameduri (2003) in which patients are required to identify whether they are touched with one finger or two. A statistically low percentage of correct choices suggests an invalid response, because someone without sensation who merely guessed would be likely to get approximately 50% correct.

Fess (1995), in her article "Guidelines for Evaluating Assessment Instruments," describes four essential criteria for all assessment instruments. The first is reliability, which

Figure 9-6 Sensory testing using an aesthesiometer for static or two-point discrimination. Vision must be occluded during testing. Using a screen, file folder, or clipboard such as this is usually more comfortable for patients than closing their eyes or being blindfolded.

includes accuracy of the instrument measurements as well as test–retest stability and interrater repeatability. Second, she describes validity as the tool's ability to measure the sensory modality for which it was designed. Third, standards for the manufacture, administration, and scoring of the assessment and interpretation of the results must be set and followed. Finally, there must be normative data and, ideally, diagnosis-specific normative data.

Specific descriptions of the administration of commonly used sensory evaluations are shown in Tables 9-2 and 9-3. The more standardized evaluations of sensation appear in Table 9-2, and the less standardized evaluations are shown in Table 9-3. Sensory testing tools have been the target of much criticism for their lack of standardization, reliability, and validity. Although the sensory tests are divided into standardized and nonstandardized tests in Tables 9-2 and 9-3, few of the tests in Table 9-2, presented as standardized, meet all of the criteria described by Fess (1995). Assessment Table 9-1 provides a summary of psychometric data regarding selected assessments. Resources 9-1 lists companies that provide assessment instruments.

Therapists must consider the various qualities of the types of sensory tests as they choose and administer them. Threshold tests determine the smallest stimuli that can be noticed by the patient. They are the most sensitive and have numeric results that can easily be compared over time. Two-point discrimination measures innervation density

in the fingers and is quite sensitive to change. Touch localization evaluates not only sensation but also whether that sensation is accurately perceived. Touch, temperature, vibration, and pain awareness are simple to administer but are not very sensitive to change. Tests of kinesthetic and proprioceptive sensations are less commonly used and are not very sensitive to change but are believed to be related to the specific type of sensory feedback required for coordinated movement. The Moberg Pick-Up Test and stereognosis test are more functional but require combined motor and sensory function in the hand. Both the DASH (Disabilities of the Arm, Shoulder, and Hand) and Quick DASH Outcome Measures are questionnaires designed to look at changes in motor and sensory function of the upper extremity (Institute for Work & Health, 2006). The HASTe (Hand Active Sensation Test) is a functional tool designed to assess the haptic perception of people who have sustained a stroke (Williams et al., 2006).

Computerized evaluations of sensation are often used for research and are becoming available in a limited number of clinics (Benton, 1994; Dellon, 2000; Riggle, 1999). The Pressure Specified Sensory Device measures pressure threshold for one- and two-point discrimination (Williams et al., 2009). The prototype Robotic Monofilament Inspector has been found to be a more sensitive screen of diabetic neuropathy than manual tests. It is only used in research and is not yet available to occupational therapists in clinic settings (Wilasrusmee et al., 2010). The QST of the German Research Network of Neuropathic Pain involves a protocol as well as instruments to test somatosensation to determine sensory loss (small and large nerve fiber functions) or gain (hyperalgesia, allodynia, and hyperpathia) as well as cutaneous and deep pain sensitivity. The QST tests vibration, pain, and mechanical thresholds at the face, hands, and feet (Rolke et al., 2006).

Although sensory tests are usually administered with the patient rested and in a comfortable, supported position, exceptions to this principle occur in the case of patients with peripheral nerve compression. For those patients, provocative testing, which determines whether increases in symptoms occur as a result of additional stress or compression on the peripheral nerve, is used. Increased sensory loss in the median nerve distribution with the wrist in flexion implicates compression of that nerve in the carpal tunnel area. Elbow flexion is the stress position for suspected cubital tunnel syndrome, which is compression of the ulnar nerve in the elbow area. Manual pressure over the nerve can be combined with the provocative position to further increase stress on the nerve (Callahan, 2002/2011; Novak & Mackinnnon, 2005; Szabo et al., 1999).

Recording Assessment Results

Documentation should include the type of test, the skin area tested, and the response. One easy way to document

Table 9-2 Standardized Sensory Testing Techniques

Sensory Test	Test Instrument	Stimulus (S) and Response (R)	Scoring and Expected Results
Touch threshold Measure of threshold of light touch sensation (Bell-Krotoski, 2011; Bell-Krotoski & Tomancik, 1987; Stoelting Company, 2001)	Semmes-Weinstein monofilaments OR Weinstein Enhanced Sensory Test (WEST)	Semmes-Weinstein S: Begin testing with filament marked 2.83; hold filament perpendicular to skin, apply to skin until filament bends (Fig. 9-7). Apply in 1.5 seconds, and remove in 1.5 seconds. Repeat three times at each testing site, using thicker filaments if the patient does not perceive thin ones (except for filaments marked >4.08, which are applied one time to each site). R: Patient says, "yes" upon feeling the stimulus. WEST S: Patient is prompted to stimulus, and then filament is applied perpendicular to skin and held for 1 second, then slowly lifted. Catch trials consisting of prompt without filament applications are randomly inserted within test sequence. R: Patient responds with "yes" or "no" to indicate whether stimulus was felt.	Semmes-Weinstein Score involves recording the number of the filament or the actual force of the thinnest filament detected at least once in three trials; results are usually recorded according to a standard color code using colored pencils or markers and a diagram of the hand/limb (Table 9-4 and Fig. 9-4; see also Fig. 9-9 in the case example). Normal touch threshold for adults is the perception of the filament marked 2.83 (force, 0.08 g) except for the sole of the foot, where the normal threshold is the filament marked 3.61 (force, 0.21 g). WEST Results are recorded according to the color of the filament. Normal touch threshold is perception of the thinnest monofilament. There are two WEST devices, one for the hand and another for the foot. The WEST is meant to be a quick screening tool of sensation. When needing to track recovery, the Semmes-Weinstein is used.
Static two-point discrimination Measures innervation density of slowly adapting fibers of the hand (Callahan, 2002/2011; Dellon, 2000)	Disk-Criminator OR aesthesiometer (Fig. 9-8)	S: Begin with a 5-mm separation of points. Lightly (just to the point of blanching) apply one or two points (randomly sequenced) in a transverse or longitudinal orientation on the hand; hold for at least 3 seconds or until patient responds. Gradually adjust distance of separation to find least distance that patient can correctly perceive two points. R: Patient responds by saying, "one," "two," or "I can't tell."	Score is smallest distance at which perception of one or two points is better than chance. When the patient's responses become hesitant or inaccurate, require two of three, four of seven, or seven of ten correct responses. Norms 3–5 mm in fingertips ages 18–70 years (Bell-Krotoski, 2011); 5–6 mm in fingertips ages 70 and above (Desrosiers et al., 1996) 5–9 mm for middle and proximal phalanges in adults age 18–60 years, 0–12 mm middle and proximal phalanges of those age 60 years and older (Shimokata & Kuzuya, 1995)
Moving two-point discrimination Measures innervation density of quickly adapting fibers of fingertips (Callahan, 2002/2011; Dellon, 1988, 2000)	Disk-Criminator OR aesthesiometer (Fig. 9-8)	S: Beginning with a 5- to 8-mm distance, move one or two points randomly from proximal to distal on the distal phalanx with points side by side and parallel to the long axis of the finger. Use just enough pressure for the patient to appreciate the stimulus. Gradually adjust distance of separation to find least distance that patient can correctly perceive. R: Patient responds by saying, "one," "two," or "I can't tell."	Score is smallest distance at which perception of one or two points is better than chance. When the patient's responses become hesitant or inaccurate, require 2 of 3, 4 of 7, or 7 of 10 correct responses. Norms 2–4 mm for ages 4–60 years (Dellon, 2000) 4–6 mm for ages 60 years and older (Dellon, 2000; Desrosiers et al., 1996)
Touch localization Measures spatial representation of touch receptors in the cortex (Nakada, 1993)	Semmes-Weinstein monofilament number 4.17, pen, or pencil eraser	S: Apply touch to patient's skin with vision occluded. R: Patient remembers location of stimulus. With vision no longer occluded, patient uses index finger or marking pen to point to spot just touched.	Score is the measured distance in millimeter between location of the stimulus and location of the response. Normal response is approximately 3–4 mm in digit tips, 7–10 mm in palm of hand, 15–18 mm in forearm (Schady, 1994; Sieg & Williams, 1986).

| Table 9-2 | **Standardized Sensory Testing Techniques** *(continued)* |

Sensory Test	Test Instrument	Stimulus (S) and Response (R)	Scoring and Expected Results
Touch localization or locognosia Measures ability to localize touch in hand (Jerosch-Herold, Rosen, & Shepstone, 2006)	Semmes-Weinstein monofilament number 6.65 or black filament on WEST, grid superimposed on the hand or a drawn map of the hand divided into zones	S: While vision is occluded, apply touch to patient's skin on palmar side of tips of fingers for 2 seconds followed by an interval of 3 seconds before next stimulus. Test the unaffected hand first. Each zone is stimulated twice. R: Patient identifies the location of the stimulus by calling out the corresponding number on the map.	A score of 2 points is given for each zone identified correctly. When localization is correct orientation but in an adjacent finger or correct finger but adjacent zone, a score of 1 is given. When zone cannot be identified, but correct digit is perceived, a score of 1 is also given. Anything worse or nonresponse is scored 0. Maximum score is 56 points for the area of the median nerve and 24 points for the area of the ulnar nerve.
Vibration threshold Measures threshold of rapidly adapting fibers (Callahan, 2002/2011; Dellon, 2000)	**Vibrometer**: biothesiometer, Vibratron II, automated tactile tester, Case IV System	Protocols vary with instrument S: Generally, vibrating head is applied to area to be tested. Stimulus intensity is gradually increased or decreased R: Patient indicates when vibration is first felt or no longer felt	Scoring varies with instrument; norms usually provided by manufacturer
Modified Pick-Up Test Dellon's modification of the Moberg Pick-Up Test measures the interpretation of sensation in the distribution of the median nerve (Dellon, 1988).	A small box and 12 standard metal objects: wing nut, screw, key, nail, large nut, nickel, dime, washer, safety pin, paper clip, small hex nut, and small square nut	Part 1 S: Tape small and ring digits to palm to prevent use. With patient using vision, have him or her pick up and place objects in a box as quickly as possible; time performance on two trials R: Patient picks up each object and deposits it in the box as quickly as possible Part 2 S: With patient's vision occluded, place one object at a time between three-point pinch in random order and measure speed of response R: Patient manipulates object and names it as rapidly as possible	Part 1 Score is total time to pick up and place all 12 objects in the box for each of two trials Normal response Trial 1, 10–19 seconds Trial 2, 9–16 seconds Part 2 Score is time to recognize each object on each of two trials (up to a maximum of 30 seconds) Normal response: 2 seconds per object
Erasmus MC Revised Nottingham Sensory Assessment Quantitative functional measure of sensation after stroke. Sensations assessed include: light touch, pinprick, pressure, two point discrimination, and proprioception (Stolk-Hornsveld et al., 2006)	A blindfold, cotton wool balls, neurotips, cocktail stick, aesthesiometer	S: Subjects are tested for light touch, pinprick, sharp-blunt discrimination, pressure, two-point discrimination, and proprioception. Areas tested are the face, trunk, shoulder, elbow, wrist, hand, hip, knee, ankle, and foot. Each stimulus is assessed three times on each area to the left and right sides in random order. For proprioception, the body part is moved by the researcher/therapist, and the subject is asked to replicate the position. R: Subjects indicate whether the stimulus is same as on unaffected side, different, or absent either by verbal response or movement of body.	All areas are scored based on 2 for normal response, 1 for impaired response, or 0 for absent response. For all categories, it is expected that the subject score "2 for normal response" for all areas

(continued)

Table 9-2	Standardized Sensory Testing Techniques *(continued)*		
Sensory Test	**Test Instrument**	**Stimulus (S) and Response (R)**	**Scoring and Expected Results**
Hand Active Sensation Test (HASTe) Quantitative functional measure of haptic perception in the hand (Williams et al., 2006)	Objects of various weights and textures	S: To complete the HASTe, subjects use one hand to manually explore objects that vary by weight and texture by using a match-to-sample forced choice recognition task without visual assistance R: Subjects indicate their choice without identifying or describing the matching object property	Eighteen trials are completed; nine test objects are matched twice, once to texture and once to weight. The total number of accurate matches (0–18) is recorded.
Quick DASH (Institute for Work & Health, 2006). Self-report tool for people with musculoskeletal disorders of the upper extremities. Measures perceived abilities to do tasks requiring sensory feedback.	None	S: Survey of 11–19 items provided to patient to complete. R: Patient fills out items on the scale and grades ability on a scale of 1–5 (no difficulty to unable, respectively).	At least 10 of the 11 items must be completed for a score to be calculated. Assigned values for completed responses are summed and then averaged, producing the score. This score is then converted to a 100 scale by subtracting 1 from the average score and multiplying by 25. A higher score indicates greater disability. The optional modules, which look at items more specific to athletes, musicians, or people whose work is physically demanding, are scored similarly to above.

touch threshold testing with monofilaments is to use a color code or a pattern code on a drawing of the body part (Fig. 9-4; see also Fig. 9-9 in the Case Example). The standard colors and patterns used to document results for the Semmes-Weinstein monofilaments and Weinstein Enhanced Sensory Test (WEST) are indicated in Table 9-4. A series of sensory maps completed over time can easily and quickly demonstrate sensory recovery.

For standardized tests, results can be compared with norms; however, age should be taken into account because studies show a decline in sensation with age (Desrosiers et al., 1996; Norman et al., 2011). Normative monofilament expectations for adults older than age 60 years are shown

in Table 9-5. For both standardized and nonstandardized tests, results from the affected area of the patient can be compared with results from the corresponding, contralateral unaffected area to determine the individual's "norms."

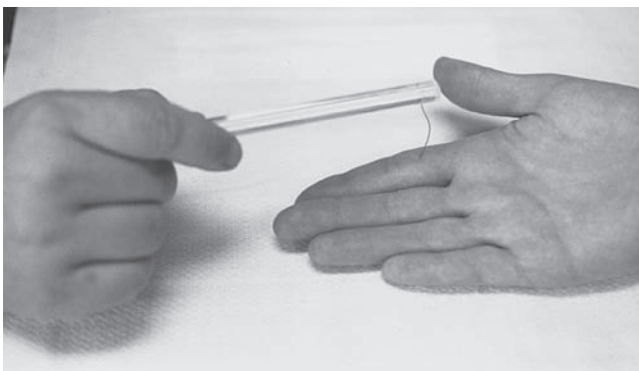
Sensory evaluation findings are often summarized as absent, intact, or impaired. *Absent* describes a total loss of sensation or inability to detect a specific sensory modality. *Intact* describes normal sensation. Sensation is *impaired* when the patient is able to detect some but not all of the stimuli or when the perception of the stimulus is different from that of an area of skin that has intact sensation.


Figure 9-7 Testing of the median nerve distribution using Semmes-Weinstein monofilaments.
Figure 9-8 Tools used in two-point discrimination tests: Disk-Criminators (*top*) and an aesthesiometer (*bottom*).

Table 9-3 Nonstandardized Sensory Testing Techniques

Sensory Test	Test Instrument	Stimulus (S) and Response (R)	Scoring and Expected Results
Touch awareness Measures general awareness of light touch input (Ropper & Samuels, 2009)	Cotton ball or swab, fingertip, pencil eraser	S: Light touch to a small area of the patient's skin. R: Patient says "yes" or makes agreed-upon nonverbal signal each time stimulus is felt.	Score is number of correct responses in relation to number of applied stimuli. Expected score is 100%.
Pinprick or pain awareness Measures discrimination of sharp and dull stimuli, which indicates protective sensation (Brand & Hollister, 1999; Reese, 2011)	New or sterilized safety pin	S: Randomly apply sharp and blunt ends of safety pin, perpendicular to skin, at the pressure that was necessary to elicit correct response on uninvolved side of body. R: Patient says "sharp" or "dull" after each stimulus.	Score is number of correct responses divided by number of stimuli. Expected score is 100%. Correct responses to sharp stimuli indicate intact protective sensation; incorrect responses to sharp stimuli indicate some awareness of pressure but absent protective sensation.
Temperature awareness Measures discrimination of warm and cool stimuli (Waylett-Rendall, 1988)	Hot and cold discrimination Kit or glass test tubes filled with warm and cool water	S: Apply cold (40°F) or warm (115°F–120°F) stimulus to patient's skin. R: Patient indicates hot or cold after each stimulus.	Score is number of correct responses divided by number of stimuli. Normal response is 100%.
Vibration awareness Measures awareness of input to rapidly adapting alpha-beta (α, β) fibers (Dellon, 1988)	Tuning forks: 30 cycles per second 256 cycles per second	S: Strike tuning fork with force to cause vibration; place prong tangentially to fingertip of injured and then uninjured hand; ask patient, "Does this feel the same or different?" R: Patient responds same or different and describes difference in perception.	Scoring is normal if stimuli to both hands feel the same, altered if stimuli feel different. The 30 cycles per second tuning fork is used to test the Meissner afferents, and the 256 cycles per second tuning fork is used to test the Pacinian afferents.
Stereognosis Measures the ability to identify objects, which requires interpretation of sensory input. Motor function is prerequisite. (Eggers, 1984).	A number of small objects known to the patient	S: Place a small object in the hand to be tested. R: Patient may manipulate object within the hand, patient names object.	Scoring is number of correct responses divided by total number of objects presented or time to identify each object. Normal response is correct identification of almost all objects within 2–3 seconds (Lederman & Klatzky, 1996).
Moberg Pick-Up Test Measures the function of slowly adapting alpha-beta (α, β) fibers in medial nerve injury (Callahan, 2002/2011; Dellon, 1988)	An assortment of small objects and a small box	S: Instruct patient to pick up objects as rapidly as possible and place them In the box, using right and left hands, with and without vision. R: Patient quickly picks up objects and places them in box.	Scoring is total time to pick up objects. Compare scores of left and right hands and those with and without vision. Mean times for 12 standard objects were found by Ng, Ho, and Chow (1999) to be 10–12 seconds with vision and 20–23 seconds without vision.
Proprioception Measures sense of joint position, which relies on input from an unknown combination of muscle, joint, and skin receptors (Ropper & Samuels, 2009)	None	S: Hold body segment being tested on the lateral surfaces; move the part into different positions and hold. R: Patient duplicates position with opposite extremity.	Graded as intact, impaired, or absent. Usually, reproduction of position can be accomplished within a few degrees. One study of the knee joint found on average 4° of error in normal subjects younger than age 30 years and 7° of error in normal subjects older than age 60 years (Kaplan et al., 1985).
Kinesthesia Measures sense of joint motion, which relies on input from an unknown combination of muscle, joint, and skin receptors (Ropper & Samuels, 2009)	None	S: Hold body segment being tested on the lateral surfaces; move the part through angles of varying degrees. R: Patient indicates whether part is moved up or down.	Graded as intact, impaired, or absent. Nearly 100% correct identification is expected.

Assessment Table 9-1	Summary of Assessments of Sensation

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Monofilaments Available from AliMed, North Coast Medical, or Patterson Medical (see Resources 9-1)	Measures low threshold of touch perception on an ordinal scale. Results can be documented with a color-coded drawing or with numbers. 2.83 represents normal sensation, and >6.65 represents absent sensation.	5–30 minutes or more, depending on area tested	Using Semmes-Weinstein monofilaments, diminished light touch associated with longer response time for object identification (King, 1997). Weinstein Enhanced Sensory Test (WEST) monofilament testing compared with distal motor latency using electoneurometer revealed $r = 0.659$–0.886 for individual fingers (Schulz, Bohannon, & Morgan, 1998).	Repeatability of the force of application was demonstrated by Bell-Krotoski and Buford (1997). Test–retest reliability reported by Novak et al. (1993) $r = 0.78$–0.89 and interrater reliability ICC = 0.965.	Seventy-two percent sensitive in diagnosis of carpal tunnel syndrome (MacDermid & Wessel, 2004).	Strengths: Excellent reliability and validity. Widely used. Weaknesses: Relies on subjective responses from patient. Filaments are easily damaged. WEST test not helpful in tracking nerve regeneration.
Prototype Robotic Monofilament Inspector (Wilasrusmee et al., 2010).	Measures touch threshold including protective sensation. Created for detecting diabetic neuropathy.	Not reported but presumably more accurate and quicker than manual administration	Not established; however, strong agreement with Semmes-Weinstein monofilament test as well as vibration threshold perception test. Accurately identified diabetic neuropathy.	Not established	Not established	Strengths: The current model is simple to implement. Pressure application is consistent compared with manual administration, which can vary based on rater. Weaknesses: Requires training and an instrument. Psychometrics are incomplete.

| Locognosia Test (Jerosch-Herold, Rosen, & Shepstone, 2006). Available from Dr. C. Jerosch-Herold; email: c.jerosch-herold@uea.ac.uk | Measures touch localization on an ordinal scale | 5–10 minutes per hand, but recommended to wait 30 minutes between hands | Discriminant validity was measured by looking at the difference in scores between unaffected and affected hands. For the median nerve zone, the mean difference between the affected and unaffected hands was 11.1 (with a range of 1–33 and a standard deviation of 7.40). This difference was statistically significant ($p < 0.0001$; effect size $d = 1.2$). For the ulnar nerve zone, the mean difference was 4.75 (range = 1–13.5; standard deviation = 3.16), which again was a statistically significantly difference between hands ($p < 0.0001$; effect size $d = 1.3$). | The test–retest ICC for the median nerve zone was 0.924 (95% confidence interval 0.848–1.00), indicating a very high level of reproducibility. For the ulnar nerve zone, the ICC was 0.859 (95% confidence interval 0.693–1.00) again showing a high level of reproducibility. | Not established | Strengths: Valid and reliable tool to determine touch localization in fingers. Decreased ceiling and floor effects compared with Semmes-Weinstein and WEST. Weaknesses: If comparing scores of affected hand with those of unaffected hand, it is time consuming to wait the recommended 30 minutes in between testing of hands. Discriminant validity was determined based on the correlation between subjects' unaffected hand and the matched control hand of subjects with no nerve injuries. |
| Disk-Criminator and aesthesiometer Available from Lafayette Medical Instruments, North Coast Medical, or Patterson Medical | Measures two-point discrimination in millimeters, a ratio scale. | 5–10 minutes | The dynamic threshold values were lower than the static scores. The two-point discrimination values obtained correlated significantly with the arm grade of the overall disability sum score (static values: $r = 0.33$, $p = 0.04$; dynamic values: $r = 0.37$, $p = 0.02$) and the scores of the Weinstein Enhanced Sensory Test in patients (static values: $r = 0.58$, $p = 0.0001$; dynamic values: $r = 0.55$, $p = 0.0002$) (van Nes et al., 2008). | Test–retest reliability for two-point discrimination using the Disk-Criminator was reported as $r = 0.961$ for static and 0.922 for moving by Dellon, Mackinnon, and Crosby (1987) Interrater reliability ICC = 0.989 for static and 0.991 for moving (Novak et al., 1993). | Study by MacDermid & Wessel (2004) reported static testing has 24% sensitivity and 62% specificity in diagnosis of carpal tunnel syndrome. The sensitivity values for the static and dynamic threshold values were 28% and 33%, respectively, for normal aging and those with polyneuropathy (Van Nes et al., 2008). | Strengths: Excellent reliability. Widely used. Inexpensive, durable. Useful in documenting nerve regeneration. Most useful on fingertips. Weaknesses: Variation in force of application has been shown by Bell-Krotoski and Buford (1997), which may affect results. |

(continued)

Assessment Table 9-1	Summary of Assessments of Sensation (*continued*)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Tuning forks (128 Hz frequency) Available from Patterson Medical	Indicates whether or not vibration is perceived, a nominal scale.	5 minutes	Concurrent validity using Pearson's product moment correlation was moderate to strong (0.515–0.634) between the tuning fork and Vibrameter, supporting concurrent validity (O'Conaire, Rushton, & Wright, 2011).	Moderate interrater reliability for median nerve was determined for the Vibrameter ICC = 0.798 and for the tuning fork Icc = 0.520 (O'Conaire, Rushton, & Wright, 2011).	Sensitivity for diagnosis of carpal tunnel syndrome is reported at 55% and specificity at 81% (MacDermid & Wessel, 2004).	Strength: Low-frequency tuning fork is useful to document regeneration of nerve Weaknesses: Relies on subjective responses from patient. Application techniques are not standardized.
Hot and cold temperature probes Available from Patterson Medical	Indicates whether or not temperature is perceived; a nominal scale.	5 minutes	Not established	Not established	Not established	Strengths: Assesses functional sensation. Is useful to identify loss of protective sensation. Weaknesses: Relies on subjective responses from patient. Tool does not test fine gradations of temperature discrimination and therefore may not be sensitive to change.
Vibrometer Biomedical Instrument Company, Sensortek, Inc., or WR Medical Electronics	Determines lowest intensity of vibration that can be perceived, an interval scale	20 minutes	Not established	Interrater reliability using Vibratron II, ICC = 0.982 (Novak et al., 1993).	In diagnosis of carpal tunnel syndrome, sensitivity is 50% and specificity is 73% (MacDermid & Wessel, 2004).	Strengths: Multiple kinds of instruments. The manufacturers provide protocols for testing. Instruments score small gradations. Weaknesses: Limited availability in occupational therapy clinics. Expense.

Instrument	Description	Time	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Pressure-specified sensory device Neurotherapy DX	Measures pressure threshold and ability to feel and distinguish the distance between two points with results graphically generated by a computer and quantified on an interval scale with a range of 0.1–100 g/mm² for touch threshold	10–20 minutes	Results correlate well with timed object identification, $r = 0.691$ (Dellon, 2000).	Test–retest reliability is $r = 0.93$ for moving two-point discrimination, $r = 0.97$ for single-point static touch threshold test. Interrater reliability is $r = 0.61$. (Dellon, 2000).	In diagnosis of nerve entrapment, sensitivity is 100% (Tassler & Dellon, 1995).	Strengths: Computerized. Quantifiable. Measures both threshold and innervation density. Excellent sensitivity. Weaknesses: Limited availability in occupational therapy clinics. Expense.
Moberg Pick-Up Test (Dellon, 1988; Ng, Ho, & Chow, 1999) Available from Lafayette Instrument Company or Patterson Medical	Timed picking up of objects and timed identification of objects, resulting in an interval scale score	10 minutes	Performance of young, middle aged, and elderly subjects with carpal tunnel syndrome as denoted by nerve conduction study found to have significantly decreased performance on Moberg Pick-Up Test ($p < 0.05$). (Amirjani et al., 2011).	Interrater reliability $r = 0.67$ with patient's eyes open and $r = 0.80$ with eyes closed. (Ng, Ho, & Chow, 1999) Test–retest reliability found in people with carpal tunnel syndrome: ICC = 0.91 (95% confidence interval = 0.87–0.95), was highly significant ($p < 0.001$) (Amirjani et al., 2011).	Not established	Strengths: Simple, quick to administer. Functional. Easy to replicate. Inexpensive. Useful to assess function of median nerve. Weaknesses: Useful for limited diagnostic category. Lack of standardized protocol.
Erasmus MC modifications to Nottingham Sensory Assessment (Stolk-Hornsveld et al., 2006)	Measures light touch, pinprick, pressure, sharp-blunt discrimination, two-point discrimination, and proprioception	10–15 minutes	Not established	Interrater Weighted κ values ranged 0.66–1.00 for good to excellent agreement; except two-point discrimination was −0.10 at the fingertips. Intrarater Weighted κ values ranged 0.77–0.96 good to excellent agreement except for two-point discrimination, which was 0.11–0.63 poor to fair agreement.	Not established	Strengths: Quick and portable to administer. Provides sensory information about several areas. Weaknesses: Although validity of original Nottingham Sensory Assessment has been established, it has not been established for the Erasmus MC NSA. Reliability for two-point measures is poor to fair.

Assessment Table 9-1 | Summary of Assessments of Sensation (*continued*)

Instrument and Reference	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Hand Active Sensation Test (HASTe) In pilot research stage available from University of Ohio through Williams et al., 2006	Measures haptic perception of the hand	Maximum of 90 minutes to complete 18 trials. For the stroke/experimental group, the average time to complete was 25 minutes (range 11–55 minutes) and for the control group, time to complete was 14 ± 3 minutes (range 10–20 minutes)	HASTe accuracy discriminated between stroke survivors and controls ($p < 0.001$) with mean accuracy scores of 14.86 ± 1.53 for controls and 8.46 ± 3.51 for stroke survivors. Both groups scored significantly higher ($p < 0.001$) on the nine texture trials (6.36 ± 2.50) than the nine weight trials (5.30 ± 2.31); however, the HASTe discriminated between stroke survivors and controls for discrimination of weight and texture ($p < 0.001$). HASTe showed moderate negative correlation with Wrist Position Sense Test (WPST) and two-point discrimination tests (because the scores of these tests decrease with improvement, whereas the score of the HASTe increases with improvement).	Test–retest reliability for the HASTe across all subjects was strong (ICC = 0.77, Pearson $r = 0.78$), indicating that the scores for the test and the retest were both correlated and in agreement despite a significant difference found for the paired t-test analysis of actual scores ($p = 0.03$). Internal consistency of the 18-item instrument was also strong (Cronbach's α coefficient = 0.82).	Not established	Strength: Uses functional objects to determine sensory recognition for people with no apparent sensory deficit, including those with stroke and the normal population. Weaknesses: Time consuming to perform. Still in pilot/research stage. Despite the quality of results, to be useful, the HASTe needs to provide unique information about hand function not currently available to the clinician.

Quick DASH	Format		Validity	Reliability	Responsiveness	Strengths/Weaknesses
Quick DASH The Quick DASH Outcome Measure is available free of charge (for noncommercial purposes) and may be downloaded from the DASH website at www.dash.iwh.on.ca. Information on scoring is also available on-line.	Survey of 11–19 items are rated on a 1–5 scale by patient with upper limb involvement.	Not stated	Convergent construct validity with a visual analog scale (VAS) of patient's estimation of overall problem $r = 0.70$. Convergent validity with VAS of patient's estimation of overall pain $r = 0.73$. Convergent validity with VAS of patient's estimation of ability to function $r = 0.80$. Convergent validity with VAS of patient's estimation of ability to work $r = 0.76$.	Internal consistency: Cronbach's $\alpha = 0.94$ Test–retest reliability: ICC = 0.94	Responsiveness: Change in group of patients undergoing treatment; expected to improve SRM = 0.79. Change in those rating their problem as better SRM = 1.03.	Strengths: Quick to perform and quantifies patient's perceived severity of problems. Appears to be useful in demonstrating improvements or change in overall rating of problem. Weaknesses: Scoring does not give adequate treatment planning guidance because a higher score only indicates increased problems but not specifically what problem. Responsiveness is measured by SRM, which is a weak measure of sensitivity to change (Stratford & Riddle, 2005).

ICC, intraclass correlation (Shrout & Fleiss, 1979); SRM, standardized response mean (Stratford & Riddle, 2005).

Interpretation of Evaluation Findings and Treatment Planning

In analyzing sensory evaluation findings, compare the results with those expected based on the patient's diagnosis. If the results differ from what was expected, further testing might be recommended. Individual sensory distributions sometimes vary from the illustrations of typical sensory distributions included in this and other texts. Furthermore, although there are clear lines of demarcation on the illustrations, humans generally have some overlapping areas of innervation along the borders of sensory receptive areas (Ropper & Samuels, 2009).

Consider whether the actual and expected results are different enough to suggest that there might be neural issues other than the diagnosis. If a peripheral nerve is compressed at one site, it is more sensitive to compression at other sites. Double and multiple neural compression sites can produce unexpected patterns of sensory impairment (Novak & Mackinnon, 2005).

Touch threshold testing with monofilaments can be interpreted based on categories of sensory loss as indicated in Table 9-4. With decreased light touch, patients often do not realize that they have a loss of sensation. There is no effect on the motor use of the hand, and patients can identify temperatures, textures, and objects by touch.

Table 9-4	**Semmes-Weinstein and Weinstein Enhanced Sensory Test Hand Monofilaments**						
Filament Number	**Diameter (mm)**	**Mean Force (g)**	**Color Code**	**Alternate Code**	**Interpretation**	**Hand Function and Use**	
2.83	0.127	0.076	Green	White	Normal	Normal	
3.61	0.178	0.209	Blue	Dotted	Diminished light touch	Stereognosis and perception of temperature and pain are good, close to normal use of hand	
4.31	0.305	2.35	Purple	Horizontal lines	Diminished protective sensation	Decreased recognition of objects and painful stimuli, difficulty in manipulating objects	
4.56	0.356	4.55	Red	Crisscrossed	Loss of protective sensation	Greatly impaired perception of pain, temperature, and object recognition; no manipulation of object without vision; marked decrease in spontaneous hand use	
6.65	1.143	235.61	Red-orange	Black	Loss of all sensation except deep pressure	Unable to identify objects and temperature; hand use only with visual guidance	
No response to 6.65	—	—	Red lines		Absence of all sensation	Unable to identify objects, temperature, and pain; minimal hand use	

Based on information in Bell-Krotoski and Tomancik (1987), Stoelting Company (2001), and Bell-Krotoski (2011).

Diminished protective sensation results in decreased motor coordination, as evidenced by slower manipulation and dropping objects from grasp, whereas identification of temperatures and painful stimuli are intact. Loss of protective sensation causes an inability to use the hand when it is not in view. Patients will feel pinpricks and deep pressure but will be less able or unable to determine temperatures. Those patients who cannot feel the thickest monofilament may or may not be able to feel a pinprick but have no other feeling and require visual guidance for all hand function (Bell-Krotoski, 2011).

In planning treatment, diminished or lost protective sensation or absence of sensation indicates that the patient is at risk for injury of the affected body part or parts. The patient must be taught to use vision and an adapted environment to compensate for lost sensation and avoid injury. Results that indicate impaired sensation need further investigation to determine the appropriate course of intervention. If there is hypersensitivity or hyperesthesia of the body part, a program of desensitization is indicated. If there is a decrease but not total loss of sensation within an area, the patient may be a candidate for sensory retraining, as long as the diagnostic prognosis indicates that there is a potential for improvement. Chapter 22 describes each of these interventions in detail.

Table 9-5	**Semmes-Weinstein Results for Subjects Older Than Age 60 Years: Median Monofilament Marking Number by Gender and Age**	
Age	**Women**	**Men**
60–69	3.22	3.61
70–79	3.61	3.61
80+	3.61	3.84

Based on information from Desrosiers, J., Hébert, R., Bravo, G., & Dutil, A. A. E. (1996). Hand sensibility of healthy older people. *Journal of the American Geriatrics Society, 44*, 974–978.

CHOOSING EVALUATION METHODS

Therapists use clinical reasoning to select appropriate sensory evaluation techniques for each patient. Diagnostic and procedural reasoning suggests that certain tests are best at answering certain kinds of clinical questions. Ethical reasoning suggests that the tests should be the best

available for each patient and that the practitioner has developed competence in test administration and interpretation. Pragmatic reasoning suggests that tests should be readily available and quickly administered (Schell, 2009).

Before choosing an evaluation method, decide why the test is necessary and what information is needed. Consider the diagnosis and the patient's description of the problem. For instance, for a patient with spinal cord injury, it is important to know whether sensation is intact, impaired, or absent in each sensory dermatome. A light touch awareness and pinprick test is common, with the results recorded on a schematic of the sensory dermatomes (Consortium for Spinal Cord Medicine, 2008).

If the purpose is to assist in the diagnosis of a nerve compression, such as carpal tunnel syndrome, it is necessary to use a highly sensitive test, such as a monofilament test. Sensation can be evaluated in positions that are likely to provoke more symptoms, for example with the wrist flexed (Szabo et al., 1999). A self-report of sensory loss has also been found useful in the diagnosis of carpal tunnel syndrome (Katz & Stirrat, 1990).

During observation of dressing or grooming by a patient with a diagnosis of stroke, a suspicion may arise that the observed errors are related to a loss of proprioception. An evaluation of proprioception can confirm or refute this hypothesis. For this same patient, it is important to know whether there is a risk of injury because of a loss of pain and temperature sensation (protective sensation). Either a pinprick and temperature test or monofilament test can provide this information. The monofilament test is more standardized and therefore a better choice, although it usually takes more time.

A test of stereognosis is most appropriate to predict, for example, whether a patient with a hand injury who is an auto mechanic can feel for and locate unseen automobile parts. The result of a two-point discrimination test or a monofilament test correlates with but does not totally predict the ability to identify objects with vision occluded, also known as stereognosis or haptic perception (Bell-Krotoski, 2011).

Optimal Assessment of Sensation

Ideally, patients are thoroughly assessed using standardized, reliable assessments that are easy to perform and that provide a complete understanding of sensation. A battery of tests is recommended if it is desirable to get a complete understanding of tactile sensation because no one test can assess this complex sense (Reese, 2011; Rosen, 1996). In clinical practice, however, therapists must sometimes balance the ideal with practical constraints. Schell (2009) described pragmatic constraints that affect sensory assessment in occupational therapy. These include the availability of equipment and supplies, time availability, team roles and responsibilities, reimbursement constraints, and the therapist's clinical competencies or preferences. Brand and Hollister (1999) charge that much time is wasted in sensory testing and that the results are open to question. Therapists should carefully assess their practices periodically to ensure that they are providing intervention that is as close to the ideal as possible despite pragmatic constraints. Great improvements can and should be made in tests of sensation so that they are meaningful, quantitative, and meet the criteria for good test instruments (Peripheral Neuropathy Association, 1993).

case example
Mr. T.: Sensory Problems Following Cumulative Trauma

	Clinical Reasoning Process	
Occupational Therapy Assessment Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Mr. T. is a 45-year-old man who presented to his primary care physician with progressive weakness, pain, and sensory changes in his arms. Mr. T. works full-time as a quality assurance inspector for a machine shop. He needs to travel to various locations to inspect equipment to ensure that it is functioning correctly. He also inspects final products before they can be distributed to clients.	Understand the patient's diagnosis or condition	"I suspect that the issues Mr. T. is experiencing in his arms, especially his hands, are stemming from repetitive compression of his peripheral nerves. He describes himself as healthy and active. His job inspecting equipment requires that he keep his elbows flexed and propped up on the equipment. This positioning, as well as repetitive movement, has probably compressed his nerves (medial antebrachial cutaneous, median, and ulnar)."

When not working, Mr. T. spends time with his teenage son, for whom he functions as a single parent. They spend lots of time working around the house on various projects, especially fixing and maintaining cars. Mr. T. is the primary caregiver to two cats and one dog. He is having the most difficulty with walking his dog because he sometimes drops the leash as a result of numbness and weakness in his hands.

Mr. T. is unable to recall a specific traumatic event that coincides with the changes in function but instead reports that he has been noticing changes for more than a year. He reports pain in his forearm when it is pronated for a long time. He reports numbness and tingling in his hand especially when sleeping and when using his arms overhead. Mr. T. says that opening and manipulating small objects has become more challenging. He sometimes loses his grip on things, especially if he is not looking at his hands. At the end of a long workday, Mr. T. reports that he needs to take a long rest break as well as pain medication to stop his elbows from hurting.

Know the person	"Mr. T. appears to be hardworking. His work demands both gross and fine motor control. In work and his leisure, he needs to rely on the sensory capacity and grip of his hands. I wonder how he has been dealing with the progressive changes to his function over the past year."
Appreciate the context	"I wonder how the progressive changes to his upper extremities has affected his performance at work as well as his activities with his son?"
Develop provisional hypotheses	"Given Mr. T.'s history, I would expect that I will find changes to his peripheral nerve function, specifically that of the median and ulnar nerves. Furthermore, I would expect to find decreased proprioception, light touch, pinprick, and possibly thermal and vibratory sensory dysfunction not only because of the troubles he reports but also based on my understanding of sensory deficits after prolonged compression of peripheral nerves."

Assessment Process

The occupational therapist selected the following sensory evaluation tools:

- Touch threshold test using Semmes-Weinstein monofilaments
- Static and moving two-point discrimination
- Touch localization
- Dellon's modification of the Moberg Pick-Up Test
- Pinprick Test
- Thermal threshold test
- Vibrometer threshold test
- The Quick DASH

Consider evaluation approach and methods	"This is a good time to do a thorough sensory assessment because it will determine objectively what has happened over the past year to his peripheral nerve function. The monofilaments will give reliable information about all areas of the hand and indicate whether protective sensation is present or reduced. We need to determine whether perception of moving touch is involved, so we will also use static and moving two-point discrimination. The touch localization test will show how the brain is interpreting tactile sensations and how accurate the interpretation is. The pick-up test relates sensation to functional hand use. The pinprick test will show interpretation and accuracy of pain responses. The thermal threshold test will determine concerns about thermal discrimination. The vibrometer will help determine involvement as well as potential severity of the median nerve damage (Konchalard, Suputtitada, & Sastravaha, 2011). The Quick DASH is useful in determining Mr. T.'s subjective rating of his sensory and functional changes. These tests will provide good information for what is going on with Mr. T. and for treatment planning. The results will provide a baseline to demonstrate sensory recovery over time."

Assessment Results

The results of the Semmes-Weinstein monofilament test for bilateral forearms, palms, and fingers are shown in Figure 9-9. Mr. T. was not able to feel the Disk-Criminator anywhere on the fingertips in the moving test nor on the fingers or thumb in the static test. Touch localization in the lateral portion of bilateral forearms was 15–18 mm (normal). For the medial portion of the left forearm, touch localization measured 18–20 mm, and it measured 25–30 mm on the right forearm. The radial portion of the right palm measured 18–25 mm; that of the left palm measured 12–16 mm. Touch localization in the ulnar portion of the right palm measured 15–20 mm; that of the left palm measured 11–15 mm.

Interpret observations	"Sensation is severely compromised in the right, dominant hand as well as the medial forearm, consistent with involvement of the ulnar and medial nerves. The left side is also affected but not as severely as the right. Loss of protective sensation indicates potential for harm, especially when Mr. T. is working on cars with his son or completing his work. The incoordination found with the Moberg Pick-Up Test could be the result of motor and/or sensory deficits. Because of lack of sensation in the fingertips, object identification as well as protective responses are not possible now. I hope that we can intervene and help with return of both sensation and function. It is no wonder that Mr. T. is having difficulty with both his work and leisure pursuits."

Figure 9-9 Results of initial monofilament testing for Mr. T. (see Case Example). (Reprinted with permission from North Coast Medical, Inc. [2011]. *Touch test sensory evaluator's hand screening form*. Gilroy, CA: North Coast Medical, Inc.)

Mr. T.'s scores on Dellon's modification of the Pick-Up Test were as follows:
Part 1: Left/Right
    Trial 1: 30 seconds/70 seconds
    Trial 2: 35 seconds/75 seconds
Part 2 No objects could be identified without vision.

Both the pinprick and thermal threshold tests showed moderate to severe impairment for the right medial forearm and hand, especially at the digits, and mild impairments for the left forearm and hand and moderate impairments at the digits. The vibrometer threshold was elevated bilaterally consistent with neuropathy. The score for the first 11 questions of the Quick DASH was 63.54, and the score was 75 for the questions pertaining to work-related problems. These results indicate moderate to severe issues with perceived function.

Occupational Therapy Problem List	Synthesize results	"Mr. T. is probably at some risk for injury to the fingertips, because he lacks any protective sensation in the digit tips, a likely place for thermal injuries or lacerations. The presence of some protective sensation in the palm and the mislocalization of touch stimuli suggests that retraining of sensation in this area may be effective. He might have a tendency to avoid using his right hand because of his decreased coordination. I'll need to provide functional activities to encourage bilateral functional use. Perhaps some work simulation or leisure activities will be motivating for Mr. T. I'll need to set up a plan for reducing further job-related cumulative trauma to prevent further compression of the median and ulnar nerves."

Occupational Therapy Problem List

1. Absent and decreased protective sensation in the first through fifth digits and entire palm on the right hand.
2. Mislocalization of touch sensations in the entire palm, right worse than left. Mislocalization of touch on medial forearms bilaterally.
3. Decreased ability to pick up and manipulate objects; unable to pick up objects without vision.
4. Decreased use of the right hand in functional activities, which is affecting job performance.

Clinical Reasoning in Occupational Therapy Practice

Interpretation and Treatment Planning for Peripheral Sensory Problem

Mr. T.'s touch threshold test is shown in Figure 9-9. After you provide intervention, how will the mapping likely change when Mr. T. is reassessed after 6 more weeks? What kind of sensation, pain or touch, will he be able to feel first in his fingertips? Compare his current functional hand use with his expected hand use when his fingertips regain touch sensation. What would you anticipate he will still have difficulties with as a quality assurance inspector, father, and pet owner? After 2 months of treatment, Mr. T. is still experiencing moderate issues with both nerves and is a candidate for surgery to both the median and ulnar nerves. What would you expect to change and, when cleared by neurosurgery, what assessments would you select and why?

Summary Review Questions

1. What pattern of sensory loss would be expected in a patient with a T10 spinal cord injury? In addition to performance and findings of the ASIA Impairment Scale, the gold standard in neurological classification after spinal cord injury, which tests light touch and pinprick/pain of key sensory points, what additional quantitative sensory tests could be performed and why?

2. What pattern of sensory loss would be expected in a patient with peripheral polyneuropathy?

3. Which patient will have a better prognosis for recovery of sensation: one with a peripheral nerve compression or one with a middle cerebral artery stroke?

4. Name and describe the purposes of at least three standardized and three nonstandardized sensory tests.

5. Describe or demonstrate the administration and scoring of a touch threshold test, a pain awareness test, and a touch localization test.

6. Which sensory test or tests would you select for a patient with peripheral polyneuropathy? Justify your response.

Glossary

Aesthesiometer—Instrument designed for sensory testing. The term usually indicates a tool consisting of a ruler type of scale and two prongs that can be moved progressively closer or farther apart that is used for assessing two-point discrimination (Figs. 9-6 and 9-8). Monofilaments are occasionally called pressure aesthesiometers in the literature.

Allodynia—A condition of pain caused by a stimulus that does not normally provoke pain (Gilron et al., 2011).

Haptic Perception—The process of recognizing objects through active touch. It involves a combination of somatosensory and proprioceptive input.

Hyperalgesia—An increased response to stimulus that is normally painful (Gilron et al., 2011).

Hyperpathia—An abnormally painful reaction to a stimulus, especially a repetitive stimulus, as well as an increased threshold (Gilron et al., 2011).

Hypersensitivity—Increased sensitivity to stimulation (Gilron et al., 2011).

Kinesthesia—The ability to identify active and passive movement of a body part (Ropper & Samuels, 2009).

Monofilament—Thin nylon strand resembling fishing line, of graded thicknesses, attached to a handle and used in testing the threshold of light touch sensation.

Paresthesia—An abnormal sensation such as a feeling of pins and needles, tingling, or tickling in the absence of tactile stimulation or in response to tactile stimuli that ordinarily do not evoke tingling or tickling.

Proprioception—Awareness of body position in space (AOTA, 2008, p. 635).

Stereognosis—The tactile identification of common objects. It involves the recognition of physical characteristics such as texture (Carr & Shepherd, 2010). Astereognosis is the term used to describe the absence of this ability.

Vibrometer—Instrument designed to test the threshold of vibration sensation. It consists of a vibrating head that is applied to the patient's skin and a control unit that allows for gradual changes in the amplitude and frequency of vibration.

Zone of partial preservation—In spinal cord injury, a region where there may be only partial damage to spinal nerves, including one to three spinal segments below the level of injury. Only calculated for people with complete spinal cord injuries (i.e., no sacral sparing or motor movement below the level of injury).

Assessing Environment: Home, Community, and Workplace Access and Safety

Patricia Rigby and Oana Craciunoiu

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the roles and responsibilities of the occupational therapist in the evaluation of environmental access.
2. Identify factors that act as environmental or contextual enablers or barriers/hindrances to occupational performance.
3. Identify environmental features that influence the safety of the client and the occupational therapist.
3. Apply critical appraisal when selecting assessment instruments appropriate for use in evaluating access to home, community, and workplace.
4. Explain how legislation and building standards influence the degree of environmental access that is available for people with disabilities.

The environment influences human behavior and provides the context within which all occupational roles are performed. The environment is viewed broadly in prominent frameworks and models that guide occupational therapy practice (e.g., American Occupational Therapy Association [AOTA], 2008; Kielhofner, 2008; Law et al., 1996; Townsend & Polatajko, 2007; Trombly Latham, 2005). Most authors agree that the environment has physical, social, cultural, institutional, and temporal dimensions that can influence the performance and engagement in occupations at a personal, community, and societal level. Central to these models of practice are the notions that (1) environmental barriers or hindrances to occupational performance for people with disabilities can be modified or eliminated more easily than most other negative influences, and (2) environmental supports or enablers promote optimal engagement in occupations.

What makes occupational therapy assessment unique, compared with other disciplines, is the analysis of the person-environment-occupation (PEO) relationship and the level of congruency in this relationship or PEO fit as it affects occupational performance (Law et al., 1996). The better the PEO fit, the more optimal the occupational performance. Occupational therapists are frequently called upon to determine the degree of congruence between people with disabilities, their chosen occupations and roles, and the various environments in which they live, work, and play. Thus, assessment of the performance context is a critically important step in the occupational therapy assessment process. According to the Occupational Functioning Model, the therapist assesses whether the environment enables or hinders occupational functioning (Trombly Latham, 2005). These assessment findings can guide the therapist to develop strategies to eliminate or ameliorate barriers and to use resources and supports to improve occupational functioning. To assess the environment and the PEO relationship, the therapist should:

- identify and evaluate environmental hindrances or barriers that may challenge the competency and ability of individuals to carry out their chosen occupations and roles;
- identify and evaluate environmental resources that will support occupational performance and occupational functioning.

This chapter focuses on the assessment of the environment for occupational performance. Specifically, it will consider the environment that is external to the client when assessing occupational functioning: the physical, social, and institutional attributes of the environment. The assessment measures selected are those that the authors consider the best available and that reflect the transactive nature of the PEO relationship among people, their chosen occupations, and the occupational environment.

EVALUATION OF THE ENVIRONMENT

The environment provides the context for occupational functioning. Consequently, an assessment of its attributes should also include information about those who will use the environment and the functions they will carry out there. In the practice of occupational therapy, it is important to begin this process with the person.

Client-Centered Approach

The client is central to all occupational therapy services, and much has been written about the need to engage and involve clients in all stages of the occupational therapy process (Townsend & Polatajko, 2007). The client–therapist interaction begins with an interview and assessment so that the therapist can gain an understanding of the client's occupational profile (AOTA, 2008). This involves determining what roles and occupations the client previously had and what the client currently wants or is expected to be able to do. Collaborative goal setting is an important stage in establishing client-centered occupational therapy (AOTA, 2008; Townsend & Polatajko, 2007).

Once the occupational profile is established, the occupational therapist then completes an analysis of occupational performance to better understand the client's performance skills, patterns, and challenges, considering the contexts within which activities and roles will be carried out. This is also when environmental assessment is undertaken. For example, a therapist and client could focus on community mobility and access because it is important to the client to continue participating in a volunteer role at the local public library. The therapist would consider the client's abilities by assessing his or her mobility using a wheelchair in the hospital setting, assessing the client's ability to access community transportation systems, and assessing the library's accessibility to ensure that the client could negotiate the entrances, work areas, and public washrooms.

Roles

The roles carried out by clients address purposeful activities related to self-maintenance, self-enhancement, and self-advancement (Trombly Latham, 2005). Each individual ascribes different meaning to his or her roles.

Environmental Barriers and Enablers

The occupational therapist must be able to identify the key environmental barriers and enablers that influence the fulfillment of valued roles and occupational functioning of clients. In clinical practice, barriers and enablers are broadly defined. However, this chapter discusses barriers and enablers in the external environment; the personal, social, cultural context, and payer reimbursement are described in Chapter 3.

The International Classification of Functioning, Disability and Health (ICF) classifies environmental factors as the natural and human-made environments; assistive products and technology; supports and relationships; attitudes; and services, systems, and policies (World Health Organization, 2001). The therapist is encouraged to consider these factors during assessment. For example, physical barriers in the natural environment can prevent or impede a person with a disability from participating in daily activities, whereas human-made resources can improve accessibility. Consider the challenge that stairs or rocky paths impose on a person using a wheelchair. These barriers can be removed or reduced by adding enablers such as elevators or ramps to replace stairs and a ramped bridge across the rocks to allow access for a wheelchair.

Access that is discriminatory or inconvenient, such as forcing persons with physical disabilities to use freight elevators or ramped entrances at the back of buildings, is no longer considered a viable solution to eliminating access barriers (World Health Organization, 2011). Improved accessibility through the use of universal design (UD) and barrier-free design is preferred. These two terms are similar but not synonymous. UD refers to features of the built environment that enhance optimal function and convenience for everyone, regardless of ability. Barrier-free design refers to features of the built environment that remove physical barriers to allow full and equal accessibility for all persons with disabilities. UD can encompass barrier-free design, but the converse is not necessarily true. For this reason, it is preferable to promote the use of UD (see Resources 10-1).

Influences on Environmental Accessibility and Safety

Various societal and cultural attitudes influence the degree to which the physical environment is made accessible, inclusive, and safe for people with disabilities. Occupational therapy practice standards also reflect these global views. These influences manifest as national and state or provincial legislation, building standards, and professional practice requirements.

Legislation

Over the past two decades, great strides have been made around the world in enacting laws to protect the rights of persons with disabilities and to ensure their full and effective participation and inclusion in society. The United Nations Convention on the Rights of Persons with Disabilities was adopted in December 2006 and came into force in May 2008. The convention is a great achievement after decades of work by the United Nations to change attitudes and approaches to persons with disabilities. The convention adopts a broad categorization of persons with disabilities, and its purpose is to promote, protect, and ensure the full and equal enjoyment of all human rights and fundamental freedoms by all persons

Resources 10-1

Internet Resources for Assessing Home, Community, and Workplace Access

- Adaptive Environments: Institute for Human-centered Design (http://www.adaptenv.org) provides access to resources on universal design and on accessibility and the ADA (e.g., book titled, *Achieving Physical and Communication Accessibility*).
- Americans with Disabilities Act (ADA) (http://www.ada.gov/) provides information and technical assistance on the ADA and the ADA standards for accessible design.
- Canadian Mortgage and Housing Corporation (http://www.cmhc-schl.gc.ca/en/) provides many resources about housing accessibility for persons with disabilities, including funding options; very useful resources for therapists and clients.
- Centre for Universal Design (http://www.ncsu.edu/project/design-projects/udi/) includes overviews of the principles of universal design, publications and information on Fair Housing and home modifications.
- Fair Housing Accessibility FIRST (http://www.fairhousingfirst.org) provides information and resources to support implementation of the Fair Housing Act amendments, such as the Fair Housing Act Design Manual.
- International Code Council (www.iccsafe.org/safety/Pages/accessibility-1.aspx) provides resources on accessibility, safety, etc.
- Job Accommodation Network (JAN) (http://askjan.org/).
- U.S. Department of Labor Occupational Safety and Health Administration (http://www.osha.gov/index.html).
- U.S. Department of Transportation (http://www.dot.gov).
- National Highway Traffic Safety Administration (http://www.nhtsa.gov/).

with disabilities and to promote respect for their inherent dignity (United Nations, 2001).

In the United States, the Americans with Disabilities Act (ADA) (1990), and, in Canada, the Ontarians with Disabilities Act (2001) were both designed to enable the participation and inclusion of people with disabilities in society. Key to these laws is the obligation of society to provide reasonable accommodations to ensure that public services, facilities, transportation, employment, accommodations, and telecommunications are accessible. Reasonable accommodations ensure that no person with a disability is excluded from or denied services. Titles II and III of the ADA provide detailed steps to be taken by public and private sector services, programs, and facilities to comply with and implement the requirements of the ADA. They address the accommodations required and the availability of resources; modifications to policies, practices, and procedures; the removal of barriers; and alternative forms of services, such as

accessible transit services when mainline public facilities are unavailable. In addition, the ADA Amendments Act (2008) provides a revised definition of "disability" to more broadly encompass impairments that substantially limit participation in major life activity, such as work. The 2010 ADA Standards for Accessible Design outline how both public and private-sector services, programs, and facilities should comply with and implement accessibility requirements (see http://www.ada.gov/2010ADAstandards_index.htm). Titles II and III of the ADA have undergone revisions recently to provide greater clarity and guidance about requirements in the ADA amendments (see http://www.ada.gov/regs2010/ADAregs2010.htm), particularly with respect to their limited authority over private sector services. Changing the physical environment can be expensive and complicated to implement. Under the ADA, employers are expected to make "reasonable accommodations" for employees with disabilities, as long as these do not cause "undue hardship" to the employer. In Ontario, Canada, the Accessibility for Ontarians with Disabilities Act (2005) provides timelines and more specific requirements toward achieving full accessibility across the province by 2025.

These laws are expected, over time, to eliminate barriers and improve accessibility for people with disabilities. However, analysis of the impact of the ADA is mixed. Social policy analysis demonstrates changes in the attitudes and practices of Americans and shows that the ADA has improved the quality of life for persons with disabilities (Harrison, 2002). A large representative survey of small business owners shows that their businesses comply with the ADA by accommodating customers with disabilities and disabled employees who are already on the job (Moore, Moore, & Moore, 2007). They also report that the benefits have outweighed the costs. Hopefully the amendments to the ADA will continue to improve accessibility for persons with disabilities, because the view from persons with disabilities was not promising a decade ago. They reported that the ADA had not been very effective in improving accessibility (Hinton, 2003) (see Resources 10-1 for further information on the ADA).

Although the ADA and similar legislation in many jurisdictions does not mandate professional involvement in achievement of the criteria set forth, occupational therapists, skilled in occupational analysis, environmental assessment, and determining PEO fit are well suited to assist with meeting the requirements of the legislation. Because these laws are critical for improving accessibility, independence, and empowerment of persons with physical disabilities, occupational therapists must take action to become familiar with and use these laws.

Building Standards

In 2004, the U.S. Access Board released the updated ADA-ABA (Architectural Board Act) Accessibility Guidelines for new or altered buildings, which provide the accessibility requirements for public and private facilities (U.S. Access Board, 2004). The specifications in these guidelines are based on adult and child dimensions and anthropometrics and should be applied during the design and construction or alteration of buildings and facilities covered by titles II and III of the ADA. Specifications are provided for most aspects of the built environment, including space required for maneuvering wheelchairs in corridors and rooms (Figs. 10-1 and 10-2), washrooms, building entrances, and parking lots.

Other standards have been developed for specific environments such as the workplace. For example, the National Institute of Occupational Safety and Health (NIOSH; see http://www.cdc.gov/NIOSH/) publishes criteria directed at reducing the rate of workplace injuries. Occupational therapists who work in these environments must become familiar with the standards and guidelines relevant to their area of practice.

The Americans with Disabilities Act Checklist for Readily Achievable Barrier Removal (Adaptive Environments Center, 1995) was developed for owners and managers of public buildings and businesses to identify barriers in their facilities. Although this survey tool is based on the original ADA Accessibility Guidelines, it is still relevant and easy to use to identify accessibility barriers, along
Figure 10-1 Accessibility requirements indicate that a person maneuvering a wheelchair needs a clear space of a minimum of 30 × 48 inches (760 × 1220 mm) for either forward or parallel approach in a corridor or doorway. (Adapted from the U.S. Access Board. [2004]. ADA-ABA accessibility guidelines. Retrieved August 23, 2011 from http://www.access-board.gov/ada-aba/final.cfm.)
Figure 10-2 Accessibility requirements indicate that a person maneuvering a wheelchair needs a clear width of a minimum of 42 inches (1065 mm) at the approach to a turn, and 48 inches (1220 mm) at the turn. (Adapted from U.S. Access Board. [2004]. ADA-ABA accessibility guidelines. Retrieved August 23, 2011 from http://www.access-board.gov/ada-aba/final.cfm.)

with suggestions for "readily achievable" access solutions. For example, requirements for a ramped entrance to a building are shown in the checklist in Figure 10-3. The occupational therapist can assist businesses to use this tool and set priorities for achieving accessibility.

Professional Practice Requirements

The practice of occupational therapy is also guided by professional regulations. Standards of practice, core competencies, and functions expected of therapists are developed at the national and state or provincial levels and provide performance evaluation criteria. These guidelines are usually generic in nature, and apply to all therapists, regardless of the area, setting, or focus of practice (AOTA, 2009; Canadian Association of Occupational Therapists, 2007). Knowledge of, and ability to perform assessments of context or environment are considered to be core competencies and functions of practice for all occupational therapists (AOTA, 2010; Association of Canadian Occupational Therapy Regulatory Organizations, 2012).

ENVIRONMENT ASSESSMENT

Ideally, the occupational therapist should select instruments with standardization that assess PEO fit, in order to take into consideration the relationship between the

RAMPS

QUESTIONS	MEASUREMENT	YES	NO	POSSIBLE SOLUTIONS
Are the slopes of ramps no greater than 1:12? **Slope is given as ratio of the height to the length.** 1:12 means for every 12 inches along the base of the ramp, the height increases one inch. For a 1:12 maximum slope, **at least** one foot of ramp length is needed for each inch of height.	slope = _____			☐ Lengthen ramp to decrease slope. ☐ Relocate ramp. ☐ If available space is limited, reconfigure ramp to include switchbacks.
Do all ramps longer than 6 feet have railings on both sides?				☐ Add railings.
Are railings sturdy, and between 34 and 38 inches high?	height = _____			☐ Adjust height of railing if not between 34 and 38 inches. ☐ Secure handrails in fixtures.
Is the width between railings or curbs at least 36 inches?	width = _____			☐ Relocate the railings. ☐ Widen the ramp.
Are ramps non-slip?				☐ Add non-slip surface material.
Is there a 5-foot-long level standing at every 30-foot horizontal length of ramp, at the top and bottom of ramps and at switchbacks?	length = _____			☐ Remodel or relocate ramp.
Does the ramp rise no more than 30 inches between landings?	rise = _____			☐ Remodel or relocate ramp.

Figure 10-3 Requirements for an accessible approach ramp to a building. (Adapted from Adaptive Environments Center. [1995]. Americans with disabilities Act checklist for readily achievable barrier removal. Boston: Adaptive Environments Center. Retrieved August 23, 2011 from http://www.ada.gov/checkweb.htm.)

personal factors and the characteristics of the environment and the occupation. The PEO relationship is dynamic, complex, and interwoven and therefore more difficult to measure than interactions that can be understood by assessing discrete components. Because very few measures have been developed to assess this complex PEO relationship, we have included not only the measures in this chapter but also an array of useful tools that measure the person–environment relationship or specific characteristics of the environment.

In this chapter, the assessments have been categorized by setting: those suitable for assessing homes (Assessment Table 10-1), the community (Assessment Table 10-2), and the workplace (Assessment Table 10-3). Key information about each assessment, including an analysis of the tool's strengths and weaknesses, is included in the tables to assist occupational therapists to identify the most appropriate tool(s) for their purposes. The critique of each tool was guided by using the Outcomes Measures Rating Form and Guidelines (Law, 2004). Most tools included here have established measurement properties. We have, however, included some unique measures that have good content validity and clinical use but for which formal studies of measurement properties are unavailable or incomplete.

Assessment of Access to Home

A home assessment completed by an occupational therapist can be an important component of the occupational therapy process, particularly during the discharge planning process for clients going home from a hospital or rehabilitation setting. Assessment of occupational performance in the client's home is contextually relevant (Ngyard et al., 2004). In a study comparing assessment results among home, client, or proxy report and clinic-based performance assessment, Rogers et al. (2003) found that home-based performance assessment provides an accurate reflection of the clients' ability to manage in that setting, which cannot be replaced by self-report, caregiver proxy, or clinic-based performance assessments. During a home assessment, therapists can assess the degree of fit for the person, the completion of his or her daily roles, and the home environment. This individualized approach is critically important, because the factors influencing PEO fit will vary across health conditions and disabilities. For example, the nature of safety and accessibility issues in the home will be quite different for a person with Alzheimer's disease compared with a person with a spinal cord injury. Thus, therapists can identify barriers to participation and recommend modifications to the environment that ensure optimal independence and safety for each individual client.

Ensuring that clients' home environments are able to provide them with the supports they need is vitally important to enable them to continue living safely at home. Also critical is that therapists recognize that people have great attachment to their home. Both their belongings and the way their home looks are meaningful for them (Cristoforetti,

Gennai, & Rodeschini, 2011). Although the therapist may see specific features as barriers and hindrances to occupational performance and safety, the client may have a different view about the significance of those features. Thus, therapists should demonstrate sensitivity to their clients' perspectives about their homes during home assessments.

Several standardized home assessments are available for occupational therapists to use with clients and families to identify occupational performance problems in the home and environmental barriers and potential resources. Researchers have discussed the limited use of standardized home assessments by occupational therapists (Mitchell & Unsworth, 2004). In clinical practice, where service provision needs to be justified, the use of standardized home assessments can be important to ensure that a comprehensive assessment is completed both to meet the needs of the client and to justify requests for equipment and home modifications. A review of assessment tools to guide home adaptations (Rousseau et al., 2001) presented information on 16 assessments; however, only 6 of those tools included evidence for their measurement properties. Although some home assessments focus almost exclusively on the physical environment (e.g., accessibility and home hazards), a number are now available that take into consideration such factors as personal preferences for environmental resources, social supports provided by caregivers, and caregiver attitudes.

Home assessments typically involve the examination of PEO fit for a client within his or her home environment and recommendations related to home modifications and suggestions for environmental supports. The Housing Enabler (Slaug & Iwarsson, 2001) addresses environmental factors explicitly in relation to clients' needs and abilities. It includes separate components that first address the client's abilities and disabilities and then examines the home environment in relation to these factors. It is administered through an interview and observations of the physical environment. The Home Falls and Accidents Screening Tool (HOME FAST) (Mackenzie, Byles, & Higginbotham, 2000), the In-Home Occupational Performance Evaluation (I-HOPE) (Stark, Somerville, & Morris, 2010), the SAFER-HOME (Chiu & Oliver, 2006), and the Westmead Home Safety Assessment (Clemson, 1997) are also useful tools that require clinicians to integrate information about the client's abilities with observations about the environment. For example, when using the SAFER-HOME to determine the extent to which an item such as toileting is a problem, the therapist must consider the client's ability to safely transfer onto and use the toilet while simultaneously considering the availability of physical supports (such as grab bars) and social supports (family caregiver assistance), as well as how willing the client is to make use of the supports available (Fig. 10-4 is an example of the SAFER-HOME tool). The Home Safety

Assessment Table 10-1 — Access to Home Assessments

Assessment	Description	Time to Administer	Validity[a]	Reliability[b]	Sensitivity[c]	Strengths and Weaknesses
The Housing Enabler (Slaug & Iwarsson, 2001) Ordering and pricing information available from: http://www.enabler.nu/index.html	Questionnaire to assess the congruence or fit between an individual with a functional impairment and his or her home environment. Measures functional limitations (15 items) and physical environmental barriers (188 items). Available in several languages. Scoring level: Dichotomous ratings for steps 1 and 2; step 3 ordinal scale (4-point predetermined Likert scale). Summary scores are best calculated with the use of The Housing Enabler Software. Range of scores: Dependent on the number of functional limitations, use of mobility aids, and the number of environmental barriers.	Up to 2 hours, depending on functional limitations and physical environment. In particular, step 2 can be time consuming to administer because 188 environmental items are reviewed.	Content: Item selection based on literature review and expert opinion; adjusted after pilot studies. Convergent: Swedish accessible housing standards provide the gold standard against which the environmental assessments are measured. Construct: Established theoretical agreement for person–environment relationship and for construct of housing accessibility. References: Fange & Iwarsson, 2003; Iwarsson & Isacsson, 1998; Iwarsson, Isacsson, & Lanke, 1998.	Interrater: Studies report excellent results ranging from 81% to 100% agreement; pilot 2 (n = 440 occupational therapists, 26 cases) overall mean κ = 0.76 for person and 0.55 for environment; pilot 3 (n = 430 occupational therapists, 30 cases) mean κ = 0.82 for person, 0.68 for environment (188 items), and 0.87 for accessibility problems; interclass correlation coefficient (ICC) range = 0.92–0.98. A multinational study with raters with different professional backgrounds (n = 64) resulted in moderate to good overall interrater reliability; sample of 422 housing adaptation cases, mean κ = 0.62 (good interrater reliability). Test–retest: Strong; ICC = 0.92–0.98 References: Fange, Risser, & Iwarsson, 2007; Iwarsson & Isacsson, 1998; Iwarsson, Nygren & Slaug, 2005.	In two separate studies, person–environment fit scores captured significant differences between baseline and follow-up by means of the Sign and McNemar's tests, respectively (Fange & Iwarsson, 2003; Iwarsson, 2005).	Strengths: Meticulous development and testing. Up-to-date website. Widely used in Europe. Step 3 provides a predictive score of accessibility problems and measure of handicap. Useful for both clinical and research purposes. Weaknesses: Rater training more difficult to arrange outside Europe. Step 2 can be time consuming to administer.

Home Falls and Accidents Screening Tool (HOME FAST) (Mackenzie, Byles, & Higginbotham, 2000). The appendix of the article includes all items of the HOME FAST along with definitions.	Health care provider completed questionnaire; designed to identify risk of falls as a result of home hazards, may be used as an outcome measure to evaluate interventions for improving function in the home environment. Scoring level: Nominal (items are scored as a hazard, not a hazard, or not applicable). Range of scores: 0–25 (indicating the number of items for which hazards are identified).	20–30 minutes	Content: Based on the literature; field testing with 83 older adults; review of content and field testing data by an expert panel reduced number of items; content further examined in a cross-national validation (Australia, Canada, and United Kingdom) where occupational therapists, physiotherapists, and nurses responded to a survey regarding the content and weighting of items. Construct: Initial evidence suggests that the *HOME FAST* may be useful in identifying relative risk for falls associated with exposure to home hazards (99% confidence intervals). Predictive: Longitudinal study ($n = 727$, community dwelling veterans) suggests HOME FAST may predict falls in older adults Responsiveness: Initial data ($n = 727$) HOME FAST items can identify change in home hazards over time. References: Mackenzie, Byles, & D'Este, 2009; Mackenzie, Byles, & Higginbotham, 2000, 2002a.	Interrater: Evaluated ($n = 40$) using κ for individual items and weighted κ for the total number of hazards; overall weighted κ was 0.56 (considered fair to good agreement); κ values for individual items indicated that 4 items had excellent reliability, 20 items had fair to good reliability, and 1 item (hazardous outside paths) had poor reliability (Mackenzie, Byles, & Higginbotham, 2002b).	Sensitivity shown by comparison of expert ratings and second ratings of home hazards; 68.6% agreement (95% confidence interval [CI] 63-4–73-6) ($n =$ 844 sample ratings) (Mackenzie, Byles, & Higginbotham, 2002b.	Strengths: Can be quickly administered as a screening assessment. Research has been conducted in various countries. Initial psychometric research is positive. Initial evidence suggests the HOME FAST may potentially be useful as an outcome measure. Weakness: Further examination of the predictive validity, responsiveness, and test–retest reliability would strengthen our understanding of the measure.

Assessment Table 10-1 | Access to Home Assessments (*continued*)

Assessment	Description	Time to Administer	Validity[a]	Reliability[b]	Sensitivity[c]	Strengths and Weaknesses
Safety Assessment of Function and the Environment for Rehabilitation-Health Outcome Measurement (SAFER-HOME V3) (Chiu et al., 2006) VHA Rehab Solutions 477 Mount Pleasant Road, Suite 500, Toronto, Ontario M4S 2L9, Canada Phone: 416-489-753 E-mail: info@vha.ca Order form can be downloaded from http://www.vha.ca/ SaferHome OrderForm.pdf	SAFER-HOME based on SAFER tool: Designed to measure intervention effectiveness and changes in safety intervention over time (12 domains: living situation; mobility; environmental hazards; kitchen; household; eating; personal care; bathroom and toilet; medication, addiction, and abuse; leisure; communication and scheduling; and wandering). Scoring level: SAFER-HOME – Ordinal (4-point rating scale [0 – 3]: No problem, mild problem, moderate problem, severe problem) Range of scores: SAFER-HOME: 0–228.	45–90 minutes	Content: For both the SAFER and the SAFER-HOME content validity has been established through review by experts and clinicians as well as statistical analysis of completed measures. Construct: For SAFER, total scores have been associated with cognitive status and independent living in houses, but not directly to ADL or instrumental ADL. For SAFER HOME, total scores were compared to functional status scores; Cronbach's α coefficient = 0.26 (weak correlation) confirmed that the SAFER HOME is measuring more than functional abilities. References: Chui & Oliver, 2006; Letts et al., 1998.	SAFER - Interrater: κ or percentage of agreement: Acceptable to excellent for 92 items. Test–retest: κ or percentage of agreement: Acceptable to excellent for 90 items. References: Letts et al., 1998. SAFER-HOME - Internal consistency: Cronbach's α for total scores = 0.8593; subscales ranged from 0.539 to 0.789 References: Chui & Oliver, 2006.	No formal studies have directly examined sensitivity to detect change; preliminary investigations show promising results; occupational therapists (n = 95) administered the SAFER-HOME V1 twice; 76% indicated the assessment measured changes in the client (Chui & Oliver, 2006).	Strengths: Comprehensive coverage of home safety. Both tools developed and tested rigorously. Comprehensive training manual provided. Weaknesses: Length of administration may be problematic in some clinical situations. Further research on responsiveness to change needed.

Instrument	Description	Time	Validity[a]	Reliability[b]	Sensitivity to Change[c]	Strengths and Weaknesses
Westmead Home Safety Assessment Co-ordinates Publications, a division of Co-ordinates Therapy Services Pty. Ltd., P.O. Box 59, West Brunswick, Victoria 3055, Australia Phone: 6139-380-1127 Fax: 6139-387-4829 http://www.therapybookshop.com/coordinates.html	Assessment to identify fall hazards in the home environments of older adults. Scoring level: Nominal (dichotomized relevant or not; each relevant item is rated as a hazard or not; hazards are presented by type).	One home visit	Content: Established through content analysis of the literature and a rigorous expert review process (Clemson, Fitzgerald, & Heard, 1999). Criterion: Not established (as no gold standard exists).	Interrater: Tested in a sample of 21 clients' homes; κ values of >0.75 for 34 items and between 0.4 and 0.75 for 31 items; κ could not be calculated for some items (Clemson et al., 1999).	Not established	Strengths: Comprehensive and systematic assessment of home hazards specific to falls in older adults. Manual is helpful and provides operational definitions for key hazards. Weaknesses: Does not address home hazards besides falls; further psychometric testing required.
The Safe Living Guide: A Home Hazard Checklist for Seniors (Public Health Agency of Canada, 2007; http://www.phac-aspc.gc.ca/seniors-aines/alt-formats/pdf/publications/public/injury-blessure/safelive-securite/safelive-securite-eng.pdf)	Self-completed questionnaire; designed to identify potentially hazardous areas in the home. Scoring level: Dichotomous (yes/no checklist).	20–30 minutes	Content: Items identified using literature review, consultation with seniors, seniors' agencies, and professionals. References: Clark, Shaw, & Kahn, 2002; Sorcinelli et al., 2007.	Interrater: Average κ between expert raters ($n = 76$) = 0.73 (substantial agreement); average κ between expert raters and seniors ($n = 76$) = 0.51 (moderate agreement) References: Sorcinelli et al., 2007.	Not established	Strengths: Captures the client's perspective on hazardous areas. Manual is comprehensive; provides operational definitions for key terms. Weakness: Limited evidence of measurement properties.

n, number; κ, kappa; α, alpha

[a]Validity is the ability of an instrument to measure what it is intended and presumed to measure. Criterion validity is determined by comparing its results to an agreed-on *gold standard* (accepted test). Predictive validity is its ability to predict future outcomes.

[b]Reliability is a measure of an instrument's stability. Interobserver or interrater reliability refers to the ability of two different individuals to administer the instrument to a particular person and achieve similar results. Test–retest reliability refers to the constancy of results over repeated use of the instrument in the absence of change in the patient.

[c]Sensitivity to change is the ability of an instrument to detect clinically important changes.

Assessment Table 10-2 | Access to Community Assessments

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Craig Hospital Inventory of Environmental Factors (CHIEF and CHIEF Short Form) http://tbims.org/combi/chief/ http://www.tbims.org/combi/chief/CHIEF.pdf	Assessment of the frequency and magnitude of environmental characteristics that act to impede accomplishment of daily activities and social roles. Five categories: attitude and support, services and assistance, physical and structural, policy, and work and school. Self-administered or administered by interview. Full CHIEF: 25 items. Short form: 12 items.	Self-administered: 10 minutes; short form, 5 minutes. Interviewer administered: 15 minutes; short form, 10 minutes	Content: Established by literature review and consultation with experts. Four advisory panels involved. Construct: Shows differences in reported frequency and magnitude of environmental barriers between groups with different impairments and activity limitations (e.g., Whiteneck, Gerhart & Cusick, 2004; Whiteneck et al., 2004). Discriminitive: Established with persons with polio (Lund & Lexell, 2009)	Internal consistency: Moderate to high ratings for total score (0.93) and subscales (ranging from 0.76 to 0.81). Authors recommend that proxies should not be used to complete CHIEF. Test–retest: Showed an overall inter-class correlation (ICC) of 0.92 for total score, and ICCs for individual items ranged from 0.33– to 0.88 (Whiteneck et al., 2004).	The authors recommend that multiple measurements using CHIEF be taken over the course of a person's lifetime to assess changes with adaptation to the disability and to gain insight into changes in environmental barriers that may occur over time. Sensitivity to change shown in scores for sample of persons living with AIDS (Nichols et al., 2009)	Strengths: Based on ICF. Comprehensive inventory of environmental factors. Quick and easy to administer and score. Appropriate for both population-based or individual-focused assessment and research. Weaknesses: Further evaluation of measurement properties needed. Scale for assessing magnitude of barriers has only two points (little vs. big problem).

Instrument	Description	Time	Validity	Reliability		Clinical Utility
Facilitators and Barriers Survey/ Mobility (FABS/M) (Gray et al., 2008)	A self-report survey of environmental facilitators and barriers to participation by people with mobility impairments (e.g., stroke, cerebral palsy, polio, and spinal cord injury). 133 items in six domains: personal mobility device, home built features, community built and natural features, community destinations access, community facilities access, and attitudes.	40–60 minutes	Content: Established through interviews and 15 focus groups; 5 with persons with various mobility impairments (5 diagnostic groups), 5 with significant others from the first 5 groups, and 5 with health professions serving various diagnostic groups. The qualitative data formed the content for the FABS/M. Discriminative: Able to distinguish differences between different diagnostic and device user groups (Gray et al., 2008).	Internal Consistency: (n = 604 people with mobility impairments from five diagnostic groups; a range of mobility devices used) ranged from low to high internal consistency across the domains (moderate to high for community destinations and facilities). Test–retest: With same sample; showed moderate to high reliability across the domains (Gray et al., 2008).	Not established	Strengths: Designed specifically for people with lower limb impairments and mobility impairments. Used at the individual level to develop community participation interventions. Can be used as an outcome measure of the effectiveness of those interventions. Scores can be aggregated across diagnostic groups and/or mobility device groups for broader view of environmental factors influencing participation. Weaknesses: Only applicable to targeted diagnostic groups. Further measurement studies needed.

Assessment Table 10-2 | Access to Community Assessments (*continued*)

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Measure of Quality of the Environment (MQE) Version 2 Long version: 84 items Short version: 26 items (Fougeyrollas et al., 2008); RIPPH/INDCP 525, boul. Wilfrid-Hamel Est, A-08 Québec (Québec) Canada G1M 2S8 (http://www.ripph.qc.ca/?rub2=4&rub=18&lang=en).	Measures environmental facilitators and obstacles to social participation and accomplishment of daily activities (7-point scale from major facilitator to major obstacle). Six categories: Support and attitudes of family, job and income security, government and public services, physical environment and accessibility, technology, and equal opportunity and political orientations. Interview format.	Long version, less than 30 minutes Short version, less than 10 minutes	Content: Based conceptually on the Disability Creation Process model and input from individuals with spinal cord injury and clinicians (Fougeyrollas, Noreau, & Boschen, 2002). Construct: Has been demonstrated (Noreau, Fougeyrollas & Boschen, 2002).	Internal consistency: Moderate concordance scores across items. Test–retest: Good (Boschen, Noreau & Fougeyrollas, 1998).	Not established	Strengths: Applicable for people with and without disabilities. It covers a broad scope of environmental factors. Manual with questionnaire and score sheets available. Tool is easy to administer. Used at the individual level; can be applied at population level. Some evidence of validity and reliability. Weakness: Further examination of measurement properties is recommended.
The Multidimensional Scale of Perceived Social Support (MSPSS) (Zimet et al., 1988)	Assessment of perceptions of social support from three sources: family, friends, and significant other. Inventory/list of 12 statements of relationships; each item rated on 7-point Likert scale.	2–5 minutes	Content: Established through factor analysis. Construct: Established through multiple studies with numerous health constructs, psychopathology, suicidal behavior, anxiety, and depression. Marginalized groups demonstrate lower perceived social support.	Internal consistency: Good with Cronbach's α's ranging from 0.81 to 0.91 in multiple studies. Test–retest: in study with undergraduate psychology students, good for total score (0.85) and subscales (0.72, 0.85, and 0.75) (Zimet et al., 1988). Good reliability shown in study with older adults (Stanley, Beck, & Zebb, 1998).	Not established	Strengths: Simple to use and score in a short time. Has been used primarily with mental health populations; appears to have use for populations with physical disability. Weaknesses: Need to be wary of socially desirable responses. Requires evaluation of sensitivity to change and use as an outcome measure.

Assessment Table 10-3 Access to Workplace Assessments

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Checklist of Health Promotion Environments at Worksites (CHEW) (Oldenburg et al., 2002); contact Sallis, J. Department of Psychology, San Diego State University. 6363 Alvarado Court, #103 San Diego, CA 92120 USA. (http://www .drjamessallis.sdsu .edu/measures.html)	An observational measure of environments (in and around work sites); designed to assess environmental influences on health behaviors and evaluate health promotion programs. Scoring level: Separate scores computed for each content areas (physical, information, neighborhood, and surroundings); summary scores are computed for physical and information domains.	20–50 minutes; administration time can vary according to size of work site	Construct: Items selected based on multiple revisions from focus group consultation and pilot testing at 20 work sites (Oldenburg et al., 2002).	Interrater: ICC = 0.80–1.00 (n = 2, tested at 12 work sites) (Oldenburg et al., 2002).	Not established	Strengths: Can be used to assess changes over time in health-promoting environment characteristics. Manual with procedures and scoring key provided at no cost. Weaknesses: Further testing of measurement properties would strengthen our understanding of the measure.
Environmental Assessment Tool (EAT) (DeJoy et al., 2008) Department of Health Promotion & Behavior, College of Public Health, University of Georgia, Athens, GA 30602-6522 dmdejoy@uga.edu The appendix of the article (articleplus version) includes a copy of the measure.	Observation-based assessment; designed to measure work site physical, social, and institutional environment supports that may influence healthy behaviors and capture change across time. Scoring level: dichotomous (yes/no responses). Scores: Range from 0 to 100 points (divided among three subscales); scores weighted within each subscale.	Variable with work site	Content: Items selected based on literature review, contextual analysis of work environments, pilot testing, multiple revisions; weighted scoring values decided by field experts. Concurrent: Agreement with the Leading by Example questionnaire Predictive: Captured changes in workplace environments over time (n = 12). References: Baker Parker et al, 2010; DeJoy et al, 2008.	Inter-rater: Agreement ranged from 83% to 100% across 2 raters for 12 work sites (κ scores for individual items ranged from 0.56–1.00) (DeJoy et al., 2008).	Changes in EAT scores shown over time and across work sites (n = 12) for one of three subscales (Baker Parker et al., 2010)	Strengths: A more inclusive measure (incorporates the social/administrative environments). Initial evidence supports its use as a quantitative measure to track changes over time. Weakness: A more extensive manual and testing measurement properties would strengthen our understanding of the measure.

Assessment Table 10-3 | Access to Workplace Assessments (*continued*)

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Work Environment Scale (WES) Version 4 (Moos & Insel, 2008) Mind Garden, 855 Oak Grove Avenue, Suite 215, Menlo Park, CA 94025 U.S.A. Phone: 650-322-6300 Fax: 650-322-6398 Available from: http://www.mindgarden.com/products/wes.htm#ms	Measures the social environment of all types of work settings. It comprises 10 subscales or dimensions, which are divided into three sets: the relationship dimensions, the personal growth or goal orientation dimensions, and the system maintenance and system change dimensions.	15–20 minutes per form 5–10 minutes to score	Face: Established in manual; tools based on social climate scales. Multiple studies demonstrate construct validity. References: Moos & Insel, 2008; Staten et al., 2003	Test–retest: At 1 month, Cronbach's α coefficients = 0.69–0.83; at 12 months, test–retest coefficients = 0.51–0.63; intraclass coefficients >0.70. Internal consistency: Pearson $r > 0.60$. Reference: Moos, 1994.	Not established	Strengths: Standardized; established measurement properties; readily available, portable. Promotes discussion and identifies clients' views. Useful on an individual basis, groups, or with organizations. Weaknesses: Scores alone should not provide direction for intervention. Need further study with populations with physical disability.
Work Experience Survey (Roessler & Gottcent 1994; Roessler, 1996) Available from the National Clearinghouse of Rehabilitation Training Materials http://library.ncrtm.org/pdf/193.054A.pdf	Interview used to identify job accommodation needs (work site accessibility, performance of essential functions, job mastery and job satisfaction).	30–60 minutes	Face: Based on relevant tools and sources of information (Roessler & Gottcent, 1994) Has been used across groups of clients with a range of diagnoses (i.e., MS, blindness, diabetes, arthritis) and frequently cited as a valid tool, although specific psychometric data could not be located.	Cronbach's α values for assessing job mastery and assessing job satisfaction reported as 0.74 and 0.78, respectively, in one study (Roessler, 1996).	Not established	Strengths: Facilitates identification of barriers and reasonable accommodations. Assists in empowering clients to address work barriers with employers. Has been used with individuals with a variety of disabilities. Weaknesses: Need to look at use of WES in follow-up interviews. Additional measurement data required.

Workplace Environment Impact Scale (WEIS) V. 2.0 (Moore–Corner, Kielhofner, & Olson, 1998). Model of Human Occupation Clearinghouse, University of Illinois at Chicago www.moho.uic.edu/ Order form available from: http://www .moho.uic.edu/assess/ weis.html	Semistructured interview; addresses individuals' experiences and perceptions of their work environments. Designed for use with individuals with physical or psychosocial disabilities; for use with individuals who are employed or are planning to return to work after an interruption in employment (caused by injury/illness). Scoring level: 4-point ordinal scales (17 items).	30–45 minutes to conduct interview (depending on interviewer's abilities and the client) 15 minutes to complete scoring	Construct: Established (based on Rasch analysis in which infit MnSq = 1.6 and Zstd = 3.0). Found to measure a single construct (none of seventeen items fit criteria for misfit) Found to be valid across two distinct cultures. References: Corner, Kielhofner, & Lin, 1997; Kielhofner et al., 1998.	Rasch analysis: Item separation statistic was 2.77 (reliability of 0.88); items were consistently separated into distinct (nonoverlapping) groups. Found to lack ability to discriminate groups in another study, although population was found to be homogeneous. References: Corner, Kielhofner, & Lin, 1997; Kielhofner et al., 1998.	Kielhofner et al. (1998) report that this scale can separate and group subjects into many levels of psychosocial ability to return to work. Strengths: Items work well to measure the construct of work environment impact. The scale is suitably matched to the clients and effectively discriminates different levels of work environment. Both Swedish and English language versions of the WEIS are equal and free of cultural bias. Manual includes suggested questions. Weaknesses: Need to be very familiar with interview and scale to ensure appropriate use.

Assessment Table 10-3 | *Access to Workplace Assessments (continued)*

Assessment	Description	Time to Administer	Validity	Reliability	Sensitivity	Strengths and Weaknesses
Worker Role Interview V. 10.0 (WRI) (Braveman et al., 2005) Order form available from: http://www .uic.edu/depts/moho/ assess/wri.html Model of Human Occupation Clearinghouse, University of Illinois, Chicago, Department of Occupational Therapy Phone: 800-377-8555	Semistructured interview; designed to identify potential barriers that will interfere with return to work. Scoring level: 4-point ordinal scale (17 content areas).	40–60 minutes	Content: Item selection based on literature review, expert clinical input, extensive pilot testing from multiple studies and multiple revisions. Construct: in agreement with the Model of Human Occupation's conceptualization of behavior; Rasch analysis ($n = 119$) results separate participants into different levels of ability. Predictive: ($n = 53$; 24-month period), overall correct prediction = 81%–96% Internal: Thirteen of 17 content areas demonstrate acceptable fit in Rasch measurement model ($n = 440$) References: Ekbladh, Thorell, & Haglund, 2010; Forsyth et al., 2006; Velozo et al., 1999.	Interrater: ICC = 0.46–0.92 ($n = 30$). Test–retest: High reliability (ICC = 0.86–0.94; $n = 20$) Reference: Biernacki, 1993.	Scale items significantly separated the potential of clients ($n = 146$) of differing psychosocial ability to return to work into three distinct levels; however, a "ceiling effect" was observed (21% of measured ability) (Fenger & Kramer, 2007).	Strengths: Comprehensive manual and training videotape with case example available. Reliability and validity testing across multiple populations and cultures. Translated into multiple languages. Weakness: Further testing of measurement properties within populations with chronic disability needed.

MnSq, mean square, a measure of "item fit" in a Rasch Model; Zstd, standardized z value, another "item fit" statistic in a Rasch Model.

SAFER HOME
Safety Assessment of Function &
the Environment for Rehabilitation
Health Outcome Measurement and Evaluation
© COTA Comprehensive Rehabilitation and Mental Health Services

Client Name: Mrs. P.

Date of Assessment: Nov. 3, 2011

Type of housing: **x** Apartment
__ House
__ Other

No identified problem	Following observation, interview and/or task performance, no safety concern was identified at time of assessment, including not applicable items.
Mild problem	When an identified safety concern has never been a problem and is unlikely to be so in the future. (1% - 33% chance of negative consequences)
Moderate problem	A safety problem that needs to be addressed but is not likely to cause immediate danger to the client and/or the environment. (34% - 66% chance of negative consequences)
Severe problem	When a safety problem requires urgent attention or when it could put the client, others or their environment in immediate danger. (67% - 100% chance of negative consequences)

		No	Mild	Moderate	Severe	COMMENTS
LIVING SITUATION (3)						
1	Security & screen /admit visitors		x			Unable to answer door when husband away
2	Living conditions/occupants	a				Lives with husband.
3	Availability/quality of support	a				Daughter lives nearby – very supportive.
	Total	2	1			
MOBILITY (10)

Figure 10-4 *(Continued)*

Self Assessment Tool (HSSAT) Version 3 is a promising new assessment designed to identify home hazards and reduce the occurrence of falls and is available from the authors' website (Tomita et al., 2011). Evaluation of the measurement properties of this tool is currently underway. The I-HOPE is also a promising new performance-based assessment of activities that a client finds challenging to perform at home and includes ratings of environmental barriers that influence performance (Stark, Somerville, & Morris, 2010).

Ideally, all of these assessments should be conducted in the client's home. However, in clinical settings where it is not possible to visit the home, the occupational therapist may choose to conduct an interview using the items of the SAFER-HOME with the client and/or a family member or friend selected by the client who knows the client's home well. However, the interview cannot definitively determine whether or not a client can manage safely at home or what modifications may be needed. Rather, it can be used to highlight issues that clients and/or caregivers need to consider in the home. Other very good options include self-assessment guides to home adaptation, which can be used in collaboration with a client (e.g., *Maintaining Seniors' Independence: A Guide to Home Adaptations* [Canadian Mortgage and Housing Corporation, 1989/2008a], *Maintaining Seniors' Independence through Home Adaptation: A Self-assessment Guide* [Canadian Mortgage and Housing Corporation, 2008b], and *A Consumer's Guide to Home Adaptation* [Adaptive Environments Center, 2002]). These tools provide practical suggestions for home adaptations in relation to functional problems, such as difficulty entering the shower stall/bathtub, as shown in Figure 10-5. The therapist helps the client to select solutions that best fit his or her situation (see overview of home assessments in Assessment Table 10-1). Figure 10-6 shows an example of the Functional Independence Measure (FIM™), which can help assess a client's abilities.

Home Safety and Fall Prevention

A home assessment, such as those described above, can also provide occupational therapists and their clients with specific details to enable the prevention of injuries resulting from home hazards or unsafe practices. Research on the effectiveness of home assessments to prevent falls in older adults demonstrates that home assessments reduce the risk of falls, especially in people who have a history of past falls (Pighills et al., 2011). There is considerable research evidence that shows the effectiveness of home environmental interventions for the prevention of falls in older adults, particularly those who are at high risk for falls (e.g., people who had been hospitalized for a fall and those who showed functional decline) (Clemson et al., 2008; Gillespie et al., 2009). The consequences of falls have been well established and can include long-term

disability and the need for long-term care, loss of confidence, depression, social isolation, and even premature death. Thus, the role of OT to address home safety and fall prevention is of critical importance.

Housing Options

Housing options can also be reviewed with home assessments to determine the best fit for the client. Options are numerous, and most communities have innovative, barrier-free housing with access to attendant care and other support services, meals, and recreation. Many seniors and persons with severe physical disabilities choose to live in these housing projects because they can more easily achieve independence within the supportive system. Transitional housing programs also assist clients to cultivate both independent living skills and knowledge of available resources. The occupational therapist can use assessment tools such as The Housing Enabler (Slaug & Iwarsson, 2001) to evaluate the need or probable benefit of such solutions.

The U.S. Office of Fair Housing and Equal Opportunity administers the federal laws and policies that make sure persons with physical disabilities have equal access to the housing of their choice (U.S. Department of Housing and Urban Development, 2011). Specific accessibility requirements have been established to ensure that the design and construction of new residential buildings comply with the Fair Housing Act (e.g., buildings must have an accessible entrance on an accessible route). Occupational therapists conducting an environmental assessment of an apartment should also remember to evaluate building access, parking, halls, facilities, and fire routes to ensure that these requirements have been met. Many of the home assessments presented in this chapter offer suggestions relevant for single-family as well as multi–unit dwellings.

Therapists are often unaccompanied during home visits, so therapist and client safety must be considered. Although a therapist may be very confident about her or his safety with the client, other occupants of the home, building, or even the neighborhood (including animals) may put the therapist at risk. Home and community settings can present risks because they are complex and often unfamiliar to the therapist. Therefore, it is always advisable for therapists to maintain vigilance about their personal safety when conducting home visits. The points in Safety Note 10-1 have become standard practice in many communities and are useful to ensure that the therapist and client are safe during home visits.

Assessment of Community Access

Occupational therapists are involved in changing environments to enable their clients' participation and fulfillment of community roles. As noted earlier in this chapter, community businesses, services (including public transportation)

A   **Do you perform the following activities alone and without difficulty:**

Taking a shower ☐ N.A. ──────────➤ go to question 28
24. Get in/out of shower stall/bathtub?

☐ No   ☐ Yes   ☐ N.A.

Functional Limitations	Home Check-List	Recommendations	
	Check:	**Housing**	**Other**
☐ Poor coordination (lower limbs)	■ Height of step	☐ Eliminate/reduce step	☐ Supervision
☐ Poor balance	■ Existence of non-slip surface in and outside shower	☐ Install vertical grab bar	☐ Assistance
☐ Limited range (lower limbs)	■ Existence of grab bars or support	☐ Slip resistant flooring inside/outside shower stall (or bath) via non slippery coating, abrasive strips or rubber mats	
☐ Muscle weakness		☐ Add transfer board	
☐ Reduced mobility		☐ Improve floor drainage	
☐ Wheelchair dependent		☐ Change tub or shower stall if possible	
☐ Obesity			

B   **Do you have any difficulty stepping into or out of the bathtub?**

☐ **No** ➤   If no, go to next question

☐ **Yes**   If yes, check the adaptations below
       which would help you

☐   Install a vertical and an horizontal or angled grab bar by the tub

☐   Install non-slip flooring throughout the bathroom

☐   Install a non-slip surface in the bathtub

☐   Install a commercial or custom-made transfer bench so that the tub can be entered from a seated position

☐   Replace bathtub with a shower stall, if difficulty is severe

☐   Install a separate shower stall, if difficulty is severe

☐   Other (describe)

A vertical grab bar provides support when entering the tub, while an horizontal (or angled) bar helps you to complete the entrance and lower yourself onto a shower seat or to the bottom of the tub.

Safety Note 10-1

Therapist Safety on Home Visits

- Ensure that someone knows the location and approximate times for your home visit. If you are aware the visit will be challenging, request the presence of a case manager, second therapist, or a member of the client's family, if possible. When a visit is conducted outside of normal business hours, it is good practice to phone someone when you have completed a visit and are on your way home, to let him or her know that you are safe.
- Carry a mobile phone to use in case of emergency during the travel and home visit. Keep the battery charged.
- When you arrive at the home, assess the surroundings and inside the home to identify any potential hazards.
- Throughout the visit, be aware of exits and escape routes.
- If you feel unsafe or uncomfortable at any time, leave immediately.
- Have the client lead you to different areas of the home, including up and down stairways.
- Park as close as you safely can to the client's home.
- If traveling by car, ensure that it is in good repair and prepared for emergencies. Be cautious about leaving items in the car that may attract attention.
- If taking public transportation, follow safety recommendations related to its use.
- Adhere to any policies or procedures of your employer, including conducting joint visits, and report any unusual or unsafe situations immediately.

and programs must be made accessible for persons with disabilities in many jurisdictions. For example, it is unacceptable for wheelchair users to have to use a freight elevator at the back of a building, take safety risks to maneuver sidewalk curbs, or need someone to lift them up even just a few stairs to enter a building. In order for persons with physical disabilities to fully engage in and feel included in community life, they should experience easy, convenient, and safe access to the places, services, and programs they wish to use or participate in. Occupational therapists can assume consultation or advocacy roles with groups seeking to make educational, cultural, commercial, and religious facilities accessible. Therefore, they should become familiar with and can refer to the ADA-ABA Accessibility Guidelines (U.S. Access Board, 2004, 2007).

UD principles are now being applied across most community settings, and occupational therapists can play an important role in promoting this mainstream approach to design (Ostroff, 2001). UD is a philosophy and practice of creating products and environments that are usable by everyone, regardless of age or ability.

A variety of tools are now available to assess community environments. Three subjective measures developed

for rehabilitation practitioners are the Craig Hospital Inventory of Environmental Factors (CHIEF), the Facilitators and Barriers Survey (FABS/M), and the Measure of Quality of the Environment (refer to Assessment Table 10-2 for details). All can be used to obtain the perspective of persons with disabilities (through self-report or interview) about a breadth of environmental enablers and barriers (i.e., physical, social, institutional and attitudinal) to their participation in community life.

Two tools that facilitate discussion with a client about environmental factors influencing participation are the Multidimensional Scale of Perceived Social Support (MSPSS) (Zimet et al., 1988) and the Home and Community Environment Instrument (HACE) (Keysor, Jette, & Haley, 2005). The MSPSS targets the social environment and is useful for quickly identifying a client's perception of social supports available from family and friends to lead into a discussion of social resources enabling greater community participation. The HACE targets person–environment fit and enables a client to describe aspects of the home and community environment that hinder participation (i.e., physical characteristics and social attitudes).

Another aspect of community participation that is drawing attention is the walkability of community settings in relation to access, physical activity, and safety. Although a number of tools have been developed to evaluate walkability of neighborhoods, two are mentioned here: the Neighbourhood Walkability Scale (NEWS) (Saelens & Sallis, 2002), and the Irvine Minnesota Inventory (IMI) (Day et al., 2005). These tools measure built environmental features associated with physical activity and walking and include architectural, traffic, and aesthetic features as well as proximity of services and retailers. These features can have a positive impact on the ability of persons with disabilities to access their neighborhood community. In addition, the transportation needs of persons with disabilities should not be overlooked in communities. The Travel Chain Enabler was successfully piloted in Sweden (Iwarsson, Jensen, & Stahl, 2000); however, no recent studies have been published to support this tool.

Assessment of Access to Workplace

Occupational therapists play an important role in enabling clients to fulfill self-advancement roles by assisting them to seek or return to work. On-site assessment of workplace safety and accessibility is critical, insofar as workplace environments can differ significantly, and the needs of clients will differ depending on the nature of their condition. For example, a client with a cognitive impairment from a traumatic brain injury will have very different needs from a person returning to work following a spinal cord injury. Workplace assessment is a key step in helping the occupational therapist to learn how workplace factors impact work performance and safety (Bootes & Chapparo, 2002)

(see Procedures for Practice 10-1 and 10-2 for suggestions related to conducting work site assessments).

Knowledge of the ADA and the supporting guidelines are critical for guiding workplace assessment. For practical assessment purposes, the occupational therapist may wish to use the guidelines together with the ADA Checklist for Readily Achievable Barrier Removal (Adaptive Environments Center, 1995). Other tools, such as the ADA Work-Site Assessment (Jacobs, 1999a) and the Job Analysis during Employer Site Visit (Jacobs, 1999b), may also be used to help the therapist focus on specific environmental factors in addition to work demands that may influence work performance and safety. Note, however, that these checklists have not undergone measurement studies.

Occupational therapists recognize that there is a range of environmental factors that can affect one's ability to work. Therefore, it is also important to assess the sociocultural environment, including social supports, staff interactions, and attitudes of coworkers and supervisors (Dekkers-Sánchez et al., 2010). Tools such as the Work Environment Scale, Work Experience Survey and the Workplace Environment Impact Scale (refer to Assessment Table 10-3 for details) are not limited to physical access issues because they also address such areas as social environments and resources.

Persons with disabilities may also face challenges while volunteering or attending school. Many of the tools previously discussed to address work environments or community access may be of use in these instances. Occupational therapists may also use tools such as the St. Lawrence College Accessibility Checklist (St. Lawrence College, 2005). This informal checklist briefly addresses physical, policy/programmatic, information, and attitudinal environments from a post–secondary school perspective.

Through partnering with clients and employers, occupational therapists help identify environmental factors that can affect clients' ability to work. The Job Accommodations Network website (http:/askjan.org/) can assist the team in identifying workplace modifications to address specific challenges a person with a disability might experience in the workplace. For example, workstation modifications and assistive technologies can be implemented to reduce performance barriers (see Chapter 31 for discussion of specific strategies).

Procedures for Practice 10-1

Preparing for a Site Visit

When the occupational therapist is asked to perform a work site assessment to determine accommodations that may be necessary for a client's successful return to work, the following preparations should be made:

- Obtain a description of the job (e.g., duties, responsibilities, sequence, temporal patterns, risks, variations in complexity of tasks, and essential functions) from both employer's and employee's perspectives, if possible.
- Obtain a description of the workstation and the work site (e.g., structure, ambience, layout, environmental hazards, and location).
- Obtain written consent from employer/business/industry representatives and client (including the nature of client's wishes regarding information to be shared) both for completing the assessment and for using any digital recording devices (if applicable).
- Gain an understanding of worker's and employer's perspectives (e.g., expectations, issues, abilities, etc.).
- Make arrangements for the visit, including consent and preparatory planning, with appropriate personnel (e.g., client's supervisor) well in advance of visit.
- Ensure the presence of a contact person during the visit (e.g., client's supervisor and occupational health personnel).
- Prepare an evaluation framework including list of questions, activities, safety concerns, etc.
- Prepare and bring charts/assessment forms to record findings.
- Consider contributions from a second person (e.g., physiotherapist), depending on nature of assessment.
- Consider relevant workplace legislation (e.g., from the U.S. Department of Labor, Occupational Safety and Health Administration, and the Workplace Safety and Insurance Act in Canada).

Procedures for Practice 10-2

Supplies and Materials Required for Work Site Visit

Planning with employer (including a preliminary understanding of the work site) may help to determine with greater accuracy in advance of the visit what supplies and materials may or may not be required. Recommendations include:

- tools for data recording (e.g., forms, paper, pens, laptop, or tablet computer)
- measuring tape and wheeled measuring device
- stopwatch
- force gauge dynamometer
- push-pull gauge
- personal protective equipment as appropriate (e.g., steel-toed footwear and protective glasses)
- thermometer
- digital camera (with video recording capacity); tripod, if necessary
- photo release forms (to protect confidentiality and privacy of workplace and client)

General Comments on Assessing Access to Home, Community, and Workplace

Many occupational therapists rely mainly on experience, observation, and interviews when called on to evaluate the environment. Although these strategies are necessary components of good practice, they cannot stand alone.

The use of standardized instruments that have evidence of acceptable measurement properties is also necessary. In this chapter, we have described a number of home, community, and workplace environmental assessments that will assist the occupational therapist identify suitable interventions to enable and optimize client occupational functioning.

	Objectives	**Example of Internal Dialogue**
Patient Information	Understand the patient's diagnosis or condition	"Mrs. P. had a right-sided stroke 2 months ago. Although she is still early in her recovery, I would expect that her hemiparesis still limits her basic personal care, homemaking and community living skills, and safety. I also need to be aware of any cognitive and perceptual changes that may be affecting her abilities. Depression is also possible after stroke, so I will need to be on the lookout for any mood changes as well."
Mrs. P. is an 80-year-old woman who sustained a right-sided cerebrovascular accident (CVA) 2 months ago, resulting in left-sided hemiparesis. She was recently discharged from the rehabilitation center to an apartment that she has shared with her husband for more than 30 years. Results from the Functional Independence Measure FIM™ (Uniform Data Systems, 1993), which were conducted at time of discharge, are available from the referral. Her total FIM™ score improved from 70 (at time of admission) to 97 on discharge. Mr. P. and their daughter are presently doing the housekeeping and most of the meal preparation. Mr. P. would like to hire an attendant to work a few hours a day to assist with Mrs. P.'s personal care and to help with the housekeeping, but financial constraints do not allow for this. Both Mr. P. and their daughter have reported becoming increasingly frustrated and fatigued. They both say that they do not believe that they can leave Mrs. P. alone because of their concerns about her safety and independence. Prior to her stroke, Mrs. P. prided herself on her ability to care for her husband and her home. Mrs. P. is becoming increasingly concerned about becoming too much of a burden on her family and thinks that they are being overly protective. Mrs. P. has been referred to the community occupational therapist to address concerns about her independence and safety in her home environment.	Know the person	"It sounds like her ability to care for herself and her family was extremely important to her. I wonder how she is coping now. Because she may have been the person who took care of everything and everyone at home, I wonder how well the daughter and husband are able to pick up the slack. Not having worked with many older people, I know that I may have some stereotyped expectations of her readiness to change; I will need to be careful, as I could very well be wrong about this. However, I am a bit concerned about how willing she will be to make modifications to her home if I suggest them."
	Appreciate the context	"I want to know more about her relationship with her husband and her daughter. Are they supportive, or have they been negatively affected by the changes? I also wonder how well she is able to get around her small apartment with the quad cane she uses at home. Although I have not worked with many older adults, I have worked with many adults who have had strokes, so I may need to consult my colleague/supervisor who has more experience with this age group. I may also want to consult the occupational therapist who worked with Mrs. P. at the rehabilitation center for more information."
	Develop provisional hypotheses	"Given her diagnosis, I am assuming that there may be cognitive and perceptual impairments in addition to the more obvious physical problems that will impact Mrs. P.'s occupational performance. I also think that the environment will play a big role in how independent and safe she is at home."

Assessment Process

The therapist decided to use the Canadian Occupational Performance Measure (COPM) (Law et al., 2005) to identify Mrs. P.'s perceptions and priorities for therapy. The SAFER-HOME was chosen to assess Mrs. P.'s ability to safely engage in occupations in her home. The SAFER-HOME allowed both Mrs. P. and her family to discuss her abilities and challenges and demonstrate a variety of occupations in her home. Use of the SAFER-HOME assisted the occupational therapist to identify areas of concern and make recommendations to enhance safety and independence.

| Consider evaluation approach and methods | "I would like to get a sense of her priorities from her perspective. I want to learn more about her abilities to advocate for herself and make her ideas heard. The COPM will give me a better understanding of her awareness and priorities. The SAFER-HOME will provide me with information about her home environment and safety." |

Assessment Results

Based on the COPM, Mrs. P. indicated that her priorities were to bathe, prepare meals, complete housekeeping, and do the laundry. The SAFER-HOME highlighted areas of safety concern that Mrs. P. had not raised previously, including issues associated with medication use, vision, and remembering to turn off appliances (refer to Fig. 10-4, the SAFER-HOME results for this case study).

| Interpret observations | "Mrs. P. seems to have limited awareness of possible cognitive, visual, or perceptual changes since her stroke. However, she is very aware of physical changes. Further assessment may be helpful to explore cognitive, visual, and perceptual difficulties impacting occupational performance. I was surprised that Mrs. P. was having difficulties remembering to turn off the stove, because she does not seem to have memory problems in more social situations. She is occasionally missing things on the left, so I am wondering whether she has any visual attention difficulties as well." |

Occupational Therapy Problem List

1. Decreased independence in self-care, particularly in bathing and toileting.
2. Decreased independence in instrumental activities of daily living including meal preparation, laundry, and housekeeping.
3. Physical barriers to independence and safety identified in home (particularly kitchen and bathroom).
4. Limited funds available for assistive devices, home modifications, and support services.
5. In addition to changes in motor function since the CVA, cognitive, visual, and perceptual difficulties may also be impacting safety and independence in daily occupations.

| Synthesize results | "Overall, Mrs. P. seems to be able to benefit from occupational therapy intervention. She clearly has many areas she would like to address and is very motivated to work on these areas. The safety concerns I have identified will need to be addressed as priority areas as soon as possible. Although Mrs. P. does not seem to be as concerned about the safety issues, she is open to addressing them if only to help her husband and daughter feel a bit better. I will need to develop a plan to address the areas where I suspect that more assessment would be beneficial. I should consult with a colleague regarding options for funding. I wonder what programs Mrs. P. may qualify for in order to help supplement funding for equipment I may recommend. I am glad that I used the SAFER-HOME and the COPM because I can reuse both of these tools in the future as part of my outcome evaluation." |

Clinical Reasoning in Occupational Therapy Practice

Assessing Mobility within the Home and Fall Prevention

In the case example of Mrs. P., the 80-year-old woman with left-sided hemiparesis, you have observed that she can walk short distances using a cane (see Case Example). Her husband would like to leave her alone for an hour or so during the day so that he can go out for groceries and other errands. Typically, Mrs. P. sits in a comfortable chair in the living room during the day, not in her wheelchair. She may need to use the toilet when her husband is out. What environmental factors might help or hinder her when she is left alone? What are the safety issues? What environmental enablers would you suggest to address this issue?

Clinical Reasoning in Occupational Therapy Practice

Assessing Community Mobility and Accessibility

In the case example of Mrs. P., she has indicated that she would like to go out shopping with her husband to get groceries at the nearby supermarket and to stop for lunch or coffee at a nearby café that they had previously frequented. Mrs. P. can walk short distances using a cane (see Case Example).

What are the environmental factors that could impact her occupational functioning and how might they help or hinder her engagement in this outing? What environment assessment tool(s) would you use to address the various occupations within this outing?

Summary Review Questions

1. Why would an occupational therapist assess the environment?

2. List seven examples of environmental barriers that a person with mobility impairment might encounter when returning to work. Now list seven examples of environmental barriers that a person with cognitive impairments following a traumatic brain injury might encounter. Compare and contrast the types of environmental barriers each might encounter and discuss any differences. How would these differences influence your choice(s) of assessments of the environment?

3. List seven examples of environmental supports that would allow an older adult with arthritis to continue to live at home.

4. Identify two home assessments that address fall prevention and safety in the home. Look around your own home and describe environmental features that would put you at risk for a fall if you had a balance or mobility impairment.

5. What assessments would you use to evaluate whether a client with a spinal cord injury can live independently in the community?

6. As a consultant to an assisted-living facility, what assistance could you offer the facility's administration regarding their plans to renovate the building?

7. If you, as an occupational therapist, were making a home visit to a client's apartment, what precautions would you take for your visit to protect your own safety?

Glossary

Accessibility—The ease with which the physical environment may be reached, entered, and used by all individuals.

Accommodations (environmental)—Removal of environment barriers and provision of environmental supports and resources to enable a person with a disability to enjoy equal opportunity.

Barrier-free design—Design features of the built environment that remove physical barriers to full and equal accessibility for all persons with disabilities.

Environmental barrier—Any component of the environment that impedes optimal occupational functioning.

Environmental support—Any component of the environment that encourages, facilitates, or provides assistance to allow a person to achieve optimal occupational functioning.

PEO fit—Person-environment-occupation fit. The level of congruency across personal factors (e.g., functional, social,

and psychological), the characteristics of the environment (e.g., barriers and enablers), and the characteristics of the chosen occupation.

Physical environment—The natural or human-made (built) features of the environment within which occupational functioning occurs.

Standardization—The process of making an assessment available in a manual with standard procedures for testing, scoring, and interpreting the results. Environmental assessments do not usually undergo a normative process because of the variability in environments, yet many are based on standards or perspectives of persons with disabilities.

Transactive—Dynamic, reciprocal relationship; integrated.

Universal design (UD)—Design features of the built environment that enhance optimal function and convenience for all individuals, regardless of their ability.

Occupation: Philosophy and Concepts

Catherine A. Trombly Latham

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define occupation.
2. Discuss the importance of occupation in people's lives.
3. Discuss the concept of occupational balance.
4. Discuss occupation as a therapeutic medium.
5. Characterize occupation-as-end and occupation-as-means.
6. Discuss the therapeutic qualities of occupation: purposefulness and meaningfulness.
7. Cite evidence that supports the use of occupation as therapy.
8. Describe how therapeutic occupation is implemented in practice.
OCCUPATION DEFINED

Occupation is both the center of human experience and the core of our profession (Harris, 2008). Occupation is defined by the general public as an activity in which one engages, especially the principal business of one's life (vocation) (Merriam-Webster Online, 2012). Occupational therapists define occupation in various ways, but all definitions include the idea of activities of everyday life that are meaningful to individuals (American Occupational Therapy Association [AOTA], 2008). "Occupation is everything people do to occupy themselves, including looking after themselves, enjoying life and contributing to the social and economic fabric of their communities" (Law et al., 1997, p. 32). Personal identity emerges from a harmonious balance of the many meaningful occupations in which a person engages over time (Christiansen, 1999/2011; Häggblom-Kronlöf et al., 2007; Unruh, 2004). People engaged in occupation not only define their identity but also achieve a sense of competence and report a sense of satisfaction and fulfillment (AOTA, 2008).

Although the terms occupation and purposeful activity are used interchangeably by most therapists, the Occupational Therapy Practice Framework (OTPF) (AOTA, 2008) distinguishes between occupation and purposeful activity on the basis of meaningfulness. The key difference is that occupations are central to a person's identity, and they influence how one spends time and makes decisions (AOTA, 2008), whereas purposeful activity is a class of human actions that are goal directed and allow a person to develop skills that enhance occupational engagement but do not assume a place of central importance or meaning to the life of the person (AOTA, 2008; Rogers, 2007). Each occupation is composed of several purposeful activities. Purposeful activity is circumscribed; it demands particular responses within particular contexts and is used therapeutically to facilitate change in impairments and functional limitations. In this text, occupation-as-end is equated to occupation, and occupation-as-means is equated to purposeful activity.

IMPORTANCE OF OCCUPATION IN PEOPLE'S LIVES

Occupational engagement contributes to the experience of a life worth living (Hammell, 2004). Engagement in positive occupations (e.g., care of self, others, and property and creative or productive endeavors) that the person has the capability to accomplish and chooses to accomplish regulates the rhythm of personal and community life. Such occupations absorb attention and evoke creativity, promote feelings of satisfaction with achievement, and contribute to a sense of self-esteem and self-efficacy (Fig. 11-1). These occupations are potentially therapeutic.

Time-use studies indicate that people who are mentally able to envision goals fill their time with activities and tasks (Grady, 1992; McKinnon, 1992; Pentland et al., 1999; Yerxa & Baum, 1986; Yerxa & Locker, 1990). Beyond the organization and positive feelings generated by engagement in occupation, there is evidence that social and productive occupations are independently associated with survival (Glass et al., 1999). Failure to engage in meaningful occupation by older Swedish adults was found to be associated with a reduced sense of hope (Borell et al., 2001). In the absence of social and productive occupation (as occurs, for example, early in retirement, in the acute stage of motor disability, or immediately after a profound loss [Hoppes, 2005]), a person may experience a sense of disorganization, depression, and loss of a sense of self-worth.

Not all occupation or purposeful activity is beneficial. Attempts to engage in occupations beyond one's capabilities can lead to frustration, anxiety, and depression (Rebeiro & Polgar, 1998). Engagement in negative occupation (e.g., crime and destruction) disrupts personal and community life. Doing the same activity repetitively beyond the requirements of the task, as seen in obsessive-compulsive disorder (OCD), reinforces pathology. Imposition of unsuitable, negatively meaningful activities (e.g., children's games as therapy for elderly patients) fails to build a sense of self-esteem and satisfaction. These types of occupation are not therapeutic. Therapeutic occupation, a special type of occupation, is defined as the use of positive, relevant, meaningful, and purposive activities to improve a person's ability to participate in his life (Strzelecki, 2009), or to improve abilities and capacities to enable improved occupational functioning.

Occupational Balance

Occupational therapy subscribes to the belief that the balance of engagement in life occupations, including rest, is basic to health and wellness (Meyer, 1922/1977; Rogers, 1984; Strzelecki, 2009). The ideal configuration of this balance changes as the person matures from infancy to old age (Rogers, 1984) and is individually defined, consisting of occupations that are meaningful to the particular person and that promote wellness (Hammell, 2009; Stamm et al., 2009; Wilcock, 1997). What is considered "balance" by one person may not be seen that way by another. As part of the occupational history interview, the therapist can ascertain whether the patient feels that he or she is in occupational balance or not and on what basis the person defines that balance.

Balance may be defined on the basis of a mixture of challenging versus relaxing occupations, a mixture of activities meaningful to the individual versus those meaningful to society, or a mixture of activities intended to care for oneself versus those intended to care for others (Stamm et al., 2009). Other gradients on which to establish balance

Figure 11-1 Occupation-as-end. Baking brownies again under new circumstances (after spinal cord injury). **A.** Preparing the pan. **B.** Transporting to the oven. **C.** Putting the brownies into the oven.

include allotment of time among physical, mental, social, and rest occupations or mixing physically taxing occupations with light, relaxing occupations (also called pacing, which is commonly used in the treatment of persons with arthritis, cumulative trauma, or cardiopulmonary disorders), or balancing occupations of doing with occupations of being (Wilcock, 1997).

If the balance is skewed toward one end of the continuum or the other, then the person suffers occupational dysfunction. For example, if too much time is spent in self-enhancement activities (e.g., video gaming) to the detriment of other roles or rest, then the person's work, social life, and/or self-care suffers, and he is occupationally "out of balance." If the person engages in mentally challenging occupations without balance with rest or lesser challenging occupations, then the person becomes stressed ("burned out"), unhealthy, and ineffective in other areas of his life (Wilcock, 1997). If the person engages in physically stressful occupations or movements without rest, damage occurs to the body structures involved (cumulative trauma) (Barcenilla et al., 2012; Walker-Bone et al., 2012).

OCCUPATION AS THERAPY

Occupational therapists work with people who have experienced, or are in danger of experiencing, significant occupational dysfunction secondary to changes in their physical, cognitive, emotional, or social well-being or their environments. It is the role of the occupational therapist to help the person to grieve his or her loss and to reconstruct an acceptable occupational identity (Unruh, 2004).

Occupation is used to create or promote health, to remediate impairments or restore an ability or skill, to modify or adapt performance, to maintain performance capabilities, or to prevent disability (AOTA, 2008). To be therapeutic, occupation must involve the patient in active participation, must evoke in the patient a willingness to participate and must hold meaning for the person to engage in it. The appropriate occupation results in a sense of mastery by the participant (Laws, 2012). Occupational intervention becomes therapeutic when it is guided by theory (Dooley, 2009). In this text, the theoretical guideline is the Occupational Functioning Model, but therapists may choose to use other guidelines or frames of reference.

Occupation is the unique therapeutic medium of occupational therapy (National Society for the Promotion of Occupational Therapy, 1917; Reilly, 1962/2011; Slagle, 1914). Occupation is both intervention and outcome (Amini, 2010; Trombly, 1995/2011).

What about occupation maintains or restores health? That question is still debated, but one suggestion is that occupation is therapeutic when it appeals to the patient (has meaning for the patient); when it advances therapeutic goals (makes demands on the system needing improvement); and when it is carried out in the space, time, and sociocultural conditions that it would be in real life (fulfills a purpose in the person's life) (Dooley, 2009; Pierce, 1998). The notion that purpose is necessary for the therapeutic effect has persisted throughout the history of therapeutic occupation, whereas the ideal of meaningfulness of occupation got lost temporarily after World War II, during the biomechanical era of occupational therapy, which, for efficiency's sake, promoted exercising using the motions of an activity—thereby "preserving" meaningfulness—without true meaning (e.g., "weaving" on a floor loom for exercise without thread on the loom) (Laws, 2012). Another aspect of therapeutic occupation is the "just right" challenge, the optimal fit between demands of the occupation and the skills of the person (Lowenstein, 2009; Rebeiro & Polgar, 1998). An occupation is therapeutic when it requires effort for the patient to accomplish but is possible for the patient to accomplish. By accomplishing it, the patient improves the impaired ability or capacity being challenged. By succeeding

in the challenge, the patient is motivated to continue or repeat the experience (Rebeiro & Polgar, 1998). A successful therapeutic occupation results in feelings of self-efficacy, self-esteem, and self-satisfaction, as well as improved occupational functioning.

Today, as in the past, occupational therapists help people achieve satisfying occupational competence in several ways. One way is to adapt the environment or tools and teach the person how to use these contextual adaptations or other adapted methods to accomplish activities and tasks of daily life (Clark et al., 1997; Jackson et al., 1998; Moyers & Dale, 2007). In this case, occupation is both the treatment and the end goal (occupation-as-end). Occupation-as-end may remediate impairments, but this benefit is serendipitous, and the occupation is not chosen for that purpose. The second way is to remediate impaired capacities and abilities that prevent successful performance of activities and tasks required of a patient's roles (Moyers & Dale, 2007). In this case, occupation is the means to remediate impairment (occupation-as-means) (Fig. 11-2). The occupation used may actually be the same, for instance, chopping apples to make a pie. If the goal is to relearn how to make an apple pie, then we consider it occupation-as-end. If the goal is to improve strength of grasp to enable multiple other life occupations, then we consider chopping apples occupation-as-means.

The key skill of the occupational therapist is the ability to analyze activities in terms of the required skills, abilities and capacities; what influence the social and physical environments have on the likelihood of successful

Procedures for Practice 11-1

What is occupation? What is occupational therapy?

Many people will ask you, over your working lifetime, what do you mean by "occupation"? Those who are not occupational therapists equate occupation *only* with a job or work (Thomas, 2012). They often ask whether it is your job as an occupational therapist to find work for people with disabilities. You need to develop your own brief answer that clarifies those concepts for people who have no inkling of the profession and are usually only casually interested, such as people you would meet on a bus or at a cocktail party. However, you may also want to embellish your answer if your grandfather asks about your chosen profession. Points to consider include:

- Historical aspect, i.e., why we use the term occupation. You can seek your answer at the Wilma L. West Library of the American Occupational Therapy Foundation (http://www.aotf.org).
- Current usage. You can seek your answer in published position papers and guidelines of the American Occupational Therapy Association (www.aota.org) or other occupational therapy associations.
- Research evidence of the effectiveness of engagement in occupation on wellness, the recovery of health, and the

reorganization of the brain. You can refer to studies cited in this chapter and textbook or other publications that provide evidence that occupation organizes one's brain, one's life, and/or one's behavior or that occupation motivates engagement in life. Conversely, you can cite studies that indicate that the lack of occupation is disorienting, results in failure to develop, and depression.

Then you can add for your grandfather: We study the science of engaging in activity and the effects that has on the body, brain, and psychological and emotional well-being of people from birth to old age. If he asks you, "What science?" you will be prepared to answer because you have studied the research. If he asks you, "Who thought that up?" you will have the answer because you have studied the history of occupational therapy.

I am a retired "phys dys" occupational therapist, so my "elevator speech" goes like this: Occupational therapy helps people who have had an accident or an illness, like a stroke, to recover their ability to take care of themselves, their homes, and any other life activities that they need to, or want to, or are expected to do. We use various activities, which we call occupations, to help people recover lost skills, or we teach them to do activities in new ways or change their surroundings so that they can succeed even if they have some disability.

---

occupational performance; and what abilities and capacities the person brings to the therapeutic encounter. Analysis allows selection, gradation, and adaptation of activities to promote a therapeutic outcome (Watson & Wilson, 2003). Chapter 12 describes the analysis, gradation and adaptation processes. Procedures for Practice 11-1 discusses how one might explain the skills and responsibilities of an occupational therapist.

Occupation-as-End

Occupation-as-end is the complex of activities and tasks that comprise roles (Figs. 11-3 and 11-4). It is a person's functional goal that he or she tries to accomplish in a given environment using what abilities and capacities he or she has and any adaptations that may be necessary. Relearning the occupation within the customary environment is the goal. The occupational therapist uses a person-environment-occupation focused analysis (see Chapter 12), sometimes referred to as PEO fit (Thomas, 2012). Successful intervention involves a match among the client's goals and abilities, the task itself, the client's perception of the challenge of the task, the client's sense of self-efficacy regarding the task (Lowenstein, 2009; Lowenstein & Tickle-Degnen, 2008), and the environment in

which the task is to be carried out. This view is consonant with dynamical motor control theory, which suggests that movement patterns emerge from the interaction among the person's abilities, the environment, and the goal of the occupation (Mastos et al., 2007).

Occupation-as-end is more or less equivalent to *areas of occupation* of the OTPF (AOTA, 2008) and *activities*

Figure 11-3 Occupation-as-end. Relearning to make the bed after stroke.

Figure 11-4 Occupation-as-end. Relearning to vacuum after stroke.

and participation of the World Health Organization's International Classification of Functioning (ICF) (World Health Organization, 2001) (see Chapter 1).

Occupation-as-end achieves its therapeutic effect from the qualities of purposefulness and meaningfulness (Definition 11-1). Purposefulness is hypothesized to organize behavior, and meaningfulness is hypothesized to motivate performance (Trombly, 1995/2011).

Purposeful occupation-as-end organizes a person's behavior, day, and life (Meyer, 1922/1977; Slagle, 1914; Yerxa & Baum, 1986; Yerxa & Locker, 1990). Occupation-as-end is purposeful by virtue of its focus on accomplishing activities and tasks, on accomplishing goals. Client-centered goal setting focuses the patient's attention and enthusiasm on occupations that matter. The patient will need the therapist's help to develop his or her more general goals into SMART goals, that is, ones that are **s**pecific, **m**easureable, **a**ttainable, **r**ealistic, and **t**ime specified (Mastos et al., 2007). From such goals, both patient and therapist can estimate progress.

Occupation-as-end is not only purposeful but also meaningful because it is the performance of activities or tasks that a person sees as important. Only meaningful occupation remains in a person's life repertoire. Meaningfulness of occupation-as-end is based on a person's values and context. Context includes the physical, social, cultural, temporal, personal, and sometimes virtual milieu in which occupation occurs (AOTA, 2008; Coppola et al., 2006). Meaningfulness also springs from a person's desire to preserve his or her personal integrity, defined as a satisfying sense of wholeness (Leidy & Haase, 1999); from a sense of the importance of participating in certain occupations or performing in a particular manner; from the person's estimate of his or her reward in terms of success or pleasure; or possibly from a threat of bad consequences if the occupation is not engaged in. Meaning is individual (Bruner, 1990; Harmer & Orrell, 2008), and although the occupational therapist can guess what may be meaningful to the patient based on the person's life history, the therapist must verify with each patient that the particular occupation *is* meaningful to that person *now* and verify that the person sees value in relearning it. What a person finds meaningful may not only have to do with occupational history but may be a function of where he or she is on the recovery/adaptation trajectory. That is, even if someone has an occupational history of loving to cook, she may not be ready emotionally to take on cooking tasks

Definition 11-1

Therapeutic Characteristics and Effects of Occupation-as-Means and Occupation-as-End

	Occupation-as-Means	Occupation-as-End
Purposefulness	**Organizes** abilities and capacities, e.g., movement, cognition, and perception	**Organizes** capacities and abilities into activities, tasks, and roles
Meaningfulness	**Motivates** engagement in therapeutic occupation	**Motivates** engagement in activities, tasks, and life roles
Effect	Occupation, through task demand, remediates capacities and abilities	Occupation, through adaptation or education, restores activities and tasks of life roles

after a devastating injury or illness because that occupation would force her to confront her loss and therefore would not be positively meaningful to her. Occupational therapists practice a client-centered approach that involves the patient choosing the occupational goals of most importance at this time. The therapist cannot substitute his or her own values or judgments based solely on occupational history in selecting appropriate occupational goals for the patient. A new assessment, the Meaningful Activity Participation Assessment (MAPA) appears to be a valid and reliable measure of meaningful activity (Eakman, 2007; Eakman, Carlson, & Clark, 2010a, 2010b). The MAPA measures the time spent doing 28 types of activity (respondent can add to the list), how much each matters or is personally fulfilling, how much each contributes to physical or mental health, and the reason why the person does the activity (needs to, seeks new experience, connects with people, or gives sense of accomplishment).

Meaningfulness is not only a psychological term but also a mechanism of change. It affects neurological functioning, as was seen in a positron emission tomography (PET) study by Decety et al. (1997), who discovered that brain activation differed with the meaning of an action regardless of subjects' strategies. Newman-Norlund et al. (2010) discovered, using functional magnetic resonance imaging, that certain neurons in the brain, the human mirror neuron system, distinguishes between meaningful and meaningless actions.

Habits and Routines as Components of Occupation-as-End

Most self-maintenance and many self-advancement and self-enhancement roles depend on habits and routines, which are long practiced and automatic. Injury, disease, environmental change, and significant life changes (e.g., moving, marriage, birth of a child, death of a spouse, retirement, or first job) disrupt useful routines and habits which may cause occupational dysfunction.

Clark and colleagues (2007) synthesized literature pertaining to habits. They described nine types of habits, ranging from tics (spasmodic recurrent actions of a body part) to habitus (a person's disposition or usual manner of acting in society). Occupational therapists who treat persons with physical dysfunction are interested in habit as an everyday activity, such as brushing the teeth, and routine, defined as a well-defined pattern of behavior, a string or sequence of activities that enable complex action to be completed efficiently and with little attention, such as driving or bathing and dressing in preparation for going to work. Routines are performance patterns that give life order (AOTA, 2008; Clark et al., 2007; Segal, 2004). Both habit and routine are automatic, controlled without conscious thought, until either they are disturbed by change in the environment or person's capabilities or they fail to

accomplish the goal, at which time the person must pay attention and modify actions. Both habit and routine free the mind to pay attention to more complex occupations (Clark et al., 2007).

Habits are learned through repetition of an action under particular cue conditions, and the action results in a reward that can be as simple as successfully shaving one's face cleanly in the morning. In the beginning, the person must focus on the action, but with repetition and consistency of context, little to no attention is necessary.

Habits and routines may be preserved after injury or illness if the patient is placed in the customary context or environment that provides the cues to enactment of the habitual action. Such preservation would enable the person to engage in formerly important, albeit automatic, occupations when he may not be able to learn new methods easily because of brain damage. Therapists would be interested in determining whether such habits were preserved in patients with brain injury by setting the context in such a way that it might trigger the habitual response.

When habits or routines are disturbed, for example moving to a nursing home or after a sudden trauma, life suddenly becomes chaotic and confusing, unlike the orderliness of morning preparation, commuting, working routines, etc., that contributed to an efficient and goal-directed life prior to the change (AOTA, 2008; Segal, 2004). The therapist will acknowledge this loss with the patient and prepare to develop new habits and routines, given the new circumstances. To develop new routines or habits, therapists can manipulate the environment as well as teach the person in a consistent manner new strings of actions tied to a cue that will evoke the sequenced action.

In a study of Swedish adults aged 42–82 years old who had suffered a stroke, patients were frustrated in their daily occupations because they were not able to carry out their former habits because of their impairments (Wallenbert & Jonsson, 2005). However, they resisted making adaptations or developing new habits because they feared doing so would diminish gains they could make for their physical impairments by struggling. They saw development of new habits as detrimental. The possibility of this type of thinking needs to be explored with patients who resist the benefits of learning new habits.

Some habits or routines are not health promoting and need to be changed, for example, sitting for long periods without changing positions to relieve pressure on insensitive skin. The context may trigger habitual action even when the person intends to act differently (Clark et al., 2007), such as engaging in attention-absorbing activities, such as playing video games. In that case, therapists would attempt to interrupt the habitual aspect of the action (prolonged sitting in this case) by (1) changing the cues (environment/context) and/or (2) changing the reward, that is, ensuring that the habitual action does not

accomplish the goal the person expected. For example, the therapist could install a pressure-sensitive switch that has a timer under the wheelchair cushion that would turn off the computer if pressure is not relieved after so many minutes.

Occupation-as-Means

Occupation-as-means is the use of occupation as a treatment to improve a person's impaired capacities and abilities to enable eventual occupational functioning. Occupation-as-means refers to occupation acting as the therapeutic change agent. An occupational therapist uses the client-focused activity analysis (see Chapter 12) in prescribing therapeutic occupation. It is important to remember that whereas the linkage between occupation-as-means and the remedial goal is crystal clear to the therapist, it is likely not to the patient. Therefore, when using occupation-as-means, the therapist must *repeatedly* and clearly explain why a given activity is being recommended or used in therapy. Various arts, crafts,

games, sports, exercise routines (Figs. 11-5 and 11-6), and daily activities that are systematically selected and tailored to each individual are used as occupation-as-means (Cynkin & Robinson, 1990).

Occupation-as-means is therapeutic when the activity has a purpose or goal that makes a challenging demand to the capacities and abilities that need to be improved yet has a prospect for success and that engages the person repeatedly in the action. Because the central nervous system (CNS) is organized to accomplish goals (Granit, 1977), the goal or purpose seems to organize the most efficient response, given the constraints of person and context (Wisneski & Johnson, 2007; Wu et al., 2000). Furthermore, if an activity has meaning and relevance to the individual who is to change, it motivates the will to learn and improve (Cynkin & Robinson, 1990).

Meaningfulness in the sense of occupation-as-means has an immediate aspect. Choice to participate in an activity at the moment is based on immediate motivation that is guided by currently perceived needs, feelings, and desires that may or may not be related to life goals.

Figure 11-5 Occupation-as-means. Lady playing virtual reality games on X-Box 360 Kinect to improve dynamic balance and use of affected upper extremity. **A.** Bowling. **B.** Table tennis game on TV showing the "opponent." **C.** Patient laughing about a good return.

Figure 11-6 Occupation-as-means. Playing cribbage using an adapted board to improve coordination.

The meaningful aspect of occupation-as-means may be the emotional value that an interesting and creative experience offers the patient (Ayres, 1958). Meaningfulness may also stem from familiarity with the occupation, its power to arouse positive associations, the likelihood

that completion of it will elicit approval from others who are respected and admired, its value in learning a prized skill, or its potential to contribute to recovery (Cynkin & Robinson, 1990; Grady, 1992). Thus, the therapeutic aspects of occupation used as a means to change impairments are purposefulness and meaningfulness (Definition 11-1).

Evidence That Occupation-as-Means Organizes Responses

Evidence of changes in organization of emotions, cognition, and perception secondary to engagement in occupation or activity having the therapeutic quality of purposefulness is not easily obtained. However, evidence concerning the organization of movement can be easily gained using instruments designed to track the spatial–temporal aspects of movement. Movement organization can be detected from the shape of the **velocity profile** (Georgopoulos, 1986; Wisneski & Johnson, 2007). Different velocity profiles, which indicate differences in movement organization and CNS control, emerge for particular goals or purposes (Jeannerod, 1988; Nelson, 1983) (Fig. 11-7). Some of that evidence will be reported here.

In 1987, Marteniuk et al. demonstrated for the first time the effect of goal on the organization of movement as detected from velocity profiles. They found that five university students organized movement differently when they reached for the same object for different purposes. One goal was to pick up a 4-cm disk and *place it* into a slot. The other goal was to pick up the disk and *throw it* into a basket. They measured the reach *to* the disk, not the placing or throwing motion. The distance and biomechanical demands were exactly the same under both conditions. Only the intent after reach was different.
Figure 11-7 Velocity profiles of reaches to two different targets. The profile on the left is symmetrical and bell-shaped, which is commonly seen in planned reach to a stationary, large target or to a familiar object. The peak of the velocity profile (end of the acceleration phase) occurs between 33% and 50% of the reach. The profile on the right is left-shifted, which is commonly seen in guided reach to a small target or to an imaginary place on the table (rote exercise). The peak velocity occurs early in the reach, and the deceleration phase is extended as the person guides the hand to the target.

The two goals produced different velocity profiles for reaching for the disk, indicating different movement organizations.

Goal or purpose is generated from the patient's own intention, from the therapist's directions (Fasoli et al., 2002; Fisk & Goodale, 1989; Massie & Malcolm, 2012), or from the context, including what objects are available, the relevance of the objects, and what the objects afford the person in terms of action. We are familiar with generation of goals by the person and by the therapist, but contextual indication of goal may be unfamiliar, so a few studies concerning this will be reviewed.

Wu et al., (2000) used a counterbalanced repeated-measures design to examine the effects of context on reaching performance in neurologically impaired and intact populations. Context was varied by the presence or absence of objects used to complete a task. Each participant was tested under two conditions: presence of the object, in which the participant reached forward with the impaired, or corresponding, arm to scoop coins off the table into the other hand; and absence of the object, in which the participant reached forward to a place where the coins would be placed if the object were present. The kinematics of reaching to the coins or point on the table were significantly better ($p < 0.0055$) when the object was present as compared with when the object was absent. Better performance was defined as faster (shorter movement time), more direct (less total displacement), more planned and less guided (greater percentage of reach where peak velocity occurs), and smoother (fewer movement units).

Evidence that full context or presence of real functional objects affect the trajectory of reach, as opposed to imagined or absent objects, has been verified in other studies (Cattaneo et al., 2009; Ma, Trombly, & Robinson-Podolski, 1999; Mathiowetz & Wade, 1995; Trombly & Wu, 1999; Wisneski & Johnson, 2007; Wu et al., 1998, 2000), implying that the goal, as defined by the object, organizes movement.

Filippi and colleagues (2010) mapped gray matter volume changes associated with motor learning of goal-directed motor sequences and nonpurposeful motor actions in 31 healthy subjects. The goal-directed action group showed gray matter volume increase of the hippocampi as compared with those who learned nonpurposeful action, whereas the grey matter of the ones who learned nonpurposeful action increased in the inferior parietal lobule as compared with the goal-directed group. The researchers concluded that motor learning results in structural changes of the brain, the specific areas depending on whether learning involves a goal.

The speed or complexity parameters of the task also changes the organization of movement, as found through kinematic analysis of checker playing, in a sample of healthy elders (Ma & Trombly, 2004) and kinematic analysis of target pointing by 11 poststroke survivors (Massie & Malcolm, 2012).

In terms of motor responses, then, purposiveness, as transmitted by context, does appear to organize behavior and may affect brain structure and function. Of course, much more study is required to verify these ideas and confirm them to be true for other performance skills.

Evidence That Occupation-as-Means Motivates Participation

Although the meaningfulness of occupation to a person must be determined by interview and discussion with that person, *meaningfulness* has been operationalized in occupational therapy research in four ways: (1) provide enjoyment, (2) offer a choice, (3) offer the end product to keep, and (4) enhance the context or make the context more applicable to the person's life. The response, *motivation*, is operationally defined as the number of repetitions or length of time engaged in the occupation or the effort expended.

Fun or Enjoyment. Fun is immediately motivating. Several studies confirm that fun or enjoyment derived from play motivates attempts to perform an action or prolongs engagement in an action (Hoppes, 1997; King, 1993; Melchert-McKearnan et al., 2000; Omar, Hegazy, & Mokashi, 2012).

Choice. Provision of a choice presumably creates emotional value because the person is likely to choose an activity that is interesting and creative and/or arouses positive associations from the past. LaMore and Nelson (1993) found a significant increase in repetitions when 22 adult subjects with mental disabilities were given a limited choice of which ceramic object to paint (26 repetitions) as compared with being told to paint a particular one (17 repetitions). Zimmerer-Branum and Nelson (1995) gave 52 elderly nursing home residents a choice between a simulated basketball game chosen to encourage shoulder flexion and rote shoulder flexion exercises. After trying both, 69% chose the game for the actual treatment session. Choice or perceived control was also found to result in more effective and efficient performance in both younger and older adults whether the task was familiar or novel (Dickerson & Fisher, 1997). Pride of performance may be part of the motivating force when choice is offered.

Keeping an End Product. Presumably, letting a patient make a product that he or she can keep may motivate by arousing positive emotions or through the potential of gaining approval from others (Davis, 2010; Murphy et al., 1999).

Enriched Context. Enriched or natural contexts motivate through the positive emotions associated with familiarity and arousal of positive associations with one's home, culture, or previous life. Lang, Nelson, and Bush (1992) tested the responses of 15 elderly nursing home residents under three conditions: kicking a red balloon as one might do as a child, kicking a described imagined balloon, and exercise in which they kicked as demonstrated. A significantly greater number of repetitions was associated with really kicking the balloon (54) versus in the imagery or exercise conditions (26 and 18, respectively). This study was later replicated by DeKuiper, Nelson, and White (1993) with similar results. A number of other researchers demonstrated significantly greater numbers of repetitions or duration of performance under enhanced context conditions (Bloch, Smith, & Nelson, 1989; Kircher, 1984; Miller & Nelson, 1987; Steinbeck, 1986; Thomas, Vander Wyk, & Boyer, 1999; Yoder, Nelson, & Smith, 1989). Meaningfulness, as operationalized by fun and enjoyment, enriched or natural context, and possibly choice, appears to motivate continued performance, but much more research is needed.

EFFECTIVENESS OF THERAPEUTIC OCCUPATION

Long before there was scientific evidence, occupational therapists believed, based on personal experience and observation, that occupation maintained or restored health and gave meaning and quality to one's life through its organizational and attention demanding aspects (Laws, 2012; Rebeiro, 1998; Reilly, 1962/2011). Later, on the basis of deductive reasoning and anecdotal accounts, that belief was extended to include restoration of physical function through the biomechanical aspects of engagement in occupation. Occupational therapy started as a philosophically based profession and is now in the process of becoming a scientific, evidence-based profession (AOTA, 2007; Holm, 2000/2011; Laws, 2012). Although existing knowledge is primarily theoretical and little empirical support can be found in occupational therapy literature to substantiate the effectiveness of particular interventions (Orellano, Colón, & Arbesman, 2012; Stav et al., 2012), as occupational therapy approaches its 100th year, the research efforts of occupational and other scientists have begun to establish a solid experimental basis for the health-regaining action of occupation. For example, advances in technology have enabled neuroscientists, over the past 20 years, to examine brain function of humans engaged in functional occupations. This has resulted in remarkable advances in knowledge that the cortex is functionally and structurally plastic throughout life and that engaging—or not engaging—in behavioral experiences [occupation] modifies the brain's topography

and physiology (Nudo, 2007). To change the brain in a positive direction, that is, to enhance brain reorganization toward enabling better performance, the occupation must be meaningful and require effort or be challenging to the outer limits of one's capabilities but still within possibility (Nudo, 2007).

There is, however, an urgent need to experimentally verify the effects of occupation to cause particular changes and to promote a sense of well-being (Hammell, 2009; Orellano, Colón, & Arbesman, 2012). This is especially true concerning *how* occupational interventions cause the therapeutic change (Stav et al., 2012).

Evidence That Occupation Restores a Sense of Self-Efficacy or Self-Esteem

The qualitative study by Rebeiro and Cook (1999) provides the best evidence we have at this time that engagement in occupation restores a sense of self-efficacy and self-esteem. The participants were eight long-time members of an outpatient women's group at a mental health facility who engaged in a cooperative occupational project—making a quilt. On interview after 25 weeks of participation, the participants reported that engagement in the occupation gave them a sense of self-confidence and competency because of their accomplishment, which they did not have before the introduction of occupation to the group. The qualitative study of 12 persons with chronic obstructive pulmonary disease (COPD) by Leidy and Haase (1999) also found that purpose and meaning through activity resulted in a satisfying sense of wholeness and preservation of personal integrity.

Evidence That Occupation-as-End Restores Self-Maintenance, Self-Enhancement, and Self-Advancement Roles

Research Note 11-1 describes a review of studies on the effectiveness of occupational therapy to restore the role of independent person poststroke. In addition, Orellano, Colón, and Arbesman (2012) reviewed 38 studies, of which 82% offered level I evidence, to determine the effectiveness of occupation- and activity-based interventions on performance of instrumental activities of daily living (IADL) basic to role engagement by community-dwelling elders. They concluded that the evidence was moderate to strong in support of these interventions. Another systematic analysis of studies (Trombly & Ma, 2002) determined from 15 studies involving 895 elderly persons poststroke that there was a 16% increase in success rate for improved IADL and a 30% increase in success rate for improved basic activities of daily living or self-care as a result of home-based, task-specific, occupation-based training as compared with control conditions. Trombly, Radomski, and Davis (1998) and Trombly et al. (2002) studied the

Legg, L., Drummond, A., Leonardi-Bee, J., Gladman, J. R. F., Corr, S., Donkervoort, M., Edmans, J., Gilbertson, L., Jongbloed, L., Logan, P., Sackley, C., Walker, M., & Langhorne, P. (2007). Occupational therapy for patients with problems in personal activities of daily living after stroke: Systematic review of randomised trials. *British Medical Journal, 335,* 922–929.

Abstract

Objective: To determine whether occupational therapy focused specifically on personal activities of daily living [occupation-as-end] improves recovery for patients after stroke.

Design: Systematic review and meta-analysis.

Data sources: The Cochrane stroke group trials register, the Cochrane central register of controlled trials, Medline, Embase, CINAHL, PsychLIT, AMED, Wilson Social Sciences Abstracts, Science Citation Index, Social Science Citation Index, Arts and Humanities Citation Index, Dissertations Abstracts register, Occupational Therapy Research Index, reference lists, personal communication with authors, and manual reference searching.

Review methods: Trials were included if performance in personal activities of daily living was the target of occupational therapy intervention, delivered or supervised by a qualified occupational therapist, to a stroke population. Original data were obtained from authors of eight studies and reanalyzed to standardize outcomes.

Results: Out of a possible 14,593 studies, 9 randomized trials, which included 1,258 participants, met the inclusion criteria. Participants who received occupational therapy after stroke were significantly more independent in personal activities of daily living than those who received no intervention or "usual care." Performance scores increased (standardized mean difference = 0.18, 95% confidence interval = 0.04–0.32, $p = 0.01$) as a result of treatment (equivalent to approximately 1 point on the Barthel Index). The odds of a poor outcome were significantly lower in those who received occupational therapy as opposed to 42% of control participants who experienced poor outcome, defined as death, deterioration of ability to perform personal care, or requiring institutional care.

Conclusions: Occupational therapy that focuses on improving personal activities of daily living after stroke can improve performance and reduce risk of deterioration in these abilities.

Application to practice:

- Intervention using occupation-as-end to improve self-care in persons who have suffered stroke is effective.
- Persons who have suffered a stroke and do not receive targeted occupation-as-end intervention may become or remain dependent in self-care.
- Client-centered goal setting and task-specific practice are successful interventions. The studies reviewed included these interventions: teaching and practice of new skills for dressing, bathing mobility, etc.; provision and teaching the use of adapted equipment and/or clothing; practice of energy conservation methods; and homework to increase the intensity of practice.
- Some patients benefit more than others, so key predictive variables need to be determined.

achievement of valued IADL goals in persons with mild to moderate brain injury and found that goal-directed, occupation-based therapy resulted in achievement of 81% of all goals named by the participants. Levine and Gitlin (1993) reported that 17 randomly selected chronically disabled community-living elders engaged in a greater range of tasks such as wine making, visiting relatives, attending church, and cleaning after receiving home-based occupational therapy as compared to before the intervention. As a result of that program, they became more engaged in life, as shown by their volunteerism and increased social activities.

Evidence That Occupation-as-Means Remediates Impairments

Studies of the effects of occupation-as-means on persons with physical impairments are few and scattered. Some are presented as case reports. While offering the lowest level of evidence, case reports do serve as models for clinical reasoning (Earley, Herlache, & Skelton, 2010; Earley & Shannon, 2006).

One systematic review (Ma & Trombly, 2002) of 29 studies with 892 participants on the effects of occupational therapy on psychosocial, cognitive-perceptual, and sensorimotor impairments poststroke concluded that homemaking tasks resulted in greater improvement in cognitive ability than paper-and-pencil drills and that practice of movement to achieve a specific action goal had small to moderate positive effects ($r = 0.27$) compared with control conditions. Two studies of particular interventions that found positive outcomes are described in Evidence Table 11-1. Other studies of constraint-induced movement therapy, also successful for selected patients poststroke, are described in other chapters of this textbook. However, two studies in Evidence Table 11-1 failed to

Evidence Table 11-1 | Best Evidence Regarding Occupation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Occupation-as-end: Goal-specific training to achieve valued occupational goals	Experimental: Long-term activities of daily living (ADL) goals valued by the participants and carers and considered amenable by the staff were worked toward via a series of written contracts that specified interim and short-term goals. Carried out in homes, day centers, and work place by two occupational therapists, one physical therapist (PT), one speech-language pathologist, one psychologist, and one social worker. Control: Booklet that listed resources with those particular to the participant highlighted.	One hundred ten (75.5% male) community-dwelling persons with moderate to severe traumatic brain injury (TBI) aged 16–65 years, in acute to chronic stages of recovery. Randomized to group. Ninety-four (85%) available at 2-year follow-up, but only 75 (68%) available for analysis of BICRO-39.[a]	Two to 6 hours per week for a mean of 27 weeks for experimental group and one visit for control group. The independent variable was compromised because some of the patients in the control group received up to 1 month of experimental treatment before randomization.	Randomized controlled trial. Level IA3a	Yes. Practice of valued goal activities in a community setting yielded benefits to persons with severe TBI that outlived the active treatment period by at least 18 months.	Thirty-five percent of the experimental participants versus 20% of the control group improved from baseline to follow-up on the Barthel Index (Mann-Whitney $U = 831$, $p < 0.05$). The experimental participants scored significantly better at posttest than the control on the total BICRO-39 score (Mann-Whitney $U = 517$, $p < 0.05$) and self-organization (Mann-Whitney $U = 474$, $p < 0.05$) and psychological well-being (Mann-Whitney $U = 469$, $p < 0.05$) subscales. No improvements and no significant differences between groups on subscales of socializing or productive employment. Effect sizes could not be calculated from data provided.	Powell, Heslin, & Greenwood (2002)
Occupation-as-end: Group-based and individual task-specific dressing retraining	Group-based for outer garment dressing retraining supervised by two occupational therapists + individual occupational therapy (OT) treatments for training with underclothing and particular dressing problems. Multiple repetitions were encouraged.	Consecutive cohort of 119 patients; ~2 weeks poststroke, medically stable	Group: 1 hour twice weekly during admission. Mean = 4.0, 1-hour group sessions. No record of number of individual treatments.	Pretest–posttest design; retrospective analysis of data. Level IIIA3a	Yes. Task-specific practice of dressing tasks made a clinically important difference to dressing performance.	Three subgroups: upper body dressing, lower body dressing, and both upper and lower body dressing. All groups improved significantly ($p = 0.0001$) on the questions relating to dressing on the Functional Independence Measure (FIM). The effect size is estimated to be small to medium ($r = 0.34$).	Christie, Bedford, & McCluskey (2011)

Intervention	Description	Participants	Dosage	Design/Level	Findings	Results	Citation
Occupation-as-end: Occupation- and activity-based health management and health maintenance interventions	Interventions were within the scope of occupational therapy practice and included an activity- or occupation-based component	Twenty-eight articles met inclusion criteria of targeting health routines; 24 were level I randomized controlled trials.	NA	Systematic review. Level I	Yes. There is moderate to strong evidence that occupational therapy improves occupational performance related to health management.	NA; not a meta-analysis.	Arbesman & Mosley (2012)
Occupation-as-means: Game to increase arm reach	Condition #1: Participant reached to a point 3 inches above the center of the table placed to require full forward reach. Condition #2: Participant reached the same distance to play the Simon® computer-controlled game of flashing lights and sounds.	Twenty (17 men; 3 women) brain-injured adults with mild to moderate spasticity of the upper extremity	Ten trials of each condition in a laboratory setting	Nonrandomized, counterbalanced design. Level IIC2c	Yes. The use of the game elicited significantly more range of motion of the affected upper extremity than the rote exercise. The results support the use of an occupationally embedded intervention.	$t_{(19)} = 5.77, p < 0.001, r = 0.80$.	Sietsema et al. (1993)
Occupation-as-means: Game to decrease pronator spasticity and to increase supination (external rotation) range of motion	Experimental: Bilaterally assisted supination exercise in the context of a dice game that required the subjects to supinate to dump out the dice for a score. Control: Bilaterally assisted supination exercise using the same apparatus without the game.	Twenty-six women in acute stage after stroke (11 LCVA[a]; 15 RCVA[c]; mean age = 68.4 years. Participants were randomly assigned in a stratified balanced way to either the experimental or the control condition.	Two sets of 10 trials for each condition; different days	Randomized controlled trial. Level IC2c	Yes. Those who participated in the game demonstrated significantly greater handle rotation (supination) (95.3°) than the controls (81.9°).	Mean gain of 13.4° in handle rotation by the experimental group was significant ($p = 0.016, r = 0.42$).	Nelson et al. (1996)
Occupation-as-means: Hand Dance Pro™ gaming system to reduce upper extremity (UE) impairment and improve function	High repetitions (mean = 1,118 per session) of unilateral and bilateral reaching to targets coordinated to music and visual prompts with immediate performance feedback. Subjects seated at table; the up/down target buttons aligned with affected shoulder and placed to encourage maximum elbow extension. Trunk restrained to prevent substitution.	Nine persons post-stroke (chronic), categorized by Fugl-Meyer Upper Extremity Motor Assessment to mild (>50/66; $n = 3$), moderate (26–50/66; $n = 5$), or severe (<26/66). All able to actively raise the involved arm from side (0°) to 45° in any plane.	Fifteen 2-minute songs per session with at least 1-minute rest between songs; 18 sessions over 6 weeks.	Single group cohort pretest–posttest design. Level IIIC2b	Partially. The gaming intervention improved UE movement kinematics, but not clinical measures in this group. The subjects enjoyed playing the game and were motivated to improve scores. Carryover of kinematic improvements to functional tasks may require concurrent practice of those tasks.	Statistically significant ($p < 0.05$) improvements and medium to large effect sizes in kinematic measures of movement duration ($d = 0.67$,[d] velocity ($d = 0.97$, and elbow excursion ($d = 0.45$). Some subjects improved in performance time, grip strength, and hand function, but no significant differences for Wolf Motor Function Test ($d = 0.04–0.17$) or Stroke Impact Scale ($d = 0.08–0.34$).	Combs et al. (2012)

Evidence Table 11–1 | Best Evidence Regarding Occupation *(continued)*

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Occupation-as-means: Purposeful activities to improve gross and fine manual dexterity	Experimental: Task-oriented intervention to enhance arm function supervised by an occupational therapist. Patients identified activities they wanted to improve. If patients had voluntary movement, they actively practiced the tasks; if not, the therapist guided the limb through the tasks and modalities to facilitate muscle tone. Control: Walking program of 10 functional tasks supervised by a physical therapist All subjects had a home program to be done 15 minutes/day.	Ninety-one persons post-stroke (chronic) discharged from nine hospitals and two rehab centers; 44 were randomized to the control condition, and 47 were assigned to the arm training program. No requirement for voluntary movement in the arm for inclusion.[e]	Ninety-minute sessions, 3 times/week for 6 weeks. One on one.	Randomized controlled trial. Level IB3a	No. Those assigned to arm training did not improve their arm function to a greater extent than people assigned to walking training.	There was no significant difference in improvement between groups on Box & Block Test ($x^2 = 0.09$,[f] $df = 3$); the arm intervention group improved in measures of arm impairment, but not significantly more than controls and not a clinically significant amount.	Higgins et al. (2006)

df, degrees of freedom

find improvement in clinical measures of motor function. The study by Higgins et al. (2006) had many limitations, the most serious being that patients without any voluntary control of arm movement were included in the sample; some voluntary movement control is a basic prerequisite to regaining motor function. This study needs to be repeated under more controlled conditions. The study by Combs et al. (2012) found improvement in the organization of movement but not in clinical measures. The authors suggested that task-specific training may need to be combined with reaching training. It also may be that the intervention period was too brief (18 treatments) for the improvements in movement organization to translate into the more gross and observable improvements that the clinical measures assess. Clearly, much more research is needed.

IMPLEMENTATION OF THERAPEUTIC OCCUPATION IN PRACTICE

Occupation-as-end is implemented by teaching the activity or task directly, using whatever abilities the patient has or by providing whatever adaptations are necessary to enable performance. Because occupation occurs within a person-task-environment interaction, change in any one of these variables may result in successful performance. Implementation of occupation-as-end focuses on changing the task demands and/or the environment, whereas occupation-as-means focuses on changing the person. Therapeutic principles for application of occupation-as-end derive from cognitive information processing and learning theories. It was once called the rehabilitative approach (Trombly & Scott, 1977). In this approach, occupations are analyzed to ensure that they are within the capabilities of the patient, but they are not used to bring about change in these capabilities per se. The patient learns, with the help of the therapist as teacher and adaptor of the task demands and context. In the therapeutic encounter, the therapist:

- analyzes the task and environment to determine whether the task is within the person's capabilities in that environment
- organizes or modifies the environment or task demands to facilitate success
- organizes the subtasks to be learned so the person will succeed
- provides clear instructions
- provides feedback to promote successful outcome

- structures the practice to ensure improved performance and learning

To implement occupation-as-means, occupations of interest are analyzed to determine that they demand particular responses from the person and that the responses demanded are slightly more challenging than what the person can easily produce (see Chapter 12). The therapist provides the opportunity to engage in the potentially therapeutic occupation (Meyer, 1922/1977; Yerxa, 1966/2011), and as the person makes the effort and succeeds, the particular impairment the occupation-as-means was chosen to remediate is reduced. In the therapeutic encounter, the therapist:

- ascertains the patient's interests
- selects occupations that reflect those interests
- analyzes the occupations to determine which would be appropriate to achieve the patient's goal
- lets the patient choose from among several offered occupations
- instructs the patient in the correct procedure for doing the activity to derive the most therapeutic benefit
- grades the occupation to increase the challenge as the patient improves

Lyons, Phipps, and Berro (2004) described ways they organized one clinic to efficiently use occupation therapeutically. The treatment areas in the clinic were rearranged to resemble a homelike environment (e.g., bedroom, living room, and nursery). The therapists prepared "occupation kits," which were large plastic boxes containing all the props necessary to engage in an occupation. Occupation kits were made for gardening, letter writing, pet care, fishing, scrapbooking, and car care, which were the most commonly named activities by their clients. Furthermore, therapists in this clinic were encouraged to work with the patients in the various areas of the hospital campus and surrounding environment, the larger community, and the client's own community (e.g., barbershop, market, or place of worship) to provide meaningful occupation-based interventions in the clients' natural contexts. Davis (2010) also described her method of choosing meaningful and purposeful client-centered activities that successfully addressed the specific impairments of her patients.

The processes involved in using occupation therapeutically are activity analysis, selection and gradation, and adaptation. Guidelines for these processes are presented in Chapter 12.

case example
Ms. C.: Using Occupation Therapeutically

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Ms. C. is a 55-year-old, right-handed woman who began inpatient rehabilitation after a left cerebral vascular accident (LCVA). She was originally from the Philippines, where she worked as a school teacher. For the past few years, she has been living in the United States with one of her daughters.
Evaluation:

1. *Occupational history interview.* Ms. C. described her life through a series of stories, allowing her self-story to become evident. Several themes of meaning and important occupations emerged: (1) the theme of being a teacher, which was evident in her communication style, her previous role as teacher, and the educational play she described with her grandchildren; (2) the theme of cleanliness and efficiency, which was evident through her report that she had to finish all the housework before playing with her grandchildren; and (3) the theme of spirituality when she discussed the importance of daily church attendance.
2. *Description of a typical day* in chronological sequence revealed that her routine consisted of cooking breakfast for her granddaughters, doing housework, playing with her grandchildren, going to church in the evening, and sending text messages to her friends in the Philippines.
3. *Evaluation of impairments* revealed (1) decreased motor control but developing volitional movement throughout her right arm; (2) decreased sensation; (3) poor muscle tone of the right side of her body, although she was able to stand for short periods of time; (4) impaired but improving expressive language; and (5) poor executive cognitive functioning.

Objectives

Appreciate the context

Develop intervention hypotheses

Select an intervention approach

Reflect on competence

Examples of Therapist's Internal Dialogue

"Ms. C. is a relatively young woman who has experienced a stroke affecting her dominant side. She is depressed because she fears the loss of important roles and occupations. I chose to use a narrative approach to begin the evaluation so that I can understand Ms. C. as an occupational being and so that she can gain hope that someone is going to help her resume her life activities. Three themes of meaning emerged as she talked—teaching, home management, and spirituality. These will become important components of the treatment planning process."

"Occupation-based treatment will initiate the development of Ms. C.'s new view of herself as someone who could now continue to participate in her roles and occupations. This new vision of herself will lighten her depression and assist her in setting goals for her future. I notice that by providing Ms. C. with the opportunity to make decisions regarding her goals and preferences for treatment, she is becoming empowered and demonstrates increased motivation to participate in therapy."

"I will use a client-centered, occupation-based approach."

"I have treated many patients of Ms. C.'s age with similar disability. My client-centered, occupation-based approach has been universally successful with them; therefore, I am competent to treat Ms. C."

Recommendations

Ms. C. will attend inpatient occupational therapy for 60- to 90-minute treatment sessions, six times a week for 3 weeks.

The long-term goal is to return home and resume valued roles of grandmother, homemaker, and church attendee.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"I have helped Ms. C. notice that she is able to incorporate her returning motor, cognitive, and language skills directly into occupation-based treatment so that her impairments will improve as she relearns the activities and tasks of her valued roles. This pleases her."

"Intensive therapy during her brief inpatient hospitalization is warranted. Ms. C. agrees with this plan."

Summary of Short-Term Goals and Progress

Goal setting was accomplished using the COPM (Canadian Occupational Performance Measure). Ms. C.'s goals included the following most valued occupations:

1. performing household chores
2. cooking
3. storytelling with her grandchildren
4. sending text messages to the Philippines
5. going to church

The initial occupation-based session with Ms. C. involved engaging in household management occupations. To prepare for engaging in these roles at home, she began cleaning, vacuuming, and doing laundry in a homelike setting within the clinic.

A subsequent intervention session was held in a simulated living room environment. Her daughter brought her two children, along with some of their storybooks. During the session, Ms. C. had difficulty maintaining the attention of the children and physically calming them down. She then used her teaching skills to explain to her grandchildren her new participation level in her role as grandmother and taught them to help hold her right hand as they played together.

One of Ms. C.'s final intervention sessions involved going on a market outing to prepare for a cooking activity. This session provided Ms. C. with opportunities to relearn how to push a grocery cart, reach for and manipulate items in the store, attend to tasks despite increased ambient noise, and practice mobility within the store.

Next Steps

Again, using the COPM, these short-term goals were identified for outpatient rehabilitation:

1. clean the bottom of her bathtub
2. clean the bathroom sink
3. carry a heavy laundry basket
4. carry heavy grocery bags long distances
5. cut vegetables with her right dominant hand
6. write letters to friends in the Philippines
7. find transportation to attend church daily
8. kneel to pray and read the Bible in church

Know the person

"We are using occupation-as-means, so by performing valued activities, Ms. C. is improving motor control by incorporating her right arm into activity completion. She is also learning how to structure her day to complete the activities she wants to include in her day. She is using the household management occupation kit to practice opening containers of laundry products, which promotes fine motor skills as well as prepares her for an important activity. Vacuuming is challenging her dynamic balance. Ms. C. told me that she saw her new role as an assistant in home management so, through the use of occupation-as-end, Ms. C. is beginning to form a new self-identity and vision for her future."

Appreciate the context

"In the play session with her grandchildren, Ms. C. gained insight into the process of role resumption for this activity at home. In addition, her family was able to see her potential for participating in the children's play."

"The shopping session allowed Ms. C. to carry over some of the skills that she had learned in the clinic into the real world. The experience supported her continual formation of herself as an occupational being, and it provided her with hope for participation in this role."

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether he or she should continue or discontinue therapy and/or return in the future

"At discharge from inpatient rehabilitation, Ms. C. believed she would be able to return to her chosen occupations, such as self-care, light household management, playing with her grandchildren, and preparing light meals. She was able to initiate and integrate the use of her right side, so she expected she could participate in her typical day when she returned home. Armed with strategies and ideas regarding how to more fully participate in her life roles and occupations, she felt that she had a good foundation to return home.

However, Ms. C. found that the transition from the structure of the inpatient rehabilitation setting to home and community settings presented greater challenges to her participation than she had anticipated. She was tearful about diminished participation in occupations that held considerable meaning for her life. Outpatient occupational therapy was required, and I recommended that she be seen for 60- to 120-minute sessions, once a week for 4 weeks to facilitate the transition."

Clinical Reasoning in Occupational Therapy Practice

Implementing Therapeutic Occupation in Practice

One way to efficiently incorporate occupation into practice is to use "occupation kits" (Lyons, Phipps, & Berro, 2004; Rogers, 2007). Occupation kits are used to implement occupation-as-means or purposeful activity. Kits are made up of objects pertaining to a certain occupation, all contained in a box. They enable an occupational therapist to engage a person in valued activity without having to spend time in assembling the paraphernalia needed for that activity. For example, an occupation kit for the activity of wrapping gifts may include wrapping paper, tissue, ribbon, scissors, tape,

and boxes. Using the kit, the patient would practice wrapping and tying gift packages (Rogers, 2007). Describe the contents of occupation kits and the activity(ies) to be practiced for these interests:

- home repair
- baking
- grooming (male or female)

Design a kit for one of your favorite activities and share with the class.

Summary Review Questions

1. Define occupation and purposeful activity.
2. State some reasons why occupation is important in a person's life.
3. Are you in occupational balance? Which basis would you use to evaluate your own occupational balance—time, level of challenge, sociability, self/others, etc.?
4. Define occupation-as-end.
5. Define occupation-as-means.
6. Therapeutic occupation is both purposeful and meaningful. What effects do these qualities produce?
7. List two examples of evidence that occupation is therapeutic.

Glossary

Activity analysis—A process by which properties of a given activity, task, or occupation are identified for their ability to elicit targeted responses or enable a person to accomplish successfully.

Constraints—Limitations imposed on purposeful movement or the completion of occupational performance. Extrinsic constraints include the physical and sociocultural contexts and environments and task demands. Intrinsic constraints include personal factors such as biomechanical and neuromuscular aspects of a person's body (Newell, 1986), vision, sensation, cognition-perception, cardiorespiratory capacity, and so on (AOTA, 2008).

Habit—A habit is a performance pattern that is automatic (AOTA, 2008). It is a behavior pattern acquired by frequent repetition or physiologic exposure that shows itself in regularity or increased facility of performance (Merriam-Webster Online, 2012).

Occupation—The profession of occupational therapy uses the word, occupation, to capture the breadth and meaning of everyday activity (AOTA, 2008, p. 628). The term *occupation* encompasses activity (p. 629). Occupations have specific meaning and relevance to the client (Greening, 2009).

Purposeful activity—Purposeful activity is a general class of human actions that are goal directed. Purposeful activity involves specific components of occupations that help the client develop skills to enhance occupational engagement (Greening, 2009). They are activities that are goal directed and characterized by purpose and meaning as determined by the person participating in the activity (Omar, Hegazy, & Mokashi, 2012).

Task demands (activity demands)—The specific features of an activity that influence the type and amount of effort to perform the activity or that evoke certain maneuvers required to accomplish the goal of the task (AOTA, 2008). The features or context of an activity include the shape, size, texture, number of objects; the visual, auditory, physical or emotional impact of surroundings; the meaning of ritual associated with the activity; the size, shape, weight, configuration of tools; and the colors, textures, weight, familiarity, etc., of materials.

Velocity profile—A graph of time (e.g., seconds) versus speed of movement (e.g., mm/second), the latter being derived from position data recorded by kinematic instrumentation.

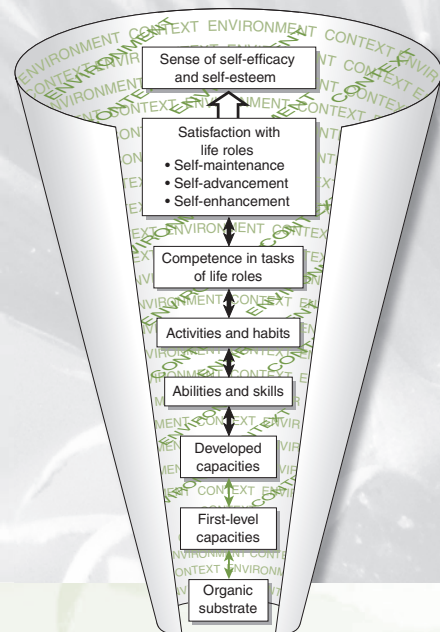
Occupation as Therapy: Selection, Gradation, Analysis, and Adaptation

Catherine Verrier Piersol

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Select occupation-as-means to achieve particular client-centered therapeutic outcomes.
2. Grade occupations/activities/tasks to challenge the person's abilities to improve performance.
3. Analyze occupations/activities/tasks to determine their therapeutic value for remediation of decreased abilities.
4. Analyze occupations/activities/tasks to determine whether they are within the capabilities of a particular person.
5. Adapt occupations/activities/tasks to increase their therapeutic value or to bring them within the capability of a person.
6. Apply the evidence that supports activity analysis and occupation as therapy.


Occupations are central to an individual's identity and competence and offer meaning and value (American Occupational Therapy Association [AOTA], 2008). As described in the previous chapter, occupation is the therapeutic medium of occupational therapy with the outcome of facilitating the patient's health and participation in life (AOTA, 2008). The therapist must select the appropriate occupation for the patient that will remediate a skill or ability (occupation-as-means) or enable performance of valued occupations (occupation-as-end) (AOTA, 2008; Trombly, 1995/2011). To be able to select an appropriate occupation, the therapist must be able to analyze activities. To improve decreased abilities, the occupation must appropriately challenge those abilities and continually be adjusted as the patient's performance changes. The therapist controls the challenge by grading the activity along particular therapeutic continua and/or by adapting the method. When the patient's impairments and limitations prevent usual engagement in the occupation, therapists adapt the activity demands and/or the contexts and environments in order to enable performance in a desired occupation (occupation-as-end). This chapter instructs how to select, analyze, grade, and adapt occupation.

SELECTION AND GRADATION

The therapist skilled in activity analysis can match the patient's abilities with activities and tasks the patient needs or wants to do (occupation-as-end) and select the most appropriate activity for remediation from those that are available and are of interest to the patient (occupation-as-means).

Selection of Occupation-as-End

Occupation-as-end activities and tasks are those that comprise the patient's perceived life roles. The patient and therapist identify key tasks and activities that would enable the patient to engage in his or her desired roles within a particular context and environment. Through activity analysis, the therapist matches the particular patient's capabilities and skills to the demand level of each activity and task. The comparison between activity demands within the usual context and environment and the patient's skills determines whether the patient will be able to perform the activity independently, with adaptation, or not at all. A person feels best when engaging in activity if his or her skills match the situational challenges posed by the activity and the challenge of the activity matches the person's skills—called "flow" by Csikszentmihalyi (1990; Engeser & Rheinberg, 2008; Moneta & Csikszentmihalyi, 1996).

Selection and Gradation of Occupation-as-Means

An activity that is to be used to restore one or more skills must be within the patient's capacity and challenge the patient's level of ability so that, through effort and/or practice, the patient's performance improves (see Definition 12-1). Some specific characteristics of the goals commonly addressed by occupational therapists who treat persons with physical disabilities are listed here and are summarized in Procedures for Practice 12-1. The dimensions along which the activity is to be graded are also listed. When more than one dimension is listed, the therapist should be careful to grade the changes one dimension at a time so that change in each dimension can be monitored and the patient has more of a chance at success. The best activity for remediation is one that intrinsically demands the exact response that has been determined to need improvement and that allows incremental gradations starting where the patient can be successful. Contrived methods of doing an ordinary activity to make it therapeutic may diminish the value of the activity in the eyes of the patient. Contrived methods also require the patient constantly to focus directly on the process rather than the goal of the activity, undermining the therapeutic value.

To Retrain Sensory Awareness and/or Discrimination

The activity must provide components that offer a variety of textures, shapes, and sizes, graded from large, distinct, common shapes to small, less common shapes with less distinct differences between them. The texture of the various objects should be graded from diverse to similar and coarse to smooth materials. The therapist must also involve the patient in a teaching–relearning interactive experience in which the characteristics of the objects are discussed and correct identification by touch is rewarded.

Definition 12-1

Characteristics of Therapeutic Occupation

Generally, activities should:
- have the necessary inherent characteristics to evoke the desired response
- allow gradation of response to progress the patient to the next level of performance
- be within the patient's capabilities
- be meaningful to the person
- be as repetitive as required to evoke the therapeutic benefit

Procedures for Practice 12-1

Selecting and Grading Therapeutic Occupation-as-Means

Remediation Goal	Key Factors of the Activity
To retrain sensory awareness and/or discrimination	Offer various textures, sizes, shapes. Grade from diverse to similar, coarse to smooth, large to small.
To decrease hypersensitivity	Offer various textures and degrees of hardness or softness. Grade from acceptable to barely tolerable.
To relearn skilled voluntary movement	Require sought-after, purposeful movement; allow feedback. Grade from simple to complex movements.
To increase coordination and dexterity	Require skilled motor actions the patient can control. Grade from slow, gross movement involving limited number of joints to fast, precise movement involving a greater number of joints.
To increase active range of motion (ROM)	Require repeated movement to the limit of range, graded to demand greater amounts of movement.
To increase passive ROM or elongate soft tissue contracture	Provide controlled stretch or traction. Grade from lesser to greater ROM.
To increase strength	Require movement or holding against resistance. Grade from lesser to greater resistance or from slow to fast movement.
To increase cardiopulmonary endurance	Use activities rated at the patient's current metabolic equivalent (MET) level. Grade by increasing duration, frequency, then intensity (METs).
To increase muscular endurance	Require repetitive movement or holding against 50% or less of maximal strength. Grade by increasing repetitions or duration.
To decrease edema	Allow use of the extremity in an elevated position and require isotonic contraction.
To improve perceptual impairments	Perform activities that require perceptual processing at the outside edge of current skill. Grade by complexity of stimuli.
To increase attention	Practice activities that are graded from less distracting to more distracting and from less time demand to more time demand.
To increase memory	Practice activities that are graded from simple to complex in terms of demand on the patient's ability to remember.
To improve problem solving	Practice activities that are graded from simple (one step) to complex (multiple steps), concrete to abstract, and familiar to unfamiliar. Higher level activity should include unexpected challenge.

To Decrease Hypersensitivity

The activity should involve objects or media whose textures can be graded from those that the patient perceives to be least noxious to textures perceived to be tolerably noxious. Another plan grades textures and objects from soft to hard to rough and grades the contact with the objects from touching them to rubbing them to tapping them.

To Relearn Skilled Voluntary Movement

Organization of voluntary movement depends both on the unique problem or purpose to be addressed and the constraints operating at a given time (Jordan & Newell, 2004; Newell, 1986). The activity must have a clear goal or purpose, demand the sought-after movement or movements, and offer the opportunity to self-monitor success (feedback). The contextual and task constraints should support natural

responses. Grading should provide increasingly more difficult motor challenges (e.g., moving the body in various directions, moving the limbs in various directions, isolated movement of particular joints, faster movement, more accurate movement in more challenging contexts, or greater number of submovements [Ma & Trombly, 2004]). Constraint-induced movement therapy (CIMT) is an approach used to progressively increase the function of a hemiplegic extremity in which the unaffected limb is purposefully restrained, thus forcing the use of the affected limb (Bolduc & Lawrence, 2011). Evidence supports a reduced level of disability, improved ability to use the paretic upper extremity, and enhanced spontaneity of movement in patients who receive a modified CIMT protocol (Shi et al., 2011). However, some kinematic data indicate that improved performance may be due to learned compensation rather than improved motor control (Kitago et al., 2012).

Sensorimotor learning requires practice, so opportunities for vast amounts of varied practice should be provided in treatment sessions and in a home program. The activity may provide an opportunity for practice simply through the accomplishment of the intended purpose. For example, weaving requires multiple passes of the shuttle to produce the desired product and offers repetitive practice of bilateral horizontal abduction and adduction. For other activities, the specific movement may be achieved quickly, so practice is sought through repetition of the whole action, as with ironing, polishing silverware, throwing a ball, putting cans on a shelf, and other activities of daily living. Variable practice promotes learning. Unvaried (blocked) practice improves performance within a session but does not generalize to long-term learning. Blocked practice is used, however, to begin to develop a new movement or skill (see Chapter 13).

To Increase Coordination and Dexterity

The activity should allow as much active range of motion (ROM) or skilled motor actions as the patient can control and allow grading from slow, gross motions to precise, fast movements involving greater skilled movement at more joints. At first, if the therapist is grading along the continuum of increasing speed, expect accuracy to suffer. A speed-accuracy trade-off is basic to the organization of the central nervous system (CNS) (Fitts, 1954).

To Increase Active Range of Motion

The activity must require that the part of the body being treated repeatedly move to its limit and is graded, naturally or through adaptations, to demand greater amounts of movement as the patient's limit changes.

To Increase Passive Range of Motion or Elongate Soft Tissue Contracture

The activity must provide controlled stretch or traction to the part being treated and be held at the end of range for several seconds. *Safety Message: Stretch should be slow and gentle to avoid tearing the tissue, causing inflammation, or increasing abnormal muscle tone*. Grade from lesser to greater range of motion (ROM).

To Increase Strength

Stress to muscle tissue increases strength. Stress can be graded by activities that increase the velocity and/or resistance needed to complete the activity or, for very weak muscles, by increasing the number of repetitions of an isotonic contraction or the amount of time an isometric contraction is held while performing the activity.

To Increase Cardiopulmonary Endurance

The metabolic demand of the activity (metabolic equivalent [MET] level) should match the patient's health status. The demand can be graded by increasing the duration of an activity, by increasing the frequency of doing the activity, by changing the muscles used in the activity (smaller muscles increase metabolic demand), or by increasing the intensity (METs). The metabolic intensities (METs) of 605 physical activities, including activities of daily living and sexual activity, occupation (work), transportation, volunteering, religious activities, and sports and recreational activities, have been measured and reported (Ainsworth et al., 1993, 2011).

To Increase Muscular Endurance

The activity must be repetitious over a controlled number of repetitions or duration. To increase muscle endurance, the resistance provided should be held to 50% or less of maximal strength.

To Decrease Edema

The activity should entail repetitive isotonic contractions of the muscles in the edematous portion of the body structure. An activity that requires repeated movement of the extremity into an elevated position helps to drain the fluid out of the extremity.

To Improve Perceptual Impairments

The activity should involve varied practice of information processing or perceptual processing at the outside edge of the person's capability. For example, if the person has impaired figure-ground discrimination skill, practice may start with detecting one object from a plain background (white sock on a black table) and progress through finding multiple objects on a plain background (various clothing items on a dark surface) or finding one object in more complex backgrounds (white sock in a drawer filled with clothes) until the person has developed the skill he or she

requires (e.g., able to find the scissors in a kitchen "junk" drawer). Gradation is along a continuum of increasing complexity (more stimuli).

To Increase Attention

Attention involves multiple capacities including noticing an environmental cue, sustaining attention over time, attending to relevant stimuli, alternating attention between different tasks, and keeping track of two or more items during an ongoing activity (Toglia, Golisz, & Goverover, 2009). An activity can be graded by increasing the demand in one or more of these capacity domains. For example performing an activity in a quiet room without distraction and increasing the demand by introducing extraneous noises. The amount of time the patient is able to sustain attention can be measured.

To Increase Memory

Memory is described as a multistep process including the encoding, storing, and retrieving of information (Levy, 2005). There are four types of memory that individuals use: working memory (e.g., temporary storage of information during an event or task), declarative memory (e.g., conscious memory of events and facts), procedural memory (e.g., unconscious memory of how to perform an activity), and prospective memory (e.g., remembering information for the future) (Toglia, Golisz, & Goverover, 2009). An activity should increasingly challenge the patient to encode, store, and retrieve information based on the type of memory needing remediation. Gradation occurs on a continuum from simple to complex. For example, remembering increasingly more activity steps or number of items/events.

To Improve Problem-Solving Strategies

Practice may start with simple activities that present concrete problems involving objects that the patient can see and touch, such as asking the patient to get soup out of a can, with soup can, manual can opener, and electrical can opener in clear view. The patient must determine that the can must be opened to get the soup, select a can opener, and figure out through exploration how to use the can opener. Gradation involves proceeding to more complex activities that require a higher level of abstraction, such as asking the person to make soup in an unfamiliar kitchen without obvious supplies. Further gradation can involve unexpected challenges for which the patient must solve a problem. For example, while preparing soup, something spills on the floor. Another example of an activity is to have a patient figure out how many pills he or she needs for the week if he or she should take one (or two or more) pill(s) every day. The pill bottle, calendar, and weekly pill minder container are present. The patient may solve the problem in one of several ways: using arithmetic (unlikely, because the patient may have other cognitive deficits); using a calendar; taking out the pill or pills for each day and lining them up on the calendar and counting them; or putting a pill in each compartment of the pill minder and then counting them. Gradation is along a continuum of concrete to abstract and few objects or ideas to multiple objects or ideas (see Chapter 24 for suggestions for particular impairments).

ANALYSIS

Activity analysis, or task analysis, is a fundamental skill of occupational therapists. Occupational therapists analyze an activity because they want to know (1) whether the patient, given certain abilities, can be expected to do the activity and (2) whether the activity can challenge latent abilities or capacities and thereby improve them. Through activity analysis, one gains an appreciation of the activity's components and characteristics (Greene, 1990).

Activity analysis developed from industrial time-and-motion study methods. Military occupational therapists applied these methods to rehabilitation of injured soldiers during World War I (Creighton, 1992) at the suggestion of Gilbreth and Gilbreth (1920), industrial engineers who observed injured soldiers in military hospitals. Gilbreth (1911) listed these steps for analyzing a task: "(1) Reduce practice to writing; (2) enumerate motions used; (3) enumerate variables which affect each motion" (p. 5). Variables considered were characteristics of the worker, the surroundings, and the motion. This method has been used by occupational therapists for many years when focusing the analysis on the activity. Other methods of occupational analyses that focus on the performance of the patient are performance analysis (Fisher & Bray Jones, 2010), ecological task analysis (Burton & Davis, 1996; Davis & Burton, 1991), and dynamic performance analysis (Polatajko, Mandich, & Martini, 2000), described below. Both activity and performance analyses entail unnesting the component tasks and activities that constitute the occupation and determining what abilities and skills are needed to do the specified activity or that may improve through the person's performance of the activity (Mayer, Keating, & Rapp, 1986; Trombly, 1995/2011).

The therapist begins the activity analysis by stating the purpose and by identifying the task demands, that is, the constraints that will control or impinge on performance. Some constraints to be considered are the size and type of tools, placement of the selected tools and equipment in relation to the patient, the speed at which the activity is to be accomplished, the complexity of the task, and the physical and/or social environment in which it will be carried out. Changes in any of these variables change the task demands and require a different analysis. The prerequisite abilities and capacities for accomplishing

the whole activity are identified. If these prerequisite abilities are lacking and the goal is to accomplish the activity (occupation-as-end), then the way the goal is to be accomplished would have to be modified (e.g., if the patient is blind). Alternatively, if the goal is to improve one or more of the required abilities (occupation-as-means), then the activity would be adapted to reduce the demands to just challenge the patient's level of performance.

In order to capture different types of activity analysis, three perspectives are helpful: (1) activity-focused analysis, (2) client-focused activity analysis, and (3) environment-client focused activity analysis. *Activity-focused analysis* focuses on the activity itself without considering the characteristics of the client or his or her environment and is used to develop a repertoire of therapeutic activity interventions (see Procedures for Practice 12-2 and 12-3). *Client-focused*

activity analysis focuses on the therapeutic utilization of the activity for a particular client toward a specific therapeutic goal, an occupation-as-means intervention (see Procedures for Practice 12-4 and 12-5). Alternately, the *environment-client focused activity analysis* is an occupation-as-end approach that focuses on the fit between the person and the environment with regard to the activity in order to determine and/or optimize the potential for successful performance (see Procedures for Practice 12-6 and 12-7).

Analyzing the activity in order to determine the abilities and capacities required to carry out the activity presupposes that activities have reliably identifiable inherent therapeutic qualities. This belief is stated in a position paper of the AOTA (1995): "Whether physical or mental in nature, the behaviors necessary for completion of tasks in daily occupations can be analyzed according

Procedures for Practice 12-2

Activity-Focused Analysis

1. Describe the activity
2. Describe the task demands
   - Objects used: What are the properties of the utensils, tools, and materials and their locations relative to the person?
   - Environmental demands: What are the characteristics of the environment in which the activity is usually performed, including possible environmental barriers and enablers?
   - Social demands: What is the nature of and extent to which the activity involves others and/or holds particular meaning associated with social roles?
   - Contextual demands
   - Sequencing and timing
   - Required actions: What are the steps of the activity?
   - Prerequisite capabilities, abilities, and skills (sensorimotor, visual-perceptual, cognitive, or emotional/relational)
   - Safety precautions
3. Identify the primary therapeutic aspects of the activity/adapt activity demands to align with therapy goals
   - Sensorimotor (ROM, strength, motor control, postural control, endurance, or coordination/dexterity). If analysis of specific muscular requirements is required, complete a biomechanical activity-focused analysis, which describes the biomechanical internal constraints for the most therapeutic or repetitive step, using the table below. Include what must be stabilized to enable doing this activity and how that stabilization will be provided. If appropriate, estimate the MET level of the activity.

Motions	ROM	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction

   - Visual-perceptual (visual scanning, perception of objects in space, and awareness of extrapersonal space)
   - Cognitive (attention, memory, executive functioning, problem solving, and awareness)
   - Emotional/relational (mood, engagement, and interactions with others)
4. Modify the activity demands to calibrate difficulty level
   - Objects used
   - Space demands
   - Social demands
   - Contextual demands
   - Sequencing and timing

◉ Procedures for Practice 12-3

Activity-Focused Analysis: Vacuuming the Hallway Carpet

Task Analysis Process			Example
Describe the task demands	Objects used	Properties of the utensils, tools, and materials and their locations relative to the person	*Lightweight upright vacuum cleaner with 25-foot cord* *Stored in closet next to the area to be cleaned*
	Environmental demands	Characteristics of the environment in which the activity usually is carried out, including possible environmental barriers and enablers	*The hallway is 30 feet long and 3 feet wide* *The electrical outlet is halfway between the two ends of the hallway, 5 inches from the floor* *No furniture is in the way* *The carpet is a low pile type*
	Social demands	Nature of and extent to which the activity involves others and/or holds particular meaning associated with social roles	*Does not require the participation of others* *Vacuuming may fulfill a valued role*
	Contextual demands	Nature of and extent to which the activity or the way it is carried out holds particular meaning to certain cultures or age groups	*The person takes pride in a clean, well-vacuumed home* *The person is not willing to switch to a lighter, nonmotorized carpet sweeper because of the belief that it does not do a thorough job*
	Sequencing and timing	Monological task (requiring a singular sequence in order to be performed correctly) or a multilogical task in which a variety of sequences will work Extent to which the task involves temporal requirements or timing requirements	*Monological—there are not many alternative approaches or sequences that will satisfy the task requirements* *Can be completed in one therapy session* *There is no limiting time factor involved in the activity under normal circumstances*
	Required actions	Steps that comprise the activity	*1. Retrieve the vacuum cleaner from the closet* *2. Unwind the electric cord* *3. Plug cord into wall outlet* *4. Adjust height of vacuum cleaner for carpet use* *5. Turn on vacuum cleaner* *6. Push vacuum cleaner back and forth* *7. Move vacuum on carpet to complete entire carpet* *8. Unplug cord from outlet* *9. Wind cord on vacuum cleaner* *10. Place vacuum cleaner in closet*

Procedures for Practice 12-3 *(continued)*

Activity-Focused Analysis: Vacuuming the Hallway Carpet

Task Analysis Process			Example
Prerequisite capacities, abilities, and skills necessary to successful task performance		Sensorimotor: range of motion, strength, motor control, postural control, endurance, and coordination/dexterity	*Volitional function of at least one upper extremity to move against gravity with moderate resistance; shoulder flexion/extension, elbow flexion/extension, scapular protraction/retraction, cylindrical grasp, and wrist stabilization*
			Trunk flexion/extension
			Standing balance
			Ambulation forward/backward
			Estimated required 2–3 MET level
		Vision-perception: visual acuity, visual scanning, visual perception, and awareness of extrapersonal space	*Visual proficiency in acuity, scanning, and perception (figure-ground, spatial relations)*
		Cognitive: attention, memory, executive functioning, problem solving, and self-awareness	*Procedural memory of how to use a vacuum cleaner*
			Ability to sustain attention for 10–15 minutes
			Ability to complete multistep activity
			Ability to problem solve
		Emotional, relational	*The person takes pride in a clean, well-vacuumed home*
			Performed without social interaction
	Safety precautions	Nature of safety considerations if performed in a therapy context	*Patients may need guarding/supervision and rest periods related to balance and/or endurance*
			Patients may need cueing related to cognition
			Patient my need adaptations because of low back pain
Identify the primary therapeutic aspect of the task; adapt task demands to align with therapy goals	Sensorimotor Refer to The biomechanical activity-focused analysis mentioned later in this table for specific muscular requirements	Range of motion	*Upper extremity is moved to its limit while vacuuming*
		Strength, motor control	*Use a heavier vacuum cleaner*
			Vacuum a thicker pile carpet
			Lift objects out of the way to vacuum
		Postural control, endurance	*Bend to reach outlet and behind furniture*
			Increase the time spent vacuuming
		Coordination, dexterity	*Place furniture in the area so patient has to change directions of the vacuum to go around obstacles*
			Larger or smaller handled vacuum cleaner
			Type of on/off switch

Procedures for Practice 12-3 *(continued)*

Task Analysis Process			Example
	Vision-perception	Visual scanning	*Find vacuum cleaner in cluttered closet*
			Items that need to be picked up before vacuuming are placed on the carpet
		Visual perception, extrapersonal space	*Spread "dirt" that is in contrast or similar to the color of the carpet*
			Place objects that cannot be moved on the carpet so the patient must move around them
	Cognition	Attention, memory	*Add distractions during the vacuuming activity, e.g., additional noise in the room*
			Interrupt the patient during the activity, e.g., someone asks the patient a question
		Executive functioning, problem solving, awareness	*Use an unfamiliar vacuum cleaner so patient must figure out how to use it*
			Have the patient predict performance before task performance and analyze the performance after completion of task
	Emotional-relational	Mood, engagement, interactions with others	*Patient expresses pride in accomplishment*
Modify task demands to calibrate difficulty level	Objects used		*Weight and size of vacuum cleaner*
			Type of vacuum cleaner handle and control switches
			Low or high pile carpet
	Space demands		*Size of space to be vacuumed, e.g., hallway and living room*
	Social demands		*NA*
	Contextual demands		*Set personal goal to complete vacuuming activity by a certain time*
	Sequencing and timing		*Set specific time parameters to vacuum a certain amount of carpet in a designated amount of time*

Biomechanical Activity-Focused Analysis

Motions	ROM (degrees), Distances	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction
Shoulder flexion	0–75	Anterior deltoid, coraco-brachialis, pectoralis major	Resists	4− to 4	Concentric
Elbow extension	90–0	Triceps	Assists	4− to 4	Concentric
Scapular protraction	1.5 inches	Serratus anterior	No effect	4− to 4	Concentric

Procedures for Practice 12-3 *(continued)*

Biomechanical Activity-Focused Analysis

Motions	ROM (degrees), Distances	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction
Shoulder extension	0–45	Posterior deltoid Latissimus dorsi Teres major	Assists No effect Resists	4− to 4	Concentric
Elbow flexion	90–120	Biceps, brachialis	Resists	4− to 4	Concentric
Scapular retraction	1.5 inches	Middle trapezius	No effect	4− to 4	Concentric
Cylindrical grasp		Finger flexors, finger extensors, interossei	No effect	4− to 4	Isometric
Wrist stabilize		All wrist muscles	No effect	4− to 4	Isometric
Trunk flexion	0–30	Back extensors	Assists	3+ to 4−	Eccentric
Trunk extension	30–0	Back extensors	Resists	4− to 4	Concentric

Procedures for Practice 12-4

Client-Focused Activity Analysis

1. Specify the primary goal that this task is intended to advance through client performance
2. Specify which primary ability and/or capacity the task is intended to challenge:
   - ROM
   - strength
   - motor behavior
   - praxis
   - sensation
   - vision-visual perception
   - cognition
3. Evaluate the therapeutic value of activity based on these characteristics:
   - inherently evoke desired response
   - be gradable to progress the patient to higher function
   - be within patient's capabilities
   - be meaningful
   - be repetitive
4. Specify task parameters to calibrate difficulty level of the task:
   - method of instruction
   - nature and level of cueing
   - objects and their properties (materials and equipment)
   - environmental demands
   - social demands
   - sequence and timing
   - required actions and performance skills
   - required body functions
   - required body structures
   - context or environment

Procedures for Practice 12-5

Client-Focused Activity Analysis: Meal-Preparation Task to Improve Ability to Compensate for Memory Problems

Patient Information

D.B. (a 26-year-old man, 3 months post-traumatic brain injury) participated in an outpatient occupational therapy (OT) assessment, and these problems were identified: (1) decreased initiation of activities of daily living (ADL) and instrumental ADL (IADL), (2) decreased productivity because of poor stamina and limited appropriate avocational outlets, (3) memory impairment and inadequate repertoire of memory compensation strategies, and (4) decreased awareness of cognitive deficits interfering with compensatory strategy use. The therapist decided to incorporate task performance into the intervention plan to help advance D.B.'s progress toward the following goal: *D.B. will independently initiate note-taking when presented with occupational therapy homework (at least 60% of the time) and thereby improve his follow-through on intended tasks.*

	Task Analysis Process	Intervention Planning	Clinical Transactions: Preparation for and Interactions at the OT Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
S E L E C T I O N	Specify the primary goal that performing this task is intended to advance	Improve ability to follow novel instructions after a time delay	The therapist selected a meal preparation task as a venue for building note-taking skills. The therapist decided to focus on the instruction giving/taking aspect of the meal preparation task.	"The therapeutic aim of this task is to develop the skills of note-taking. I am not specifically training D.B. to cook but am using a meal preparation task as occupation-as-means as one way to help him learn when and how to take effective notes. That said, he has told me in the past that he would like to learn more about cooking, and so I thought that this task would be of some interest to him." "I want to create a situation in which D.B. needs to take effective notes in order to successfully complete a task that he is interested in. I believe that this experience will help him learn to compensate for his memory problems and heighten his appreciation of the need to take notes with adequate detail."
	Specify the primary abilities and capacities that the task is intended to challenge: • ROM • Strength • Motor behavior • Praxis • Sensation • Vision-visual perception • Cognition	Cognition	The therapist built memory demands into the task in order to build D.B.'s skills with cognitive compensatory strategies.	"I am not at all concerned about the physical challenges of this task, but I am setting it up so that it challenges self-awareness and D.B.'s note-taking and organizational skills."

Procedures for Practice 12-5 *(continued)*

	Task Analysis Process	Intervention Planning	Clinical Transactions: Preparation for and Interactions at the OT Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
A N A L Y S I S	Evaluate the therapeutic value of activity based on these characteristics: ● Inherently evoke desired response ● Be gradable to progress the patient to higher function ● Be within patient's capabilities ● Be meaningful ● Be repetitive	Use of multi-step, multi-ingredient task that relates to D.B.'s personal goal and involves structured, personal choice	Prior to the session, the therapist preselected five main dish recipes that D.B. could likely prepare in 30 minutes or less. Each involved less than six ingredients and involved some details that will be new to D.B. At the OT session, the therapist asked D.B. which of the five main dishes he wanted to prepare at a subsequent session. He selected a stovetop pasta dish involving sautéed shrimp and vegetables.	"I thought it was important that I set up the parameters of this task so that D.B. could be challenged and yet successful. I have learned from past experience that with too much choice, some patients select food to prepare that is way beyond their skill level or the time available for the treatment session." "I used unfamiliar recipes because I hope that he will remember that when faced with an unfamiliar task, he should take detailed notes to guide future performance."
G R A D A T I O N & A D A P T A T I O N	Specify task parameters to calibrate difficulty level of the task: ● Method of instruction ● Nature and level of cueing ● Objects and their properties (materials and equipment) ● Space demands ● Social demands ● Sequence and timing ● Required actions and performance skills ● Required body functions ● Required body structures ● Context or environment	Oral instructions evoke the desired response of awareness of the need to take notes as will building in a delay between instruction and performance.	After discussing that D.B. would prepare the dish at his next outpatient OT session, the therapist orally presented the task (recipe) instructions. Grocery items that D.B. was to purchase and bring to the session were also orally presented. In order to make the task simpler, the therapist ensured that the treatment sessions were carried out in a quiet place where interruptions were minimal. If D.B. had too much difficulty with note-taking, the therapist planned to grade the task to make it easier by giving him written recipes that included some but not all of the details. If the task of taking and relying on notes was easily accomplished by D.B., the therapist was prepared to grade the task difficulty by adding nonobvious substeps to the cooking task that D.B. would likely perform only if he had taken notes with adequate detail and thought to refer to them.	"I am using oral instructions (rather than providing a written copy of the recipe) so that the task will challenge D.B.'s awareness that he needs to take notes that are usable in the future. I am also building in a delay by providing the instructions at one session and asking him to actually perform the task at a session next week. This will increase the likelihood that he will realize that he needs to rely on his notes rather than his memory and that the notes need to be of a quality that will enable performance." "It can be very difficult or stressful for some people to take written notes on a lot of unfamiliar information. If this is the case with D.B., he can use a written copy of some bare-bones notes that I have prepared and add any additional information that he needs. This will also give me a sense of how aware he is of his need for note-taking." "If this task proves to be too easy for D.B., I will add some prospective memory demands by asking him to step away from the task after sautéing the vegetables and call my voice mail to leave me a message about how it is going and then return to the task. I am trying to create a situation in which D.B. must rely on his notes rather than proceeding on his own instincts."

Procedures for Practice 12-6

Environment-Client-Focused Activity Analysis

1. Specify the task that the person wants or needs to perform in a given environment
2. Specify the performance environments (e.g., environment in which the client will perform the desired activity or environment in which the therapy session with occur)
3. Evaluate the barriers or enablers to performance of this activity in this environment:
   - task
   - environment
   - person
4. Determine solutions that will enable performance:
   - person
   - environment
   - task

5. Specify task and environmental parameters to calibrate difficulty level:
   - method of instruction
   - nature and level of cueing
   - objects and their properties (materials, equipment)
   - space demands
   - social demands
   - sequence and timing
   - required actions and performance skills
   - required body functions
   - familiar or novel task or environment
   - known adaptations or specifics to design & build the needed adaptation

Procedures for Practice 12-7

Environment-Client Focused Activity Analysis: Advancing Homemaker Role

Patient Information

Mrs. B. is a 45-year-old woman who sustained a right-sided cerebrovascular accident 2 months ago. After inpatient rehabilitation, she was discharged home. She lives with her husband, who works full-time, and daughter who is a senior in high school. Mr. B. would like to hire a housekeeper to help with the housekeeping, but finances are tight. Both he and their daughter are managing to do the household tasks now, but Mrs. B. realizes that they are fatigued by this extra burden. Prior to her stroke, Mrs. B. prided herself on her ability to care for her family and home. She has been referred to home care and is working with an occupational therapist to address her desire to recover her role as homemaker.

	Task Analysis Process	Intervention Planning	Therapeutic Transactions: Preparation for and Interactions at the OT Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
S E L E C T I O N	Specify the task that the person needs or wants to perform in a given environment	Mrs. B. wants to assist daughter in meal preparation activities (occupation-as-end) in her own home and to eventually regain her homemaker role, of which meal preparation is a key task. Mrs. B. likes to cook and has been feeling bad that her daughter has been doing the meal preparation.	In consultation with Mrs. B., the therapist selected preparation of bagged lunches for Mrs. B.'s daughter and husband and making lunch for herself.	"Mrs. B. is aware of the burden that her family feels because they have to do so many of the tasks she ordinarily did before her stroke. It is important to her to lessen that burden as well as to recover her homemaker role."
	Specify the performance environments (environment in which the patient will perform the desired activity; environment in which the therapy session will occur)	The therapy session will occur in the kitchen of Mrs. B.'s home, which is where she will ultimately perform the task.		"Being able to work with Mrs. B. in her home will eliminate any potential performance problems associated with an unfamiliar environment."

Procedures for Practice 12-7 *(continued)*

Task Analysis Process		Intervention Planning	Therapeutic Transactions: Preparation for and Interactions at the OT Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
A N A L Y S I S	Evaluate the barriers or enablers to performance of this activity in this environment: ● Task ● Environment ● Person	Barriers: ● Mrs. B.'s left hand is weak for grasping objects and her standing tolerance is limited to 10 minutes. ● Mrs. B. has a throw rug in front of her sink, which may be a hazard. ● Mr. B. is very interested in supporting his wife, but his presence in the kitchen appears to distract the client. Enablers: ● Mrs. B. has intact visual perception and cognition. ● Her kitchen has ample counter space with utility drawers located under the counter where Mrs. B. could work. A refrigerator is located to the left of the counter space. ● Selected task is time limited, and adaptations can be used to minimize effects of poor standing tolerance and weak left hand	Materials required: ● High stool ● Cutting board with corner guards ● Bread ● Condiments ● Luncheon meat ● Fruit ● Napkins ● Knife ● Dishes ● Paper bags ● Mounted jar opener Safety precautions: ● Guard Mrs. B. when she gets onto stool and when she walks to refrigerator ● Cover the spikes on the cutting board with corks to prevent cuts	"Before we get started, I want to optimize some aspects of the work environment. I have asked Mrs. B. if we can remove the throw rug and asked that Mr. B. join us in the kitchen at the end of our session. I need to instruct Mrs. B. in the use of the cutting board with guards to 'trap' the bread while she spreads the condiments on each slice and how to use the mounted jar opener, which will compensate for the weakness in her left hand. As she is right-hand dominant, I will encourage her to use her left arm and hand as an assist during the activity. I need to teach Mrs. B. how to use her body to hold the refrigerator door open as she gets the items out. I will watch Mrs. B. carefully as she moves about the kitchen and gets onto the stool. I will not 'hover,' but allow Mrs. B. to solve some of the problems she will encounter if she can. In that way, she will gain confidence, and the learning will generalize to other activities."
	Determine solutions that will enable performance: ● Person ● Environment ● Task	Solutions: ● Sit to work to relieve fatigue and increase safety ● Use a cutting board with corner guards to compensate for weak left hand ● Use a mounted jar opener to compensate for weak left hand ● Ensure that the countertop is uncluttered to ease performance (remove clutter if necessary)

	Task Analysis Process	Intervention Planning	Therapeutic Transactions: Preparation for and Interactions at the OT Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
G R A D A T I O N	Specify task and environmental parameters to calibrate difficulty level: • Method of instruction • Nature and level of cueing • Objects and their properties (materials and equipment) • Space demands • Social demands • Sequence and timing • Required actions and performance skills • Required body functions • Familiar or novel task or environment • Known adaptations or specifics to design and build the needed adaptation	To advance Mrs. B. toward greater involvement in her valued role as homemaker, food preparation activities can be graded by changing the number of objects and their properties (size, weight, shape, and texture), by changing required actions and performance skills (stand for longer periods of time), and later by changing the novelty of the recipe.	Challenge Mrs. B. to include sliced tomato and lettuce in the sandwiches, using the cutting board to hold the tomato and a proper knife. Materials needed: • Cutting board • Tomato • Several knives from which to choose the correct one • Sandwich materials as above • Stool Challenge Mrs. B. to prepare a salad that requires handling and preparing different sizes and shapes of vegetables or fruits and a large bowl. Materials needed: • Large bowl • Variety of vegetables or fruits • Cutting board • Knives • Stool	"I want to see if Mrs. B. will remember to use the cutting board. If she does not, I will coach her. I will coach her to use the safest knife for cutting the tomato." "When preparing the salad, I will want to see her solve how to position each differently shaped fruit or vegetable to cut it. I will coach her to move the large bowl by sliding rather than lifting."

to specific components related to moving, perceiving, thinking, and feeling" (p. 1015). Although tasks and activities require particular performance skills, abilities, and capacities, identification of these (activity analysis) is a high-level skill that requires practice under supervision.

Activity-Focused Analysis

Using an analytical approach, the therapist examines an activity to determine its components and the level of ability and skill demanded. The outcome can be used to select activities for remediation or to match a particular person's skills with the demands of the activity.

All analyses should occur within some conceptual framework to give them direction, coherence, and meaning (Mosey, 1981). For example, planting a tulip bulb in a plant pot can be analyzed from various frames of reference. The biomechanical approach prompts the therapist to examine the physical requirements, such as grasp, coordination, and ROM, whereas the cognitive-perceptual approach examines the activity according to its cognitive or

perceptual demands, such as attention, problem-solving, and spatial requirements.

Whereas biomechanical analysis observes joint ROM and estimates muscle contraction used to carry out the activity based on knowledge of anatomy and kinesiology, electromyographic (EMG) and kinematic research indicates that this type of analysis may not be wholly valid because of individual differences in muscle action and differences in movement strategies secondary to learning, maturation, injury, and perception of goal (Illyes & Kiss, 2005; Jordan & Newell, 2004; Kelly et al., 2005; Trombly & Quintana, 1983) that are not detectable by an observer without instrumentation. Each person's CNS plans movement to accomplish the goal with the resources the person has. Reaching for a glass of milk on the table may or may not activate the anterior deltoid. If that muscle is weak, the patient may accomplish the goal by substituting other muscles or strategies, such as turning sidewise to the table to make use of the stronger middle deltoid to reach the glass. The substitutions listed in the muscle testing section are common ways people accomplish the movement goal when the prime mover is weak. The idea that doing a certain activity will always exercise a certain weak muscle may be naive. If it is essential that a particular muscle of a particular patient be contracting to a certain level of activity, as may be the case in tendon transfer rehabilitation, it is best to monitor the muscle directly using EMG biofeedback as the patient does the activity (Trombly & Cole, 1979; Trombly & Quintana, 1983) (see Chapter 19).

On average, certain motions and muscle actions are more probable than others, and therefore, an analysis can be based on observation if the therapist realizes that actual performance of a particular patient must be verified and not assumed. As instrumentation to measure human movement is too complex to be used clinically at this time; by default, the traditional biomechanical activity-focused analysis continues to be the method used by practicing therapists and is described in Procedures for Practice 12-2 and 12-3.

The first step of an activity analysis is to identify the exact activity. Next, a detailed description of the task demands is completed, followed by the primary therapeutic aspects of the task, and finally the gradations to task demands that can calibrate the level of difficulty or challenge. If analysis of specific motor requirements is required (e.g., ROM and strength), a specialized biomechanical analysis should be completed, as done in Procedures for Practice 12-3, in which the potential repetitions of each motion are noted. Only the sixth step of the activity, pushing the vacuum cleaner back and forth, would be analyzed biomechanically if vacuuming were going to be used as occupation-as-means because it is the repetitive, therapeutic aspect of this activity. The other steps occur too infrequently to be therapeutic. Each repetitive step is subdivided into motions. For

example, pushing the vacuum back and forth involves shoulder flexion with elbow extension, shoulder extension with elbow flexion, and trunk flexion and extension, although trunk movement may be eliminated, depending on how the person moves in relation to the machine. Wrist stabilization (cocontraction) in extension and cylindrical grasp are also "motions" associated with vacuuming.

The range of each motion is estimated by observing another person or by doing the activity oneself. Each motion is further analyzed to determine which muscle or muscles are likely responsible, based on anatomical, kinesiological, and electromyographical knowledge. Examining the effect of gravity allows estimation of the minimal strength necessary to do the motion. The kind of contraction demanded for each muscle group in each motion is established by definition.

Activities selected to restore motor function must also take into account the person's cognitive and perceptual skills, emotional status, cultural background, and interests. An analysis of the cognitive functions required for the activity should include the number and complexity of the steps involved in doing the activity, the requirements for organizing and sequencing of the steps or stimuli, and the amount of concentration and memory required. Some perceptual factors to be considered are whether the activity requires the patient to distinguish figure from ground, determine position in space, construct a two- or three-dimensional object, or follow verbal or spatial directions. Other cognitive-perceptual considerations are found in Chapters 23 and 24. Some psychosocial aspects of an activity that may be important to patients include whether the activity must be done alone or in a group, the length of time required to complete the activity, whether fine detailed work or large expansive movements are involved, how easily errors can be corrected, the value of the activity from the person's particular cultural and social background, and the likelihood of producing a satisfying outcome.

Other methods of analysis of activities have been published. Gentile (2000) has provided a detailed taxonomy of task analysis to be used for evaluation and selection of functionally relevant activities. The taxonomy is related to the learning of motor tasks. Her taxonomy is briefly described here, although the reader should see the original material for a complete description and rationale. The taxonomy consists of 16 categories composed of movement types and environmental regulatory constraints. The dimensions of environmental regulation and movement type are presented separately in Definition 12-2 for the sake of clarity, but they are meant to be combined. The easiest tasks are repetitive ones done in a stationary environment with the body in a stable position, such as sitting and brushing one's hair. Tasks are

Definition 12-2

Examples of Tasks Described According to the Taxonomy of Gentile

Environmental Regulatory Dimension

Environmental Regulatory Conditions during Performance	*No Differences in Performance between Trials*	*Differences in Performance between Trials*
Stationary: objects, people, and/or apparatus do not move	**Closed tasks** Climbing stairs at home Brushing teeth Unlocking the front door Turning on the bedroom light	Tasks in which objects are different but stationary during performance: Walking on different surfaces Drinking from mugs, glasses, cups Putting on shirt, sweater
Motion: objects, people, and/or apparatus move	Tasks in which objects move consistently over repeated encounters: Stepping onto an escalator Lifting luggage from the conveyer belt at the airport Moving through a revolving door	**Open Tasks** Propelling a wheelchair down a crowded hall Catching a ball Carrying a wiggling child

Movement Type Dimension

Body Orientation	*No Manipulation*	*Manipulation*
Stability: body is positioned in one place	Body stability: Sit Stand Lean on table	Body stability plus manipulation: Hold object while standing Reach for hairbrush while sitting Using a keyboard while sitting at a computer
Transport: body is moving through space	Body transport: Walk Run Drive an automobile Propel wheelchair	Body transport plus manipulation: Run to catch a ball Dial phone while walking

Skill acquisition: Action, movement and neuromotor processes. In J. H. Carr, R. B. Shepherd, J. Gordon, A. M. Gentile, & J. M. Held (Eds.), *Movement science: Foundations for physical therapy in rehabilitation* (2nd ed., pp. 111–187). Rockville, MD: Aspen Systems.

graded by changing the various parameters one at a time (e.g., environmental regulatory conditions, differences in performance between trials, body orientation, and manipulation demands). The most demanding tasks are those done in an environment that changes with the performance, with requirements that change between trials, and with the body in motion while manipulating an object, such as playing basketball.

Some therapists keep files of activity-focused analyses, which they can adapt to client-focused, based on particular patients, whereas others prefer to use an environment-client activity analysis, focusing on a particular patient in a particular context. Over the years, activity-focused analyses have been published for general use by therapists: Hi-Q game (Neistadt et al., 1993); macramé (Chandani & Hill, 1990); planting a small garden (Nelson, 1988); using a computer for skill development, education, and prevocational training (Okoye, 1993); hand activities (Trombly & Cole, 1979); donning a sock (Greene, 1990); and bilateral inclined sanding (Spaulding & Robinson, 1984). Watson and Wilson (2003) published a task-analysis form based on the American Occupational Therapy Association's Occupational Therapy Practice Framework.

Performance-Focused Analysis (Client-Focused and Environment-Client Focused Activity Analyses)

Using an analytic approach, the therapist observes the patient's performance of role-related occupations. Figure 12-1 and Procedures for Practice 12-8 depict analysis of role performance within the environment using the Occupational Functioning Model as the basis (Trombly, 1993). The first step is to determine whether the person is accomplishing the role as he or she wants, needs, or expects to do. If not, the patient identifies the tasks and activities within the role that are not being accomplished to criterion. Observing the person's attempt to do an activity gives the therapist clues about which abilities and capacities may need further evaluation and treatment. This is the assessment described in Chapter 1. It is similar to the Dynamic Performance Analysis (DPA) proposed by Polatajko, Mandich, and Martini (2000). The DPA is described as a performance-based dynamic iterative process of analysis that is carried out as the client performs an occupation. The steps are: (1) establish whole-task performer prerequisites (motivation and knowledge of the task), (2) analyze observed performance to identify where the patient demonstrates performance difficulties, and (3) establish the source of the difficulties within the relationship between client abilities and the environmental or occupational supports or demands. Analysis according to the Occupational Functioning Model is also similar to

Figure 12-1 Performance-focused analysis according to the Occupational Functioning Model. One role is composed of several tasks. Each task consists of several activities. Each activity depends on varying degrees of sensorimotor, cognitive-perceptual, and psychosocial abilities. Those abilities depend on supporting capacities. The performance-focused analysis examines these components of the model from the top down by observing the patient. When the patient has difficulty performing, the therapist examines the next lower levels and/or the environment as possible constraints to the performance.

Procedures for Practice 12-8

Performance-Focused Analysis According to the Occupational Functioning Model

1. Name the role
2. List the tasks the person identifies as important to this role
3. List the activities the person identifies as part of a key task
4. Describe the environment and context in which the person will be performing the activity
5. Observe the person performing one of the activities within the environment
6. If the person is able to perform the activity, observe another of the activities. When the person is unable to do an activity, one of three directions can be taken:
   - Teach the person adapted methods to accomplish the activity
   - Modify/simplify the environment to allow the person to perform the activity
   - Remediate impaired abilities and capacities to enable performance
7. If remediation is chosen, analyze what ability limitations are interfering with performance
8. After identifying particular ability limitations, measure those abilities to confirm the limitation
9. If the ability is significantly limited, analyze what deficit capacities are causing that limitation
10. Measure those capacities and treat when verified

the analysis based on the Occupational Therapy Practice Framework, 2nd ed. (Watson & Wilson, 2003) but is less complicated.

The performance analysis proposed by Fisher and Bray Jones (2010) involves observational evaluation of the "transaction between the client and the environment as the client performs a task that is familiar, meaningful, purposeful and relevant" (p. 517). To do this, Fisher uses a standardized performance analysis, the Assessment of Motor and Process Skills (AMPS) (Fisher & Bray Jones, 2010; Merritt & Fisher, 2003), although it can also be done by informal observation. The quality of performance, not the patient's underlying capacities, is graded, although the capacities are considered when interpreting the outcome and planning treatment.

The Ecological Task Analysis (ETA) is based on ideas of the dynamical systems theory of movement and Gibson's (1977) theory of affordances (Burton & Davis, 1996; Davis & Burton, 1991). This environment-client activity analysis examines the interacting constraints (limitations and enablers) of performer, environment, and task as the occupation is undertaken. The ETA is

based on the premise that there are many solutions to a particular task, determined by the unique interaction of performer and environment with the goal or intent of the action. The steps are as follows: (1) the therapist selects and establishes the task goal, structures the physical and social environments, and provides verbal and other cues to allow for an understanding of the task goal by the patient; (2) the patient practices the task, with the therapist allowing the patient to choose movement solutions; (3) the therapist manipulates the performer, environment, or task variables to find the optimal performance; (4) the therapist identifies specific contexts in which the person can always (sometimes, never) accomplish the task and discovers by perturbation (e.g, increase speed, force, or other potentially controlling variable) the importance of performer or environmental variables on the performance of the task or movement; and (5) the therapist provides direct instructions of other possibilities of movement solutions (see Chapter 21 for application of this analysis and teaching process).

ADAPTATION

Activity adaptation is the process of modifying an activity of daily living, craft, game, sport, or other occupation to enable performance, prevent cumulative trauma injury, or accomplish a therapeutic goal (Definition 12-3). Although we may like to think that occupational therapists devised this process, actually Gilbreth devised it in the early 1900s (Creighton, 1992, 1993). He proposed adapting activity to suit the anatomy of workers to make work more efficient (Gilbreth, 1911).

There are four reasons to adapt an activity in the treatment of patients with physical disabilities. One is to modify the activity to make it therapeutic when ordinarily it would not be so. Many examples of this can be seen in

Figure 12-2 Therapist and patient playing tic-tac-toe in an adapted way that requires reaching up.

occupational therapy clinics. For example, in wall checkers, the board is mounted on the wall and has pegs at each square to hold the checkers. Tic-tac-toe can be adapted similarly by drawing the grid on the wall and using Velcro-backed Xs and Os or Xs and Os drawn on sticky notes (Fig. 12-2).

The second reason for adaptation is to graduate the exercise offered by the activity along therapeutic continua to accomplish goals. Grading of activity for this purpose is an original principle of occupational therapy (Creighton, 1993). For example, to increase coordination, the activity must be graded along a continuum from gross, coarse movement to fine, accurate movement. Checkers and other board games lend themselves easily to such gradations. For example, checkerboards or cribbage boards and the pieces can be changed in size so that the aficionado can continue a favorite game while continuing to benefit therapeutically (Fig. 12-3, A & B).

The third reason for adapting activities is to enable a person with physical impairments to do an activity or task he or she would be unable to do otherwise. For example, after having a stroke that causes paresis of one upper limb, a patient can learn a new method of putting on a shirt that requires only one hand. Or the environment in which a favorite activity was accomplished can be modified to allow engagement. For example, a gardener who undergoes bilateral lower extremity amputation because of diabetes can continue to garden from a wheel-

Definition 12-3

Characteristics of a Good Adaptation

A good adaptation:

- accomplishes the specific goal
- does not encourage or require odd movements or postures
- is not dangerous to the patient
- intrinsically demands a certain response on which the patient does not have to concentrate
- does not demean the patient (some contrived adaptations may seem ridiculous to the patient and thus are embarrassing and nontherapeutic)

Figure 12-3 A. Standard-sized cribbage board demands fine coordination. **B.** Enlarged cribbage board and pegs allow a person with deficient fine coordination to play (occupation-as-end) or demand greater range of motion of reaching (occupation-as-means).

chair if the beds are raised (Harnish, 2001). Figures 12-4 and 12-5 (A & B) show other examples of contextual adaptation to enable performance. Chapters 25–28 outline ways to compensate for particular disabilities to enable role performance.

The fourth reason for adapting activities, especially work activities that are engaged in for long periods of time, is to prevent cumulative trauma injury. Examples of such adaptation are changing the table height to reduce strain on the back or upper extremities or doing the work task while seated to reduce stress on the lower back.

As with all therapeutic techniques, for patients that are cognitively intact, it is vital for the patient to understand the reason why an activity is adapted (Peloquin, 1988). For patients who have cognitive impairment, it is important to determine their cognitive capacity to process complex and/or abstract information and explain the reason for an activity at the level they will understand (McCraith, Austin, & Earhart, 2011).

Using the activity demands described in the Occupational Therapy Practice Framework (AOTA, 2008), specific methods to modify activities for therapeutic purpose are described here and listed in Procedures for Practice 12-9.

Parameters Used to Adapt or Modify Activities

Activity Demand: Required Body Functions

This group of adaptations focus on specific body functions that support the actions used to perform activities (e.g., muscle strength and standing balance).

Position the Activity Relative to the Person. The position of the person relative to the work to be done dictates the movement demanded by the activity and therefore which muscle groups are likely to be used (McGrain & Hague, 1987). Poor positioning of work equipment relative to the size of the person may result in musculoskeletal discomfort or repeated stress injuries (Sung et al., 2003). Adaptation by positioning refers to changes in incline of work surface, height of work surface, location of work equipment, or placement of pieces to be added to the project in order to require a specific body function that is the target of the therapeutic activity.

Activities that are usually done on a flat surface, such as finger painting, board games, and sanding wood, can be made more or less resistive by changing

Figure 12-4 A pull-out shelf with cut-outs that accommodate bowls or pots enables a person to cook efficiently from a sitting postion, e.g., when in a wheelchair.

Figure 12-5 A, B. Scissors have been stabilized in a wooden block to enable cutting by a person who lacks finger dexterity.

the incline of the surface. For example, if the surface is inclined down and away from the patient, resistance is given to shoulder extension and elbow flexion. If the incline is up and toward the patient, resistance is given to shoulder flexion and elbow extension. Similarly, the standard horizontal work surface itself can be raised or lowered to make demands on certain muscle groups or to alter the effect of gravity. For example, a table raised to axilla height allows flexion and extension of the elbow on a gravity-eliminated plane and may enable a person with grade 3+ muscles to eat independently. The purpose of these changes in position would be to increase joint strength and ROM or enable performance.

Placing items, such as nails, mosaic tiles, pieces of yarn, beads, darts, bean bags, and paint brushes, in various locations changes the motion required to reach them when performing the activity in an otherwise standard manner. Placement may be high enough to encourage shoulder flexion or abduction; lateral to encourage shoulder rotation, trunk rotation, or horizontal motion; or low to encourage trunk

flexion or lateral trunk flexion. All of the placements would encourage improvement in dynamic balance (Fig. 12-6).

Arrange Objects Relative to Each Other. To grade an activity for improving perceptual skills (e.g., figure-ground discrimination or unilateral neglect), the arrangement of objects to be used, the printing on a

Procedures for Practice 12-9

Adaptations for Therapeutic Purpose

Activity Demand	Adaptation	Therapeutic Purpose	Activity Demand	Adaptation	Therapeutic Purpose
Body function	Position the task relative to the person	Increase ROM Target specific muscles, motions Enable performance	Object properties	Change the size or shape of objects	Improve dexterity Enable performance Increase strength Increase ROM
Body function	Arrange objects relative to each other	Improve perceptual skills Require specific movements Decrease energy expenditure Enable performance	Object properties	Change color contrast between objects	Improve figure-ground discrimination Enable performance
Body function	Change lever arms	Increase strength Reduce required strength Prevent injuries	Object properties	Modify or use supplemental tools and utensils	Enable performance Prevent deformity Prevent cumulative trauma disorders
Required actions	Change method of doing the activity	Enable performance Increase strength Increase ROM Increase coordination and dexterity Increase cognitive-perceptual skills	Object Properties	Add weights	Increase strength Reduce incoordinated movements Provide passive range of motion (PROM)
Required actions	Change level of difficulty	Increase cognition Increase perception Increase motor planning Enable performance	Object properties	Add springs or rubber bands	Increase strength Reduce incoordinated movements Provide PROM Assist weak muscles
Required actions	Change materials or texture of materials	Increase strength Increase coordination Challenge sensory system	Sequence and timing	Modify steps	Enable performance Increase attention and concentration Increase memory
Object properties	Change handles of tools and utensils	Reduce stress on painful joints Enable performance	Sequence and timing	Modify time	Enable performance Increase attention and concentration Increase muscular endurance

page, and so on can be graded from sparse to dense (i.e., fewer objects or words with space between versus many objects or words with no space between). Putting game pieces on the right side of the game board encourages use of the right hand, while placement on the left encourages use of the left hand. Placement of ingredients on a kitchen counter across the room from the mixing

bowl encourages walking in the kitchen that would not occur if all were together. On the other hand, placing all objects needed for a task together reduces the energy required to do the task.

Change Length of the Lever Arm The amount of work a muscle or muscle group is doing depends on

Figure 12-6 Christmas tree lights are placed to the left of a right-handed person to encourage reaching and development of dynamic standing balance.

Figure 12-7 Retrieving toast with a spring clothespin.

with decreased strength to use them (Fig. 12-8). Furthermore, this idea guides workers in methods of lifting and handling on their jobs to avoid musculoskeletal injuries (see illustrations of lever arms in Chapter 20).

the resistance. Resistance is determined by the pull of gravity on the limb and the implements the patient is using, which together act as the resistance lever arm. The effect of a given amount of resistance can be altered by lengthening or shortening the resistance arm. The longer the resistance arm, the greater the force required to counterbalance it. The resistance arm can be altered by shortening or lengthening the limb; for example, flexing the knee, which shortens the limb, offers less resistance to hip extension than if the knee were extended. Another example is carrying an object close to the body, which requires less involvement of back muscles than if the object is carried at arm's length.

On the other hand, increasing the length of the force lever arm decreases the muscle activity needed to accomplish a task. For example, in Figure 12-7, if the clothespin were adapted to have longer handles, less pinch would be required to open it to the same width.

Attention to lengths of lever arms is important not only in adapting the required body functions of an activity to make it more therapeutic but also in adapting objects used in daily activities to enable patients

Figure 12-8 A patient who has weak upper extremities is able to crush cans for recycling because the handle (force arm) of the crusher has been elongated.

Activity Demand: Required Actions and Performance Skills

This group of adaptations focuses on methods used for adapting the actions and skills that are required to carry out the activity.

Change Method of Doing the Activity; Change Physical Context. Change of method is used both for occupation-as-means (Fig. 12-2) and for occupation-as-end (Figures 12-3B; 12-4; 12-9, A & B; 12-10, A & B; and 12-11). Such compensatory adaptation allows performance of an activity that would otherwise be impossible because of the person's disability. Bowling, basketball, and many other sports can be done seated instead of standing. A change of rules adapts some sports, such as track and field events, to certain requirements of the physically impaired. Sewing and needlework, normally bilateral activities, can be made unilateral by adaptations that hold the material steady for the working hand (Fig. 12-12). Books, notebook computers, or other tools can be transported via a rolling backpack or rolling table instead of carrying them.

By altering the physical context, individuals are able to move at the edge of their competence (Nilsen, Kaminiski, & Gordon, 2003). For example, if a person cannot flex his shoulder against gravity, by placing him in a side-lying position, the effects of gravity are minimized, allowing the movement. Movement organization in a gravity-eliminated plane, however, differs from movement in an against-gravity context.

Movement organization is also different in simulated contexts using simulated objects compared with natural contexts with actual objects (Dunn, Brown, & McGuigan, 1994; Flinn, 1999; Ma, Trombly, & Robinson-Poldolski, 1999; Mathiowetz & Wade, 1995; Trombly & Wu, 1999; Wu et al., 1998, 2000). Because movement organization is sensitive to contextual changes (Nilsen, Kaminiski, & Gordon, 2003), some rehabilitation centers now have manufactured "real" environments or have renovated their clinic spaces to allow patients to practice in realistic contexts to enable best performance and to facilitate carry over to actual contexts (Fig. 12-13).

Change Level of Difficulty Patterns for craft activities, game rules, extent of task (e.g., prepare instant coffee versus espresso), and level of creativity can be downgraded to enable the patient to succeed or upgraded to demand performance at higher levels. Changing the difficulty entails changing the number of pieces or the ideas that must be

Figure 12-9   **A.** Therapist adapting a pen with built-up handle. **B.** Writing using built-up pen.
Figure 12-10 A, B. Checkers and tic-tac-toe pieces adapted with looped handles. This enables a person to play who otherwise could not (occupation-as-end) or challenges abilities not used when playing standard games (occupation-as-means).

Figure 12-11 A patient with spinal cord injury is learning to feed himself in a new way. He is using a mobile arm support, a fork held in a universal cuff, and a plate guard to prevent food from being pushed off the plate.

Figure 12-12 An adapted hoop that fastens to the table enables a person with the use of only one hand to embroider.

Figure 12-13 "Shopping" at Independence Square Market, a manufactured "real" environment to promote best performance in preparation to return to the community. (Photo by Mary Vining Radomski.)

manipulated, changing the problem-solving level from concrete reasoning to abstract reasoning, changing the directions from specific to general, and so on. For example, a patient with traumatic brain injury may be unable to pay the bills if the top of the desk is littered with bills and papers but may be able to manage if one bill is taken out at a time. A patient with low cardiopulmonary endurance may not be able to stand for long periods of time to prepare a simple meal in the kitchen; however, would be able to complete a kitchen activity while sitting on a stool. As endurance increases, the level of difficulty can be increased to include standing positions during portions of the activity.

Activity Demand: Objects and Their Properties

This next group of adaptations moves the focus of adaptation to the tools, materials, and equipment that are used to perform the activity.

Change Materials or Texture of Materials. Gradation along the strengthening continuum may be accomplished by selection of material by type and also by variations of texture or density to change resistance. Resistance can be changed, for example, by starting a cutting project with tissue paper and then progressing to heavier materials. Metal tooling can be graded for resistance by choosing materials in grades from thin aluminum to thick copper. Sandpaper is graded from extra fine to coarse, and resistance increases as the grade coarsens. Mixing can be graded from making gelatin dessert to scrambled eggs to biscuit batter and so on. If materials are graded in the opposite direction, that is, from heavy to light, the activity demands increased coordination from the patient. Weaving may begin using thicker material

like rug roving and be graded toward fine linen threads as the patient progresses in coordination.

Cutaneous stimulation changes with the amount of texture of objects or surfaces. By making balls from yarn or terry toweling, carpeting the surfaces the person works on, padding handles with textured material, and so on, the therapist adapts the activity to increase sensory stimulation.

Change Handles of Tools or Utensils. Padding the handles of utensils or tools with high-density foam or other firm but soft material (Fig. 12–9, A & B) reduces stress on painful finger joints and/or enables persons with poor grip to use the utensil or tool.

Change Size or Shape of Objects. Playing pieces of board games can vary in size and shape and can therefore offer a therapeutic benefit that the standard objects would not. For example, checkers, which are usually flat pieces approximately 2.5 cm in diameter, can be cylinders, squares, cubes, or spheres; can range in size from tiny to as large as a person's grasp permits; or can have handles attached (Fig. 12-10, A & B).

Reducing the size or changing the shape of the pieces being worked on facilitates the goals of increased dexterity and fine coordination. Therapists creatively change sizes of craft materials (e.g., weaving thread, tiles, paint-by-number guidelines, and ceramic pieces) and recreational materials (e.g., puzzle pieces, chess pieces, and target games) to increase coordination. Tools and utensils can be adapted by changing the length, diameter, or shape of their handles or by adding handles to tools that do not normally have them.

The actual size of the tool can be chosen to offer more or less resistance. For example, saws range in size from small coping saws and hacksaws to large cross-cut and rip saws. The resistance of saws can also be graded by the number of teeth per inch on the blade; the fewer the teeth, the greater the resistance. Woodworking planes vary in size, and the amount of exposed blade can be adjusted to provide resistance. Size of scissors, screwdrivers, stirring spoons, and other tools and utensils can also be varied.

Change Color Contrast between Objects. Neistadt et al. (1993) suggested grading challenge to figure-ground discrimination ability by changing game objects from contrasting colors to increasingly similar colors.

Modify or Use Supplemental Tools and Utensils Using tools when normally none are used or modifying tools or utensils enables a person to accomplish activities and tasks that he or she would not be able to do otherwise. For example, toast can be retrieved from a toaster by use of a wooden spring clothespin when sensory precautions are in effect (Fig. 12-7). Angling the handles on carving knives allows a person with rheumatoid arthritis to cut meat or vegetables without putting deforming forces on the wrist and fingers. Changing keyboard or mouse designs can prevent carpal tunnel

syndrome. Including the tool in a specially designed splint can reduce symptoms caused by prolonged holding (Bockman, 2004). Although manufacturers are offering tools and household utensils designed to enable persons with weak grasp or arthritic pain to use them comfortably, therapists must not assume that tools labeled "ergonomic" produce better positioning or less discomfort than nonadapted tools. Patients' perceptions of comfort and ease of use need to guide the selection (Tebben & Thomas, 2004).

Add Weights. The addition of weights adapts an activity to meet such goals as increase of strength, promotion of cocontraction, and increase of passive ROM by stretch. Some nonresistive activities can be made resistive by adding weights to the apparatus directly or by use of pulleys; others may be made resistive by adding weights to the person, as with weighted cuffs (Fig. 12-14). Tools also are weights, and they can be selected or adjusted to offer graded resistance; for instance, hammers range from lightweight tack hammers to heavy claw hammers.

Add Springs or Rubber Bands. Springs and rubber bands are means of adapting activity to increase strength through resistance, to assist a weak muscle, or to stretch muscle and other soft tissue to increase passive ROM. When offering resistance, the spring or rubber band is positioned so that its pull is opposite to the pull of motion of the target muscle group, whereas if used for assistance, the spring or rubber band is set to pull in the same direction as the contracting muscle group. Springs and rubber bands applied for the purpose of stretching are placed so the pull is against the tissue to be stretched.

Springs of graduated tensions may be applied directly to larger pieces of equipment. Rubber bands can be added to smaller pieces of equipment and can be graded from thin with light tension to thick with heavy tension. For

Figure 12-14 Weight cuff used to add resistance to an action that is not normally resistive.

example, a rubber band can be wrapped around the pincer end of a spring-type clothespin to add resistance when it is used in games involving picking up small pieces.

Activity Demand: Sequence and Timing

This final group of adaptations involves changing demands related to the steps involved in an activity including the sequence of the steps and the time required to complete the steps

Modify Steps. An activity can be modified by increasing the number of steps to complete the activity. Grading the number of steps from one or two steps to multiple steps can be used to increase attention and concentration skills and memory. For example, the activity of "brushing teeth" can be graded from two steps: (1) brush teeth and (2) rinse mouth to five steps: (1) get supplies from cabinet, (2) put toothpaste on brush, (3) brush teeth, (4) rinse mouth, and (5) return supplies to cabinet.

To enable occupation-as-end, the activity can be adapted to include a sequential checklist of the steps to perform the activity. Depending on the person's cognitive ability, the checklist can be written or pictorial. Using the same example above, a written checklist for the steps involved in brushing teeth could be posted on the mirror in the bathroom (Fig. 12-15, A & B).

Conversely, the patient may receive a singular instruction to a multi-step task (such as prepare and clean up a light lunch within 30 minutes) to engage decision-making and problem-solving skills.

Modify Time. Changing and monitoring the length of time to complete the individual steps of an activity or the entire activity can be used to increase attention and concentration skills. For example, making a peanut butter and jelly sandwich can be graded by increasing the required time to make additional sandwiches. Devices can be used to promote a therapeutic goal or enable performance such as the use of a kitchen timer or alarm clock.

EVIDENCE PERTAINING TO OCCUPATIONAL ANALYSIS, GRADATION, AND ADAPTATION

Additional helpful information is listed in Resources 12-1. However, evidence concerning the effectiveness of gradation and adaptation of activity to accomplish therapeutic goals is sparse. The three practice skills of activity analysis, gradation, and adaptation discussed here are basic to the practice of occupational therapy and as such have been practiced with success clinically and universally accepted with little objective study. Some studies, other than the classic ones mentioned in this chapter, are described in Evidence Table 12-1. Continued research is needed in this area in order to support the efficacy of occupational therapy practice.

Suggested adaptations to enable one-handed typing or keyboarding.

Evidence Table 12-1	**Best Evidence for Occupational Therapy Practice Regarding Selection, Gradation, and Adaptation of Occupation**						
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Task constraints: #1: Different sized handles #2: Different weight cups	#1: Three ceramic cups 12 cm high, weighing 309.0 g, having handles of 2, 4, and 8 cm #2: Two cups, 12 cm high with 2-cm handles, weighing 309.0 g and 705.9 g when filled with water	Thirty healthy women aged 20–45 years	Three trials for each cup; carried out in a laboratory	One group, repeated-measures design, randomized of condition; Level: 1B1b	Mixed #1: Yes. The size of the handle significantly affected the number of fingers being placed through the handle; the larger the handle, the more fingers. #2: No. Weight did not significantly affect the number of fingers used to support the cup.	#1: $x^2_{(2)}$ = 49.8, $p < 0.001$; effect size could not be calculated #2: Not significant	Fuller & Trombly (1997)
Exercise apparatus adapted into a game	Experimental: Exercise using a game apparatus that required supination to dump dice out to score Control: Exercise using the same apparatus without the game	Thirty patients with acute stroke, mean age = 68.4 years	Two sets of 10 trials for each condition; different days	Randomized controlled trial; Level: IC2c	Yes. The game significantly increased the degrees of handle rotation (supination) achieved. Mean of 13.4° more in experimental group compared with control group.	$p = 0.016$, $r = 0.42$, indicating a 42% improvement caused by meaningfulness of game as compared with rote exercise	Nelson et al. (1996)
Functional activity (goal object present) versus rote exercise (goal object absent)	Present: Reach to scoop coins off the table in the laboratory Absent: Reach forward without functional goal	Fourteen patients with chronic stroke, mean age = 61.8 years; 24 healthy persons, mean age = 63.2 years	Ten trials within 1 day; in a laboratory	Randomized controlled trial; Level: IC1c	Yes. Both groups demonstrated significantly better movement organization with goal object present. The results are reported for the stroke patients only.	Overall effect size = 0.63. Speed, $p = 0.003$, $r = 0.70$; straightness of path, $p = 0.002$, $r = 0.72$; smoothness, $p = 0.005$, $r = 0.66$; automaticity of movement, $p = 0.001$, $r = 0.75$. Force of movement, $p = 0.28$, $r = 0.17$	Wu et al. (2000)

Grade speed of action; grade work surface	Condition: #1: Rest #2: Unilateral horizontal sanding at 15 cycles/min #3: Same as #2 at 30 cycles/min #4: Unilateral sanding with board inclined to 15° at 15 cycles/min #5: Same as #4 at 30 cycles/min	Eight patients with stroke of unknown chronicity, mean age = 67.6 years	Three minutes each of five conditions with rests between; all conditions within 1 day	One group, repeated-measures design without randomization of condition; Level: IIC2c	Mixed. When tested together, speed and angle significantly increased cardiopulmonary measures above resting. When separated, only different velocities affected the outcome.	$p < 0.01$; effect size could not be calculated; no statistical information available concerning the tests of angle and speed separately	Muraki et al. (1990)
Weighted cuff	Weighted cuff applied to forearm to decrease tremors and increase functional feeding in adults. Each person ate half the meal with the weighted cuff and half without the cuff. Weight determined individually by trial and error.	Five adults aged 30–81 years; all had tremor secondary to various diagnoses	Eight or 16 meals	AB single-case design; conditions alternated randomly; Level: IVC3b	Partial benefit for some participants. Time to acquire food on utensil decreased significantly for four of five participants. The number of spills decreased significantly for two of five participants. The amount of food consumed did not change significantly.	Time to acquire food on utensil: $p < 0.013$; effect size, $r = 0.97$. Number of spills: $p < 0.012$; effect size, $r = 0.96$.	McGruder et al. (2003)

Clinical Reasoning in Occupational Therapy Practice

Adaptation and Gradation

The occupational therapy department in a busy rehabilitation hospital received a donation of 25 new jigsaw puzzles from a grateful patient. The donation included a variety of puzzles, ranging from 100- to 500-piece puzzles, small- to large-sized puzzle pieces, and various types of themes from landscapes to sports teams. For her patient, the therapist chose a 100-piece puzzle of medium-sized pieces that pictured, in a simple way, a Golden Labrador dog. For what impaired ability and skill competence might this activity have been chosen? What are three types of adaptations the therapist can use to adapt this activity to address different therapeutic goals? State the type of adaptation, the therapeutic purpose (goal) of the adaptation, and how the therapist could grade the activity to accomplish the goal.

Clinical Reasoning in Occupational Therapy Practice

Adaptation

Joan has hemiplegia in her right upper extremity because of a recent cerebrovascular accident (CVA) and cannot use her right arm or hand, which are flaccid and supported in an arm trough positioned on her wheelchair. She is right-handed. Joan's sitting balance is impaired; she can sit unsupported only for short periods of time. Her cognitive abilities are intact. She has fair cardiopulmonary endurance. Joan is currently receiving occupational therapy in a skilled nursing facility. During the occupational therapy evaluation, Joan told her therapist that she loves to do needlepoint and is currently working on a very special project for her "soon-to-arrive" granddaughter. She is very upset that she will not be able to finish the project.

How can the activity of needlepoint be adapted so Joan could resume this meaningful occupation?

How can needlepoint activity be used therapeutically in Joan's occupational therapy treatment?

Summary Review Questions

1. What is the difference between occupation-as-end and occupation-as means? Give an example of each type of therapeutic use of occupation.
2. What would a therapist need to know in order to select an appropriate occupation-as-end for a particular patient?
3. What would a therapist need to know about the patient and activity to select occupation-as-means?
4. List the general required characteristics of an activity used as occupation-as-means for the following impairments.
   - Voluntary movement
   - Active ROM
   - Cardiopulmonary endurance
   - Memory
   - Problem solving
5. Describe how the process of activity analysis relates to selection of an occupation or activity for a particular patient.
6. What therapeutic purpose and goal(s) might be accomplished by engaging a patient in occupation-as-means that requires moving at different speeds?
7. What are two reasons for adapting an occupation used as means? An occupation used as end?
8. What are the five characteristics of good adaptations?
9. What therapeutic goals can be accomplished by the following?
   - Changing the position of the task relative to the person
   - Adding weights to tools or game pieces
   - Adding springs or rubber bands to craft equipment or tools
   - Changing the length of lever arms of tools, equipment, or the limb itself
   - Changing the material to be used in a project
   - Modifying the steps of the activity

Glossary

Activity analysis—A systematic process through which activities, tasks, and occupations are analyzed in order to understand "their component parts, their possible meaning to clients, and their therapeutic potential" (Crepeau & Schell, 2009, p. 360). This chapter describes three approaches to activity analysis: (1) activity-focused analysis, which focuses on the activity itself without considering the characteristics of the client or his or her environment to build a repertoire of activity knowledge; (2) client-focused activity analysis, which focuses on the therapeutic utilization of the activity for a particular client toward a specific therapeutic goal, an occupation-as-means approach; and (3) environment-client focused activity analysis, which is an occupation-as-end approach that focuses on the fit between the person and the environment with regard to the activity in order to determine and/or optimize the potential for successful performance.

Activity demands—See *Task demands*.

Closed task—A closed task involves the least interaction with the environment (Gentile, 2000). A closed task is one in which the task demands remain constant and for which habits can develop so that little conscious control is required once learned.

Constraints—Limitations imposed on purposeful movement or the completion of occupational performance. Extrinsic constraints include the physical and sociocultural environment and task demands. Intrinsic constraints include biomechanical and neuromuscular aspects of a person's body, as well as other personal contextual factors (Newell, 1986).

Electromyographic—Pertaining to recording the electrical activity produced by a contracting muscle. When a muscle is at rest, no electrical activity is recorded. As the muscle contracts, the electrical activity increases proportionally.

Kinematic—The branch of mechanics that studies the motion of a body or a system of bodies without consideration given to its mass or the forces acting on it (*American Heritage Dictionary of the English Language*, 2009). Kinematics describe motion in terms of displacement (position), velocity (a derivative of position), and acceleration (a derivative of velocity). For example, by recording the displacement of the wrist in space, the velocity or acceleration of reach can be derived. Kinematic analysis allows detection of strategies for the organization of movement (Georgopoulos, 1986; Jeannerod, 1988).

MET (metabolic equivalent)—The amount of energy expended when a person is engaged in activity. At rest in a semireclined position and with the extremities supported (basal state), that amount is 3.5 mL of oxygen per minute per kilogram of body weight (1 MET). Energy expenditure of activities is rated in terms of multiples of METs.

Occupation-as-end—Activities and tasks that constitute the roles of a given individual (Trombly, 1995/2011).

Occupation-as-means—Activities and tasks chosen to remediate deficient abilities or capacities (Trombly, 1995/2011).

Open task—Task with most interaction between the performer and environment (Gentile, 2000). An open task is one for which the environment and/or objects may vary during performance and between trials. Open tasks require attention and vigilance.

Task analysis—Similar to activity analysis; term used primarily in relation to work assessment (ergonomics). Analysis of the dynamic relationship among a person, a selected task or occupation, and a specific context or environment (Watson & Wilson, 2003).

Task demands—The context (e.g., objects, surroundings, and ritual) that evokes certain maneuvers required to accomplish the goal of the activity or task.

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Differentiate between patient performance and patient learning.
2. Outline clinical considerations necessary for planning patient-specific teaching.
3. Explain the roles of context, feedback, and practice in the acquisition of both task-specific skills and general strategies.
4. Identify strategies for facilitating caregiver education and training.
5. Identify the guiding principles of motivational interviewing.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

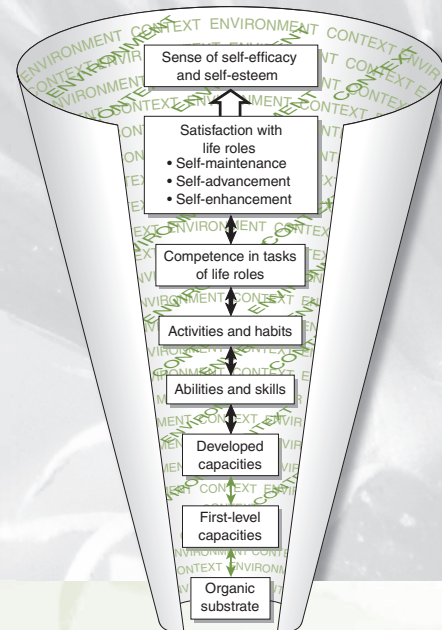
Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate


Learning is a primary therapeutic mechanism underlying many, if not all, occupational therapy interventions. Occupational therapists teach patients to perform activities of daily living (ADL), teach family members home programs, teach other therapists new techniques, and teach the public in community education courses. Each teaching opportunity requires preparation: the physical environment needs to be prepared; any needed materials, props, or equipment needs to be gathered; and most importantly, the learner must be prepared for the session. Teaching strategies need to be consciously designed to maximize learning, using methods designed to support different learning styles (e.g., visual, aural, read/write, or kinesthetic learners) (Lofland, 2009). Any handouts should address health literacy concerns and are developed with an understanding of the cultural, social, and cognitive issues that might affect the teaching session (DeWalt et al., 2010). All of these concerns need to be addressed in order for effective teaching to take place.

Finally as teachers, therapists must determine whether learning has taken place. For example, after a 30-minute dressing session, a patient who has had total knee replacement surgery is able to don his pants, socks, and shoes. From a traditional learning perspective, the patient's performance at the end of the session reflects the extent to which he has learned the desired skill or strategy. However, what if a nurse later reports that the patient is unable to carry out the activities he demonstrated proficiency with the day before? One can easily see that although within-session performance was buoyed by cues and practice, true learning did not occur.

Schmidt and Lee's (2011) contemporary definition of motor learning allows us to differentiate learning from within-session performance: ". . . motor learning is a set of processes associated with practice or experience leading to relatively permanent changes in the capability for responding" (p. 327). Based on this definition of learning, we would expect the patient with knee replacement to demonstrate similar levels of proficiency after the occupational therapy session as during. The term *performance* is used to describe what is seen during training, that is, short-term capabilities resulting from instruction, cues, or assistance. For occupational therapy to help patients resume occupational roles, therapists must understand the process of transforming performance into learning and use teaching methods that help the patient learn new skills.

This chapter discusses the role of information processing in learning and then summarizes the array of variables that affect the patient-specific teaching plan. Key influences on learning are detailed, and the chapter concludes with specific applications to occupational therapy practice. Regarding issues of learning, there has been a traditional division in the research between motor and cognitive tasks. In clinical practice, however, it is unusual to find motor tasks that do not have a cognitive component

or the reverse. Because this distinction does not translate into practice and because principles in the two areas are similar, the principles are combined in this chapter.

HUMAN INFORMATION PROCESSING MODEL OF LEARNING

Learning is inextricably linked to memory, specifically the encoding and retrieval of information. As explained in Chapter 6, people hold environmental stimuli very briefly in a series of short-term sensory stores before transferring it to limited-capacity working memory (Atkinson & Shiffrin, 1971). In working memory, sometimes called short-term memory, people may use control processes to encode information for storage in long-term memory (Schneider & Shiffrin, 1977). These control processes include techniques such as rehearsal, coding, and imaging (Atkinson & Shiffrin, 1971). Rehearsal is rote repetition of information, whereas coding entails linking the new information to something meaningful. Imaging transforms verbal information to visual images that are stored in memory. Craik and Tulving (1975) found that the durability of the memory trace is a function of depth of processing. That is, deep processing, as in the time-consuming process of linking new information to personally relevant old knowledge, results in better retention than shallow processing, such as rote rehearsal. If the learner does not use some form of conscious control, the memory trace quickly fades from working memory and cannot be recovered (Atkinson & Shiffrin, 1971). From the standpoint of human information processing, learning is the transfer of information from short-term or working memory to long-term memory (Shiffrin & Schneider, 1977).

Controlled versus Automatic Information Processing

Consider the attentional resources required of you the first time you drove a car compared with the attention required for the same task now. After years of experience, the car seems to drive itself, freeing the driver to concentrate on plans for the day or talk to a passenger. This example typifies the difference between controlled and automatic processing.

Controlled Processing

Controlled processing is technically a temporary activation of a series or sequence of elements in long-term memory under the attention and control of the thinker (Schneider & Shiffrin, 1977). For example, the new driver must actively recall specific rules and instructions and direct his attention to each motor sequence of the task. Controlled processing is limited by the capacity of working memory and is therefore effortful but flexible in handling novel situations. When learning a new task or skill that requires effortful concentration, people employ controlled

processing. Thus, patients learning new skills or behaviors can process only a limited number of inputs (instructions, cues, and environmental distractions) at a time.

Automatic Processing

With enough controlled processing, a task requires less and less concentration to carry out (Shiffrin & Schneider, 1977). That is, the task becomes increasingly automatic, as in the example of the proficient driver. Automatic processing occurs when specific contextual stimuli internal or external to the person trigger the activation of a specific learned sequence in long-term memory (Schneider & Shiffrin, 1977). Given enough repetition, the individual performs the skill or task in a consistent manner with little or no attention. Sternberg (1986) suggested that development of a full level of automatization requires at least 200 trials of a task but that automatization begins in as few as 10 trials, so long as those trials are consistent. With fully automatic skills, people cannot stop themselves from performing the overlearned sequence unless control processes are employed to override it. Definition 13-1 discusses implications related to helping patients with memory impairment to reacquire skills. According to Giles (2005), overlearning is practice of a skill or strategy well beyond demonstration of learning or proficiency; it increases the likelihood that the skill or strategy will become automatic. These automatic skills and strategies become the easiest behaviors to initiate from an array of possible behaviors (Giles, 2005), minimizing demands on attention and decision making. Habits and routines are examples of automatic motor sequences that, according to Kielhofner, Barris, and Watts (1982), organize a person's tasks, space, and time. Characteristic of automatic skills and strategies, habits and routines are responsive to the environmental conditions under which they are learned and develop with repetition (Kielhofner, Barris, & Watts, 1982; Wood, Quinn, & Kashy, 2002). Habit learning is a form of implicit learning, which is described in Definition 13-2. Occupational therapists often help patients resume or relearn self-maintenance tasks so that they are once again automatic.

Implications of the Information Processing Memory Model

Attention and memory play important roles in many aspects of learning, and so occupational therapists assess these domains before they try to teach patients skills or

Definition 13-1

Errorless Learning

Errorless learning is a technique that involves encoding new information without error (Tailby & Haslam, 2003). Learners are helped to do it right each time the new skill is performed by introducing and then fading preemptive cues and/or assistance. Wilson and Evans (1996) propose errorless learning methods for persons with severe memory impairments. They suggest that these individuals have difficulty remembering what they learned if they made errors during the training process. Guessing and trial-and-error are avoided, and because training generally occurs in the context in which the new skills will be used, expectations of transfer are minimized. In a clinical trial, individuals with cognitive impairment and transtibial amputations benefited from an errorless learning protocol for donning their prosthesis, both in remembering more steps and making fewer errors (Donaghey, McMillan, & O'Neill, 2010).

Definition 13-2

Implicit and Explicit Learning

People learn through two key processes that are supported by separate brain structures and have very different characteristics.

Explicit learning (sometimes called declarative learning) refers to the conscious encoding and recollection of specific events, task rules, and facts (Deckersbach et al., 2002; Eldridge, Masterman, & Knowlton, 2002). It relies on the integrity of the medial temporal lobe and diencephalic structures, particularly the hippocampus (Eldridge, Masterman, & Knowlton, 2002). It can be facilitated by a therapist through direct instruction about key environmental features, task-relevant feedback, and cues (Reber & Squire, 1994). Explicit learning is more flexible than implicit learning and has been shown to generalize more easily, probably because it is not as context dependent (Squire, 1994).

Implicit learning (also called procedural learning) refers to an unconscious change in behavior resulting from repetition within a stable context. There appear to be several forms of implicit learning including skill and habit learning, some forms of conditioning, and the phenomenon of priming (Squire, Knowlton, & Musen, 1993). Much of the learning of a motor task is thought to be implicit, including the dynamics of force production in the task, which is the interaction of active and passive components of the multiple joints involved in the task. The therapist facilitates implicit learning by structuring the environment to create consistent cues and frequent opportunities for appropriate task practice (Gentile, 1998). Implicit learning is more robust than explicit learning and retains its strength even when the explicit knowledge about a task has decayed (Lee & Vakoch, 1996). The basal ganglia support implicit learning rather than the medial temporal lobe (Packard & Knowlton, 2002). This suggests that even people with impaired explicit memory systems (e.g., Alzheimer's disease) are capable of implicit learning (Eldridge, Masterman, & Knowlton, 2002).

strategies. Therapist awareness of distractions, such as pain, fatigue, and noise, allows therapists to plan sessions so that patients can use limited-capacity cognitive resources to hold and store stimuli related to the new skills or strategies. Therapists do this by helping patients use effective control processes, such as linking the new information to something they already know. Finally, therapists recognize that, for many skills, the learning end point is not proficiency but automaticity. Therapists ultimately enable their patients to carry out these tasks with accuracy and ease if they encourage consistency in performance (consistent environment and consistent sequence of steps).

CLINICAL CONSIDERATIONS IN TEACHING CLIENTS

In advance of every teaching intervention, occupational therapists make deliberate decisions regarding appropriate teaching methods. These decisions are based on the characteristics of the learner, anticipated length of intervention, desired learning outcome (specific task versus general strategy), and expectations for transfer and generalization. Evidence Table 13-1 lists some of the best evidence of the positive effects of learning- and teaching-related intervention.

Learner Characteristics

A client's learning potential is determined by many factors. Variables affecting cognitive status (reviewed in Chapter 6) are critical contributors to learning potential. Remember, these considerations apply to family caregivers as well as patients (see Procedures for Practice 13-1). Literacy is one important dimension of the experiential sociocultural influence on learning, with many implications regarding teaching methods (see Chapter 3). Neistadt (1995) suggested that occupational therapists attempt to answer four questions regarding patients' learning capacities during the course of their traditional evaluation. These questions include the following:

1. What modes of input (e.g., visual, auditory, and tactile) can this patient process most easily?
2. What approaches to tasks (outputs or behaviors) are still available to this patient?
3. What tasks remain meaningful or are most likely to facilitate learning for this patient?
4. How well is this patient able to transfer learning, that is, apply specific skills to a variety of tasks under a variety of circumstances?

Anticipated Length of Treatment

Occupational therapists also consider how many teaching sessions are likely to be available, as dictated by expected length of stay at the hospital, rehabilitation center, or nursing facility; insurance coverage of rehabilitation services; acuteness of medical condition; and learning potential of the patient. The clinician selects learning goals based on this awareness of the constraints on teaching. Discharge planning then incorporates recommendations for continuing and extending the learning that began in treatment.

Stages of Learning

In 1967, Fitts and Posner described three sequential stages of learning, or acquisition, of motor skills: cognitive, associative, and autonomous. Each of the stages requires different kinds of attention resources (Eversheim & Bock, 2001). During the cognitive stage, the patient tries to understand the requirements of the task. The patient uses conscious control to acquire the new skill or strategy: thinking through or verbalizing the steps, attending to visual and verbal feedback from the therapist, and determining what cues to heed. In the associative stage, the patient is able to generally perform the task but now begins to make refinements in performance. The learner relies less on vision and verbal feedback and begins to use internal feedback mechanisms. During this stage, practice takes on primary importance; this important dimension of learning is discussed in more detail later in this chapter.

During the autonomous stage, the new skill or strategy becomes increasingly automatic or habitual. The patient can accurately perform most of the skill or strategy without thinking about it and is less subject to interference from other activities or environmental distractions.

Desired Learning Outcomes: Task-Specific Skills versus General Strategy Related to Expectations for Transfer and Generalization

Occupational therapy clients have a variety of learning needs. Therapists deliberately determine the patient-specific learning end point because it dictates teaching methods, length of treatment, and expectations for transfer and generalization.

Task-Specific Skills and Transfer of Training

After a stroke, many patients receive occupational therapy services to learn task-specific skills such as how to dress themselves using only one hand. For example, a client who receives home-based treatment may learn techniques specific to donning her housecoat and slippers (her usual attire) at the side of her bed, which rests on shag carpeting. Teaching in this situation (within the environment and context that the skill will be used) is task-specific. The learning process is embedded in the performance environment, with surroundings and objects becoming cues. The therapist does not expect the client to apply skills learned

Evidence Table 13-1 | Best Evidence for Learning–Teaching–Related Intervention

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Training in reaching tasks using either task-related or movement-related instructions	Participants practiced three reaching tasks with two types of instructions. One set of instructions focused on the task, and the second set of instructions focused on their arm movement.	Sixteen stroke survivors and 17 age-matched adults without neurological impairments were taught three reaching tasks with different instructions.	Forty-eight training trials on 1 day; eight trials for each task condition on each of three tasks	Counterbalanced repeated measure design, with random assignment to AB or BA sequence of task performance; Level: 1B1a	Participants directed to focus on the task had shorter movement times and greater peak velocity than participants directed to focus on the movement itself.	Can task: CVA group movement time $p = 0.002$, $r = 71$; peak velocity $p = 0.002$, $r = 61$. Control group movement time $p = 0.009$, $r = 0.61$; peak velocity $p = 0.0001$, $r = 0.79$. Mug task: CVA group movement time $p = 0.027$, $r = 0.68$; peak velocity $p = 0.013$, $r = 0.61$; control group movement time $p = .003$, $r = .68$; peak velocity $p = 0.003$, $r = 0.68$	Fasoli et al. (2002)
Training in a task in a natural or simulated context	Participants practiced an eating task using chopsticks in a natural or simulated context.	Forty right-handed college students without disabilities and without previous experience with using chopsticks. Mean age = 23.75 years.	Sixty training trials on 1 day; 24-hour retention measured on a transfer task	Randomized controlled study; Level: IB1c	Participants in natural context performed better than those in a simulated context on the transfer task.	Natural context: $p = 0.03$, $r = 0.30$ for success rate at retention trial in the transfer task	Ma, Trombly, & Robinson-Podolski (1999)
Effect of goal-directed action	Experiment 1: Subjects reached in a goal-directed action or to a spatial location. Experiment 2: Subjects reached for phone, disconnected receiver, and a stick.	Fourteen stroke survivors (nine LCVA, four RCVA, and one bilateral CVA). Mean age = 65 years; average time since onset of stroke = 39 months	Each participant tested under several conditions	Randomized controlled repeated measures counterbalanced design; Level: IC1b	Participants reaching for an object were faster, smoother, and took less time to reach peak speed than when they reached for a point in space.	Experiment 1: number of movement units, $p = 0.05$, $r = 0.55$; movement time $p = 0.02$, $r = 0.62$; percentage of reach to peak velocity, $p = 0.04$, $r = 0.57$; peak velocity, $p = 0.01$, $r = 0.66$; Experiment 2: no effect	Trombly & Wu (1999)
Presence or absence of objects used in movements	Participants were evaluated for movements with object or without object.	Fourteen stroke survivors (nine LCVA, five RCVA, and one bilateral CVA) and twenty-five neurologically intact adults	Each participant was tested under two conditions: reaching to scoop up coins and reaching to where the coins would have been	Randomized controlled repeated measures counterbalanced design; Level: IC1b	Using real objects elicited better performance of reaching, as measured by decreased movement time, decreased displacement, higher velocity, and fewer movement units.	Stroke survivor data: movement time, $p = 0.0028$, $r = 0.70$; total displacement, $p = 0.0019$, $r = 0.72$; percentage of reach where peak velocity occurs, $p = 0.0011$, $r = 0.75$; movement units, $p = 0.0055$, $r = 0.66$	Wu et al. (2000)

RCVA, right cerebral vascular accident; LCVA, left cerebral vascular accident; CVA, cerebral vascular accident.

Procedures for Practice 13-1

Caregiver Education and Training

Ever-decreasing hospital lengths of stay continue to increase the demands and responsibilities of family caregivers (Clark et al., 2004). Occupational therapists and other rehabilitation professionals can contribute to clients' quality of life by providing multidimensional education and training to their caregivers (Chee et al., 2007; Kalra et al., 2004; Pasacreta et al., 2000). Here are some important considerations and strategies:

- Acknowledge and validate the pivotal role that family caregivers play in the recovery and quality of life of your client. Make sure that your occupational therapy intervention plan incorporates specific goals, strategies, and timelines for caregiver training.
- Appreciate the complex demands placed on people when they assume caregiver roles. Remember that family caregivers typically have to juggle the needs of other family members and their own jobs and activities in addition to their caregiving responsibilities (Carter & Nutt, 1998; Pasacreta et al., 2000). Adjust your teaching methods in consideration of these demands and distractions on caregivers and expect that you will need to repeat information and instructions more than once.
- Empathize with the emotional burden often carried by family caregivers. Appreciate that they carry an array of worries about their loved one's condition, the quality of care their loved one is receiving, and what the future holds in terms of their caregiving responsibilities (Hong, 2005). Make a point of structuring your education and training efforts to address these worries.

- Incorporate caregiver education and training into your intervention from day 1 by showing family members how to participate in providing care. Ask family members to attend therapy sessions and include them as active participants. Show them how they can extend the benefits of occupational therapy intervention by, for example, prompting and assisting with ADL or reinforcing the use of adaptive equipment.
- Often, therapists are well acquainted with the client's medical and social history, but the caregiver's situation may be less well known. Caregiver factors that are important to investigate include the caregiver's health and their understanding of the client and the client's condition (Chee et al., 2007). When caregiver health is a concern, the caregiver may need to be encouraged to address their personal health concerns.
- Collaborate with other health care professionals to ensure that caregiver education and training is multifaceted and ongoing. Appreciate that current and premorbid family functioning is an important predictor of caregiver stress and adjustment (Clark et al., 2004). Refer caregivers and their family members to counselors, psychologists, and social workers when necessary (Nabors, Seacat, & Rosenthal, 2002).
- Take responsibility for helping family caregivers to transfer what they have learned in the hospital or clinic setting to their home and family contexts. Consider making a home visit before discontinuing your services to review information and techniques within the client's home environment.

---

in this sequence to new tasks, and therefore training time is minimized. The therapist plans that with consistent repetition, the routine will be carried out automatically.

However, occupational therapy intervention, such as ADL training, often begins while the patient is hospitalized. Patients learn one-handed dressing techniques from hospital beds in rooms that are very different from those of their homes. For the intervention to improve the patient's level of independence after discharge, the therapist must train to transfer. That is, therapists employ teaching techniques that optimize patients' chances of being able to apply the task-specific dressing skills learned at the hospital when they get home.

Transfer of learning refers to a person's ability to carry out the same task in a different environment. According to Toglia (1998), transfer is not an all-or-nothing phenomenon. She described three levels of transfer—near, intermediate, and far—based on the number of differences in the surface characteristics between the learning and real-life environments. In general, near transfer requires the person to apply the same skill in very similar circumstances,

whereas far transfer implies greater differences in application environment (Perkins, 1995). Transfer is associated with perceptual similarities of tasks, not similarities in underlying principles (Perkins, 1995). Therefore, transfer places minimal demands on metaprocessing abilities and requires less training time than generalization of newly learned strategies (Saloman & Perkins, 1989).

Strategies and Generalization of Learning

Whereas acquisition of task-specific skills involves learning targeted behavioral sequences, the acquisition of strategies entails learning rules or principles that can be broadly applied. For example, many therapists expect persons with stroke to learn this general strategy: dress the weak side first. This rule or principle enables patients to don sweatshirts, dress shirts, slacks, and outerwear, but it presumes generalization of learning.

Generalization occurs when the person is able to apply the newly learned strategy to a new task in a new environment. For example, the patient who demonstrates the

ability to get dressed one-handed in the hospital can use the same strategies to put on a raincoat at home. Generalization, as it is here defined, depends on the learner's mindful abstraction of a principle and is based on conceptual similarities between the learning task and environment and the real-world application (Perkins, 1995). Generalization of learning places greater demands on patients' metaprocessing abilities (Saloman & Perkins, 1989).

FUNDAMENTALS OF THE TEACHING–LEARNING PROCESS

Clearly, the value of occupational therapy intervention will largely be judged by the extent to which new skills and strategies are carried out in patients' real-life environments. Therapists interested in helping patients achieve transfer and generalization objectives incorporate research findings about critical constructs in teaching–learning theory. These constructs relate to the therapeutic use of context, feedback, and practice.

Therapeutic Use of Context

The term "context" broadly refers to the setting in which an event or activity occurs. Many conceptions of context as a facilitator or barrier to function can be found in the occupational therapy and rehabilitation literature (American Occupational Therapy Association [AOTA], 2008; Fisher, 1998; World Health Organization, 1997) (see Chapters 3 and 10). The Occupational Therapy Practice Framework (AOTA, 2008) suggests that context has many dimensions: cultural, physical, social, personal, temporal, and virtual. It also defined activity demands in terms of objects and their properties, space demands, social demands, sequencing and timing, and required actions as influencing the performance of skills and patterns. A brief discussion of the influence of environmental context and activity demands on learning follows.

Role of Context in Learning

Research strongly supports that objects used in activities, the characteristics of those objects, and the goals of the activities performed have a strong influence on motor performance and must be carefully manipulated in treatment. Wu et al. (2000) demonstrated that stroke survivors and nonimpaired individuals elicited smoother, faster, and more coordinated arm movements when using real objects in movement tasks. Participants were asked to scoop money from a table or reach to a point on the table in the scooping position. The use of real objects has been found to elicit different movements and learning than imagery-based tasks or rote exercise in persons with disabilities such as cerebral palsy, stroke, and multiple sclerosis (Mathiowetz & Wade, 1995; Trombly & Wu, 1999; van der Weel, van der Meer, &

Lee, 1991; Wu et al., 2000). Mathiowetz and Wade (1995) demonstrated that both subjects with multiple sclerosis and those without benefited from the information provided by real objects. Subjects in the materials-based condition were asked to eat applesauce with a spoon, bowl, and applesauce available; in the partial-support condition, they pretended to eat applesauce with a spoon and bowl available; and in the imagery-based condition, they pretended to eat applesauce without a spoon or bowl. Again, the movement patterns in the three conditions were significantly different. These findings support occupational therapy approaches that emphasize the significance of real-life objects and tasks in optimizing function (Mathiowetz & Haugen, 1994) (see Chapters 8 and 21 for more about this approach.) These and previous findings are likely explained by two important principles: encoding specificity and contextual interference.

Encoding Specificity

The principle of encoding specificity suggests that events are stored in memory along with their contexts (Smith & Vela, 2001). That is, people encode features of the learning task and environment along with the newly acquired skill or strategy. Encoding specificity limits transfer and generalization because new tasks and environments do not have the same cueing properties as those present during original learning, making retrieval from long-term memory more difficult. For example, imagine that a patient practices the same grasp and release task every day; even the work space is consistent. Although the patient improves performance on the task, the information about control of grasp and release is stored along with the context of the practice task and environment, and he or she may not be able to demonstrate the skills during functional activities or away from the practice space.

Contextual Interference

One way to mitigate the influence of encoding specificity on learning is to employ high contextual interference training (Battig, 1978). Low contextual interference occurs when the context and training task are invariant, allowing the learner to perform the same task repetitively in a consistent environment, as in the previous example. On the other hand, high contextual interference occurs when the task and environment keep changing throughout the learning process. This principle asserts that task and environmental variation force people to use multiple and varied information processing strategies, which makes retrieval easier. Contextual interference forces elaborate processing strategies, and transfer is facilitated. As a result, the patient will be more likely to use the newly learned skills to solve problems within the inevitable variety of the real world. Therefore, to facilitate transfer of task-specific skills and generalization of newly learned

strategies, therapists deliberately vary the learning tasks and environments.

Therapeutic Use of Feedback

Feedback also can enhance or interfere with learning. Occupational therapists understand the functions of feedback and deliberately select the types and schedules of feedback in designing a patient's learning experience.

Functions of Feedback

Feedback regarding performance has several functions (Salmoni, Schmidt, & Walter, 1984). It has a temporary motivating or energizing effect and a guidance effect that informs the learner how to correct an error on the next trial. However, feedback can permanently impair motor learning if provided beyond the point that the person has a rough idea of the desired motion, because it becomes a part of the environment and is then needed for performance.

Types of Feedback

To help patients learn and sustain skills and strategies, therapists initially provide extrinsic feedback on performance but ultimately must facilitate the development of intrinsic feedback.

Extrinsic Feedback: Knowledge of Results and Knowledge of Performance. Therapists typically provide feedback about performance in verbal form. Extrinsic information presented after task completion falls into two categories, knowledge of results and knowledge of performance. This feedback allows subjects to alter or adapt their responses or behaviors on subsequent trials. *Knowledge of results* provides information about outcome, such as "You've got your shirt on" or "You took the cap off the jar." A second type of feedback, *knowledge of performance*, is related to qualitative descriptions of a performance, such as "You shifted your weight too far to the left" or "You bent your elbow." This information directs patients' attention not to outcome but to components of movement that they need to change or attend to. This type of feedback duplicates information patients already have but may serve to focus their attention to specific parts of the movement. Other external information provided to patients during practice falls into the category of encouragement. It is important that therapists not confuse encouragement ("Keep going") with feedback ("You're doing great"), especially if the latter is not true, because incorrect feedback is highly detrimental to learning (Buekers, Magill, & Hall, 1992).

Intrinsic Feedback. Intrinsic feedback, or internal feedback, is information that patients receive through their own senses, such as seeing an egg break as it hits the floor after dropping it or feeling the pain of hitting the ground after an unsuccessful transfer. Although this information is available to patients, they may need cueing to focus on the most important components of a skill or strategy, such as using vision when moving a limb with impaired sensation. Intervention that incorporates self-monitoring and self-estimation (task difficulty, completion time, accuracy score, amount of cueing, or assistance needed) enables patients to create mechanisms for self-generated feedback (Cicerone & Giacino, 1992; Toglia, 1998), lessening dependence on therapists for successful performance.

Feedback Schedules

The frequency and content of feedback are critical to the learning process and must be considered when a teaching situation is planned.

Immediate and Summary Feedback. The frequency and timing of feedback can profoundly influence the acquisition and learning of task-specific skills and strategies. Studies in this area evaluate learning during a "retention trial," which is done some time after teaching is completed. For example, Lavery (1962) wanted to know which schedule of feedback best facilitated learning: immediate feedback provided after each trial was completed, also referred to as constant feedback; summary feedback provided after a number of trials were completed; or both. Lavery found that subjects who received immediate or combined feedback improved their performance of the task more quickly during the training than the group receiving only summary feedback. However, when tested for retention of the task 4, 37, and 93 days after training, the subjects who received only summary feedback did significantly better than those who received either immediate feedback or both types.

Lavery (1962) hypothesized that people who received immediate feedback came to rely on it when performing the task and those that received only summary feedback were forced to analyze their own movements. The subjects who received both immediate and summary feedback did just as poorly as those who received only immediate feedback, suggesting that the immediate feedback interfered with the processing of the summary feedback. Beyond its implications about the schedule of feedback, these findings support the idea that performance during the training phase does not reflect actual learning of the skill and that learning can only be assessed after the training session.

Faded Feedback. Therapists are often concerned that providing only summary feedback after a series of trials will not help their patients understand tasks that are complex or new. Winstein and Schmidt (1990) evaluated the effectiveness of feedback given on 50% and 100% of trials on the learning of a task by college students. The 50% feedback was faded, with the feedback given on every trial initially and then decreased to no feedback at the end of

training, with feedback being given on an overall average of 50% of all the trials. They found a slight advantage for the 100% feedback group during acquisition of the skill, but the group that received faded feedback performed significantly better than the immediate feedback group on the retention trials. These findings point out an important irony in teaching: factors that degrade performance during acquisition often improve learning.

Bandwidth Feedback. With bandwidth feedback, an acceptable range of performance is defined, and the subject receives feedback only when performance is outside of that range. As the subject's performance improves, feedback is provided less frequently.

Therapeutic Use of Practice

In addition to planning feedback, the design of a treatment session factors in the nature of instructions and a plan for practicing the material.

Internally or Externally Focused Instructions

Research supports instruction that is focused on the task rather than on the patient's performance. For example, Fasoli et al. (2002) found that patients with strokes reached faster and more smoothly when cued to focus on the object and what they were going to do with it rather than focusing on their arm as they did the task. This means that the instructions given to patients should focus their attention on the objects and the task, rather than on the movements that they will be using to achieve the goal.

Blocked versus Random Practice

As discussed earlier, traditional models of learning did not distinguish between learning and performance. These models also promoted blocked forms of practice, such as drill, as the most efficient schedule for learning a task. Using a blocked format, the same skill or strategy is practiced over a number of repetitions, after which the next skill or strategy is rehearsed. As such, blocked practice is a form of practice with low contextual interference.

Shea and Morgan (1979) studied whether increasing the contextual interference by random practice during skill acquisition leads to improved retention and transfer of motor skills. Their experiments entailed knocking over wooden barriers with a tennis ball held in the hand. In brief, they found that blocked practice provided low contextual interference, whereas random practice provided high contextual interference, requiring subjects to formulate a new movement plan for each trial. Subjects who practiced with high contextual interference demonstrated better retention and transfer than those who used blocked practice. This study demonstrated two important findings: (1) performance during acquisition of a skill does not necessarily relate to later learning and

(2) conditions that may improve performance during acquisition do not necessarily create better learning. In fact, structuring training to improve performance during practice by using blocked practice schedules can actually decrease task retention and transfer (Brady, 2004).

The advantage of random practice over blocked practice was also demonstrated for patients with hemiplegia (Hanlon, 1996). Patients practiced a multistep functional activity that consisted of reaching for a cupboard door, opening it, picking up a coffee cup by the handle, transferring it to a counter, and releasing the handle. The subjects practiced these steps in either a blocked or a random pattern. The random pattern group performed significantly better than either the blocked or control group on both the 2- and 7-day retention trials.

Part-Whole Practice

Therapists also decide whether patients practice the whole task or components of a task (referred to as part-whole training). Ma and Trombly (2004) evaluated the characteristics of movement under part and whole task conditions. The task involved reaching for a pen, bringing the pen to paper, and signing their name. The three segments of movement were performed separately and then as a single task for each individual. The performance of the whole task elicited greater efficiency of movement, greater force during the task, and smoother movements. Winstein et al. (1989) examined the effect of part-task practice with gait training. One group of patients with hemiplegia received traditional physical therapy gait training. The second group received traditional physical therapy and specific training in standing balance symmetry (proposed as a reasonable critical component of symmetrical gait). After several weeks of training, the group that had practiced symmetry in standing showed improvement in that component of the activity, but there was no carryover to the whole task of gait. There was no significant difference in gait symmetry between the two groups.

These findings demonstrate that in some situations whole practice is more effective than part practice. It will require much more research to identify the components that will transfer to the whole task before part-task training can be the preferred method. Winstein et al. (1989) suggested that tasks that are continuous and cannot be easily separated into component parts may not be appropriate for part training. Examples of this type of movement include walking or driving a car—tasks that require many adjustments with components that occur simultaneously and cannot be easily separated.

Intensity of Practice

Much focus in motor rehabilitation over the last several years has been on techniques such as constraint-induced movement treatment for people with upper extremity dysfunction. This intervention has been found to drive neuroplasticity and improve functional use of the arm after

stroke (Wolf et al., 2006). Intensive practice has now been identified as an active component in a variety of other interventions, including partial weight supported gait training for people with stroke (Duncan, Sullivan, & Behrman, et al., 2011), and Lee Silverman Voice Treatment® Big and Loud Therapy (BIG) for people with Parkinson's Disease (Farley & Koshland, 2005). BIG is an intensive intervention specifically designed to remediate movement disorders in clients with Parkinson's Disease. Intensity of practice includes a number of features of practice, including practice of difficult tasks that are directly related to the performance objective, high rates of repetition, a focus on transfer of the skill to the performance environment, and choosing tasks with meaning to the client (Kleim & Jones, 2008). Incorporating these principles into occupational therapy treatment will increase the effectiveness of treatment, but the number of these principles that can be implemented will depend on the client's diagnosis, endurance, and the treatment environment (see Research Note 13-1).

MAKING PERSONAL CHANGE

Employing a newly learned skill or strategy is fundamentally a personal change depending not only on recall, transfer, or generalization but also on learners' beliefs about their competence and their stage in the change process.

Bandura (1977) posited that people's beliefs about their ability to handle a new situation largely determine whether they attempt the new task and their ultimate performance. Self-percepts of efficacy (self-perceptions of competence) predict success with a wide range of acquired health behaviors, including smoking cessation (Stewart, Borland, & McMurray, 1994), exercise maintenance (McAuley, 1993), medication compliance (DeGeest et al., 1994), and use of energy-conservation techniques to manage fatigue (Mathiowetz, Matuska, & Murphy, 2001). Bandura (1977) demonstrated that people make judgments about their competence (self-efficacy) by thinking about past accomplishments, vicarious experience (observing others who are similar), verbal persuasion, and emotional arousal, such as anxiety. Because self-percepts of competence seem to explain the discrepancy between what people can do and what they actually do (Bandura, 1982), occupational therapists actively create opportunities for patients to demonstrate to themselves that they are indeed competent with the new skill or strategy.

Many patients served by occupational therapists have had recent changes in physical functioning. Persons who are insulated from ramifications of these changes (perhaps those who have been hospitalized continuously since onset) may not fully appreciate the need for the skills and strategies therapists are attempting to teach them. The Stages of

Research Note 13-1

W., Corn, B. H., Maffucci, A. D., Nadeau, S. E., Conroy, S. S., Powell, J. M., Huang, G. D., Peduzzi, P. (2010). Robot-assisted therapy for long-term upper-limb impairment after stroke. *New England Journal of Medicine, 362,* 1772–1783.

Abstract

Lo and colleagues investigated the effects of robot-assisted therapy in subjects with upper limb impairment who were at least 6 months post stroke. One hundred twenty-seven participants with moderate to severe arm impairment were randomized to three intervention groups. Group 1, who enrolled an average of 3.6 years after their stroke, received 36 1-hour sessions of intensive robot-assisted therapy focused on four modules. They included a shoulder–elbow movement focusing on horizontal movements, an antigravity unit for vertical movements, a wrist unit for wrist movements, and a grasp-hand unit focused on hand opening and closing. Group 2, who enrolled an average of 4.8 years after their stroke, received 36 1-hour sessions over 12 weeks of intensive comparison therapy, including a structured high repetition protocol of assisted shoulder stretching,

arm exercises, shoulder-stabilization activities, and functional reaching tasks. Group 3, who enrolled an average of 6.2 years after their stroke, received usual and standard care that was available to all clients and was not dictated by the research project. The robot-assisted therapy and intensive comparison therapy were matched for repetitions per session, at about 1,000 repetitions per 1-hour session. At the end of the 12-week intervention period, robot-assisted therapy did not produce significantly better motor outcomes than usual care or intensive comparison therapy. However, over the 36-week study period, robot-assisted therapy was significantly better than usual care but not significantly better than the intensive comparison therapy. This study provides evidence that intensive models of rehabilitation may benefit patients even years post stroke.

Implications for Practice

- The intensity of practice, as determined by the number of repetitions, is a critical feature of a therapy intervention and needs to be included in the plan for therapy.
- Provision of therapy, even years post stroke, can provide clinically significant improvements in arm function, and potential long-term benefits from rehabilitation. This finding challenges the clinical belief that long-term stroke survivors cannot make significant improvements in upper extremity function.

Change Model (Prochaska & DiClemente, 1982) helps therapists target their teaching–learning interventions to address the learning predispositions of the client and family.

This model identifies five stages of change: precontemplation, contemplation, determination, action, and maintenance. During the precontemplation stage, clients are not even aware of the problem. In the contemplation stage, they become aware of the problem or concern, and in the determination stage, they resolve to do something about it. During the action stage, clients work to address the problem or issue. During the maintenance stage, clients must still put forth some degree of effort to sustain the desired skill or behavior. Prochaska and DiClemente (1982) suggested that verbal intervention strategies are most appropriate during the first three stages (pointing out the problem and discussing possible approaches), whereas action-oriented behavioral interventions are most helpful during the last two stages. For example, before a client routinely employs strategies for scanning the left visual field, he must believe that he is missing those parts of the environment or that personal safety is in jeopardy. Attempting to verbally convince a patient that they have a particular problem is estimated to be effective in generating behavior change in only about 15% of the time (Kottke et al., 1988). Once the patient is convinced that he has a problem and is motivated to change, he can be taught specifically how to manage the problem.

Motivational Interviewing

Motivational interviewing (MI) is a method designed to help clients make behavior changes. MI was developed in the field of chemical dependency and has been very effective in helping clients implement behavior change across a broad range of health conditions including musculoskeletal diagnoses, asthma, diabetes, hypertension, cardiovascular disease, and increasing the effectiveness of family education (Byers, Lamanna, & Rosenberg, 2010; Rollnick, Miller, & Butler, 2008; Shannon & Hillsdon, 2007). The central feature of MI is development of a client–clinician relationship that is collaborative, evocative, and honors the client's autonomy. MI's effectiveness is based on activation of the clients' own motivation for change while acknowledging their ambivalence about those changes. In the management of many chronic conditions, the problem is not necessarily an issue of knowledge about the condition: clients often know that they should take their medication, exercise, or quit smoking but are not motivated to make those changes today. MI helps clients develop the motivation to make those changes by helping them articulate the arguments for the change.

There are four guiding principles for therapists using MI: **R**esist the righting reflex, **U**nderstand the client's own motivations, **L**isten with empathy, and **E**mpower the patient through encouraging hope and optimism (Rollnick & Heather, 1992). The righting reflex (or the reflex to resist change) is a normal psychological response to being told what to do: resisting the change. This creates a conversation that includes statements like "Yes, . . . but," in which clients articulate the reasons *not* to change. As they restate the reasons they cannot change, clients become further convinced by their own arguments. Thus, this conversation actually decreases the likelihood that clients will implement the change. The goal of MI is to switch the conversation so that clients make the arguments for change. In order to do that, the occupational therapist must resist the tendency to tell clients what to do, and instead, collaborate with them to develop their own arguments for change (Rollnick & Heather, 1992). This is done primarily through the use of a communication style that is "guiding" (Rollnick, Miller, & Butler, 2008).

MI requires that occupational therapists be aware of their communication styles and have the skills to move between them as they work with clients (Rollnick, Miller, & Butler, 2008). The three communication styles used in MI are the following:

- Guiding—characterized by recognition by the occupational therapist that the client has the answers about how to change his or her own behavior and that the client is in charge of making those changes.
- Following—seeks to understand the client's story, focuses on listening, encouraging the client to talk, and asking questions only to clarify. When using a "following" style, there is no agenda other than to understand the client's perspective and experience. A following style is often appropriate when initially trying to understand clients' lives.
- Directive—used when there is a clear difference in knowledge, expertise, or power between the occupational therapist and the client. This is appropriate when we are instructing clients in techniques, strategies, or providing specific information. However, when the focus is on creating motivation for behavior change, a directive approach may trigger the righting reflex. The appearance of "Yes, . . . but" statements are a cue for the occupational therapist that she is using a directive style (Rollnick, Miller, & Butler, 2008).

The second guiding principle is to focus on the client's understanding, values, and motivations (Rollnick, Miller, & Butler, 2008). The client's situation is unique, and it is only through focusing on the client's perspective that his or her motivation can be awakened. This client-centered focus aligns well with the principles of occupational therapy.

The third guiding principle involves using open-ended questions, reflective statements, and summaries, with particular attention to statements that indicate a **D**esire for change, **A**bility to change, **R**easons for change, and **N**eed for change (DARN) (Rollnick, Miller, & Butler, 2008). DARN statements are forms of "change talk," in which clients talk

about their understanding of the pro-behavior-change side of their ambivalence. DARN statements indicate that they are in a precommitment state and reveal their values. The occupational therapist reflects these statements back to the client, which helps the client clarify desires, abilities, reasons, needs, and values. Therapists also pay particular attention to statements about committing to change and statements about taking behavioral steps (Rollnick, Miller, & Butler, 2008). As clients engage in self-talk, they strengthen their own motivation to make change.

The final guiding principle of MI is to empower clients to make changes in their behavior. The therapist may know that a client needs to do home exercises or be more active, but the client is the one who knows how to make those changes within the context of his or her daily life. By helping clients think out loud about how they might implement change within their lives, the small steps that they might take, we can help clients improve their health (Rollnick, Miller, & Butler, 2008).

While MI focuses on clients' control of their behavior, the therapist structures the interaction so that clients begin to identify the need for change through the agenda-setting process (Rollnick, Miller, & Butler, 2008). At this point, clients are presented with a variety of possible behavior change topics, always leaving the opportunity for clients to pick other areas if their target is not present. For example, you might present a number of behaviors such as exercise or losing weight, depending on the client's situation. Then the client is asked which, if any, he or she would like to work on. When the client picks his or her target behavior, the therapist continues to ask open-ended questions, reflect back the client's statements, and work toward commitment to change. If the client is not able to pick a target behavior, the therapist continues to elicit change talk. In this way, the power of behavior change is held by the client, and the therapist is there to help him or her implement those changes (Rollnick, Miller, & Butler, 2008).

OCCUPATIONAL THERAPIST AS TEACHER

The extent to which occupational therapy contributes to a client's resumption of roles depends to a large extent on the effectiveness of the therapist as a teacher. The principles of teaching parallel therapy are the following: assessment, goal setting, intervention, and evaluation (Redman, 1997). Although this process rarely follows a predictable, orderly sequence, these steps serve as a checklist to ensure that therapists consider variables affecting the outcome of their teaching efforts (Redman, 1997).

Assess Learning Needs and Readiness

Based on the therapist assessment of the client and identification of barriers to learning, the therapist determines who will be the subject or subjects of the teaching—the patient, family member, or both (Vanetzian, 1997).

Set Client-Specific Learning Goals

Therapists use the results of their assessments and estimates of the treatment time available to set learning and cognitive objectives for each patient. Therapists plan treatment around transfer and generalization goals by identifying reinforcements in the natural environment and incorporating into the treatment stimuli common to both training and real-world environments (Sohlberg & Raskin, 1996). If the intervention ultimately is to change an existing routine, skill, or strategy, the therapist attempts to identify the client's stage of change. For example, a patient with no awareness of a memory problem will see little value in learning to use compensatory memory techniques. Therefore, the therapist sets goals that move the patient toward the contemplative stage of change by allowing him or her to take the consequences of forgetting. Finally, therapists merely recommend learning goals. Goals that direct teaching–learning efforts are set in collaboration with patients and their families.

Create Learning Opportunities Throughout Intervention

Therapists deliberately use context, feedback, and practice to help patients meet learning goals (Procedures for Practice 13-2). They enhance motivation and recall by linking new skills or strategies with patients' specific interests, knowledge, and abilities. Effective teachers also make an effort to overcome barriers to learning. Clinicians recognize that literacy affects comprehension and use written materials that minimize the demand for reading (DeWalt et al., 2010). Citing the results of the 2003 National Adult Literacy Survey, Schneider (2005) reported that 13% of all Americans had "below basic" English literacy for prose material. This means that 30 million Americans cannot do much more than sign a form or review a document to see what they are allowed to drink before a medical procedure (Schneider, 2005). Another 22% had only "basic" literacy, meaning, at best, they can find information in a pamphlet about how jurors were selected for a jury pool (National Center for Education Statistics, 2005). Therefore, clinicians create and use written materials that are well organized and limit the demands on reading (Procedures for Practice 13-3).

Develop Plan to Promote Patient Adherence

As a part of teaching, therapists need to explicitly address issues of patient adherence, defined as the degree to which patients act in accord with advice of a health

Procedures for Practice 13-2

Therapeutic Use of Context, Feedback, and Practice to Promote Transfer and Generalization

- Vary the training environmental context to achieve transfer; vary training tasks and environments to achieve generalization of new strategies.
- Provide extrinsic feedback just until the learner understands the desired movement, skill, or strategy. Use cueing and the patient's own performance prediction and analysis to help the learner increasingly rely on intrinsic feedback.
- Provide summary feedback when possible. Tolerate a slower or longer acquisition phase of learning, appreciating the later benefits in terms of retention, transfer, and generalization.
- Fade therapist feedback and cues so that these elements of training do not get encoded with the new skill or strategy.
- Attempt to teach movement, skills, and strategies within whole tasks. Address components or subskills only when they are critical to whole-task performance.

Procedures for Practice 13-3

Addressing Low Literacy in Patient Teaching

Problems with literacy pervade all socioeconomic and ethnic groups (Thomas, 1999). People with low literacy tend to be ashamed of their difficulties with reading and are reluctant to admit the problem, even to family members (Parikh et al., 1996). Thomas (1999) and DeWalt et al. (2010) offer the following suggestions for addressing this issue in occupational therapy:

- Incorporate a brief evaluation of literacy into the occupational therapy assessment process (see Chapter 3).
- Limit the quantity of information to the most important messages. Collaborate with the patient, family, and other team members to establish priorities.
- Reduce the reading level of printed materials by using one- or two-syllable words, shortening sentences to 10–15 words, and targeting materials to the fifth- or sixth-grade reading level.
- Make sure text and graphics are well organized. DeWalt et al. (2010) recommend chunking information, using paragraph headings, and having white space between sections.
- Use materials that are racially and culturally sensitive. As recommended by Thomas (1999), "make sure that patients can 'see themselves' in materials provided. (p. 3)."

professional (Moseley, 2006). Critically, when therapists acknowledge the normal problems with adherence that the average client has, they give clients license to admit whether adherence is a problem at the time of future sessions (Radomski, 2011). Acknowledging that compliance is difficult also helps client and therapist set up an adherence plan at the time of the recommendations, by linking the home program to a specific point in the daily routine and purposely simplifying the recommendations. In developing this adherence plan, clients and therapists identify any social, technological, or environmental supports available to shore up adherence, such as family members who can cue the client, either in person or through text messaging, alarms that could be set, or checklists that could be followed. Finally, clients are more likely to comply with adherence plans when there is a clear benefit (Radomski, 2011). By addressing the

issue of adherence as recommendations are made, the likelihood of the recommendations being carried out is increased.

Evaluate Achievement of Learning Goals

Effective teachers routinely assess clients' progress toward learning goals, typically by changing the training task or environment and evaluating carryover. Family members perform return demonstrations of new techniques, such as transfers. Based on performance or other changes in learning status, therapists adjust learning goals throughout the intervention.

case example

Learning as Part of Clinic-Based Intervention for a Client with Mild Stroke

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Client Information

Mrs. B. is a 45-year-old woman who had a mild stroke 3 weeks ago. She is married with three grown children. She had an episode of expressive aphasia and right-sided weakness while at work. She was admitted to the hospital and given anticoagulants, and most symptoms resolved over the next 48 hours. She was hospitalized for 2 days, and hyperlipidemia and high blood pressure were identified as the causes of her stroke. She was discharged to the care of her family physician and has been off work since her discharge. She works as an executive assistant in a large insurance company.
ADL: She is able to do her self-cares but rates her fatigue, as 10/10 in severity. Currently, she tries not to rest during the day: "No pain, no gain," but becomes so exhausted by 2:00 that she falls asleep wherever she is. When asked about taking more rest breaks when she was tired, she said, "I'd be sleeping all the time—I'm tired at 9:00 in the morning!"
Upper extremity function: Mrs. B. had noticed some right upper extremity weakness on the day of her stroke but has had no difficulty since then. Mrs. B.'s arm function has normal strength and range of motion, and she uses it well in activities. Walking and mobility: Mrs. B. reports no problems with gait or balance. IADL: She is struggling with managing her low-fat diet and feels like she needs to "learn a whole new way to cook." She has been told she cannot drive for 3 months and is relying on family and friends for transportation. Cognitive function: Mrs. B. complains that sometimes her thinking is "not right," whereas at other times, she has no problems. She says she forgets things and is struggling to learn her new diet and take her new medications. She scores within normal limits on a cognitive screen. Work: She is anxious to return to work as soon as possible, but her physician has said she cannot go back for at least another month. She is afraid that her boss will not hold her job for her while she is on medical leave.
Patient's safety: Mrs. B.'s judgment and memory are intact, she is a good historian. However, the severe fatigue could lead to problems with safety, particularly while cooking or walking.

Appreciate the context

"This is a young woman who had no real health concerns prior to this stroke, so it must have been quite a shock to her. She also has other new diagnoses with major consequences, so there are lots of changes in her life right now. I think if I can help her understand her fatigue and its implications, she will be able to get back to her usual tasks. She seems very anxious to return to her life and motivated to make changes, but these are big changes and will be difficult to implement."

Develop intervention hypotheses

"I think that instruction in energy conservation principles might be helpful, but they will need to be integrated into her life. Given her level of fatigue, it is going to be difficult to balance her therapy schedule with her capacity to attend therapy. Return-to-work issues will need to be discussed, and the willingness of her employer to make adaptations for her could be a problem."

Consider the evidence

"I have read that fatigue after stroke occurs in about 50%–70% of stroke survivors (Lerdal et al., 2009) and can have a profoundly limiting effect on stroke survivors' function (Flinn & Stube, 2009). Energy conservation techniques have been shown to be promising in a pilot study (Clarke, Barker-Collo, & Feignin, 2012)."

Select an intervention approach

"I will use these intervention approaches: teach compensatory skills for fatigue, change the physical environment/context as needed to decrease fatigue, and further evaluate her work situation."

Reflect on competence

"These new diagnoses are going to be a challenge for Mrs. B. to manage and have changed how she needs to do previously automatic tasks, such as cooking. The need to change so many things at once is going to be difficult for Mrs. B. She needs to understand the role of fatigue in memory function. I know some information about reducing cholesterol through diet, but I should have Mrs. B. bring in the materials she has been given so that I am sure that what I say is consistent with what she has learned elsewhere."

Recommendations

Clinic-based occupational therapy two times a week for 2 weeks and then once a week for 4 weeks. This therapy schedule will allow Mrs. B. to practice energy conservation techniques and accommodate her overwhelming fatigue. Short-term goals for therapy include (1) client will report fatigue of 7/10 at the end of the day in her daily diary; (2) client will explain her fatigue to her husband and gain his help in making accommodations; (3) in the next 2 weeks, the client will cook three new meals that accommodate her high cholesterol diet; and (4) Mrs. B. will find out how long they will hold her job and how to go about making accommodations.

Consider the client's appraisal of performance	"Mrs B.'s fatigue is overwhelming to her, and she does not really understand how her cognitive symptoms relate to fatigue. She is so overwhelmed by all the changes in her life that she has not made changes in her diet. She will need help dealing with that additional change."
Consider what will occur in therapy, how often, and for how long	"We will meet for eight 1-hour sessions over 6 weeks, first addressing how fatigue and memory interact to allay some of Mrs. B.'s concerns. I am going to have her keep a diary so that she can record what she is doing, her fatigue levels, and how well she is implementing rest periods. In preparation for return to work, where she may need to ask for accommodations, I want her to start practicing how to explain her fatigue to her husband as way to build those skills."
Ascertain the client's endorsement of the plan	"I think that Mrs. B. is uncertain that she can learn to manage her fatigue but will be convinced if she starts to be successful."

Summary of Short-Term Goals and Progress after 3 Weeks

Once Mrs. B. understood how her fatigue affected her memory, she began to compensate for it by adding two rest breaks a day. Mrs. B. has established a routine for being home during the week that includes taking her medications and planning low cholesterol meals. She reports taking her medication regularly and has incorporated some dietary changes into her cooking. She has said that she talked to her husband about her fatigue and that she feels he understands, but she does not always tell him she is tired when they go out. She then gets overtired, and it takes her a day or two to recover. She continues to be anxious to return to work, but did talk to her employer, and got assurances that her job would be held until she is released to return to work by her physician.

Assess the client's comprehension	"It was really helpful to describe the components of memory and how fatigue and anxiety can sabotage memory function."
Understand what she is doing	"She has started to implement some principles of energy conservation, adding rest breaks at midmorning and midafternoon. She reports that her fatigue is usually about 5/10 at the end of the day, which is a big improvement. She has been inconsistent in implementing energy-saving strategies like using a tub bench or asking to rest when she and her husband go out to run errands."
Compare actual to expected performance	"Mrs. B. is not consistently implementing energy consevation strategies, and she will need to do that when she returns to work."
Know the person Appreciate the context	"I'm not sure how much Mr. B. really understands about her fatigue. Mrs. B. continues to need to ask him to make adjustments in their activities. I need to explore this further."
Anticipate present and future client concerns	"Mrs. B. is doing well, making changes and seeing benefit. She is reassured about her cognition and understands the impact of post-stroke fatigue. I think that post-stroke fatigue is going to be a major challenge to her return to work. I believe that she will be a safe driver but am recommending a driving evaluation when her physician allows her to drive again."
Analyze client's comprehension Decide if he or she should continue or discontinue therapy and/or return in the future	"Mrs. B. will be off work for another month or two. Mrs. B. and I have discussed the return-to-work services that are available through the state, and she has reluctantly applied for them. I am not suggesting continued therapy but have suggested that she return to therapy just prior to returning to work to review energy conservation strategies for work."

Next Steps

In the next three weekly sessions, continue to reinforce other energy conservation techniques by focusing on activities that she finds particularly fatiguing. Identify strategies that she could use at work to conserve energy. Encourage further changes in diet. Explore her reticence to ask her husband to accommodate her fatigue, perhaps using motivational interviewing.

Continue with revised goals.

After the first 3 weeks of treatment, new goals for therapy were set. They included the following: (1) Mrs. B. will report fatigue rating of 3/10 at the end of the day, (2) client will gain her husband's assistance in accommodating her fatigue, and (3) client will consistently modify her cooking to reduce cholesterol.

Clinical Reasoning in Occupational Therapy Practice

Designing Strategies to Increase Task Transfer and Generalization

Mrs. B.'s assessment suggested a number of learning needs related to energy conservation. List Mrs. B.'s learning needs. For two needs, give examples of how you can teach these skills to encourage transfer and generalization to other situations. Explain the difference in Mrs. B.'s learning processes for task-specific skills and general strategies in terms of speed and ease of acquisition and teaching methods.

Teaching to Increase Transfer and Generalization

For the examples listed above, explain the difference in Mrs. B.'s learning processes for task-specific skills and general strategies in terms of speed and ease of acquisition and teaching methods.

Summary Review Questions

1. List the types of practice patterns and discuss the advantages and disadvantages of each.
2. Design two ADL training sessions, one for learning a specific task and the second for learning a general strategy.
3. Discuss the different feedback schedules and compare their advantages and disadvantages.
4. Identify Fitts and Posner's (1967) three stages of learning. Describe the characteristics of performance that you might see as patients learn to use a piece of adaptive equipment.
5. List characteristics of practice most likely to facilitate transfer and generalization of practice.
6. Describe the influences on the learning readiness of a family caregiver. What will you do to optimize the learning process in response to these influences?

Glossary

Automaticity—The phase of learning resulting from numerous consistent repetitions in which a person accurately carries out a skill or task with little or no cognitive effort (Sternberg, 1986).

Contextual interference—Changes across trials in intrinsic and extrinsic factors that force learners to use multiple and variable processing strategies (Shea & Morgan, 1979).

Encoding specificity—A phenomenon of information processing wherein we store a given memory along with information about the context in which the memory occurred, and as a result, elements of the context may trigger recall and recognition of that memory in the future.

Feedback—Intrinsic or extrinsic information that patients receive while learning to perform a new skill or strategy.

Generalization—The ability to apply a skill or strategy to an altogether new task in an environment that is different from the one in which the original training occurred.

Health literacy—The cognitive and communication skills that allow individuals to access, understand, and use information in ways that promote and maintain good health (DeWalt et al., 2010).

Learning—The result of processes associated with practice or experience that leads to relatively permanent changes in a person's knowledge, skills, and behavior (Schmidt & Lee, 2011).

Performance—Temporary changes in response during practice.

Practice—The repetition of a to-be-learned task, a key ingredient in the learning of skills and strategies.

Retrieval—The search for and location of information stored in long-term memory that occurs when people remember (recall or recognize) something that they have learned (Eysenck & Keane, 1990).

Transfer—The ability to perform a new skill in an environment that is different from the training environment.

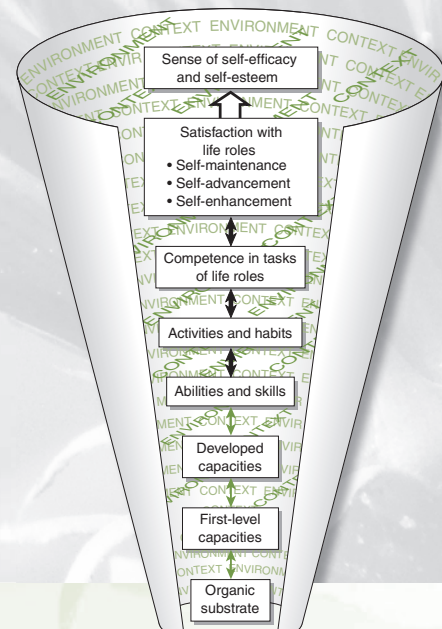
Therapeutic Rapport

Linda Tickle-Degnen

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define high therapeutic rapport.
2. Describe how rapport influences intervention and the client's occupational functioning.
3. Describe how collaboration between therapist and client contributes to achieving high therapeutic rapport.
4. Select methods to enhance rapport with a client.
5. Identify therapists' and clients' attributes that can influence the development of rapport.
6. Apply knowledge of ethics of practice to the therapeutic relationship.


The term *rapport* reflects an emphasis on communication, connection, mutual understanding, and harmony between individuals (*Oxford English Dictionary Online*, 2011). Although rapport can occur in any social situation, the type of rapport developed in therapy has its own special characteristics. Rapport is one *mechanism*, or means, by which a client achieves positive therapeutic outcomes, or in the case of occupational therapy, confident and competent occupational functioning. High therapeutic rapport involves interpersonal influences between client and therapist that support the client's desire to try occupational therapy, to maintain continued involvement in therapy despite the need for considerable effort and courage, and to participate with the therapist in constructing a new vision of life possibilities that projects into the client's occupational future (Mattingly, 1998; Peloquin, 2005; Price & Miner, 2007). The therapist and client work as a unit performing the *cooccupation* (Pierce, 2009) of therapy by immediately, spontaneously, and warmly responding to one another. This mutual responsiveness supports their occupations-as-means toward achieving therapeutic goals.

This chapter defines behaviors and feelings associated with therapeutic rapport, describes conditions affecting its development, and discusses the ethics of a therapeutic relationship. Although this chapter focuses on therapeutic rapport with a single client, its content can be applied to developing rapport with caregivers, family members, and others important in the client's social network (American Occupational Therapy Association [AOTA], 2008; Klein & Liu, 2010; Sherer et al., 2007).

DEFINITION OF HIGH THERAPEUTIC RAPPORT

High **therapeutic rapport** (Definition 14-1) is a function of the mutual experience and behavior of the client and therapist as they interact with each other plus the outcome of the interaction for the client (Tickle-Degnen, 2006):

1. It is an optimal interpersonal *experience* for both the client and the therapist that involves concentration, masterful communication, and enjoyment.

Definition 14-1

High Therapeutic Rapport

Qualities of Experience	
Concentration	Client and therapist experience deep and effortless concentration on the interaction. Distractions, worries, and self-concern disappear.
Masterful communication	They are challenged by the interaction yet feel skillful in meeting the challenge. The goals of the interaction and the effectiveness of the progress toward them are experienced as clear and shared by both.
Enjoyment	They experience the interaction with deep satisfaction.
Qualities of Verbal and Nonverbal Behavior	
Attentiveness	Client and therapist demonstrate verbally and nonverbally that their attention is focused on the other.
Interpersonal coordination	They demonstrate responsiveness to each other—behavior and emotional expression are highly coordinated between them.
Positivity	They demonstrate verbally and nonverbally that their feelings are positive toward one another and the interaction.
Beneficial Effects for the Patient	
Enhanced client performance	Qualities of the client–therapist interaction are beneficial if they improve client performance during evaluation and intervention.
Client follow-through with therapeutic activities	Qualities of the client–therapist interaction are beneficial if they support the clients' continued involvement in activities that enable them to make progress toward their goals.

2. It occurs with *behavior* that reflects high levels of mutual attentiveness, interpersonal coordination, and mutual positivity.
3. It has a *beneficial effect* on client performance and follow-through with intervention plans.

MUTUALITY AND THERAPEUTIC RAPPORT

Mutuality in the relationship between client and therapist is relatively new in the espoused philosophy of occupational therapy. In early- to mid-20th century, the American Occupational Therapy Association (AOTA, 1948) promoted friendliness and cheerfulness but not intimacy between therapists and clients. The two were not to affect each other through the force of their personal attributes. Over a decade later, *therapeutic use of self* (Frank, 1958) became a prevailing philosophical orientation. Therapists recognized that besides modalities their own selves and role modeling, with some level of professional detachment, could be agents of change in clients. In the late 1960s, occupational therapy's view of the therapeutic relationship underwent a major transformation, marked by the view that the relationship involves an exchange between equals. Yerxa (2011) stated, "The therapist allows himself to feel real emotion as he enters into mutual relation with the client. . . . The authentic occupational therapist is involved in the process of caring and to care means to be affected just as surely as it means to affect" (p. 8). In the current philosophy of the therapeutic relationship, the occupational therapist is an engaged, committed partner with the client. As coparticipants, *together* they engage in satisfying and productive interaction as they create daily life (Burke, 2010; Peloquin, 2005). The relationship between client and therapist embodies mutual respect and caring similar to that of friends or coworkers, yet it has unique qualities:

- It is client centered with focus on the client's health, perception of meaningful occupation, and social, cultural, and physical contexts of daily living (AOTA, 2008; Egan et al., 1998; Shaw et al., 2007).
- It is part of a therapeutic skill set put into service to improve client occupational performance (Burke, 2010; Taylor et al., 2009).
- The client is not expected to contribute equally to the development of rapport, especially if suffering or impairment makes the contribution difficult (Rosa & Hasselkus, 2005).
- The therapist usually is paid for services and is accountable to institutional and professional systems that are charged with monitoring therapy and tracking client outcomes.

Despite a therapeutic focus on the client, clients and therapists mutually influence one another. Evidence suggests that, if either the client or the therapist is not attentive, responsive, or positive or is perceived as such by the other, high therapeutic rapport is difficult to achieve (Crepeau & Garren, 2011; Hall et al., 2009; Shaw et al., 2007; Tickle-Degnen, 2006). Evidence Table 14-1 explains more about the benefits and practice of therapeutic rapport.

THE EXPERIENCE AND COMMUNICATION OF THERAPEUTIC RAPPORT

There are innumerable means by which one can attend, coordinate, or express positive affiliation with another person. Therapists draw on clinical reasoning and social skills to determine ways to interact with a particular client in a given context. However, evidence supports that there are fundamental and universal principles of communication that span culture, race, gender, and other qualities of human diversity, whereas simultaneously there are specific forms of communication that vary by diversity in norms and practices (Tickle-Degnen, Zebrowitz, & Ma, 2011) (Research Note 14-1). Adherence to a practice that is client centered, self-reflective, and congruent with current models of clinical reasoning may help the therapist to be sensitive and responsive to differences in verbal and nonverbal behavioral meanings during therapy and to evaluate and adjust accordingly as the interaction emerges (Bonder, Martin, & Miracle, 2004; Katz & Alegría, 2009). Nonetheless, it can be challenging to develop rapport because of (1) differences in the cultural and social identities, norms, and statuses of the therapist and client; (2) structural differences in the world views of the societies and institutions in which therapy takes place; and (3) difficulty in perceiving and evaluating implicit and automatic operation of human differences (Iwama, 2003; Kantartzis & Molineux, 2010; Pooremamali, Persson, & Eklund, 2011; Tickle-Degnen, Zebrowitz, & Ma, 2011). This chapter does not attempt to address variation among cultural and social groups, but rather to advocate for an experiential and behavioral stance to therapy that will help the therapist negotiate individual variation in all its forms. Health care research findings and client autobiographical accounts, primarily from the literature of Western culture, are used in the following sections to illustrate therapist and client rapport qualities and how these qualities affect therapy processes and outcomes.

Therapist Concentration and Attentiveness

Verbal and nonverbal attentiveness and engagement have been found to be positively associated with client disclosure about the experience of illness (Duggan & Parrott, 2000), participation in therapy (Crepeau & Garren, 2011; Mattingly, 1998; Price & Miner, 2007), client satisfaction (Feinberg, 1992; Hall et al., 2009), and occupational

Evidence Table 14–1		Best Evidence for Occupational Therapy Practice Regarding Therapeutic Rapport				
Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Therapeutic alliance	Therapeutic relationship characterized by an affective bond, shared therapy tasks, and goals	4,771 clients, 66% female, with psychiatric, neurological conditions	Average of 22.18 sessions (standard deviation = 18.76)	Meta-analysis of 79 studies	Yes. Stronger therapeutic alliance yields better client outcomes.	Mean weighted effect size was $r = 0.22$, equivalent to a 22% success rate over control treatment	Martin, Garske, & Davis (2000)
Therapeutic nonverbal behavior	Physical therapist (PT) distancing behavior (not smiling, looking away, and remaining seated)	Twenty-eight women and 20 men inpatients, ≥75 years old, mobility disorders, 11 PTs	Average of 9.3 single sessions of inpatient therapy	correlational design Level: IIB3a	Yes. Less distancing PT behavior yields better ADL, cognition, and depression outcomes.	ADL: $p < 0.001$, $r = -0.34$ Confusion: $p < 0.05$, $r = 0.29$: Depression: $p < 0.05$, $r = -0.27$ Mobility: $p > 0.05$, $r = 0.02$	Ambady et al. (2002)

Research Note 14-1

Abstract

The purpose of this study was to evaluate the effect of masking, culture, and gender on practitioners' impressions of patient psychological attributes. Practitioners ($n = 284$) in the United States and Taiwan judged 12 Caucasian American and 12 Asian Taiwanese women and men patients in video clips from interviews. Half of each patient group had a moderate degree of facial masking, and the other half had near-normal expressivity. The results indicated that practitioners in both countries judged patients with higher masking to be more depressed and less sociable, less socially supportive, and less cognitively competent than patients with lower masking. Practitioners were more biased by masking when judging the sociability of the American patients and the cognitive competence and social supportiveness of the Taiwanese patients. In response to masking, American practitioners' perceptions of patient sociability were more negatively biased than were those of Taiwanese practitioners, and the Taiwanese practitioners' judgments of patient cognitive competence were more negatively biased than were those of American practitioners. The negative response to higher masking was stronger in practitioner judgments of women than men patients, particularly American patients. The findings suggest local cultural values as well as ethnic and gender stereotypes operate on practitioners' use of facial expressivity in clinical impression formation.

Implications for Practice

- Practitioners must learn how their clinical impressions can influence therapeutic rapport with their client by understanding their own cultural values, implicit biases and stereotypes, and their expectations for what constitutes appropriate demeanor and behavior.
- Practitioners should strive to translate immediate impression into hypotheses rather than conclusions and to test these hypotheses by triangulating information from the patient, family members, and research literature.
- Practitioners can draw upon patients' storytelling and self-advocacy capacities by letting go of their sole reliance on facial cues when a person has a motor-based facial expressiveness disorder and asking about and attending to what matters most for people living with the disability.
- Practitioners should receive training that addresses the processes underlying accurate and faulty impression formation.

performance outcomes (Ambady et al., 2002). Therapists can show that they are paying attention to clients by taking the time to sit down and talk with them (Figs. 14-1 and 14-2). Attentive behavior, such as orienting the body and eyes toward the client, enables the therapist to watch the client and to pick up emotion and thought cues from the client's face and body. A serious demeanor, often with a slightly furrowed brow, may signal engaged interest and concern to the client (Sharpley, Jeffrey, & McMah, 2006). Crepeau and Garren (2011) report how Dan experienced his hand therapist, Leah, as deeply caring, with one example described by Dan

Figure 14-1 Mutual attentiveness by therapist and client forms the basis for effective communication and the development of a successful working relationship.

Figure 14-2 The therapist who is distracted by time pressure or other concerns loses the interpersonal connection with the client.

as Leah's unwavering focus on him during multiclient sessions:

> . . . there were exercises that I didn't do properly and bang, she was there saying, "Hey, you're not doing this the way I showed you." . . . Her attention's never ending, even though there were other patients there. . . . So that you knew she was watching what you were doing. (p. 879)

Paying attention to a client goes beyond physical attention. It requires listening carefully to what the client has to say about his or her life, the illness, and the experience of intervention (Crepeau & Garren, 2011; Fisher et al., 2007; Verbeek et al., 2004) and remaining open to changing one's own therapeutic ideas in response to what is heard (Jack & Estes, 2010; Shaw et al., 2007). If the therapist applies an intervention incongruent with the client's values and perceptions, the client may fail to engage in therapy. Despite strong collaborative ethics in occupational therapy, research finds that therapists often fall short of collaborative decision making, and divergence rather than convergence of therapist and patient perspective is common (Maitra & Erway, 2006; Peoples, Satink, & Steultjens, 2011; Rosa & Hasselkus, 2005; Shaw et al., 2007). One study found that clients have strong preference for shared decision making, particularly related to occupational performance compared to basic medical home care or preventative physical intervention such as exercise (van den Brink-Muinen, Spreeuwenberg, & Rijken, 2011). However, the client participants experienced the least involvement in shared decision making in the area of occupational performance intervention. An example of possible mismatched perspectives occurred in the stroke rehabilitation of McCrum (1998), who unhappily felt like a child when the therapist gave him plastic letters used to teach children the alphabet:

> . . . with my Day-Glo letter-blocks I could not escape reflecting on the irony of the situation. If only Milan Kundera, Kazuo Ishiguro, or Mario Vargas Llosa, whose texts I had pored over with their authors, could have seen their editor at that moment! (p. 139)

The plastic letters themselves do not create the potential problem here. Therapeutic rapport involves the therapist learning the client's meanings surrounding occupational processes and outcomes in order to build a therapeutic alliance. If the client views elements of therapy to be negative or unimportant, the therapist and client may decide to change the processes or outcomes, or the therapist can guide the client toward a reframing of the meanings involved. Mattingly's (1998, pp. 48–71) description of a session between a therapist and two young men in spinal cord rehabilitation demonstrates how a seemingly inconsequential and childish checker game can be transformed into an occupation that points toward more consequential adulthood occupations. As the young men increase their skilled use of mouthsticks and splints while playing the game, the three partners in therapy engage in banter that solidifies the young men's adult status, and interspersed throughout the conversation is strategic planning about performing near-future occupations (a school prom, a visit home). The game is an engaging choreographed therapeutic event that takes the young men one step closer to their desired occupational lives.

Client Concentration and Attentiveness

Therapists need attention from their clients as well. A client who does not attend to the therapist cannot give or get important information from him or her and may appear to have low commitment to therapy. Pathological conditions, such as traumatic brain damage or anxiety, can affect the ability to engage attentively with the therapist. Rehabilitation therapists rate cognitive issues as a frequent barrier to clients' ability to engage in therapy (Lequerica, Donnell, & Tate, 2009). Evidence suggests that there is a positive relationship between the attention capacity of clients with brain injury and the development of a good therapeutic alliance (Schönberger, Humle, & Teasdale, 2007). The more that these clients actively engage in early therapy sessions, the more likely they are to complete their therapeutic programs (Sherer et al., 2007) and to have more effective occupational performance outcomes (Prigatano et al., 1994).

Therapist Communication and Interpersonal Coordination

Because of their uniqueness as individuals, it is impossible for even the most attentive therapists and clients to fully apprehend one another's experiences or role obligations. However, they can maximize the exchange of their perspectives through optimal verbal and nonverbal communication (Burke, 2010; Crepeau & Garren, 2011). After the therapist focuses attention on the client, the next step is to *interpret* accurately the client's verbal and nonverbal behavior. Accurate interpretation of behavior has been found to relate to therapeutic rapport (Hall et al., 2009) and to predict occupational therapy students' clinical performance during fieldwork experiences (Tickle-Degnen, 1998). The interpretation process occurs very rapidly and involves first the observation of the behavior and then its translation into an impression, accurate or not, about the other's thoughts and emotions (Fig. 14-3) (Blanch-Hartigan, 2011; Tickle-Degnen, Zebrowitz, & Ma, 2011). Accuracy can be enhanced if the therapist encourages the client to be active in giving feedback about the accuracy of the therapist's impressions (Street & Haidet, 2011). If the client cannot give verbal feedback because of impairment, the therapist may be able to learn what the client is feeling simply by reflecting on what the therapist's own emotions are. What the therapist and client feel may be similar because of their subtle mimicry of one another's facial and bodily movements (Chartrand & van

Figure 14-3 The client's backward lean may indicate that she is withdrawing from the therapist or from the information the therapist is giving her. The therapist must determine whether or not the client's behavior is a sign of withdrawal and then whether to adjust her own behavior to maintain rapport. This therapist may decide to become less confrontational, relaxing her posture and making less intense eye contact.

Baaren, 2009) and the effect of this mimicry on their own feelings (Hatfield, Rapson, & Le, 2009). For example, while working with a client with stooped posture, a therapist may develop a stooped posture through mimicry and begin to feel dejection in response to the client's own bodily pattern of dejection. If therapists are aware of the possibility of this form of emotional influence, they may more accurately detect the unspoken emotions of clients.

After accurate interpretation of a client's message, the next step in effective communication is for the therapist clearly to *express* emotions and thoughts in a manner that is beneficial for the client (Tickle-Degnen & Gavett, 2003). Clients may respond favorably to genuine expressions of feelings conducive to rapport (Fig. 14-4)

Figure 14-4 The therapist and client show mutual positivity through their facial expressions and physical contact. Social physical contact, like holding a client's hand, is appropriate if it is an expression of professional warmth and the client gains comfort from it. Not all clients like being touched in this manner.

(Ambady et al., 2002; Di Blasi et al., 2001). Such was the case for Watt (1996), a man in severe pain:

> I believed [the nurse] would make things better. It was never anything she said. It was something in her face. (p. 13)

Facial expressiveness is one of the most impactful and rapid mediums of communication related to social and therapeutic rapport (Collins et al., 2011; Sharpley et al., 2006).

The combination of verbal and nonverbal behavior that the therapist uses to express feelings and attitudes toward the client can be profoundly moving for the client and strengthen their bond as they move through set-backs and difficulties. Brack (Brack & Collins, 1981), a woman with multiple sclerosis, could not suppress her tears of despair and shame at not being able to regain her ability to walk. Her therapist quickly wheeled her wheelchair down to the therapy office, where together they wept:

> Our eyes met. "Do you want to quit?" [the therapist] said. "I know it's tough and you know you may never get any better. But shall we try a little longer?" Right away I knew I had to. I smiled damply and dried my eyes. What a friend! (pp. 71–72)

Because the therapist had worked with Brack for a long time, she could express her genuine feelings by weeping with the client. Subsequently, they worked hard in therapy until Brack regained her mobility. The act of continuing therapy, even when it seems that hope is lost, is a message itself. In the case of Brack, the message was that hope is *not* lost.

Likewise, messages are conveyed through the objects of therapy. When an occupational therapist gives the client a buttonhook, the message can be that the client is capable of using adaptive tools, that dressing independently is a valued goal of the client, and so on. Hanlan (1979), a man with amyotrophic lateral sclerosis, wanted to maintain his daily functioning:

> Of increasing importance to me is the help of occupational therapists. . . . My first OT, a man with a direct and kind manner, provided me with a buttonhook, so I could button and unbutton my clothing. I had an almost childlike, happy response to discovering this little tool. (p. 40)

In effective therapy, the client experiences a bond with the therapist, is in agreement with the intervention methods, and is working toward goals that are important to both the client and the therapist (Martin, Garske, & Davis, 2000; Schönberger, Humle, & Teasdale, 2006b).

Client Communication and Interpersonal Coordination

Some clients, especially those with neurological conditions, have difficulty accurately interpreting a therapist's emotions or social behavior (e.g., Gray & Tickle-Degnen, 2010). Those clients with a receptive form of aphasia may be unable to understand the therapist's speech.

The therapist should make frequent attempts and multimedia adaptations to communicate with these clients (Redman, 2007). Moreover, problems of motor expression, such as that found in right brain damage and Parkinson's disease, interfere with an individual's ability to show interpretable emotions (Brozgold et al., 1998; Tickle-Degnen, Zebrowitz, & Ma, 2011). However, these individuals may be able to verbally express their emotions and preferences quite well when talking about meaningful activities (DeGroat, Lyons, & Tickle-Degnen, 2006). The case of Sofia illustrates this effect (Sunvisson et al., 2009). Sunvisson, a nursing researcher, noted that Sofia's decline in mobility and expressive capacity after moving into a nursing home was augmented by nursing staff who did not think that Sofia could either understand or express messages. Therefore, they did not try communicating with her. During one of her visits, Sunvisson activated the seemingly unresponsive Sofia by asking her if she recalled a sermon that Sofia had earlier reported as a major influence on her life:

> Then I see her erecting her body, her face opens up and she says with a quite loud voice. "Yes I do. It was a wonderful sermon." Surprised, I see her return to her former self, and we laugh and exchange thoughts. . . . (pp. 247–248)

On the other hand, if clients have low capacity to verbally communicate yet are able to nonverbally communicate, therapists can guide them to convey their thoughts and needs via various means. The medium of communication could be facial and bodily expression, use of meaningful objects or audio-video media, and family and friends as proxy self-reporters.

Therapist Enjoyment and Positivity

The expression of positive feelings, warmth, and respect is elemental to therapeutic rapport (Palmadottir, 2006; Roter et al., 2011; Sharpley et al., 2006; Shaw et al., 2007) and clinical effectiveness (Tickle-Degnen & Puccinelli, 1999). Leaning forward and spontaneous smiles of enjoyment are simple behaviors that express warmth and liking (Fig. 14-4), and a furrowed brow can express caring (Ambady et al., 2002; Sharpley et al., 2006). Most important is that the therapist's expression of positivity toward clients is derived from genuine feelings of respect and caring (Peloquin, 2005; Shaw et al., 2007). In addition, moderate degrees and changing levels of enjoyment versus serious behavior appear to be more indicative of beneficial therapy than unchanging high degrees and levels (Sharpley et al., 2001; Tickle-Degnen, 2006).

Occupational therapists strongly endorse humor, such as bantering, joke books, and shaving cream fights, as having positive therapeutic effects as long as it is embedded in a respectful relationship (Leber & Vanoli, 2001). Humor is a deeply complex medium of human relationship, as exemplified in Mattingly's (1998) description of the style of interchange between two young men with quadriplegia, Matt and

John. The style was one of "muted desire, of anger turned into an informal omnipresent derision, of extreme truth-telling in the jocular mode" (Mattingly, 1998, p. 55). When the men's therapist suggested a checker game, Matt asked "How are we going to jump one another?" in a manner that clearly infused the word *jump* with sexual innuendo (Mattingly, 1998, p. 65) and the irony that the two young men were unable to jump in any of several senses of the physical meaning of the word—sexually, by feet or by hand. The therapist, Lin, retorted "wise guy" as she laughed, thus accepting multiple meanings of the word, the cleverness of the self-put-down, and the status of these young men as adults learning to live with severe disability. Lin expertly framed the men's bantering humor with serious occupation-as-means to attaining their goals. Bantering humor was a therapeutic medium also depicted by Crepeau and Garren (2011) in their study of how a therapist, Leah, established rapport with her client, Dan. In their first encounter, Dan was negative about his previous experiences with therapy and was expecting more of the same. Leah surprised him by agreeing with his assessment, and they both laughed. Their therapy progressed in a mutually caring and respectful relationship that included teasing and laughter. As Leah stated, ". . . nothing hurts as bad when you're laughing" (Crepeau & Garren, 2011, p. 876).

Research studies are rare on the incidence or nature of harmful or disrespectful behavior by occupational therapists. As a result, we know very little about this end of the therapeutic rapport spectrum. Palmadottir (2006) interviewed 20 clients who mostly characterized their current occupational therapy experiences as satisfying. Satisfying dimensions included the therapist concern, direction, fellowship, guidance, or coalition. Some, however, had experienced neutral detachment or overt rejection, lack of interest, or humiliation. One client said that his therapist

> often spoke to me as I was a little kid . . . sometimes when I was shaving myself I forgot to turn off the water and then she would say with disdain; well, did we forget something? (p. 398)

More evidence is needed to determine the magnitude of this type of behavior, under what conditions it occurs, and what can be done to remedy harmful occupational therapy relationships.

Client Enjoyment and Positivity

Occupational therapists report feeling good about compliments from clients and enjoying their memory of them (Taylor et al., 2009), suggesting that client satisfaction and enjoyment are not rare. Therapists enjoy clients who are enthusiastic (Rosa & Hasellkus, 2005). As therapist Leah told Crepeau and Garren (2011) about her client Dan, "he just made me feel good inside" (p. 879) and had a significant impact on her life. However, because of the effects of their health condition, some clients may have lowered capacity to experience enjoyment or satisfaction. Clients who are very

anxious or depressed may demonstrate little warmth non-verbally, perhaps by infrequent smiles or eye contact, and health-related misery or pain may cause outbursts of anger.

Therapy itself may be frustrating or overly challenging to some clients, especially if they perceive the tasks as simple ones (Darragh, Sample, & Krieger, 2001). For example, Puller (1991), a Vietnam veteran with bilateral upper extremity amputations, reported that he "felt like screaming" (p. 181) when trying to learn how to button clothes or thread a needle in therapy. Such frustration should not be ignored. The therapist should reevaluate the balance of emotional costs to physical benefits of some activities as related to client goals.

Ethics and professionalism prescribe practitioners to rise above petty responses to unpleasant client behavior and to not take unpleasant behavior personally or to respond with resentment and harmful behavior (Rosa & Hasselkus, 2005). Furthermore, practitioners must be careful not to view all negative expressions as confirmation of pathology. These expressions may be indeed signs of a pathological process that requires diagnosis, or they may be normal responses to the experience of illness and intervention. Finally, seemingly pathological behavior of a client may be exacerbated through implicit features of the context. For example, the content of questions posed to clients as well as the gender of the interviewer have been found to elicit more or less expressive movement in clients with Parkinson's disease (Takahashi et al., 2010). Asking clients about enjoyable events in their lives elicited more expressiveness, particularly of a positive emotional nature, than asking them about frustrations.

BENEFICIAL EFFECT AND HIGH THERAPEUTIC RAPPORT

Possible reasons that attentive, coordinated, and positive client–therapist interactions may have a beneficial effect on client occupational outcomes and health include the following:

1. The interaction scaffolds skill development by directing attention to important features of a task problem, communicating information necessary to solve the problem, generating trust in the therapist and therapy process, giving motivational support for pursuing problem solution, and facilitating adherence to treatment recommendations (Radomski, 2011; Street et al., 2009; Tham & Kielhofner, 2003; Tickle-Degnen, 2006).
2. The interaction improves physiological and emotional health, thus enabling individuals to focus energy and effort on occupation (Di Blasi et al., 2001; Street et al., 2009). The health effects of positive therapeutic relationships, including direct effects on immune and physiological functioning and indirect effects on adherence to health interventions, are similar to the health effects of social support provided by positive familial relationships (DiMatteo, 2004).

3. The interaction creates a self-fulfilling prophecy of improved performance (Ambady et al., 2002). The therapist communicates his or her expectations for the progress of a client, with the effect that the client's actual performance conforms to those expectations. Informative, warm, and respectful behavior may affirm to clients that they are capable and valued human beings, which mobilizes clients' psychological and physical resources toward fulfillment of those qualities. Affirmation of values has been found to help change the performance of individuals who feel insecure or have low self-efficacy and reverse negative self-fulfilling prophecies (Stinson et al., 2011).

DEVELOPMENT OF A HIGH THERAPEUTIC RAPPORT RELATIONSHIP

Evidence suggests that the critical development of rapport and a working alliance begins within minutes of the first session and is achieved within the first three to five sessions of therapy (Horvath & Luborsky, 1993; Roter et al., 2011; Schönberger, Humle, & Teasdale, 2006a). First meetings tend to be somewhat superficial and rigidly constrained by role expectations around the assessment process. Through close adherence to cultural scripts of polite behavior, therapist and client offer their identities to one another as valuable and likable. In the first meeting, the client may convey private information to the therapist, but the depth of intimacy, working alliance, and mutuality continues to grow over subsequent interactions (Schönberger, Humle, & Teasdale, 2006a). The development of the relationship is not necessarily linear. A dialectical tension between the desires for intimacy and autonomy appears to manifest itself in a cyclical pattern of intimate and more distant behavior (Tickle-Degnen, 2006). The client and therapist may try out different patterns of relating to one another. There are also patterns of shifting between therapeutic work and socializing with chit-chat that may provide off-task opportunity for rest and reaffirmation of the bond between therapist and client (Crepeau & Garren, 2011; Hall, Roter, & Milburn, 1999).

Therapists' and clients' characteristics and conditions in the therapy setting can facilitate or inhibit the development of rapport. Different interpersonal styles and skills appear to be beneficial for therapeutic effectiveness in physical versus mental health settings or children versus adult populations, suggesting that therapists should adapt their styles to the specific therapeutic context (Tickle-Degnen, 1998). Through self-reflection, feedback from supervisors, colleagues, and clients, and reflective clinical experience and training, the therapist should be able to learn how to make these adaptations (Cohn, Schell, & Crepeau, 2010). Based on the evidence presented here, Procedures for Practice 14-1 gives guidelines

Procedures for Practice 14-1

Therapist Guidelines for Facilitating the Development of High Therapeutic Rapport

Create Conditions That Maximize Concentration and Attention

1. Reduce distractions and potential for embarrassment or anxiety in the therapy setting.
2. Position bodies of therapist and client for seeing and hearing each other clearly.
3. Give time for meaningful engagement, and attend to issues that are important to the client.

Create Conditions That Maximize Masterful Communication and Interpersonal Coordination

1. Provide assistance as needed for the client to express emotions and thoughts.
2. Remain open and sensitive to verbal and nonverbal messages from the client.
3. Clearly express emotions and thoughts that are consistent with the needs and goals of the client.
4. Check to make sure that each is interpreting the other accurately.
5. Create a challenging, interesting, and effective interaction for the client.
6. Involve the client collaboratively in the development of goals and the planning of intervention.

Create Conditions That Maximize Enjoyment and Positivity

1. Find a satisfying, fulfilling aspect to every interaction with a client.
2. Express genuine concern and caring for the client through verbal and nonverbal behavior.
3. Resolve personal problems and worries outside of the client–therapist interaction.
4. Provide opportunities for the client to engage in activities that he or she finds enjoyable.
5. Provide opportunities for rest and off-task recovery during potentially frustrating activities.
6. Determine the source of client negativity and respond appropriately.
7. Manage negativity and disagreements to generate a constructive and collaborative relationship.

for enhancing the development of rapport. It is not the client's responsibility to change to enhance the rapport; it is the therapist's. Therefore, the guidelines are directed at therapist actions.

Clients and therapists can experience events in their therapy sessions that create negative emotions and threaten to "rupture" their rapport and their working alliance (Safran, Muran, & Eubanks-Carter, 2011). Safran, Muran, and Eubanks-Carter (2011) found in psychotherapy that the more patients and therapists experienced "repairs" to ruptures, the more successful their outcomes. The following rupture repair strategies are adapted to occupational therapy for physical dysfunction from the suggestions of Safran, Muran, and Eubanks-Carter:

- Be attentive to possible problems as they arise.
- Be open for disagreement or negative emotions from clients.
- Remain nondefensive and talk directly about disagreements and problems in the therapy process.
- Validate the client bringing up differences of opinion or negative feelings.
- Use clinical reasoning and client collaboration to determine whether it is more therapeutic to change the tasks or goals of the intervention without exploring the rupture in depth or to deal in depth with the cause of the rupture and getting help as needed in doing so.

Typically, therapeutic relationships work toward a planned end to the relationship as goals are achieved or services are no longer needed. As discharge approaches, the therapist should work actively with the client to transform their relationship appropriately, so that the client does not feel abandoned (e.g., Klein, 1995). The form this transformation takes depends on the setting. For example, the therapist may help the client to develop other fulfilling relationships in the community or may keep in contact with the client through the phone or occasional clinic visits.

ETHICS AND THE THERAPEUTIC RELATIONSHIP

The four principles of the Occupational Therapy Code of Ethics (AOTA, 2010) that are most relevant to the therapeutic relationship are the following ones:

Principle 1 (Beneficence): Occupational Therapy Personnel Shall Demonstrate a Concern for the Well-being and Safety of the Recipients of Their Services

Beneficence refers to kindness, humaneness, and actions that benefit others. Although there is no ethical imperative to feel rapport with clients, the imperative to demonstrate a concern for the well-being of the recipient of services is consistent with developing high therapeutic rapport with the client as defined in this chapter. To maximize benefit, the therapist should use current knowledge and research in practice, evaluate the effect of services periodically, and terminate services in collaboration with the client when the needs and goals of the client have been met or when

services no longer produce changes as intended. As a therapist works to create rapport, it is important that the therapist realize that his or her own beliefs about what is important for well-being and occupation are not necessarily equivalent to the beliefs held by the client, particularly those with cultures and backgrounds different from the therapist's (Iwama, 2003; Kantartzis & Molineux, 2010; Tickle-Degnen, Zebrowitz, & Ma, 2011).

Principle 2 (Nonmaleficence): Occupational Therapy Personnel Shall Intentionally Refrain from Actions That Cause Harm

Negative therapist feelings may result in negative client outcomes. Therapists should consider changing jobs or clinical specialization if they are unable to overcome negative feelings with clients typically seen in a setting or specialization area. After an honest but unsuccessful attempt to support high therapeutic rapport, therapists may consider referring the client to a different therapist, perhaps one that is a specialist in such cases (Rosa & Hasselkus, 2005). One element of this principle is to not exploit the client sexually, physically, emotionally, financially, socially, or in any other manner. Therapists must understand how to set professional boundaries in their therapeutic relationships in order to create a friendly and engaged relationship that does not involve the same reciprocity, casualness, and interdependency of many close personal friendships. For example, therapists are selective about sharing their own personal information, and do not complain about their coworkers or supervisors. They should be careful about accepting or exchanging gifts and be aware of institutional policies that may prohibit staff members from accepting gifts of any kind. Therapists who become dependent on a client for meeting a personal need are exploitive because of their higher power relative to the clients' position of vulnerability. Furthermore, although the therapist is ethically responsible for helping the client, the client is not expected to help the therapist in any manner.

Principle 3 (Autonomy and Confidentiality): Occupational Therapy Personnel Shall Respect the Right of the Individual to Self-determination

Respect for the client's autonomy requires therapeutic relationships in which clients, including families, significant others, and caregivers, collaborate to the best of their ability in the determination of goals and priorities during intervention. Collaboration requires that the therapist must inform clients about the nature, risks, and potential outcomes of the intervention and that clients have the opportunity to suggest, reject, or refuse services or elements of services. Therapists facilitate communication and comprehension as needed in order to aid collaboration.

Figure 14-5 In a collaborative relationship, the therapist and client discuss the benefits and risks of participating in various occupational therapy interventions so that the client can make informed decisions about participating in these interventions.

Collaborative decisions are carried out not because of external pressures but because the client has an active feeling of personal control and responsibility (Fig. 14-5).

Other elements of this principle are privacy and confidentiality. During a relationship of high therapeutic rapport, the client may tell the therapist about matters that are private and confidential. The therapist must protect the confidentiality of information by not discussing it in an inappropriate context, for example, in a public elevator conversation, or inappropriate manner, for example, laughing at the client's capabilities with a colleague or any other person.

Principle 4 (Social Justice): Occupational Therapy Personnel Shall Provide Services in a Fair and Equitable Manner

Therapists are called upon to uphold the altruistic responsibilities of the profession to help ensure the common good, to advocate for just and fair treatment for all clients, and to provide services in an equitable manner to all individuals. A therapist may have fears or negative attitudes about a particular client population. Despite these feelings, therapists should provide services in an impartial manner and based on the development of an effective and health-promoting therapeutic relationship. Therapists are responsible for understanding how services can be affected by factors such as economic status, age, ethnicity, race, geography, disability, marital status, sexual orientation, gender, gender identity, religion, culture, and political affiliation.

SUMMARY

High therapeutic rapport develops as the therapist and client are mutually attentive, coordinated to one another, and mutually positive. It is one mechanism by which the

client achieves confident and competent occupational functioning. It supports the client's desire to try occupational therapy, to maintain continued involvement in therapy, and to participate with the therapist in constructing a new vision of life possibilities. Although rapport is based on a perspective of mutuality and collaboration between client and therapist, it is the therapist's responsibility to manage oneself, guide the client, and modify the environment to support attentiveness, coordination, and positivity. Through self-reflection, feedback from others, reflection about clinical practice, and careful adherence to ethical standards, the therapist can learn to facilitate therapeutic rapport with a variety of clients in a variety of practice settings.

In this chapter, the focus has been directed on individual therapist responsibility for developing therapeutic relationships. However, it is important to recognize that

the therapist works in a larger health care system and that the development of therapeutic rapport is not only a function of therapist behavior but also the societal and structural constraints operational in the health care system. It is not easy to achieve a high level of attention, concern, and caring in today's health care system, which emphasizes cost containment and adherence to protocol and provides little recognition for caring involvement (Cohn, Schell, & Crepeau, 2010). A supportive system composed not only of the therapist's personal commitment to caring but also of an institutional and societal commitment to caring are needed to sustain a therapeutic level of caring. As part of their ongoing commitment to offer services that are maximally beneficial for clients, therapists should consider advocating to their institutions and health policy bodies for resources and infrastructure that support beneficial therapeutic relationships.

case example
Mrs. S.: Establishing Rapport with a Reluctant Client

Clinical Reasoning Process

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Client Information Mrs. Smith, a 75-year-old woman (widowed) with Parkinson's disease, was referred to the adult day program by her physician and her children because of concern about her social isolation and reluctance to do basic self-care despite adequate physical and cognitive capacity. The diagnosis of depression was ruled out. Assessment identified the following: (1) rigidity, bradykinesia, and moderate facial masking (hypomimia) caused by the motor disorder; (2) self-reported stigmatization and difficulty with family and friend interactions although these were her favaorite activities; and (3) no learned compensatory strategies for handling the community and social aspects of parkinsonian symptoms.	Appreciate the context	"Because Mrs. Smith did not have cognitive or emotional impairment, I expected that she would be able to reflect upon and discuss her occupational functioning. In order to understand her limited functioning, it was important to hear and understand her perspective. A quality of life assessment procedure was appropriate for eliciting her reflection and generating a client-centered discussion."
	Develop intervention hypotheses	"Mrs. Smith's problems may be due to stigmatizing aspects of reduced motor expressiveness in her face and body. She looks apathetic and unfriendly, and interacting with her is difficult because of slowed responses. She becomes more active and quick when talking about enjoyable activities. Pleasurable activities may reduce symptoms and activate social participation."
	Select an intervention approach	"I can engage Mrs. Smith's interest through my eye contact, body positioning, and listening to her perspective. I will develop a strong therapeutic alliance to gain her commitment to working on her occupational functioning."
	Reflect on competence	"I have not worked with many clients with Parkinson's disease. Mrs. Smith can teach me what it is like to live with the disease."

Recommendations

Because of a high risk of Mrs. Smith refusing intervention, the occupational therapist suggested to her that they meet once per week for 3 weeks in order to get to know one another better before starting the day program. The immediate goal was to establish rapport and a strong working alliance, after which they could address directly her occupational functioning needs.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"Mrs. Smith is willing to meet with me for no more than three weekly 1-hour sessions before deciding about whether or not to participate in the day program. I plan to meet with her in an area where she can see what other participants in the program, who have similar interests to hers, are doing. I believe that if she became familiar with the day program in a nonpressured manner, she might start to see how it might be helpful for her."

Summary of Short-Term Goals and Progress

(1) *Mrs. Smith and the therapist will complete a task that is interesting to both.*

   The therapist and Mrs. Smith each completed an interest checklist and then discussed their responses with one another. They noted five mutual interests, one being an interest in poetry. They each brought a favorite poem to the following session to read to the other. At the end of the task, both agreed that they found the task interesting and then selected another task to do with one another in the following week.

(2) *Mrs. Smith and the therapist will have decided mutually on one goal of intervention by the end of the third session.*

   The therapist and Mrs. Smith ended each session with discussing and writing down two possible goals of intervention. Tentatively, they selected one potential goal by the end of the third session: the reduction of stigma associated with eating a meal with her family in a restaurant. Mrs. Smith did not see this goal as the one that she wanted to make a commitment to achieving as of yet.

(3) *Mrs. Smith and the therapist will have at least one positive experience during each session.*

   The therapist and Mrs. Smith agreed to try to do something that made them feel good or happy at least once during each session. They would assess their achievement of this goal during each session. At each session, they identified several times in which they experienced positive feelings.

   Therapeutic rapport was developing in a satisfactory manner by the third session. Mrs. Smith continued to be reluctant to make a commitment to attend the day program but agreed to try it out for an additional 4-week period at two half-day sessions per week.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

"Mrs. Smith has come to every scheduled session. It has gotten easier to work with her as I have learned what cues indicate that she is happy, sad, angry, or frightened. Her positive attributes are easiest to see whenever we discuss or do things related to her favorite activities and interests. Mrs. Smith appears to understand my role and the tasks involved in intervention. She responds positively to clear explanations and my undivided attention."

"I think her reluctance to attend the program is partly because she has not recently practiced socially interacting with her peers, and, as a result, has not had the experience of seeing that others accept her despite the symptoms of Parkinson's disease."

Next Steps

Revised short-term goals:
(1) *Mrs. Smith will express interest in participating in a group activity on identifying goals for daily living.*
(2) *Mrs. Smith will communicate about her ideas with the group members.*
(3) *Mrs. Smith will have a pleasant social interaction with at least one of the other group members.*

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether he or she should continue or discontinue therapy and/or return in the future

"I feel that Mrs. Smith and I have developed a good rapport with one another and that now she understands she may be able to participate in friendly interactions with other people. She is ready to try a group activity in the day program. I must prepare for the possibility that Mrs. Smith will decide not to continue the program after 1 month. I will discuss her concerns about the day program with her family and physician to determine how best to support her involvement in goal setting, and to determine what alternatives are available for helping Mrs. Smith to participate fully in her life activities."

Clinical Reasoning in Occupational Therapy Practice

When to Refer to Another Therapist

The therapist suspects that one reason that Mrs. Smith does not want to be involved in the day program is because the therapist is of a different ethnicity than that of Mrs. Smith, who seems to have a negative attitude toward the therapist's ethnic group. How should the therapist attempt to deal with this possibility? What can be done to promote rapport? At what point and under what conditions should the therapist attempt to refer the client to another therapist or program?

Clinical Reasoning in Occupational Therapy Practice

Managing Challenging Family Involvement

Mrs. Smith's son and his wife would like to increase Mrs. Smith's commitment to and involvement in the day program. On the first visit, they accompany Mrs. Smith. When the occupational therapist asks Mrs. Smith what her favorite activities are, the son and wife answer the question. They also answer the next question that the therapist asks of Mrs. Smith. Mrs. Smith listens passively. How can the therapist manage family communication in order to obtain a direct answer from Mrs. Smith?

Clinical Reasoning in Occupational Therapy Practice

An Ethical Dilemma

Mrs. Smith refuses involvement in the day program despite the therapist's, the family members', and the physician's encouragement for her to participate. What should the therapist do? What is the therapist's ethical responsibility? How will the therapist's decision affect the therapeutic relationship with Mrs. Smith?

Summary Review Questions

1. What are the elements of high therapeutic rapport?
2. How has the view of the client–therapist relationship changed over time?
3. How are the therapist's experience and behavior related to rapport?
4. How are the client's experience and behavior related to rapport?
5. What are three reasons high rapport may be beneficial for clients?
6. How can the therapist facilitate the development of high therapeutic rapport?
7. What are two ethical responsibilities that a therapist holds in a relationship with a client?

Glossary

Mutuality—Interaction between the client and therapist in which they influence one another.

Nonverbal communication—Interpreting another's nonverbal behavior and expressing one's own thoughts and emotions through nonverbal behavior. Nonverbal behavior includes positions and movements of the face and body, as well as vocal tone, intensity, and speed.

Therapeutic rapport—The qualities of experience and behavior between client and therapist that affect the client's performance and involvement in therapy.

Verbal communication—Interpreting another's words and expressing one's own thoughts and emotions through words.

Working or therapeutic alliance—Working together to achieve agreed upon goals through agreed upon methods of intervention. A positive affective bond promotes the alliance.

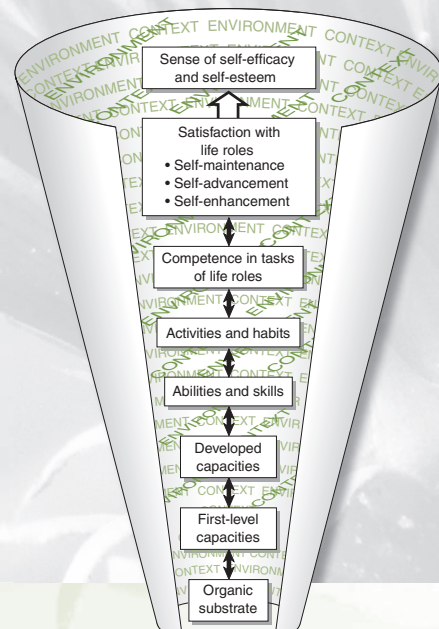
Upper Extremity Orthoses

Lisa D. Deshaies

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define and discuss key concepts and terms related to orthoses.
2. Identify major purposes for using orthoses.
3. Explain general precautions relative to the use of orthoses.
4. Identify key factors to consider when selecting the most appropriate orthosis.
5. Given a photograph or illustration, identify the orthosis and a clinical problem for which it may be used.
6. Select an appropriate orthosis for a given diagnosis based on a specific clinical need.


Orthoses are often an integral component of occupational therapy for clients with physical dysfunction. Orthotics entails prescription, selection, design, fabrication, testing, and training in the use of these special devices.

Successful use of orthoses is made possible only through an integrated team approach including the client, his or her significant others, and health care providers. Several rehabilitation professionals may bring their expertise to different aspects of the orthotic process. The physician typically prescribes the device. The certified orthotist is an expert in the design and fabrication of permanent orthoses, especially complicated spinal, lower extremity, and upper extremity orthoses used to restore function. The rehabilitation engineer is an expert in technical problem solving involving mechanical and/or electrical solutions to unique needs of clients.

The occupational therapist, as an expert in the adaptive use of the upper extremities in occupational performance tasks, has the major responsibility for the recommendation of appropriate orthoses, the testing and training in the use of orthoses for the upper extremities, and the selection, design, and fabrication of thermoplastic splints. Occupational therapists often collaborate with orthotists and rehabilitation engineers to solve problems encountered by clients in performing their occupations and activities of daily life. The therapist presents the parameters of the problem to these professionals in terms of the client's abilities and limitations and the functional and psychological goals that the prescribed device should meet or allow. The orthotist or engineer then proposes technical solutions, and together they apply them to the client and evaluate the outcome.

Finally, and possibly most importantly, the client and caregivers bring key physical, psychological, social, and functional characteristics to the orthotic process and should be considered the primary members of the team. For the orthosis to be successful, all team members must work in close collaboration.

KINDS OF ORTHOSES

The numerous kinds of upper extremity orthoses vary according to the body parts they include, their mechanical properties, and whether they are custom-made or prefabricated.

Classification Systems

An orthosis is an externally applied device used to modify the structural and functional characteristics of the neuromuscular and skeletal systems (Condie, 2008). Orthoses may also be called splints; the American Society of Hand Therapists (ASHT) (1992) validated that the two terms may be used interchangeably. Brace and support are other commonly used terms for orthoses. One challenge when discussing orthoses is the lack of uniform terminology in the medical literature, which makes it difficult to compare and contrast features and outcomes when a single orthosis may be known by many names.

Before the 1970s, there was no standard system for classifying orthoses, and orthoses were identified by proper names or eponyms based on the place of origin or the developer. A classification system was later developed to describe orthoses using acronyms based on the major joints or body parts they include. For example, a thumb carpometacarpal (CMC) support is a hand orthosis (HO); a wrist cock-up splint is a wrist–hand orthosis (WHO); an elbow brace is an elbow orthosis (EO); and a complete support for an arm is a shoulder–elbow–wrist–hand orthosis (SEWHO) (Condie, 2008). Each classification may contain several types of splints. A wrist cock-up splint and a flexor hinge hand splint are both WHOs, although they serve different purposes.

To simplify, organize, and describe a standardized professional nomenclature, the ASHT developed the ASHT Splint Classification System in 1992. It classifies splints in terms of their function and the number of joints they secondarily affect. According to this system, a wrist cock-up splint is a wrist extension immobilization, type 0, because no other joints are affected. Although the intent was to serve as a universal language for referral, reimbursement, communication, and research, the system has not been widely used outside of the hand therapy community.

This chapter uses the traditional or most commonly used names for the splints it describes.

Basic Types of Orthoses

Mechanical splint properties fall into three categories: static, static progressive, and dynamic (Colditz, 2002/2011). The static splint, which has no moving parts, is used primarily to provide support, stabilization, protection, or immobilization. Serial static splinting can be used to lengthen tissues and regain range of motion by placing tissues in an elongated position for prolonged periods (Bell-Krotoski, 2011; Colditz, 2011). With this process, splints are remolded as range of motion increases. Because immobilization causes such unwanted effects as atrophy and stiffness, a static splint should never be used longer than physiologically required and should never unnecessarily include joints other than those being treated.

Static progressive splints use nondynamic components, such as Velcro®, hinges, screws, or turnbuckles, to create a mobilizing force to regain motion. This type of splinting, termed inelastic mobilization, offers benefits not available with serial static or dynamic splinting because the same splint can be used without remolding, and adjustments can be made more easily as motion improves (Fess et al., 2005).
Figure 15-1   Outriggers directing proper 90° line of pull. **A.** High profile. **B.** Low profile. (Adapted with permission from Hunter, J. M., Mackin, E. J., & Callahan, A. D. [Eds.]. [1995]. *Rehabilitation of the hand: Surgery and therapy* [4th ed.]. St. Louis: Mosby.)

Dynamic splints use moving parts to permit, control, or restore movement. They are primarily used to apply an intermittent, gentle force with the goal of lengthening tissues to restore motion. Forces may be generated by springs, spring wires, rubber bands, or elastic cords. This type of splinting is termed elastic mobilization (Fess et al., 2005).

With dynamic splinting to increase range of motion, two concepts are critical. The first is that the force must be gentle and applied over a long time (Bell-Krotoski & Breger-Stanton, 2011; Fess et al., 2005). Safe force must be determined based on tissue tolerances. Excessive force results in tissue trauma, inflammation, and necrosis (Fess & McCollum, 1998).

The second concept is that, to be effective and prevent skin problems, the line of pull must be at a 90° angle to the segment being mobilized (Fess, 2011). To ensure this, forces are directed by an outrigger, a structure extending outward from the splint.

Outriggers may be high profile or low profile (Fig. 15-1). Each design has distinct advantages and disadvantages. Selection of outrigger design must be based on the specific client's needs and abilities. High-profile outriggers are inherently more stable and mechanically efficient, require fewer adjustments to maintain a 90° angle of pull, and require less effort for the client to move against the dynamic force. Low-profile outriggers are less bulky but require more frequent adjustments and greater strength to move against the dynamic force (Fess, 2011; Fess et al., 2005).

By allowing motion in the opposite direction, dynamic splints reduce the risk of joint stiffness from immobility, as seen with static splinting. If successful, an increase in passive joint mobility can be expected within 2 weeks (Fess & McCollum, 1998).

In addition to gaining motion, dynamic splints can be used to assist weak or paralyzed muscles. These dynamic splints may be intrinsically powered by another body part or by electrical stimulation of the client's muscles.

Orthotic Selection

Splinting is one of the most useful modalities available to therapists when used correctly and appropriately. Remember, the end result of splinting should always relate to the client's function (Figs. 15-2–15-5). McKee and Rivard (2004) caution that orthotic intervention may have become an end unto itself in the minds of therapists and clients rather than the means to enable occupational performance. The outcome of successful splinting is that the splint serves its purpose and that the client accepts and wears it. To meet these ends, the therapist must think critically and often creatively. Orthotic intervention should always be individualized with careful consideration of each client's unique physical and psychosocial needs, as well as personal factors and contexts (Amini & Rider, 2008; McKee & Rivard, 2011).

The therapist's multifaceted role is to evaluate the need for a splint clinically and functionally; to select the most appropriate splint; to provide or fabricate the splint; to assess the fit of the splint; to teach the client and caregivers the purpose, care, and use of the splint;

Figure 15-2   Wrist splints enabling gardening.

Figure 15-3 Hand splint enabling keyboarding.

and to provide related training as needed. The therapist must take a leadership role to ensure that the treatment team, including the client and caregivers, work collaboratively in every phase of the orthotic process. A client-centered, occupation-based approach empowers the client and caregivers to participate actively. This also positions them as the experts in the client's occupations, lifestyle, values, image, and activity contexts, which complements the expertise that the health care professionals bring. The therapist should clearly explain rationales, make clinically sound recommendations, and offer choices to the client whenever possible. This helps establish each team member's accountability and increases the likelihood that the client will actually use the splint.

A problem-solving approach to splinting directs the therapist to answer several key questions before splinting proceeds:

- What is the primary clinical or functional problem?
- What are the indications for and goals of splint use?
- How will the orthosis affect the problem and the client's overall function?
- What benefits will the splint provide?

Figure 15-4 Thumb splints enabling driving.

Figure 15-5 Wrist–hand splint enabling function in the kitchen.

- What limitations will the splint impose?
- What evidence is available related to the splint?

Based on these considerations, the therapist must select or design the most appropriate orthosis. In some cases, the best choice is no orthosis at all.

The growing array of commercial products has led to a greater number of choices. The first choice to be made is whether the orthosis should be custom fabricated or prefabricated. Materials must also be considered. The therapist must be familiar with properties, benefits, and drawbacks of each. Options abound, with rigid, semi-rigid, and soft materials available (see Chapter 16).

When making a splint selection, several key factors must be carefully weighed:

- Among the splint-related factors are type, design, purpose, fit, comfort, cosmetic appearance, cost to purchase or fabricate, weight, ease of care, durability, ease of donning and doffing, effect on unsplinted joints, and effect on function.
- Client-related factors include clinical and functional status, attitude, lifestyle, preference, occupational roles, living and working environments, social support, issues related to safety and precautions, ability to understand and follow through, and financial or insurance status.

Safety Note 15-1

Orthotic Precautions

The therapist must consider, carefully monitor, and teach the client and caregiver to report any of these problems related to orthotic use:

- Impaired skin integrity (pressure areas, blisters, maceration, dermatological reactions)
- Pain
- Swelling
- Stiffness
- Sensory disturbances
- Increased stress on unsplinted joints
- Functional limitations

Definition 15-1

Purposes of Orthoses

Orthoses may be used to:

- support a painful joint
- immobilize for healing
- protect tissues
- provide stability
- restrict unwanted motion
- restore mobility
- substitute for weak or absent muscles
- prevent contractures
- modify tone

Several studies have been done on clients' preferences and factors that contribute to splint wear. They show that the following factors may encourage splint wear: flexibility of the splinting regimen and vigorous teaching to enable clients to understand the purpose and wearing schedule (Pagnotta, Baron, & Korner-Bitensky, 1998), individualized prescriptions focusing on the client's comfort and preference (Callinan & Mathiowetz, 1996; Stern et al., 1996), strong family support (Oakes et al., 1970), positive attitudes and behaviors exhibited by health care providers (Feinberg, 1992), and benefits that are immediately obvious to the client (Groth & Wulf, 1995). Rapport, trust, sensitivity to individual client's learning styles, trial evaluations, and giving clients the opportunity to voice their concerns and frustrations can also greatly enhance the collaborative process and outcome (Collins, 1999). A systematic review of adherence to splint wear in adults with acute upper limb injuries found little published scientific evidence and concluded that existing studies were of varied quality (O'Brien, 2010). With the relatively small base of literature on orthotics, therapists must continue to put their clinical judgments and experience to the test and strive to develop evidence-based practice related to observed outcomes and factors that influence successful orthotic intervention.

Should problems with splint wear arise (Safety Note 15-1), the therapist should examine both the splint and the wearing schedule. The splint itself may not fit properly or comfortably. The client's functional demands may outweigh the benefits of splint wearing, or the wearing schedule may be too complex. Actively engaging the client in the problem-solving process is likely to improve the outcome. Although it is important to strive for the ideal, therapists must remain realistic in the scope of the client's daily life.

PURPOSES OF ORTHOSES

In this chapter, orthoses are categorized according to several purposes (Definition 15-1). Although a specific orthosis is discussed under the category for which it is most commonly used, that purpose may not be its only one. Also, a single orthosis may fulfill several functions simultaneously. The orthoses presented here are by no means an exhaustive list but a representative sampling of commonly used or historically significant orthoses. Inclusion of specific orthoses should not be interpreted as an endorsement of one type over another. Whenever possible, published evidence-based data have been included. Because the intent of this chapter is to provide an overview of orthotics, the reader is encouraged to explore the references and resources for more detailed information.

Support a Painful Joint

Pain in a joint or soft tissues can result from a wide variety of causes, including acute trauma (such as sprains and strains), nerve irritation (such as carpal tunnel syndrome and ulnar nerve neuritis at the elbow), inflammatory conditions (such as tendonitis and rheumatoid arthritis [RA]), and joint instability (such as degenerative arthritis, ligamentous laxity, and shoulder subluxation). When resting a joint is indicated to relieve pain, protect joint integrity, and/or decrease inflammation, supportive orthoses can be used. These orthoses are often worn all day, all night, or both to provide the maximum benefit, or they may be worn only during selected activities. Unless contraindicated, the orthosis should be removed at least once a day for skin hygiene and gentle range-of-motion exercises to prevent loss of joint mobility. The following are common examples of orthoses used for pain relief.

Support a Painful Shoulder or Elbow

Arm slings have been developed to prevent or correct shoulder subluxation or reduce pain in clients who have subluxation caused by brachial plexus injuries, hemiplegia, or

central cord syndrome injuries. Sling designs are numerous, with some commercially available and others fabricated by the therapist (see Resources 15-1).

Certain slings support and immobilize the whole arm. These slings, such as the standard pouch and the

Figure 15-6 Rolyan® Figure-of-8 sling.

double arm cuff sling (Fig. 15-6), restrict motion by keeping the humerus in adduction and internal rotation and the elbow in flexion. Although these slings may take some of the weight off the affected shoulder, downsides are that they place the extremity in a non-functional position, reinforce synergy patterns, and fail to provide the client with the opportunity for motor and sensory feedback (Bobath, 1990). Other sling designs support the shoulder but leave the rest of the arm free for function, such as a humeral cuff sling (Fig. 15-7).

Arm troughs, lapboards, and half-lapboards are also used to support the painful shoulder when the client is seated in a wheelchair. These may be more acceptable to

Figure 15-7 Hemi Shoulder Sling, a type of humeral cuff sling.

Figure 15-8 Rolyan® slide-on adjustable lap tray.

clients than slings, and they allow the arm to be ideally positioned with the scapula pulled forward and the hand supported (Bobath, 1990). It is important to remember that these supports lack the constant relationship between the client and the support as exists with slings. Any change in postural alignment will alter forces and the support effectiveness (Spaulding, 1999). Lapboards (Fig. 15-8) are generally indicated for clients with poor trunk control or visual field deficits and for those who require greater variability of upper extremity positioning or a work surface. Arm troughs (Fig. 15-9) are used for clients who need a device that does not interfere with wheelchair propulsion or transfer activities. The half-lapboard (Fig. 15-10) combines the positive features of both the arm trough and the full lapboard (Walsh, 1987). Full and half-lapboards can be purchased commercially or custom fabricated from acrylic or wood. Some designs allow the half-lapboard to be rotated up and out of the way instead of having to be removed from the wheelchair when the client needs to transfer. Arm troughs are also commercially available or can be custom-made.

The use of supports in reducing shoulder subluxation remains controversial and lacks empirical evidence. A systematic review by Ada, Foongchomcheay, and Canning (2005) found no evidence to conclude that supportive devices are effective in preventing or reducing subluxation

Figure 15-9 Otto Bock™ Arm Trough.

Figure 15-10 Clear flip-away armrest in upright position.

or in decreasing pain after stroke. In addition, whether subluxation has a causal relationship to shoulder pain is in question (Zorowitz et al., 1996). There is no consensus as to which type of support is the best in the treatment of shoulder subluxation or whether a support should be used at all. The effects of various sling and support designs have proved variable in multiple studies over the years as summarized by Zorowitz et al. (1995) and Turner-Stokes and Jackson (2002).

Ultimately, it is agreed upon that if a support is to be used, several types should be evaluated on the client to optimize the reduction of shoulder pain, the function of the affected extremity, and the ease of donning and doffing (Zorowitz et al., 1995). Therapists need to consider the different mechanical forces each support produces on the shoulder complex (Spaulding, 1999). The client's acceptance of the sling also must be considered. Relative ease of donning and doffing the sling is imperative so the limb is not damaged further from improper wearing. More definitive research on the effectiveness of slings and orthoses in the management of the flaccid or subluxed shoulder is needed, and therapists should carefully consider all options before prescribing slings.

A gunslinger orthosis is another means of supporting a painful shoulder, such as from a brachial plexus injury. This type of orthosis is commercially available or can be custom fabricated for the client. A commercial gunslinger (Fig. 15-11) can be easily adjusted to position the shoulder and elbow for maximal pain relief. A custom-fabricated gunslinger (Fig. 15-12) has the benefit of a much more streamlined design, allowing the client to wear it under clothing as desired with minor garment adaptations (Lunsford & DiBello, 2008). Also, this orthosis is much

Figure 15-11 Commercial gunslinger orthosis.

easier to don and doff. It is often the best solution for clients who require long-term or permanent use of a shoulder orthosis.

Commercial neoprene sleeves that provide neutral warmth, gentle compression, and soft dynamic support to the shoulder or elbow (Fig. 15-13) are often used to relieve pain from arthritis, tendinitis, sprains, and strains. *Safety Message: As occupational therapists are expanding their use of supports fabricated from neoprene, it is important to be aware of the potential for dermatological reactions to the material and to teach clients to discontinue use of the support should symptoms develop (Stern et al., 1998).*

Figure 15-13 Commercial soft elbow support.

The treatment of lateral and medial epicondylitis often entails the use of orthoses to relieve pain and prevent further stress to affected tissues. In both conditions, pain reduces grip strength and function. Counterforce braces (Fig. 15-14), of which there are several commercial models,

Figure 15-12 Custom-fabricated gunslinger orthosis.

Figure 15-14 VariPad tennis elbow support.

are wide, nonelastic bands designed to limit full expansion of the forearm extensor or flexor muscle masses during contraction (Fedorczyk, 2011). These braces can also be custom fabricated from thermoplastic or strapping materials. The literature reports wide variation in the success of braces (Borkholder, Hill, & Fess, 2004; Wuori et al., 1998). *Safety Message: Instruct the client that complications can result from the brace being applied too tightly, including nerve compression syndromes. The client must be carefully taught accordingly.*

A wrist splint placing the wrist in 35°–40° of extension and worn alone or in conjunction with a counterforce brace is often prescribed to rest the forearm musculature (Fedorcczyk, 2011). A study by Jafarian, Demneh, and Tyson (2009) found that use of a counterforce brace resulted in immediate increase in pain-free grip strength, whereas a wrist splint did not. Conversely, Garg et al. (2010) found that pain relief was significantly better with a wrist splint than with a counterforce brace. The prescription of orthoses must be based on the client's symptoms. It is vital that the cause of the problem and the biomechanics of loading forearm musculature are also addressed in relation to all activity demands.

Support a Painful Wrist or Hand

Resting hand splints are used to support the wrist, fingers, and thumb. The normal resting position of the hand is determined anatomically by the bony architecture, capsular length, and resting tone of the wrist and hand muscles. This is typically 0°–20° of wrist extension, 20°–30° of metacarpophalangeal (MCP) joint flexion, 10°–30° of proximal interphalangeal (PIP) joint flexion, and slight distal interphalangeal (DIP) joint flexion, the thumb CMC in slight extension and abduction, and the thumb MP and IP in slight flexion (Fess et al., 2005).

A resting hand splint is commonly prescribed for clients with RA (see Chapter 39). Resting splints can reduce stress on joint capsules, synovial lining, and periarticular structures, thereby decreasing pain (Melvin, 1989). A randomized controlled trial also found that in addition to pain relief, nighttime use of resting hand splints improved hand strength and functional status (Silva et al., 2008). With RA, splinting should be in a position of comfort regardless of whether this is the ideal anatomical position (Fess et al., 2005). During an acute exacerbation of the disease, splints are generally worn at night and during most of the day and removed at least once for hygiene and gentle range-of-motion exercises. It is recommended that splint use continue for at least several weeks after the pain and swelling have subsided (Fess et al., 2005; Melvin, 1989).

Resting hand splints can be volar or dorsal, depending on needs and preferences. Commercial splints, such as those fabricated from wire-foam (Fig. 15-15) or a malleable

Figure 15-15 LMB economical resting splint.

metal frame covered by dense foam padding (Fig. 15-16), may be used if the limited adjustments they allow for can provide the client with a proper fit. This becomes more difficult if the client has established joint deformities. Custom-fabricated splints (Fig. 15-17) allow for a precise, individualized fit.

If the thumb or IP joints of the fingers are not painful, a modified resting hand splint (Fig. 15-18) will keep these joints free. This often results in less stiffness related to splint wear, some degree of hand function while the splint is worn, and improved splint wear and comfort.

Although health care professionals generally agree on the benefits of using splints to rest inflamed and painful joints, studies have shown approximately 45% compliance in wearing resting hand splints as prescribed which is less than optimal (Feinberg, 1992). Callinan and Mathiowetz (1996) compared soft versus hard resting hand splints on pain and hand function. Their results showed that pain was significantly decreased with splint wear and that 57% of clients preferred the soft splint, 33% preferred the hard splint, and 10% preferred no splint. The rate of compliance was greater for the soft splint (82%) than for the hard splint (67%). The authors advocate that therapists provide clients with options relative to comfort and preference to ensure client satisfaction and improved outcome.

Wrist extension, or cock-up, splints are probably the most commonly prescribed type of orthosis for the upper extremity. Indications for use include sprains,

Figure 15-16 Progress™ functional resting splint.

Figure 15-17 Custom thermoplastic resting hand splint.

strains, tendonitis, arthritis, carpal tunnel syndrome, following cast removal of wrist fractures, and other conditions that cause pain. A wrist splint typically positions the wrist in 10°–30° of extension, which is thought to be the best position for hand function (Fess et al., 2005). A well-fitting splint is one that clears the distal palmar and thenar creases to allow for unrestricted mobility of the fingers and thumb and that conforms to the palm to support the arches of the hand. Wrist splints may be volar (Fig. 15-19), dorsal (Fig. 15-20), or circumferential (Figs. 15-2 and 15-21) and can be custom fabricated or prefabricated. Because these splints are intended to provide wrist support while allowing functional use of the hand, fit and comfort are crucial.

A growing variety of commercial splints are available, with designs and materials offering a range of soft to rigid support. Elasticized wrist orthoses with an adjustable metal stay that slides into a volar pocket (Fig. 15-22) are commonly used because they are cost-effective and readily available. The drawbacks of these splints are that they do not fully support the palmar arches, they do not completely clear the palmar and thenar creases, and the metal stay is often prepositioned at a 35°–45° angle of extension. Therefore, it is critical to fit and adjust the stay to the desired angle before issuing the splint. Other commercial products are made of wire-foam, neoprene, leather, canvas, and other fabric blends, all of which offer features having distinct advantages and disadvantages.

Figure 15-19 Custom thermoplastic volar wrist extension splint.

Several studies have been conducted on the effects on hand function of different styles of wrist extension splints. Stern (1991) studied hand function speed in normal subjects who wore three styles of custom-fabricated wrist splints and a commercial elastic wrist splint. She found that although all of the splints significantly slowed hand speed, the commercial elastic splint allowed for faster speeds and dexterity than the others. A later study on grip strength and dexterity across five styles of commercial wrist splints concluded that each style impeded power grip and dexterity but to different extents (Stern, 1996).

Figure 15-18 Rolyan® D-Ring™ wrist brace with MCP support.

Figure 15-20 Carpal Lock® splint.

Splints vary in the amount of motion they allow or restrict. Collier and Thomas (2002) compared range of motion at the wrist with three commercial supports and a custom-made volar thermoplastic splint. The commercial splints allowed the same amount of motion (wrist flexion to about neutral and wrist extension to about 26°–31°). In contrast, the thermoplastic splint allowed less wrist flexion (not past 14° of wrist extension) and more wrist extension (about 40°). This suggests a custom thermoplastic splint may be more appropriate for conditions where limited wrist flexion is desired.

Elastic wrist orthoses have been widely used in the treatment of arthritis to stabilize wrists, decrease pain, and improve function. Again, studies have shown conflicting results across different styles of orthoses in grip strength, dexterity, hand function, pain reduction, comfort, security during task performance, and adverse effects of stiffness or muscle atrophy caused by orthotic wear (Pagnotta, Baron, & Korner-Bitensky, 1998; Stern et al., 1996). In a related study, most of 42 subjects knew their preferred orthosis within a few minutes of wear when given three styles to try (Stern et al., 1997). These studies reinforce the importance of task analysis, having a wide variety of splints to try with each client, and a careful weighing of the benefits and limitations of splinting.

Another common indication for wrist splinting is carpal tunnel syndrome, a condition caused by median nerve compression, which results in symptoms including pain,

Figure 15-22 Norco™ wrist brace.

sensory disturbances, muscle weakness, swelling, stiffness, and frequent dropping of items. Symptoms often are worse at night or with repetitive activity involving wrist flexion (see Chapter 37). For pain and related symptoms caused by carpal tunnel syndrome, conservative or postoperative treatment often uses wrist splints to prevent the elevation of carpal tunnel pressure by restricting wrist motion (Evans, 2011b).

The ideal position of the wrist to minimize pressure in the carpal tunnel varies, according to sources, from 10°–15° of extension (Melvin, 1989) to neutral (Weiss et al., 1995) to slight flexion (Gelberman et al., 1988). There is a consensus that commercial wrist splints, which often place the wrist in excessive extension, may not be of any benefit unless they are modified to a less extended position. Dorsal wrist splints (Fig. 15-20) are often recommended because they do not create external pressure over the volar wrist. A systematic review of splinting for carpal tunnel syndrome showed benefits from splinting across splint types and wrist angles, with evidence suggesting custom splints and full-time splint wear promote better results (Piazzini et al., 2007). Splinting is most effective when initiated early after symptom onset. Control of wrist position alone may be insufficient, and blocking the MPs in slight flexion may also be needed to decrease intratunnel pressure (Evans, 2011b).

A long opponens splint (Fig. 15-23), also known as a long thumb spica, can relieve pain from wrist and thumb arthritis or from de Quervain's tenosynovitis of the abductor pollicis longus and extensor pollicis brevis. This splint is typically based on the radial aspect of the forearm

Figure 15-21 Comfort Cool™ D-ring wrist splint.

Figure 15-23 Custom thermoplastic long thumb spica splint.

Figure 15-24 Liberty™ wrist and thumb splint.

Figure 15-26 AliMed® custom-molded thumb splint.

and extends distally to immobilize the thumb CMC and MP joints. The wrist is generally splinted in slight extension, with the thumb in slight flexion and palmar abduction to enable opposition to the index and middle fingers (Lohman, 2008b). If the thumb IP joint or the extensor pollicis longus tendon is involved, the IP joint can be included in the splint as well (Fig. 15-24). Prefabricated splints often provide a softer support, whereas custom-made thermoplastic splints give more rigid immobilization.

A thumb CMC stabilization splint, or a short thumb spica, is a static splint that encompasses the first metacarpal to provide stability, reduce pain, and increase hand function. It restricts motion of the CMC and MP joints but leaves the wrist relatively mobile and the thumb IP free. A static thumb MP splint allows for CMC and IP motion and can be used when the disorder is localized to the MP joint alone.

Indications for short thumb splints include RA or osteoarthritis (OA) of the thumb CMC or MP joints or trauma to soft tissues, such as the ulnar collateral ligament of the MP. The thumb is generally positioned to enable opposition to the fingers for function while in the splint, and the splint is most often worn during functional activities that cause or aggravate pain (Melvin, 1995). Commercially prefabricated rigid CMC and MP stabilization splints are often ineffectual because they fit poorly (Melvin, 1995). For a precise fit and rigid support, splints can be custom fabricated from thermoplastic materials (Fig. 15-25).

Newer commercial products made of soft, breathable elastic material have moldable thermoplastic stays to enable a custom fit, combining comfort and ease of fabrication with the required individualized rigid support (Fig. 15-26). Rigid support may not always be needed. In comparing a custom-made thermoplastic splint and a soft neoprene support for OA of the thumb CMC joint, Weiss et al. (2004) found that the prefabricated neoprene splint (Fig. 15-27) provided greater pain relief and function and was preferred over the thermoplastic splint by 72% of the subjects. Sillem et al. (2011) similarly found that clients preferred a soft prefabricated splint even though a more rigid custom splint decreased pain slightly more. Systematic reviews found evidence for the effectiveness of splinting to relieve pain and improve function in CMC OA, found evidence of varying client splint preferences, but found no evidence of splint design superiority (Egan & Brousseau, 2007; Kjeken et al., 2011).

If the thumb or finger IP joints are painful from trauma or arthritis, lateral, dorsal, or volar gutter splints (Fig. 15-28) may be used for pain relief. Silicone-lined sleeves or pads (Fig. 15-29) can protect painful joint nodules from external trauma.

Pain, volar subluxation, and ulnar deviation of the MCPs are common sequelae of RA. MCP ulnar deviation supports may be used to provide stability, realign joints, reduce joint

Figure 15-25 Custom thermoplastic short thumb splint.

Figure 15-27 Commercial soft thumb splint.

Figure 15-28 Custom thermoplastic volar gutter splint.

Figure 15-30 LMB Soft-Core™ Wire-Foam™ ulnar deviation splint.

stress, and relieve pain. They may delay the progression of deformity but do not correct or prevent it (Beasley, 2011b; Melvin, 1995). These supports may be worn alone or incorporated into a resting hand splint.

Prefabricated and custom-designed orthoses with dividers or straps to align the digits include dynamic and static and soft and rigid. Rigid static splints (Fig. 15-30) used to achieve passive correction of deformity can create focal pressure points on the digits. It is therefore important not to try to achieve ideal alignment at the risk of creating pressure problems (Melvin, 1989).

Despite the variety of splint materials and designs, MCP ulnar deviation supports are reported to be infrequently prescribed or used by clients for a variety of reasons (Rennie, 1996). For some clients, immobilization of the MCPs impairs functional use of the hand and may increase stress and pain on the adjacent PIP joints (Melvin, 1995). Additionally, bulky or volar-based splints interfere with palmar sensation and impede the ability to grasp objects.

Some clients, however, benefit from the improved digital alignment and pain reduction that supports offer. High client satisfaction rates have been reported for a custom dorsal-based design (Rennie, 1996). Soft ulnar deviation splints are commercially available (Fig. 15-31) or can be custom fabricated (Gilbert-Lenef, 1994). The prime indicator for use and selection of an MCP ulnar deviation support should be the client's preference (Harrell, 2006; Melvin, 1995).

Immobilize for Healing or to Protect Tissues

Many of the orthoses previously discussed for pain relief can also be used to immobilize for healing or protection following injury or surgery. For example, a gunslinger orthosis used to relieve traction pain associated with a brachial plexus injury can also protect the nerve structures from overstretching during the healing phase. A thumb MP splint that relieves pain from arthritis may also be used while an acutely injured collateral ligament heals. These orthoses are not discussed in detail again; different ones are reviewed.

Figure 15-29 Silicone-lined digital sleeve and pad.

Figure 15-31 Norco™ soft MP ulnar deviation support.

Procedures for Practice 15-1

How to Adjust a Sling

- Place the client upright.
- Ensure that the elbow is flexed to 90° and is seated properly in the sling, with the hand and wrist also supported as the design allows.
- Adjust the strap or straps so that the arm is comfortably supported.
- Check for comfort.
- Teach the client and caregiver about proper donning and doffing of the sling.
- Monitor the axilla and areas where sling straps cross the body for signs of skin breakdown.
- Monitor for signs of edema and joint stiffness.

Immobilize or Protect the Shoulder, Upper Arm, or Elbow

The sling is the simplest and most commonly used device for the upper extremity when there is a need to limit motion of the shoulder yet allow for some motion of the arm on the thorax. The basic arm sling consists of a forearm pouch or cuffs, a strap, and a mechanism for adjusting and securing the strap. Guidelines for sling adjustment are in Procedures for Practice 15-1.

To further limit mobility, shoulder immobilizers (Fig. 15-32) can be used. These devices, which relatively immobilize the shoulder and elbow, are typically used following shoulder surgical reconstructions, arthroplasty, and rotator cuff repair. Immobilizers are more complex than slings, involving strapping that wraps the body to stabilize the arm against the trunk. Several commercial designs are available.

Foam abduction pillows or wedges may be used to maintain the arm at a certain elevation from the body. Abduction braces, sometimes called airplane splints, are commercially

Figure 15-32 Rolyan® universal shoulder immobilizer.

Figure 15-33 Commercial humeral fracture brace.

available or custom fabricated from thermoplastics. These devices are based on the trunk and can position the shoulder in varying degrees of abduction or rotation and the elbow in varying degrees of flexion or extension. Commercial braces offer ease of adjustability with the use of wrenches but may need extra padding to prevent skin breakdown. Indications for use include postoperative shoulder repairs, burns, and skin grafts to the axillary region.

The treatment of humeral shaft fractures often involves functional fracture bracing (see Chapter 36). A humeral fracture brace (Fig. 15-33) provides external stabilization and alignment of the fracture by compressing surrounding soft tissues while allowing for early mobilization of the shoulder and elbow. These braces may be prefabricated or custom fabricated by the therapist from low-temperature thermoplastics. They are circumferential in design, with D-ring straps to allow for a secure closure and size adjustments as edema subsides. They should be lightweight and made of a perforated material for ventilation. *Safety Message: Whether the brace is prefabricated or custom, the therapist should ensure that its distal end does not block elbow flexion motion and that its proximal end does not unnecessarily limit shoulder motion.* Excellent results with the use of functional fracture bracing of the humerus have been reported (Ekholm et al., 2006).

Casts, splints, and hinged braces can be used to immobilize and protect the elbow following fractures, burns,

Figure 15-34 Custom thermoplastic anterior elbow extension splint.

ligamentous injuries, or surgical procedures. Casts offer rigid immobilization and may be made according to a circumferential, posterior, or anteroposterior bivalve design that allows the cast to be removed for wound care or range of motion. Hinged braces are frequently used to protect healing ligaments while allowing motion of the elbow. Thermoplastic splints may be anterior or posterior and may be secured by Velcro® straps or an elastic wrap. Anterior elbow extension splints (Fig. 15-34) are most commonly used to immobilize and position the elbow following skin grafting.

Immobilize or Protect the Wrist or Hand

The maintenance of normal hand function requires strong tissue repair with free gliding between neighboring structures. Proper positioning of the wrist and hand is critical to prevent complications caused by injury, edema, and tissue healing. Splinting in the early stages of healing can counteract the typical joint contractures of the injured hand that produce common deformities of wrist flexion, MCP extension, IP flexion, and thumb adduction. It is essential to position joints correctly and keep uninvolved joints moving so that they will not stiffen (Pettengill, 2011). *Safety Message: Incorrect application of a splint or improper positioning while in a splint may lead to both joint limitations and tissue damage.*

Unless specifically contraindicated, the antideformity, or safe, position of immobilization for most hand conditions is with the wrist in 10°–30° of extension, the MCPs in 70°–90° of flexion, the IPs in 0°–15° of flexion, and the thumb in palmar abduction (Fess et al., 2005; Pettengill, 2011). This is most often accomplished through a volar custom-fabricated low-temperature thermoplastic splint (Fig. 15-35). If edema

is present, the splint should be secured by an elastic wrap or gauze wrap to avoid a tourniquet effect from straps. *Safety Message: It is crucial never to force joints into the ideal position but to position joints as closely as possible to the ideal and serially revise the splint until the optimal position is realized.*

Antideformity splints are integral to the treatment of acute dorsal hand burns (see Chapter 40). An investigation of the literature found an overall lack of consensus on the design of these splints (Richard et al., 1994). The most commonly recommended positions for joints is with the wrist in 15°–30° of extension, the MCPs in 50°–70° of flexion, the IPs in full extension, and the thumb in palmar abduction or midway between palmar and radial abduction with the MP and IP in slight flexion to full extension to prevent common burn-related contractures (Richard & Staley, 1994; Tufaro & Bondoc, 2011). Preformed splints are commercially available and may be used if adequate fit can be obtained given the size of the hand and any edema. Custom-fabricated splints, preferably of a perforated material, ensure the best fit. Splints may have to be adjusted daily for optimal fit and maintenance of proper joint positioning. For the grafting and rehabilitation phases of burn treatment, splint design varies with the positions necessary to counteract the contractile forces of the scars.

Wrist splints, as discussed in the previous section, may be used for protection or immobilization of wrists following cast removal or to treat soft tissue injuries. Athletic injuries to the wrist and hand, such as contusions, sprains, strains, fractures, and joint dislocations, often require the use of protective splints to enable the client to continue participation in sports. As with other splints, selection of material and design should be carefully tailored to the client's needs. Materials may be thermoplastic, silicone rubber, plaster, fiberglass, cloth tape, or neoprene. Selection should be based on the degree of immobilization required, material durability and breathability, the player's sport position, governing rules of the sport, and the safety of other players.

Treatment of tendon injuries and repairs may involve static positioning to immobilize the tendon for healing or dynamic splinting to protect the tendon while allowing controlled motion to increase tendon repair strength and gliding. Flexor tendon repair protocols vary, but a
Figure 15-35 Custom thermoplastic "safe position" wrist–hand splint.
Figure 15-36 Custom thermoplastic dorsal blocking splint.

Figure 15-37 Plaster digit cast.

protective dorsal blocking splint (Fig. 15-36) positioning the wrist and MCPs in flexion and blocking the IP joints at 0° of extension is typically used. Rubber band traction may be added to hold the digits in a flexed position or to enable resistive extension and passive flexion exercises. The splint is usually custom fabricated from low-temperature thermoplastic and is often worn for as long as 6 weeks (Pettengill & van Strien, 2011).

Extensor tendon injuries involve treatment and splinting based on the level of injury. For injuries at the DIP level that may result in a mallet finger deformity, the DIP is immobilized for 6–8 weeks in a slightly hyperextended position (Evans, 2011a). The PIP joint is left free. The splints used may be volar or dorsal and may be prefabricated or custom fabricated from padded aluminum strips or thermoplastics. Excellent results for the treatment of mallet finger have been reported with various splints (Pike et al., 2010). For injuries

at the PIP level, treatment includes digital cast (Fig. 15-37) or splint immobilization with the PIP in absolute 0° of extension for 6–8 weeks to prevent boutonniere deformity. For more proximal tendon injuries, splinting may involve static positioning, dynamic assists, or both (Evans, 2011a).

Splinting is an integral part of postoperative MCP arthroplasty treatment. Early positioning and motion following arthroplasty often uses a dynamic MCP extension assist (Fig. 15-38) to support the wrist, control MCP position and alignment, allow guided motion, and assist with extensor power. This controlled stress allows for joint capsule remodeling over time (Lubahn, Wolfe, & Feldsher, 2011). Dynamic MCP extension assists may use high-profile or low-profile outrigger designs. They have slings to support the MCPs in neutral extension and deviation and to provide rotatory alignment. Outrigger kits are commercially available, or the outrigger may be hand fabricated. The dynamic extension splint may be supplemented by a static positioning splint at night (Fess et al., 2005; Lubahn, Wolfe, & Feldscher, 2011).
Figure 15-38 Custom thermoplastic low-profile dynamic MCP extension splint using Rolyan® adjustable Outrigger kit.

Figure 15-39 Rolyan® buddy straps.

To protect digits but allow for stabilization or controlled motion of the MCP, PIP, or DIP joints following injury or surgery, buddy straps (Fig. 15-39) (Jensen & Rayan, 1996), buddy sleeves (Bassini & Patel, 1994), or buddy splints (Lamay, 1994), which connect an injured finger to an adjacent finger, can be used. Common indications for these include stable fractures, PIP joint dislocations, collateral ligament injuries, and staged flexor tendon reconstructions (Beasley, 2011a; Fess et al., 2005)

Provide Stability or Restrict Unwanted Motion

Orthoses can be helpful in stabilizing joints when their integrity has been compromised by an acute injury or a chronic disease such as arthritis. Stabilization or restriction of motion can often greatly facilitate functional use of a limb.

Stabilize or Restrict Motion of the Shoulder or Elbow

In addition to the purposes previously described, slings, gunslingers, and hinged elbow orthoses can also be used to provide proximal stability that may enable improved distal function.

Stabilize or Restrict Motion of the Wrist or Hand

It is essential to determine the position in which a joint is to be supported relative to hand dominance and task requirements because specific functional demands vary greatly among individual clients. The wrist is considered by many to be the key to ultimate hand function, and wrist splints are commonly prescribed to provide stability. Dorsal wrist splints allow for the greatest palmar sensation but are least supportive, volar wrist splints are most commonly prescribed and provide a moderate amount of stability, and circumferential wrist splints provide the greatest amount of stability (Lohman, 2008a).

For optimum mechanical advantage to support the weight of the hand, the forearm portion of the splint

Figure 15-40 Liberty™ short and long elastic wrist braces.

should be two-thirds the length of the forearm (Fess et al., 2005; Lohman, 2008a). Although greater length is believed to add to stability, studies have shown that a longer splint can decrease grip strength, slow finger dexterity, and decrease hand function speeds compared with a shorter wrist splint (Stern, 1996). For smaller or lighter hands and for clients who do not use their hands for high-demand activities, a shorter wrist support (Fig. 15-40) can increase comfort while being less obtrusive than a long splint (Melvin, 1995).

A lumbrical bar is a hand-based orthosis that extends over the dorsal aspect of the proximal phalanges to restrict unwanted hyperextension of the MCPs that can result from an ulnar nerve or combined median and ulnar nerve injury. By blocking this motion, IP flexion contractures can be prevented and functional hand opening can be improved as the power of the long finger extensors is transferred to the IPs for extension. Lumbrical bar orthoses using spring wire are commercially available (Fig. 15-41), but they tend

Figure 15-41 LMB MP flexion spring.

Figure 15-42 Custom thermoplastic lumbrical bar splint.

Figure 15-43 Custom thermoplastic PIP hyperextension block.

to be bulky and limit the ability to grasp objects. Custom-fabricated thermoplastic splints (Figs. 15-3 and 15-42) provide for a more intimate and streamlined fit (Duff & Estilow, 2011).

This same principle of restricting undesired motion is used in a PIP hyperextension block, also known as a swan-neck splint. Swan-neck deformities are common sequelae of RA and a possible complication following an extensor tendon injury or repair. These deformities often cause difficulty with hand closure, as PIP tendons and ligaments can catch during motion, and the finger flexors have less of a mechanical advantage to initiate flexion when the PIP is hyperextended. By blocking the PIP in a slightly flexed position, the client can

flex the PIP more quickly and easily (Beasley, 2011b; Harrell, 2006).

For short-term use or for trial purposes, custom-fabricated thermoplastic swan-neck splints (Fig. 15-43) may suffice. For long-term use or for use on adjacent digits, commercial swan-neck splints are often recommended because they are more durable, less bulky, more easily cleaned, and more cosmetically appealing. Custom-ordered ring splints made of silver or gold (Fig. 15-44) are attractive, durable, streamlined, and adjustable for variations in joint swelling, but they are more costly. Silver splints have also been shown to improve dexterity (Zijlstra, Heijnsdijk-Rouwenhorst, & Rasker, 2004). Prefabricated splints made of polypropylene (Fig. 15-45), also available commercially, offer some of the benefits of silver splints with less cost. In a study comparing commercial silver and polypropylene splints, both were equally effective and acceptable to clients (van der Giesen et al., 2009). Heavy-duty metal splints, such as Murphy ring splints, may benefit clients who use their hands in highly demanding tasks. Swan-neck splints can also be used to provide lateral stability to unstable IP joints of the fingers or thumb.

Figure 15-44 Siris™ Silver Swan neck splint.

Figure 15-45 Oval-8™ commercial ring splints.

Flexible boutonniere deformities may benefit from boutonniere splinting to block the PIP in a more extended position to allow for greater functional hand opening. These may also be custom-made by the therapist or custom ordered from

the companies that fabricate swan-neck splints (Fig. 15-46). Because there is direct pressure over the PIP, the dorsal skin must be carefully monitored for signs of breakdown.

Thumb stability is a requirement of almost all prehensile activities, so splinting of unstable thumb joints may have a particular value for function (Fess et al., 2005). Instability of the CMC often requires a long thumb splint that crosses the wrist because shorter splints may not adequately support the CMC. Short thumb spica splints (Fig. 15-25), also known as thumb posts or opponens splints, can provide MP stability and a stable post for pinching. Although a circumferential design is commonly used, problems with marked MP deformity can make donning and doffing of the splint difficult, and direct pressure over the MP may lead to breakdown of fragile skin.

Restore Mobility

Orthoses play an integral role in the restoration of mobility by correcting soft tissue or joint contractures that can occur as a result of poor positioning, trauma, scarring, or increased muscle tone, and there is evidence to support their use (Michlovitz, Harris, & Watkins, 2004). Devices providing low-load, prolonged stretch have proven to be effective in the contracture management of clients having a neurological or orthopedic disorder (Hill, 1994; Nuismer, Ekes, & Holm, 1997). As described earlier in this chapter, different types of splinting may be used: serial static plaster or thermoplastic, dynamic, and static progressive.

A therapist implementing a splinting program to regain motion must understand how splints work to affect positive change. Range of motion is gained not by tissue stretching but by actual tissue elongation from new cell

Figure 15-46 Siris™ silver boutonniere splint.

growth (Bell-Krotoski & Figarola, 1995; Fess et al., 2005). *Safety Message: The forces used must be gentle and carefully applied, and the tissue must be closely monitored for signs of excessive stress, such as redness and inflammation, which are indicators to change or stop treatment.* Inelastic mobilization applies constant forces needed to remodel tissues and is the most effective means for gaining motion in chronically stiff joints. Elastic mobilization is most indicated for acute joint stiffness or more supple joints because forces can be more easily controlled and fine adjustments made (Fess et al., 2005).

Fixed contractures and chronically stiff joints often respond best to inelastic mobilization from serial casting. Plaster is an ideal material because it conforms intimately and is more rigid than thermoplastics. Casts are changed as motion gains are achieved. In a systematic review of upper extremity casting in central nervous system disorders, there was insufficient high quality evidence on the long-term benefits from casting, and there was high variability in casting protocols (Lannin, Novak, & Cusick, 2007); therefore, it is not possible to make recommendations for practice.

Dynamic splinting is more effective when used for early contractures (Bell-Krotoski & Figarola, 1995; Glasgow et al., 2011). It allows for motion in the opposite direction, which helps prevent unwanted stiffness. Splints can also be removed for hygiene and function. Often, dynamic splints are worn at night so as not to interfere with use of the limb. This decrease in wearing time, however, means that tissues are not kept under constant tension, and less rapid gains may result. The amount and direction of force must be carefully monitored and adjusted as joint angles change.

Static progressive splinting is often indicated for fixed contractures. It has the advantage of being worn for shorter periods throughout the day, allowing for motion and functional use of the limb.

Restore Mobility of the Shoulder, Elbow, or Forearm

A serial static abduction splint can be used to apply pressure to and elongate burn scars in the axilla. The benefits of wearing this type of splint must be carefully weighed against the complete lack of function that it imposes. For flexion contractures of the elbow, thermoplastic anterior elbow extension splints (Fig. 15-34), serial casts or dropout casts, and dynamic elbow extension or static progressive elbow extension splints can be used.

Serial casting, which typically entails changing the cast weekly, can safely reposition joints without providing undue stress to tissues (Bell-Krotoski, 2011; Colditz, 2011). When the contracture is a result of increased tone, such as in the client with a brain injury, casting is often used in conjunction with nerve blocks or surgical procedures. *Safety Message: Great care must be taken with casting in the presence of severe tone, because pressure areas may develop.*
Figure 15-47 Plaster elbow dropout cast.

Dropout casts (Fig. 15-47) use the force of gravity to assist in reducing an elbow flexion contracture. The posterior portion of the cast above the elbow is removed, allowing the forearm to drop into extension. This type of casting is effective only if the client is upright most of the day.

A bivalved cast, also known as an anteroposterior splint (Fig. 15-48), is often used to maintain range of motion once it is achieved through casting or other means. This splint is well padded, with several straps holding the two halves together. The caregiver must be thoroughly trained so that it is applied properly and in the correct alignment to prevent pressure problems and skin breakdown.

Dynamic or static progressive splints (Fig. 15-49) have been reported to be successful in the treatment of elbow burn flexion contractures when static splinting was not effective. An average of 5°–10° can be gained per day (Richard, Shanesy, & Miller, 1995). They have also proven to be effective in the treatment of orthopedic and neurological flexion contractures (Marinelli et al., 2010; Nuismer, Ekes, & Holm, 1997). Elbow extension contractures, which are less commonly seen, can be treated with serial casting into flexion, dynamic flexion splinting, or static progressive splinting.

Figure 15-48 Fiberglass anteroposterior elbow splint with wrist and digits included.

Figure 15-49 JAS Static Progressive Elbow™ orthosis.

Loss of forearm rotation, often seen following spinal cord injury, peripheral nerve injury, or fracture, can be treated with dynamic forearm rotation splinting. Splints can be custom fabricated (Fess et al., 2005) or obtained commercially as a preformed product or kit (Fig. 15-50). Altering the direction of force when using these splints can produce supination or pronation. A static progressive supination splint described by Murphy (1990) achieved favorable results.

Restore Mobility of the Wrist or Hand

Serial short arm casts, with or without the fingers or thumb included, can be used in the treatment of flexion or extension contractures related to increased muscle tone. Serial plaster slab splinting (Bell-Krotoski, 2011) can be especially effective in the presence of muscle–tendon unit shortening that can result in the inability to compositely flex or extend the wrist and fingers. Long flexor tightness can develop as a result of the wrist being in a prolonged position of flexion, such as with wrist drop from radial

Figure 15-50 Rolyan® preformed dynamic pronation/supination splint.

nerve palsy, wrist fracture immobilization, and protective positioning following flexor tendon repair. A plaster slab splint or a volar thermoplastic splint that positions the wrist and fingers in maximum composite extension can help to correct tightness of the long finger flexors.

Serial static thermoplastic wrist splints, dynamic wrist splints (Fig. 15-51), and static progressive wrist splints can be used for limitations in wrist flexion or extension. These may be custom fabricated or preformed. Dynamic or
Figure 15-51 Custom thermoplastic dynamic wrist extension splint using Phoenix wrist hinge.
Figure 15-52 Custom thermoplastic dynamic MCP flexion splint.

Figure 15-54 LMB spring finger extension assist.

static progressive component kits can also be purchased commercially. This allows the therapist to custom mold the splint bases while more easily assembling force units.

Lack of MCP flexion can devastate hand function. Many dynamic splint designs to regain MCP motion are available. Custom-fabricated thermoplastic splints use individual finger loops over the proximal phalanx (Fig. 15-52). Attached to these loops are rubber bands or springs that provide the needed force for sustained tension. An outrigger is used to direct the line of pull at 90°. It is important to clear the distal palmar crease so as not to block full flexion range of motion. These splints may be forearm based or hand based, depending on the mechanical advantage needed, any adhesions, and the client's wrist strength and stability (Fess et al., 2005).

Commercial hand-based dynamic splints use springs, coiled spring wire (Fig. 15-41), or rubber bands to provide flexion force to the MCPs as a unit. These splints are effective only if all MCPs are uniformly stiff. Some force adjustments can be made, but individual finger force amount or angle adjustments are not possible, as they are with custom-made thermoplastic splints having separate finger loops. Finger flexion gloves (Fig. 15-53), which incorporate

rubber band traction, can be used to gain composite flexion of all joints, but they have the most effect on the MCPs.

Limited PIP flexion makes grasp difficult, and limited PIP extension interferes with the ability to open the hand in preparation for grasp or to release objects. PIP flexion contractures are a frequent complication of trauma or poor positioning, and extension contractures can be seen following dorsal hand burns or prolonged immobilization for fracture management.

To address these contractures, forearm- or hand-based dynamic thermoplastic splints similar to those designed for MCP flexion and extension can be used by extending the distal part of the splint across the MCP to just proximal to the PIP joint. Immobilizing the MCP applies force to the PIP.

Prefabricated spring wire and spring coil splints are also available to gain flexion or extension range of motion. In a study of prefabricated spring wire (Fig. 15-54) and spring coil (Fig. 15-55) extension splints by Fess (1988), exerted forces were found to vary in the same splint design and to vary also according to the degree of joint contracture. Some forces were alarmingly high, well above recommended limits. Callahan and McEntee (1986) found similar

Figure 15-53 Finger flexion glove.
Figure 15-55 Rolyan® Sof-Stretch coil extension splint.

results and expressed concern about whether these splints fit accurately and about forces being distributed over small surface areas as compared with custom-fabricated splints. Designs have since been improved so that tension can be somewhat modified. If used, these splints must be carefully monitored to avoid further joint or tissue damage.

Spring coil extension splints, sometimes called Capener splints, may be custom fabricated and are described in the literature (Callahan & McEntee, 1986; Colditz, 2011). A study of dynamic splinting in the management of PIP flexion contractures using Capener and low-profile hand-based outrigger splints found the two to be equally effective, suggesting that the client may prefer the less bulky Capener splint if offered a choice (Prosser, 1996). Additional findings concluded that the longer the flexion contracture was present, the less it resolved and that splint wearing time was a significant factor affecting outcome. Glasgow et al. (2012) also found the duration of dynamic orthotic use to be a key factor in PIP joint contracture resolution, with flexion motion obtained more quickly than extension.

A commercial neoprene dynamic finger extension tube (Fig. 15-56) provides circumferential pressure and a dynamic force into extension via an angled seam on its volar surface. It may also offer other therapeutic values, such as heat, mild joint distraction, and longer tolerable wearing times (Clark, 1997). PIP extension can also be gained though serial plaster casting or splinting.

Thermoplastic gutter (Fig. 15-28) or circumferential splinting and dynamic traction splinting are useful in the treatment of mild contractures, whereas serial plaster digital casting (Fig. 15-37) has been advocated for moderate to severe contractures (Bell-Krotoski, 2011). Plaster casting offers the advantages of intimate conformity, rigidity, breathability, and uniform distribution of pressure. Casting does require the client's cooperation in keeping the cast dry, and casts have the disadvantage of not being removable for function or motion. For most effective results,
Figure 15-56 Rolyan® Dynamic Digit Extensor Tube™ splint.

Figure 15-57 Custom thermoplastic thumb abduction splint.

casts should be changed every 2–7 days (Bell-Krotoski & Figarola, 1995) or sooner if they become loose or wet. The DIP joint may be left free if its motion is not limited. It is at times beneficial to involve the DIP in the cast if increased mechanical advantage is desired for PIP extension. Variations of many of these splints can be used for the treatment of DIP contractures or contractures of the thumb MP or IP.

Adduction contractures of the thumb, which are commonly seen in burns and nerve injuries, are most often treated with serial static thumb abduction splints, which conform to the first web space (Fig. 15-57). It is important to ensure that abduction forces are directed to the CMC joint by involving as much of the distal aspect of the first metacarpal as possible (Fess et al., 2005). Strapping must be designed to apply pressure in the proper direction and to prevent distal migration of the splint. This often requires a strap that crosses the wrist.

Substitute for Weak or Absent Muscles

Orthoses are commonly used to assist clients in maximizing the functional use of an affected upper extremity. Orthoses may be used temporarily, as in the case of recovering nerve injuries or neurological diseases such as Guillain-Barré, or they may be prescribed for long-term use, such as in complete spinal cord injury or progressive neuromuscular conditions like postpolio syndrome. They are generally worn only during the day or for specific functional tasks. An orthosis successful in improving the ability to function is often much more accepted and appreciated by the client than orthoses prescribed for other purposes.

Substitute for Weak or Absent Shoulder or Elbow Muscles

Proximal arm devices can support the shoulder and forearm to encourage motion of weak proximal musculature, allow for distal function, and enable occupational performance as well as prevent loss of motion and provide pain relief.
Figure 15-58 Suspension arm devices. **A.** Suspension sling with horizontal bar. **B.** Suspension sling without horizontal bar. **C.** Suspension arm support. (Adapted with permission from Redford, J. B. [Ed.]. [1986]. *Orthotics etcetera* [3rd ed.]. Baltimore: Williams & Wilkins.)

Suspension arm devices (Fig. 15-58) suspend from above the head, generally on an overhead rod that is mounted to a wheelchair. The arm swings as in a pendulum from straps attached to the overhead rod. *Safety Message: Contraindications to use include glenohumeral joint instability, and care must be used to ensure that the humeral head does not sublux or impinge on the supraspinatus when the arm is in the device.*

The suspension sling with a single strap suspended from the overhead rod has a horizontal balance bar with multiple holes for adjustment of the fulcrum and supports separate wrist and elbow cuffs. The suspension sling without horizontal bar has two straps that originate directly from the overhead rod with cuffs to support the elbow and wrist. The suspension arm support has a forearm trough suspended from a single point on the overhead rod. These can be easily attached to the wheelchair upright or to an overhead frame on the client's bed. Springs of various tensions may be added to the straps that support the limb, allowing a client with only slight active motion to produce accelerated shoulder movement by bouncing the arm up and down. Suspension devices can be adjusted to allow for certain motions (Procedures for Practice 15-2) but lack the fine adjustment that extremely weak clients may need.

A **mobile arm support** (MAS) (Fig. 15-59) is a mechanical device that supports the weight of the arm and provides assistance to shoulder and elbow motions through a linkage of ball-bearing joints (Mulcahey, 2008; Yasuda, Bowman, & Hsu, 1986). The MAS is

Procedures for Practice 15-2

How to Adjust Suspension Arm Devices

Suspension Arm Sling

- For horizontal abduction, rotate the overhead rod laterally.
- For horizontal adduction, rotate the overhead rod medially.
- For external rotation, move the arm cuffs back on the balance bar to shift weight toward the elbow.
- For internal rotation, move the arm cuffs forward on the balance bar to shift weight toward the hand.
- For elbow flexion, move the point of suspension backward on the overhead rod to put the hand toward the client's face.
- For elbow extension, move the point of suspension forward on the overhead rod to put the hand away from the client's face.
- For height adjustments, vary the length of the strap or straps that connect to the overhead rod, or raise or lower the bracket on the wheelchair upright.

Suspension Arm Support

- For horizontal motion and height adjustments, see list under Suspension Arm Sling.
- For elbow flexion, move the rocker arm farther from the trough elbow dial.
- For elbow extension, move the rocker arm closer to the trough elbow dial.

Figure 15-59 Mobile arm support.

typically mounted to a client's wheelchair, but it can also be attached to a tabletop or even a floor stand for trial use (Fig. 15-60). The mechanical principles are three-fold: (1) use of gravity to assist weak muscles, (2) support of the arm to reduce the load on weak muscles,

Figure 15-60 JAECO/Rancho MultiLink MAS with elevation assist on floor stand.

and (3) reduction of friction by using ball-bearing joints. Criteria for use include:

- a defined functional need
- an adequate source of power from neck, trunk, shoulder girdle, or elbow muscles
- adequate motor control such that the client can contract and relax functioning muscles
- sufficient passive joint range of motion, with 0°–90° of shoulder flexion and abduction, 0°–30° of external rotation, full internal rotation and elbow flexion, and 0°–80° of pronation preferred
- stable trunk positioning
- a motivated client
- a supportive environment that provides the client with the opportunity and assistance to use the device

Clients who may benefit include those with cervical spinal cord injury (Atkins et al., 2008), muscular dystrophy, Guillain-Barré syndrome, amyotrophic lateral sclerosis, poliomyelitis, and polymyositis.

Selection of MAS components, assembly of parts, and balance and adjustment of the MAS generally requires postgraduate hands-on training. Balance and adjustment principles are presented in Procedures for Practice 15-3 to give the reader a basic overview and appreciation for what is possible. This does not negate the need for additional training or consultation with experienced therapists to ensure that the best possible adjustments are made to give the client maximal mechanical advantage.

The standard MAS assembly described in this chapter consists of an adjustable arm positioner bracket (also known as a semireclining bracket), standard proximal and distal arms, a standard rocker arm assembly, and a basic forearm trough (Fig. 15-61). The many commonly used special MAS component parts include the outside rocker arm assembly and the elevating proximal arm (Fig. 15-62). The outside rocker arm (or offset swivel) has a ball-bearing joint that allows for greater freedom in vertical motion, thus facilitating hand-to-mouth or hand-to-table movements. The elevating proximal arm is useful for a client with poor to fair deltoid strength. As the client initiates the elevating motion, the rubber band assists, allowing the client to flex and abduct the humerus to a higher level.

A newer MAS system that is less complicated and more user friendly is available in standard (Fig. 15-63) and elevating models (Fig. 15-60). Advantages are their more contemporary appearance, streamlined design, and ease of adjustments (JAECO, 2008).

For a client who can walk, a gunslinger orthosis can provide both proximal stability and mobility. This type of shoulder–elbow orthosis consists of a metal forearm trough that is mechanically coupled to a plastic hemigirdle anchored on the client's pelvis. This device is most useful for clients having good distal function but proximal weakness from brachial plexus injuries, spinal cord injuries, or postpolio syndrome. Prefabricated gunslingers

Procedures for Practice 15-3

Mobile Arm Support Assembly and Training Principles

How to Assemble and Balance the Standard Mobile Arm Support Assembly

- Assemble tools (Phillips and flathead screwdrivers and Allen wrenches) and mobile arm support (MAS) parts (bracket, proximal arm, distal arm, rocker arm, and trough).
- Inspect ball-bearing components for smooth operation.
- Ensure that the client is seated properly in the wheelchair, with pelvis well back in chair and trunk in good vertical alignment.
- Fit the trough to the client's arm by bending the elbow dial toward the radial side of the trough.
- Attach the rocker arm to the trough by placing the screws in the third and fifth holes from the dial.
- Attach the bracket to the wheelchair at approximately the midhumerus level so that it is neutrally rolled[1] and pitched.[2]
- Attach the proximal arm to the bracket.
- Attach the distal arm to the proximal arm.
- Attach the trough to the distal arm.
- Balance the arm support to neutral by adjusting the pitch of the bracket and the distal end of the proximal arm so that the bearing tubes are perpendicular to the floor.
- Place the client's arm in the trough.
- Observe for abnormal shoulder elevation, and adjust the height of the bracket as needed to correct it.

Mobile Arm Support Hand-to-Mouth Movement Pattern

Instructions to Client
- Push down on the trough dial while adducting your humerus.
- Externally rotate your shoulder.
- Shift your body weight toward the MAS.
- Straighten up or lean back in your chair.
- Rotate your trunk toward the MAS.
- Turn your head toward the MAS.

Equipment Adjustments to Aid This Motion
- Move the rocker arm farther from the trough elbow dial.
- Pitch the MAS at the bracket assembly toward the wheelchair back.
- Raise the bracket assembly on the wheelchair upright.

[1] Roll is the rotation of the bracket assembly on the wheelchair upright governing the side-to-side (horizontal) slope. The name comes from the side-to-side swaying of a ship.
[2] Pitch is the tilt of the ball-bearing tube on the bracket assembly governing the upward-downward (vertical) slope. The name comes from the backward-forward pitch of a ship as it goes over waves.

Mobile Arm Support Hand-to-Table Movement Pattern

Instructions to Client
- Lift and internally rotate your shoulder to lower your hand.
- Shift your body weight away from the MAS.
- Roll your shoulder forward.
- Rotate your trunk away from the MAS.
- Tilt or turn your head away from the MAS.

Equipment Adjustments to Aid This Motion
- Move the rocker arm closer to the trough elbow dial.
- Pitch the MAS at the bracket assembly toward the client's feet.
- Lower the bracket assembly on the wheelchair upright.

Mobile Arm Support Horizontal Abduction and Adduction Movement Patterns

Instructions to Client
- Shift your body weight in the direction you want to move.
- Rotate your trunk toward the direction you want to move.
- Turn your head briskly in the direction you want to move.

Equipment Adjustments to Aid This Motion
- Roll the bracket assembly on the wheelchair upright toward the client for adduction.
- Roll the bracket assembly on the wheelchair upright away from the client for abduction.

Mobile Arm Support Controls Training and Use Training

Controls Training
- Teach the client the effects of head, trunk, and proximal movements on the movement of the MAS.
- If bilateral MASs are used, begin with one side first.
- Begin with horizontal motions by having the client practice moving the MAS as far as possible from side to side and front to back.
- Proceed with vertical motions by having the client practice moving the hand to the table and up to the mouth at various points within the horizontal range.

Use Training
- Teach the client to use the MAS for specific desired functional activities, such as eating, grooming, writing, keyboarding, texting, page turning, and power wheelchair driving.
- Encourage practice and independent problem-solving skills.

(Fig. 15-11) are commercially available, but for long-term use, a custom-designed orthosis (Fig. 15-12) is indicated.

Depending on the client's proximal muscle status and specific functional needs, the coupling between the trough and hemigirdle base can be customized to permit a variety of motions, such as glenohumeral internal–external rotation and flexion–extension. It can also be made to hold a very weak shoulder in a static position for function, which may be with the hand in midline. If the wrist also has weakness, the trough can be extended to support the hand. Usefulness must be determined for each individual case, considering factors
Figure 15-61 Standard components of a mobile arm support.

such as acceptance by the client, ease of donning, cost, and especially, functional benefit.

Substitute for Weak or Absent Wrist or Hand Muscles

The combination of sensory loss and motor imbalance caused by a peripheral nerve injury greatly impairs normal hand function. As Colditz (2002/2011) points out, it is impossible to build an external device that can substitute for the intricately balanced muscles that a splint attempts to replace. In splinting nerve palsies, the key concept is to understand the client's condition and neuromuscular status so as to prescribe or design an appropriate splint to increase function. Splints should keep areas of intact sensibility free if possible, should be as simple as possible, and should not immobilize joints unnecessarily. The splinting program must be closely monitored and altered in response to nerve recovery as the client's muscle status changes (see the Case Example). In a study to assess factors that influenced splint wear in peripheral nerve lesions, the only significant variable was a positive effect as perceived by the client; 52% of clients reported terminating wear because splints hindered their daily life and 23% reported terminating wear because splints had not been of any use. Interestingly, the highest effectiveness score was for day splints for the dominant hand aimed at replacing function (Paternostro-Sluga et al., 2003).

Radial nerve palsy, commonly associated with humeral fractures, can result in the complete loss or partial weakness
Figure 15-62 Special mobile arm support components: **A.** Outside rocker arm. **B.** Elevating proximal arm.

Figure 15-63 JAECO/Rancho MultiLink MAS.

Figure 15-64 Bunnell™ Thomas suspension splint.

of wrist, finger, and thumb extensors and weakness of forearm supination and thumb abduction. The loss of wrist extensor strength devastates hand grasp. Not only is the client unable to position the hand properly, but the inability to stabilize the wrist in extension impairs normal function of the long finger flexors. Loss of extrinsic finger extension is much less of a functional problem, because the unaffected intrinsic muscles can actively extend the IPs. Supporting the wrist in extension is the primary goal of radial nerve splinting, and the use of a simple static wrist splint may suffice in improving hand function (Fess et al., 2005).

Prefabricated radial nerve splints, such as a Thomas suspension splint (Fig. 15-64) or a wire-foam splint, are designed to dynamically extend the wrist, MCPs, and thumb. It is usually preferable not to include the thumb because of the limitation in intrinsic motion it imposes and

the danger of stressing the MP collateral ligament through poorly directed forces. Adding individual finger loops to the palmar bar, thus removing bulk in the palm and allowing individual finger motion, can enhance the Thomas suspension splint. The palmar bulk of the wire-foam splint often impedes the ability to grasp large objects. *Safety Message: Caution should be used when prescribing a dynamic orthosis because strong unopposed flexors may easily overcome the dynamic forces trying to hold the wrist and hand in extension, negating functional benefits*.

A custom-fabricated radial nerve splint, also known as a Colditz splint, has been designed to allow for partial wrist and full finger motion and a facsimile of a normal tenodesis effect (Fig. 15-65). This splint consists of a low-profile outrigger attached to a dorsal forearm base (Figs. 15-5 and 15-66). Nonelastic cords connect the splint base to finger loops. The cord length is adjusted so that, when the MCPs actively flex, the wrist is brought into extension. Conversely, when the wrist flexes, the cord
Figure 15-65 Normal tenodesis effect. **A.** When the wrist is extended, the fingers flex. **B.** When the wrist is flexed, the fingers extend.
Figure 15-66 Custom thermoplastic radial nerve splint using low-profile Phoenix extended outrigger.

tension causes the MCPs to extend. Little training is required for the client to be able to use the splint functionally, and grasp and release of objects is greatly enhanced. Further advantages of this splint are the maintenance of normal hand arches, the absence of splinting material covering the palm, the low-profile design, and the facilitation of wrist extensor strength as return of nerve function occurs (Colditz, 2002/2011). Preformed splints and outrigger kits are commercially available.

Splinting in median nerve palsy is geared toward substituting for weak or absent thenar muscles that render the thumb unable to pull away from the palm and oppose to the fingers. This is most often accomplished through a custom-fabricated thermoplastic opponens splint, which stabilizes the thumb in a position of abduction and opposition to enable pulp-to-pulp pinch (Fig. 15-25). Although such a splint often greatly improves fine motor prehension, this must be individually assessed, because substitution patterns from unaffected thumb muscles may provide sufficient thumb function (Colditz, 2002/2011; Fess et al., 2005). Clients may choose to wear an opposition splint for selected activities only.

In the presence of ulnar nerve palsy, the hand assumes a claw position, or intrinsic-minus position, with ring and small finger hyperextension of the MCPs and flexion of the IPs. This is a result of weakness or loss of lumbrical and interossei muscles, which are responsible for MCP flexion and IP extension. The prime splinting objective is to assist in grasp and release of objects by preventing the claw position. This is accomplished by a lumbrical bar splint, which blocks the MCPs in slight flexion, allowing the force of the unaffected long finger extensors to extend the IPs.

Dynamic splints, such as prefabricated spring wire splints (Fig. 15-41), do not work well because the spring tension is usually not sufficient to hold the MCPs in flexion when the

client actively opens the hand. Thus, the MCPs hyperextend against the force, which actually strengthens the long extensors and encourages deformity (Colditz, 2002/2011).

A static custom-molded thermoplastic splint is advocated as the best solution. It should be nonbulky, carefully molded to distribute pressure evenly over the dorsum of the proximal phalanges, and designed so as not to obstruct full flexion of all joints (Colditz, 2002/2011; Fess et al., 2005). The splint may include just the affected ring and small fingers (Figs. 15-3 and 15-67) or may include all fingers to distribute pressure more effectively and comfortably (Fig. 15-42). The latter splint is used in the treatment of combined median and ulnar nerve injuries, which result in the clawing of all four fingers.

For a client who has only radial nerve function, a custom-fabricated Rehabilitation Institute of Chicago (RIC) tenodesis splint (Fig. 15-68) may be used. This splint can provide minimal hand grasp by harnessing the power of the wrist extensors to bring the thumb, index finger, and long finger into a functional pinch. It has three molded thermoplastic pieces: one to position the thumb, one to position the index and long fingers, and a wrist cuff to
Figure 15-67 Custom thermoplastic lumbrical bar splint for ring and small fingers.

Figure 15-68 Custom thermoplastic RIC tenodesis splint.

Figure 15-69 Wrist support with universal cuff.

serve as the base for connecting a static line from the wrist to the fingers (Colditz, 2002/2011).

Static orthoses, which allow passive holding of functional implements such as utensils or pens, may also be used in the presence of wrist or hand weakness. Examples include a hand-based universal cuff, a wrist support with universal cuff (Fig. 15-69), and a short or long design Wanchik writing splint (Fig. 15-70).

For clients with long-term or permanent loss of muscle function, as is the case of complete spinal cord injury or progressive neuromuscular disease, permanent functional orthoses may be used. These orthoses are fabricated by experienced orthotists from metal and are recommended by occupational therapists for individual clients based on neuromuscular status and specific functional needs. Often, these distal orthoses are used in conjunction with

proximal ones (such as a MAS) if proximal weakness is also present. Although they are now less frequently used than in years past, they remain an option for select circumstances.

A ratchet WHO (Fig. 15-71) may be used for clients with weak (below grade 3) wrist extension and finger strength, such as that seen with C5 tetraplegia (see Chapter 38). A thumb post positions the thumb in abduction and in alignment with the index and long fingers, and a finger piece assembly maintains the index and long fingers in a position for pinch. A ratchet system is used to close the hand in discrete increments. Closing is accomplished by manually pushing the finger piece to flex the fingers against the thumb using the contralateral hand, the chin, or the side of a table or chair. Release is accomplished by a spring that is activated by the press of a release button (Lunsford & DiBello, 2008).

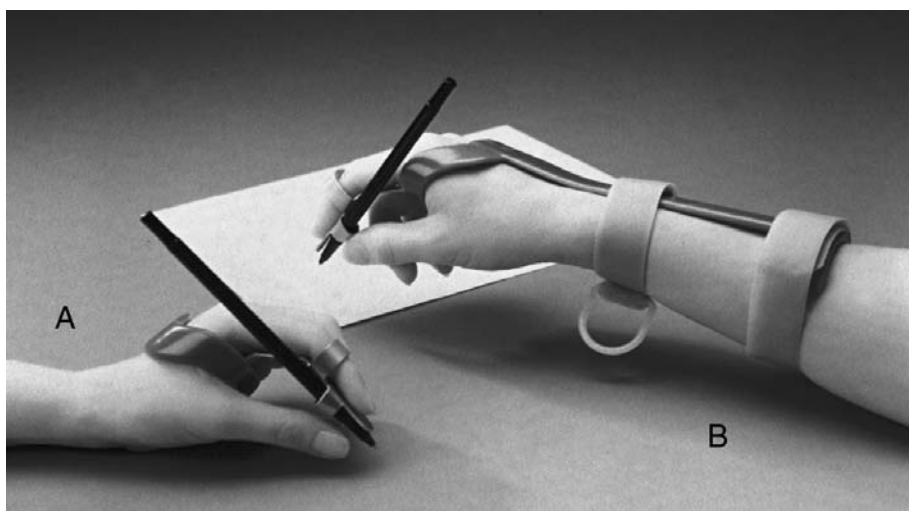
For clients with the potential for neurological return at the C6 level, a wrist-action WHO (Fig. 15-72) can be used as a transition system (Lunsford & DiBello, 2008). This orthosis allows for free wrist motion, with stops that can be adjusted to limit motion to a prescribed range. When no wrist extensors are present, the wrist is locked into a set position.


Figure 15-70 Wanchik writing splints. **A.** Short design. **B.** Long design.
Figure 15-71 Custom metal ratchet wrist–hand orthosis.

As recovery occurs and strength increases, progressive range of motion is allowed. Rubber bands are often attached to provide an extensor assist to weak muscles.

A wrist-driven wrist–hand orthosis (WDWHO) (Fig. 15-73) may be indicated for clients having 3+ or greater wrist extensor strength, such as a client with C6 tetraplegia. Using the principle of tenodesis (Fig. 15-65), this type of flexor hinge orthosis transfers wrist extensor power to the fingers for grasping. Active wrist extension operates a mechanical linkage transferring power to flex the index and long fingers against the thumb. A properly adjusted orthosis allows for 1 pound of pinch for every 2 pounds of wrist extensor force. Gravity-assisted wrist flexion opens the hand for release. An activating lever at the wrist controls the size of the opening and the resultant position of prehension to allow for grasp of various size objects and different pinch forces.

Fitting the client with bilateral WDWHOs is rare and requires a highly motivated client (Lunsford & DiBello, 2008). Bilateral orthoses are difficult to use, requiring a great deal of balance, coordination, and practice to become successful. If the client has inadequate proximal strength, it may be difficult to bring the arms into midline. If sensation has been lost, the client must rely on visual compensation, which also makes bilateral orthotic use difficult. A client generally uses one WDWHO, with the contralateral hand serving as a gross assist. Training principles are listed in Procedures for Practice 15-4.

Given the cost and complexity of fabrication and training, follow-up studies have been done to assess whether clients use WDWHOs over the long term after discharge from therapy. Knox, Engel, and Seibens (1971) reported a 51% continued use rate; Shepherd and Ruzicka (1991) reported a 50% rate; and Allen (1971) reported a 43% rate. Factors that were reported to contribute to continued use were education, commitment, and involving the client in the orthotic decision-making process (Knox, Engel, & Seibens, 1971); the ability to don the orthosis easily (Allen, 1971); and adequate training, acceptance, internal motivation, and strong functional or vocational goals (Shepherd & Ruzicka, 1991). In these same studies, reasons for orthotic discontinuation were stated by subjects to be improvement in muscle strength, use of alternative methods or equipment to perform tasks previously done with the WDWHO, poor fit, bulk, and the orthosis taking too long to put on. Orthotic intervention remains a mainstay in spinal cord injury, but lack of evidence and inadequate clinician education in how to train clients in permanent functional orthoses have limited their use (Mulcahey, 2008).

Newer orthoses are now available aimed at facilitating distal motion and motor reeducation in neurologically
Figure 15-72 Custom metal wrist-action wrist–hand orthosis with rubber band assist.
Figure 15-73 Custom metal wrist-driven wrist–hand orthosis.

Procedures for Practice 15-4

Wrist-Driven Wrist–Hand Orthosis Controls Training and Use Training

Controls Training

- The client needs to become proficient in basic orthotic skills, such as picking up, placing, and releasing objects of various sizes, textures, densities, and weights.
- Soft medium-sized objects or 1-inch firm, semirough objects are often best to start with; progress to more difficult objects as skill level increases.
- Encourage skills practice from a variety of heights because the client may have to learn to abduct and internally rotate the shoulder to approach and handle objects appropriately.

Use Training

- Teach the client to use the wrist-driven wrist–hand orthosis to perform specific functional tasks, such as writing, eating, and oral hygiene.
- Have the client practice activities under various conditions to encourage independent problem solving and spontaneous use of the orthosis.

imparied upper extremities. The SaeboFlex (Fig. 15-74) dynamic orthosis uses a fixed wrist support and a finger/thumb spring system that assists with opening the hand during grasp and release activities. The Ness H200 Hand Rehabilitation System (Fig.15-75) supports the wrist in a functional position and uses low-level electrical stimulation to assist finger and thumb motion. Specialty training in fitting and use of these devices is required, and evidence of their efficacy is limited pending more independent studies (Alon, Levitt, & McCarthy, 2007; Farrell et al., 2007).

Prevent Contractures or Modify Tone

Careful attention to positioning in the presence of wound healing, muscle imbalance, abnormal muscle tone caused by stroke or brain injury, or motor disorders such as cerebral palsy is critical in the prevention of loss of range of motion, which can lead to functional or skin hygiene problems. Many of the static splints, casts, and orthoses previously mentioned for immobilization, stabilization, or substitution can be used for this purpose. Examples of these orthoses include acute burn immobilization splints to prevent wrist and digital contractures, wrist extension splints to prevent contractures caused by wrist drop, thumb abduction splints to prevent thumb adduction contractures, and lumbrical bar splints to prevent MCP hyperextension and IP flexion contractures.

Ideally, these splints should not limit function, exert excessive stress on soft tissues, or interfere with movement of
Figure 15-74   SaeboFlex dynamic orthosis.

uninvolved joints. If splints are not required for functional use, often it is possible for clients to wear static positioning splints at night only. In addition to the prevention of contractures, splints may be used to prevent shortening of the muscle–tendon unit. For example, a volar thermoplastic or

Figure 15-75   Ness H200® hand rehabilitation system.

Figure 15-76 Rolyan® antispasticity ball splint with slot and loop strapping.

plaster splint worn at night to position the wrist and fingers in maximum composite extension can help to prevent tightness of the long finger flexors (Bell-Krotoski, 2011).

Lapboards, arm troughs, and suspension arm slings can help to position the upper extremities properly. Bivalved plaster casts or anteroposterior splints (Fig. 15-48) can be used to maintain range of motion, especially in the presence of increased tone. *Safety Message: Care must be taken to avoid pressure problems by ensuring that casts are properly padded and that the skin is closely monitored.*

The use of splinting in the modification of tone in the wrist and hand continues to be controversial in the literature and in practice. A survey of occupational therapists clearly demonstrated the conflicting practices in splinting (Neuhaus et al., 1981). Opponents of splinting argue that splinting may lead to increased muscle tone, joint stiffness, and muscle atrophy and may interfere with treatment aimed at facilitation and functional use. Proponents of splinting contend that splinting can reduce tone (McPherson, Becker, & Franszczak, 1985; Neuhaus et al., 1981). In a systematic review of hand splinting to prevent contracture and reduce spasticity following stroke, Lannin and Herbert (2003) found insufficient evidence to either support or refute its effectiveness. Tyson and Kent (2011) concluded from their systemtic review that current evidence suggests splinting does not improve function, motion, or pain following stroke.

Literature regarding optimal thermoplastic splint designs and wearing times shows no consensus. Static designs may be volar or dorsal, and comparative studies have been done in attempts to determine quantitatively which design is more effective in tone reduction. A study by McPherson et al. (1982) demonstrated no significant difference between the two basic splint designs and encouraged therapists to reexamine the amount of wearing time prescribed so that tonal reduction occurs without unwarranted secondary stiffness.

A design clinically studied by McPherson (1981) used a dorsal forearm base, volar finger and thumb pans, and finger abductors to position the wrist in 30° of extension, the MCPs in 45° of flexion, the IPs in full extension, the fingers fully abducted, and the thumb in extension and abduction. McPherson reported that splint wearing resulted in a reduction of tone related to the length of time that subjects wore the splint and that the effects of splint wearing were not necessarily permanent.

Garros, Gagliardi, and Guzzo (2010) also studied a volar dorsal orthosis worn by clients with wrist and hand spasticity post stroke. The results showed an increase in client-rated occupational performance at 3 months, but no longer term follow-up was done.

Common static splint designs include resting pan splints, finger spreaders or abduction splints, and cone splints (Coppard & Lohman, 2008). Several preformed splints are commercially available (Figs. 15-76 and 15-77), but no clinical studies have been done to establish their fit and effectiveness.

Dynamic splint designs have also been developed to reduce tone in the wrist and hand. In a study of eight

Figure 15-77 Progress™ dorsal antispasticity splint.

Figure 15-78 Rolyan® thumb loop.

subjects, the finding was a greater reduction in hypertonus using a dynamic splint as compared with static splints and passive range of motion (McPherson, Becker, & Franszczak, 1985). Scherling and Johnson (1989) studied the effects of their dynamic splint design on 18 subjects, with all subjects achieving varying degrees of tone reduction with a minimum of 4 hours of splint use per day.

Soft splints made of neoprene can be custom fabricated (Casey & Kratz, 1988) or purchased commercially. A hand-based thumb loop can be used to decrease tone and position the thumb out of the palm for function (Fig. 15-78). To position the forearm, a long neoprene strap can be added to the hand splint.

A thermoplastic hand-based inhibitive weight-bearing splint described in the treatment of children with increased flexor tone (Coppard & Lohman, 2008; Kinghorn & Roberts, 1996) can also be used with adult clients having hypertonicity. This volar splint is custom fabricated to hold the fingers in extension and thumb in radial abduction to enable the hand to be in an optimum position for upper extremity weight-bearing activities (Fig. 15-79).

Splinting may be an effective means of providing a low-cost, noninvasive method for decreasing tone in some clients but may not be effective in others (Langlois, Pederson, & Mackinnon, 1991). Continued research on the long-term effectiveness of splinting for tone reduction and the key client variables that contribute to that effectiveness is needed. Meanwhile, therapists must carefully decide on splint use and monitor outcomes client by client.

SPECIALIZED PERMANENT FUNCTIONAL ORTHOSES

Permanent functional orthoses represent a great investment of time, cost, expertise, and commitment to fabrication, fit, training, and use by the client-therapist-orthotist

team. Proper fit, training, and successful functional use are accomplished only through close collaboration and communication among all who participate in the process. As with all orthoses, this process should begin with careful consideration of functional needs, achievable goals, and education of the client and significant others in orthotic purpose and selection. Providing the client with opportunities to interact with experienced users of similar equipment can be quite helpful to the client, both before the prescription and during training.

A permanent orthosis that is useful to the client must be valued, accepted, and incorporated into the client's body image. A prime prerequisite to acceptance is that the orthosis allows the client to do something meaningful that cannot otherwise be done without it (Yasuda, Bowman, & Hsu, 1986). Because the orthosis will be used over the long term, the client and caregivers must also be

Figure 15-79 Custom thermoplastic hand-based weight-bearing splint.

educated about whom to contact should problems arise after the therapy program has ended.

The principles of orthotic training are similar to those of prosthetics. They include testing of fit and mechanics, teaching the client the names and functions of component parts, care of the orthosis, donning and doffing of the orthosis, controls training, and functional use training. Intensive practice under various conditions to encourage independent problem solving by the client and skilled spontaneous use is a key element of training. Following is a closer look at two commonly used permanent functional orthoses.

Mobile Arm Supports

As described earlier in this chapter, the MAS (Figs. 15-59 and 15-61) is a mechanical device prescribed to support the weight of an arm and assist weak proximal muscles for function.

Client and Caregiver Education

If the client has been actively involved in the decision making, a brief review of the MAS's purpose and capabilities should be sufficient. The client and caregiver should be oriented to key component names and how they operate. Finally, they should know how to care for and maintain the orthosis.

Assembling and Balancing

Procedures for Practice 15-3 has instructions on how to assemble and balance the standard MAS assembly.

Training and Adjusting

Adaptive equipment or a WHO is commonly used in conjunction with the MAS and should be integrated during all phases of MAS training and adjusting. Once the client is proficient with basic movement patterns, MAS training with all of the occupations that the client is interested in performing should be done. Any of these activities may require various fine component adjustments before final MAS adjustments are completed. Periodic follow-up may be required. Procedures for Practice 15-3 has information related to MAS training and adjusting.

Orthotic Checkout

Once final adjustments have been completed, bolts and screws should be checked for a secure fit. A MAS appraisal form (Fig. 15-80) can be used to ensure that all important details are assessed.

Wrist-Driven Wrist–Hand Orthosis

A WDWHO (Fig. 15-73), as previously described, is used to enhance hand function in the presence of distal muscle weakness by using wrist extensor power to enable prehension.

Orthotic Checkout

The therapist must begin with a careful inspection of the orthosis both on and off the client. Optimal fit is crucial for maximum function. Ensuring smooth operation of mechanical parts, proper positioning of the digits for pad to pad prehension, and proper location of splint joint axes at the wrist and second MCP is essential. The strength of pinch should be assessed, and the length of the transfer bar should be changed by the orthotist to increase pinch strength as needed.

Straps should facilitate independent application and removal of the orthosis. Loops added to the ends of the straps enable the client to use the thumb of the other hand to fasten and unfasten them with increased ease.

The client's ability to don and doff the orthosis is strongly related to independence in activities and to the client's ultimate acceptance of the device. This is true especially if the client must remove the orthosis to perform other activities such as propulsion of a wheelchair. Removal of the WDWHO is typically easier than application of it. Initially, the orthosis should be placed on the client for no more than 30 minutes. Upon removal, the skin should be carefully checked for any areas of redness. These red areas should be reassessed in half an hour, and if they are still present, the orthosis requires adjustment before the client can use it. Once pressure problems have been resolved, wearing time can be gradually increased.

Client and Caregiver Education

A brief review of the WDWHO's purpose and capabilities should be provided. The client and caregivers should be instructed in the importance of skin inspection to prevent excessive pressure and skin breakdown. Accordingly, they should also be taught wearing tolerance and the schedule. They should be oriented to key component names and how the components operate prior to orthotic controls training. Finally, they should know how to care for and maintain the orthosis. Education in these areas should be reinforced throughout the orthotic training process.

Controls Training and Functional Use Training

Procedures for Practice 15-4 shows WDWHO controls training and use training.

EFFICACY AND OUTCOMES

Although the use of upper extremity orthoses is an accepted practice with much clinical and intuitive support, the state of best evidence about upper extremity orthoses is limited (Evidence Table 15-1). Most published materials are anecdotal, based on clinical experience, are of varying study quality, and/or outdated. Good, valid studies of current practice are needed to enhance our knowledge of splinting efficacy and variables that lead to optimum outcomes.

Rancho Los Amigos National Rehabilitation Center   Occupational Therapy Department

MOBILE ARM SUPPORT APPRAISAL

Patient's Name_____   Type of MAS (L)_____

Date Fitted_____   Type of MAS (R)_____

I. PATIENT'S POSITION IN WHEELCHAIR

YES	NO	N/A	Are hips well back in wheelchair?
YES	NO	N/A	Is spine in good vertical alignment?
YES	NO	N/A	Does patient have lateral trunk stability?
YES	NO	N/A	Is wheelchair set-up providing adequate comfort and stability?
YES	NO	N/A	Is patient sitting in maximum upright position possible?
YES	NO	N/A	Does patient have needed hand splints on?
YES	NO	N/A	Does patient meet requirements for passive range of motion?

II. MECHANICAL CHECKOUT

YES	NO	N/A	Are all screws tight?
YES	NO	N/A	Is bracket tightly secured on wheelchair?
YES	NO	N/A	Are all MAS arms and joints freely movable?
YES	NO	N/A	Is proximal arm inserted completely in bracket bearing tube?
YES	NO	N/A	Is distal arm inserted completely in proximal arm bearing tube?
YES	NO	N/A	Is bracket at proper height so shoulder is not forced into elevation?
YES	NO	N/A	Does elbow dial clear lapboard when trough is in "up" position?
YES	NO	N/A	Is patient's hand (in "up" position) as close to mouth as possible?
YES	NO	N/A	Can patient obtain maximum active reach?
YES	NO	N/A	Is patient's arm secured in trough?
YES	NO	N/A	Is trough long enough to give maximum support to forearm?
YES	NO	N/A	Is trough short enough to allow wrist flexion if desired?
YES	NO	N/A	Are trough edges rolled so that they do not contact forearm?
YES	NO	N/A	Is elbow secure and comfortable in elbow dial?
YES	NO	N/A	Is trough balanced correctly?
YES	NO	N/A	During vertical motion, is elbow dial free of distal arm?
YES	NO	N/A	Are vertical stops correctly placed for both up and down motions?
YES	NO	N/A	Are rubber band hooks secured?
YES	NO	N/A	Are rubber bands securely attached?

Figure 15-80 Mobile arm support appraisal form.

III. CONTROL CHECKOUT

YES	NO	N/A	Can patient control motion of proximal arm from either extreme?
YES	NO	N/A	Can patient control motion of distal arm from either extreme?
YES	NO	N/A	Can patient control vertical motion from either extreme?
YES	NO	N/A	Have stops been applied to limit motion, if necessary?
YES	NO	N/A	Does patient accomplish maximum horizontal reach in front of body?
YES	NO	N/A	Can patient easily reach mouth?
YES	NO	N/A	Can patient easily reach tabletop?
YES	NO	N/A	Can patient horizontally adduct arm sufficiently to clear doorways?
YES	NO	N/A	Is performance consistent from day to day?

IV. USE CHECKOUT

YES	NO	N/A	Are fine adjustments necessary to enable patient to perform different activities?
YES	NO	N/A	Are there some tasks that patient can perform better without MAS?
YES	NO	N/A	Is patient able to instruct caregivers in how to assemble MAS components?
YES	NO	N/A	Have patient and caregivers been instructed in care of MAS?

Figure 15-80 *(continued).*

Evidence Table 15-1 | Best Evidence for Occupational Therapy Practice Regarding Upper Extremity Orthoses

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Hand splinting to prevent contracture and reduce spasticity following stroke	Different types of splints and splint designs	Two hundred thirty patients	Splint wear for unknown time up to 11 weeks, various wearing patterns	Meta-analysis of 21 studies	Insufficient evidence to either support or refute the effectiveness of hand splinting for adults following stroke	Heterogeneity of study design, methods, splint design and regimen, and outcomes prevented the pooling of data to determine effect size	Lannin & Herbert (2003)
Splinting for lateral epicondylitis	Six splint designs	Three hundred sixty-two participants (277 patients and 85 healthy subjects)	Splint wear for test session up to 4 weeks	Systematic review of 11 studies	Yes. Early positive, but not conclusive, effectiveness of splinting	Not reported	Borkholder, Hill, & Fess (2004)
Splinting for carpal tunnel syndrome	Different types of splints and various angles of immobilization	Four hundred four patients (452 hands)	Splint wear for night only or full-time for 2–8 weeks	Systematic review of six studies	Yes. Significant benefits from splinting across different splint types and wrist angles, especially if used full-time	Not reported	Piazzini et al. (2007)
Splinting for osteoarthritis of thumb carpometacarpal (CMC)	Different types of splints and splint designs	Three hundred forty-eight physician-diagnosed osteoarthritis of the first CMC	Splint wear for 2 weeks up to 7 years, various wearing schedules	Systematic review of 12 studies	Yes. Significant decrease in pain short term (≤45 days) and long term (≥3 months)	Heterogeneity of study design, methods, splint design and regimen, and outcomes prevented the pooling of data to determine effect size	Kjeken et al. (2011)
Adherence to splint wear	Different types of splints and splint designs	Four hundred ninety patients with acute hand, wrist, or forearm injuries	Follow-up from unknown duration to 12 months	Systematic review of six studies	Higher overall adherence rates found in acute injuries (≥75%) than comparable literature for chronic conditions (25%–65%); some evidence that immediacy of benefit, comfort, and minimizing of interference with daily tasks improve adherence	Because of heterogeneity of studies, synthesis was narrative rather than quantitative	O'Brien (2010)

case example
Ms. N.: Orthotic Intervention in a Client with Peripheral Nerve Injury

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient information	Appreciate the context	"Ms. N. is dealing with a significant injury with an enormous impact on her life. I am concerned not only about the status of her left arm but also about the disruption of her routines and roles. She is obviously frustrated about not being able to work and having to ask her mother to help with most tasks. I need to help her feel empowered and instill hope for her future."
Ms. N., a 22-year-old woman 8 weeks post motor vehicle collision, was referred to outpatient occupational therapy for evaluation and splinting of her left arm. She had a brachial plexus traction injury and a humeral fracture, treated with a closed reduction and fracture brace (purpose: to immobilize for healing). Prior to her injury, she was right-hand dominant and employed full time as a secretary.		
On initial assessment, the following problems were identified as related to her left upper extremity: (1) poor positioning of the entire arm, with Ms. N. using her right arm to help to support the left arm; (2) absent motor function and impaired sensation throughout; (3) limited passive range of motion of the shoulder in all planes, forearm supination, MCP flexion, and thumb abduction; (4) traction pain in the shoulder; and (5) lack of functional use for any activities.	Develop intervention hypotheses	"I think that poor left arm positioning is the factor contributing most to her lack of occupational functioning. If I can free up her right arm for function, I believe this will go a long way in helping her cope with her injury."
	Select an intervention approach	"Orthoses will be an integral part of Ms. N.'s treatment and will need to be carefully selected based on her clinical and functional status. From reviewing the literature, I know that collaborating with the client closely throughout the splinting process is crucial to a successful outcome. I also understand that recovery may occur at a slow rate, and orthoses will need to be durable."
	Reflect on competence	"I have treated clients having similar peripheral nerve injuries in the past and have seen good functional recovery occur in many cases. These past experiences have also taught me that I have to do what I can to help Ms. N. be patient because recovery time with these types of injury can be frustratingly slow."
Summary of Short-Term Goals and Progress	Assess the client's comprehension	"I think it is important to begin with an intensive program that will quickly address Ms. N.'s clinical and functional needs. Even though they have to travel a good distance from home, Ms. N. and her mother understand the importance of early therapy intervention to improve the prognosis for recovery. I acknowledge the hardship this causes for them, so I promise to minimize the therapy visits as much as possible."
Ms. N. was fitted with a standard pouch sling that was easy to don and doff and supported the weight of her arm with the goals of pain relief and freeing her right arm for functional use (purposes: to support a painful joint and to protect tissues); she was also fitted with a custom-fabricated static wrist extension–thumb abduction splint to prevent the loss of wrist extension and to regain MCP flexion and thumb abduction range of motion (purposes: to prevent contractures and to restore mobility).	Understand what he or she is doing	
	Ascertain the client's endorsement of plan	
	Compare actual to expected performance	
	Know the person	
	Appreciate the context	

Next Steps

As Ms. N.'s neuromuscular recovery progressed, the following orthoses were used in response to new problems and functional potential identified:

Week 11: The sling was discontinued, because shoulder and elbow strength had improved to 3 to 3+ and traction pain had resolved. Ms. N. continued to use the wrist extension–thumb abduction splint during the day. At night, Ms. N. wore a custom-fabricated composite wrist and finger extension static splint to prevent long flexor tightness from unopposed finger flexors that had regained 3+ strength (purpose: to prevent contractures).

Week 17: At night, Ms. N. wore a custom-fabricated serial static elbow extension splint to regain elbow extension range of motion lost to initial positioning from the sling, an ineffective home range-of-motion program, and return of unopposed 3+ elbow flexor strength (purpose: to restore mobility).

Week 21: A Colditz radial nerve splint was fabricated to substitute for weak muscles supplied by the radial nerve and to enhance hand function as long finger flexors and wrist flexors recovered to sufficient strength of 3+. Ms. N. wore this splint during the day to allow functional use of the hand during light tasks (purpose: to substitute for weak or absent muscles).

Week 26: The Colditz radial nerve splint was discontinued, because wrist and long finger extensors had regained 3+ strength. A custom-fabricated thermoplastic lumbrical bar splint for the ring and small fingers was issued to address residual weakness of intrinsic muscles innervated by the ulnar nerve, leading to clawing. Ms. N. wore this splint during the day to assist with hand opening and prevent IP flexion contractures (purposes: to restrict unwanted motion and to prevent contractures).

Week 28: A dynamic forearm rotation splint was fabricated from a commercial kit; Ms. N. wore it at night to regain full supination range of motion initially lost from positioning and an imbalance of forearm rotator muscle strength (purpose: to restore mobility).

Week 36: No further splinting was required, as Ms. N. had full neuromuscular recovery. Ms. N. was able to return to her previous employment with full functional use of her left arm.

Anticipate present and future client concerns	"I need to be ready to respond to Ms. N.'s unique needs. I need to closely monitor for changes in range of motion, motor function, and sensory function and be on the lookout for development of deformity that may occur from muscle imbalance. I want to optimize her ability to use her left arm as soon as her clinical status allows. To enable an optimum functional and clinical outcome, I need to discontinue orthoses as soon as they become unnecessary and implement new orthoses as different needs arise."
Analyze the client's comprehension	"It is important to continuously educate Ms. N. on her status so she can see her recovery progressing and understand how important the various orthoses are to optimize her functional outcome."
Decide if she should continue or discontinue therapy and/or return in the future	"I also need to give Ms. N. the opportunity to voice her questions, concerns, and preferences so that we can work together to select the most appropriate orthoses and design optimal wearing schedules."

Clinical Reasoning in Occupational Therapy Practice

Addressing Issues with Splint Wear

During the course of Ms. N.'s outpatient therapy program, the therapist suspects that Ms. N. is not wearing some splints as often as recommended.

How might this problem be evident to the therapist? What can the therapist do to address this issue?

Summary Review Questions

1. What is the role of the occupational therapist in orthotic rehabilitation?
2. Define orthosis.
3. Name the purposes for which splinting may be used.
4. What are key factors for selecting an orthosis for a particular client?
5. Discuss factors that may enhance splint wearing and those that may interfere with it.
6. Discuss why a static splint may be chosen and the precautions related to such splints.
7. Describe two dynamic splints and the purposes for which they are used.
8. Select an orthosis to decrease an elbow flexion contracture, discuss the reasons for your choice, and state the principle or principles that it implements.
9. Discuss two types of finger or hand orthoses that assist in restoring function while stabilizing a joint.
10. For which type of client would you choose a WDWHO?
11. Name the basic components of a standard MAS and two diagnostic categories of candidates who may benefit from its use.
12. Describe a treatment session to improve a client's hand-to-mouth and hand-to-table control of a MAS and basic adjustments that can be made to the MAS to facilitate these motions.
13. What are the pros and cons of various orthoses designed to modify tone?

Glossary

Arm sling—An orthosis that supports the proximal upper extremity to restrict motion, reduce pain, or prevent or reduce shoulder subluxation.

Arm trough—An upper extremity positioning device attached to a wheelchair armrest.

Dynamic splint—Orthosis that has moving parts; primarily used to regain joint mobility or facilitate function.

Lapboard—A portable tabletop that is applied to a wheelchair to provide a working surface or support an upper extremity; also known as a lap tray.

Mobile arm support—A mechanical device that uses ball-bearing joints, gravity, and sometimes rubber bands to support the arm and assist in movement when proximal muscles are weak; may be mounted onto a wheelchair or table; also known as a balanced forearm orthosis, ball-bearing arm support, or ball-bearing feeder.

Orthosis—Any externally applied device added to a person's body to support, align, position, immobilize, prevent or correct deformities, assist weak muscles, or improve function; also known as a splint, brace, or support.

Serial casting—Applying casts at routine intervals as range of motion improves, with the goal of restoring joint mobility.

Serial static splinting—Remolding or fabricating new static splints as range of motion improves, with the goal of restoring joint mobility.

Static splint—Orthosis that has no moving parts; primarily used to support, stabilize, protect, or immobilize.

Static progressive splint—Orthosis that uses nondynamic forces; primarily used to regain joint motion.

Wrist-driven wrist–hand orthosis—Flexor hinge orthosis that uses tenodesis to accomplish palmar pinch.

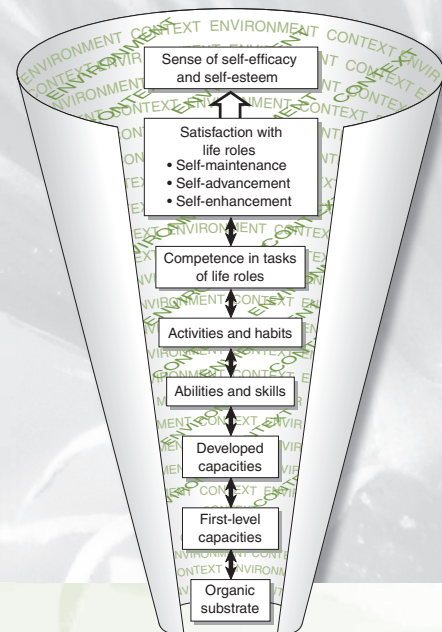
Construction of Hand Splints

Charles D. Quick and Priscillia D. Bejarano

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the anatomical, biomechanical, and mechanical principles applied to splint construction.
2. List the six primary reasons to use splinting as a therapeutic intervention.
3. Recognize factors affecting splint wear compliance.
4. Explain design, pattern making, and construction for three splints.
5. Describe the components of a splint checkout.


n order to effectively construct hand splints, one must appreciate the significance, biomechanics, and anatomy of the human hand. Mary Reilly (1962) described the significance of hand function in her 1961 Eleanor Clarke Slagle lecture when she suggested, "That man, through the use of his hands as they are energized by mind and will, can influence the state of his own health" (p. 88). Others have suggested that hands are among the features that distinguish human beings from other living creatures; hands are most certainly important to occupational performance. Many medical conditions result in hand impairments involving weakness, swelling, and/or decreased range of motion. Occupational therapists often address these issues by incorporating a splint into the intervention plan.

In this chapter, we first introduce the biomechanical and anatomical structures of the hand that occupational therapists consider in making splints. We then provide basic information about splint construction, appreciating that practice and further training is required to develop expertise in this area.

ANATOMICAL AND BIOMECHANICAL CONSIDERATIONS FOR SPLINT MAKING

A functional understanding of the human body requires the appreciation of three major areas of study; musculoskeletal anatomy, neuromuscular physiology, and biomechanics (Hamilton, Weimer, & Luttgens, 2011). Recovery of hand function following disease or injury can be optimized when the above sciences are combined with understanding of function in occupation and splinting.

Anatomy

The anatomy of the hand informs the concept, design, and construction of hand splints. Such consideration requires a basic review of the macrostructure of tissues and component structures that contribute to functional interaction with the environment. Anatomical principles that are foundational to splinting are described in Definition 16-1.

Bone

The specific functions of bone considered for splinting include structural support, levers for body movement, and protection of underlying structures. Bones are categorized according to shape and size. Long bones have a shaft that acts as a rigid tube; each end of the shaft is expanded, creating a basic component of a joint. Short bones are cube shaped, as long as they are wide. Flat bones are broad and thin with flat or curved surfaces, and sesamoid bones are round (Muscolino, 2011). The three primary arches of the hand are assured by the structural anatomy of the bones. A splint must conform to these arches to support a functional position of the hand (see Fig. 16-1).

Definition 16-1

Anatomic Principles Applied to Splint Construction

- Bones create structural support and arches of the hand. Splints conform to structure and arches to create dual obliquity and support functional position.
- Joints create levers for movement. The more stable a joint, the less motion; the more actual degrees or planes of motion, the less stable.
- Muscles create movement of joints. Splint design is intervention specific, encouraging motion, stability or immobilization of tissue and joints.
- Neuromuscular physiology is the organ system that drives function. Splint design must allow neuron to muscle fiber communication to be a beneficial intervention.
- Integumentary system encapsulates the body. Understanding the relationship of skin creases to joints is important for splint design and construction.

The metacarpals of the fingers vary in length and height. Metacarpals of the radial fingers are longer than those of the ulnar fingers of the hand. The metacarpal heads on the radial side are higher than those on the ulnar side of the hand, an effect more pronounced when the hand is closed. The therapist must apply this concept of dual obliquity to the construction of a splint. That is, the splint must be longer and higher on the radial side of the hand (Fess et al., 2004) (Fig. 16-2).

Longitudinal arch

Distal transverse (metacarpal) arch

Proximal transverse (carpal) arch
Figure 16-1 Arches of the hand must be supported in splinting.
Figure 16-2 Concept of dual obliquity applied to splinting.

Joints

A joint can be defined according to structure or function. Structurally, it is a place where two or more bones are joined to one another by soft tissue. The major function of a joint is the ability to allow movement. The hand consists of joints that have space between the articulating bones, which allows movement. The shape of the bone changes at the point of becoming part of a joint; this produces bony prominences (Tubiana, Thomine & Mackin, 2006). Adequate splint design requires conformity to bony prominences, assuring proper fit and reduced risk of pressure points from splint use (Fig. 16-3). Joints are constructed to allow for a balance between mobility and stability (Muscolino, 2011). The more mobile a joint, the less stable it is. When a joint has inherently less stability, it is at greater risk for injury. *Safety Message: The concept of joint stability and mobility must be considered in splint design and construction to assure the splint is safe and performs as intended.*

Muscle

Most skeletal muscles have attachments onto two bones, the origin, where it begins, and the insertion, where it ends. Musculotendinous structure crosses a joint or joints that are located between the origin and insertion. When a muscle contracts, it shortens toward its center; when the contraction force is sufficient, one or both of the bones to which the muscle is attached will be pulled toward the center of the muscle (Muscolino, 2011). The joint or joints between the muscle's origin and insertion function to allow movement. Understanding the action of a joint caused by the forces applied by muscle and other generated forces is critical to splint design.

Integumentary System

As the largest organ system of the human body, skin encapsulates the body uninterrupted and permits unrestricted mobility (Hedman et al., 2009). Dorsal hand skin is relatively thin with creases directly over articulations. Volar skin is fibrous and thick with more defined creases. As in the dorsal digital creases, the volar digital creases directly correlate to joint location. The palmar creases do not relate directly to the associated joints (Williams et al., 1995). The relationship of skin creases to the joints of the hand and digits is important to splint design because the creases of the hand can provide landmarks for splint fabrication (Coppard & Lohman, 1996) (Fig. 16-4).
Figure 16-3 Bony prominences can lead to pressure points, especially over the back of the hand. Careful contouring of the splinting material can minimize this problem.
Figure 16-4 Creases of the hand provide landmarks for the distal ends of the splint. For a wrist support splint, the distal end of the splint should not block the thenar eminence or distal palmar crease.

Biomechanical Principles Applied to Splint Construction

Biomechanics is the study of mechanics focused on the human body and is divided into two areas of study: statics and dynamics (Hamilton, Weimer, & Luttgens, 2011; Levangie & Norkin, 2005). Statics or kinematics study forces as though they are in balance and the body in equilibrium. There are five

variables considered in the process of applied biomechanics. The therapist considers each variable to determine how a splint will affect hand function in the transmission of forces from the unsplinted to the splinted hand (see Table 16-1).

The dynamic component of biomechanics, kinetics, introduces the application of forces on a given body (Hamilton, Weimer, & Luttgens, 2011). The force can be gravity, weight, or a choice of a dynamic or static splint that contacts the hand, wrist, or forearm to create a desired position with a desired motion during use. The therapist's understanding of biomechanical principles will allow the desired mechanics to be applied to the design of a splint.

Mechanical Principles Applied to Splint Construction

Mechanics is a branch of physics that examines cause and effect such as the force on an object and the motion or response that results (Hamilton, Weimer, & Luttgens, 2011). As exemplified in the following list, therapists use biomechanical principles to assess function of the hand and apply mechanical principles to the splint design.

- The therapist must be aware of the natural postures of the hand that affect function. For instance, when the hand is held in supination, the wrist is in neutral to slight radial deviation. When the hand is held in pronation, the wrist is more ulnarly deviated. If a splint is fitted in supination for a patient who will be using the hand primarily in pronation, the splint may not be comfortable.
- During flexion in normal biomechanics, the fingers converge toward the scaphoid bone; splint mechanics must incorporate this property for best splint function (Fig. 16-5).

| Table 16-1 | Biomechanical Considerations for Splint Design |

Biomechanical Variables	**Implications for Splint Design**
Type of motion: linear, rotary, or a combination, known as general motion	Splints can create or restrict motion to enhance function. When joint motion is to be enhanced through splinting, the motion or combination of motion must be identified. Rotary motion considers movement of a joint around an axis, and linear motion considers the distraction (or separation of joint articulations) of a joint. The therapist considers the forces required to retain balance between the two motions to obtain maximum benefit without creating joint irritation or damage.
Axis of motion considering anatomical position	When there is a therapeutic need to generate motion through static progressive or dynamic splinting, the axis of motion indicates the direction of introduced forces. Applied forces can be calculated to overcome the antagonistic forces required through the axis of motion.
Direction of displacement: flexion, extension, abduction, adduction, etc.	Consider the normal ranges of movement and desired directional motion of the joints affected by the splint.
Magnitude of displacement: range of motion	The initial and overall desired degree of motion of the affected joints from the splint applications.
Rate of displacement: speed	This pertains to the rate of motion over time desired from application of the splint. The rate can vary according to the type of splint (static, dynamic, or static progressive) and the patient's needs or goals.

(Adapted from Hamilton, N., Weimer, W., & Luttgens, K. [2011]. *Kinesiology: Scientific basis of human motion* [12th ed., Rev.]. Boston: McGraw Hill, Inc.)
Figure 16-5 Fingers flex toward the scaphoid.

- In dynamic splints or static progressive splints, the line of pull (force) must be at a 90° angle to the joint at which motion is intended (Fig. 16-32).

The therapist designing and constructing a splint considers the following principles of force distribution for best possible outcomes.

Increase the Mechanical Advantage to Reduce Pressure and Increase Comfort

Upper extremity anatomy consists of several basic lever systems. The first class lever system is the basis of mechanical principles for splinting the hand (Fig. 16-6). In a first class lever system, the combined forces in one direction must be opposed by an equal opposite force at the axis (Li, 1999). The musculoskeletal system of the hand allows forces to be transferred to and through the splinted area. Therefore, the design and construction of the splint requires the use of a favorable force delivery system (Li, 1999). One key principle is that mechanical advantage is equal to the force arm divided by the resistance arm.

With a constant resistance, the force in the lever system can be decreased at any point by increasing the length of the force arm. In the case of a wrist support splint, the forearm trough is the force arm, and the metacarpal bar serves as the resistance arm. The longer the forearm trough, the less pressure is transferred from the weight of the hand to any one part of the forearm in contact with the splint or strap. Using this principle, the forearm trough should be designed as long as possible without interfering with elbow motion, approximately two-thirds the length of the forearm. *Safety Message: The therapist risks excessive pressure to the joints and soft tissues if the force delivered by either side of the joint axis is not in balance with the other side (Levangie & Norkin, 2005; Li, 1999). Unbalanced mechanical advantage can create problems such as skin breakdown or joint compression.*

Ensure Three Points of Pressure

In splinting the wrist, forces are distributed in three areas. The concept of three points of pressure guides splint design and directs placement of straps for proper force application (Fig. 16-6). The splint acts as a counterforce proximally and distally to the forces of the forearm and hand, respectively. A strap securing the splint at the axis position provides a reciprocal parallel force (Li, 1999).

Increase the Area of Force Application to Disperse Pressure and Increase Comfort

Splints apply external forces to all areas of contact. The concept of pressure dispersion suggests that the larger the contact area, the less overall pressure for any area, given a constant resistance (Li, 1999). This means that a wide, long splint applies less pressure in any one area than a narrow, short splint. A contoured splint requires more material and surface area contact than an uneven or point-pressured design over a prominence. *Safety Message: Padding may actually increase pressure to the hand if the splint is not well molded.*
Figure 16-6 The splint as a class 1 lever system.

Add Strength through Contouring Tensile Characteristics

The response that a material has to stress and the degree of strain produced in an elastic body is described in Hooke's law of elasticity. This law suggests that if the same material is curved, the level of energy stored is greater, and the material can more effectively withstand force (*American Heritage Science Dictionary*, 2005). This means that contour mechanically increases a material's strength. Therefore, splints should be constructed with contour and extend midway around the part being splinted to create increased strength and maximum comfort (Fess et al., 2004). Curved and contoured edges are preferred over square edges.

CONSIDERATIONS REGARDING SPLINT MATERIALS

You may become biased toward certain materials that are relatively easy to work with, but with experience, you will learn to appreciate a variety of materials, each with its own benefits and limitations. The properties of various splint materials determine their suitability for use in specific and varied splint applications (Canelon, 1995). These properties have significant bearing on any splint construction: material strength or its ability to bear stress, density or thickness, conformability or drape, self-adherence or surface texture, durability or the ability to repeatedly tolerate stress, ease of fabrication, cost, and availability (Canelon, 1995).

A material's strength describes its ability to bear stress, and rigidity identifies the amount of bend or compression that occurs in response to the stress (Canelon, 1995). When heavy activity is anticipated, the ability to repeatedly tolerate stress is an important consideration, particularly if the splint is to be used for long periods of time with stress and nonstress cycles throughout the wear period (Canelon, 1995). Splint materials are also available in a variety of thicknesses. The most commonly used thicknesses are 1/8 and 1/16 inch. Thick material is preferred for rigid splints, whereas thin material is suited for finger-based or circumferential splint designs.

Available materials have varying levels of elasticity, and the demand placed on the splint is vital in selecting a material. Low-temperature thermoplastics have plasticlike, rubber, or rubberlike bases that give the splinting material its individual characteristics (Breger-Lee et al., 1993; Breger-Lee & Buford, 1992). In choosing thermoplastics, consideration must be given to these characteristics, because they are the basis for the specific physical and mechanical variations of the materials (Canelon, 1995). Materials with a plastic (polycaprolactone) base, such as Polyform™ (Patterson Medical) and NCM Clinic (North Coast Medical), may have fillers that affect their drape and durability. Materials with a rubber (polyisoprene) base, such as Orthoplast (North Coast Medical), have less drape and require firmer handling. Some of these materials, such as Aquaplast (Patterson Medical), have memory that allows them to stretch and return to their original shape with reheating (see Resources 16-1 for information about suppliers).

The degree of conformability of the splint material determines the handling techniques required (McKee & Morgan, 1998). A material with a high degree of conformability, or drape, molds easily to the contours of the hand. Conformability is suitable when an intimate contour is desired; a material with decreased drape is preferred for firm handling techniques.

A material's self-adherence or bonding strength is considered when splint design requires attaching two or more pieces of material together. Polyform (Patterson Medical) is an example of a material that has a coating, or laminate, on the surface that resists self-adherence until it is modified. This coating must be removed before attaching straps or other permanent attachments; common techniques include using a solvent or scraping the surface. If a bonding solvent is not available to remove the laminate, a cotton towel pressed into the contact sites of the heated material works well to remove the laminate from various materials.

Resources 16-1

Resources for Locations of Suppliers

Each of the resources listed has online and mail order catalogs to assist in acquiring specific materials and accessories for splinting. It is recommended to have these resources readily available to equip your splint workshop.

Once the laminate is removed, the adhesive qualities are vastly improved.

Some materials are susceptible to fingerprints. A controlled technique of smooth, gentle, stroking during molding can prevent fingerprinting. Surface textures vary as well.

Ease of fabrication is multifactorial. It includes the time, equipment, and skills or techniques used to build the splint from design to creation (Canelon, 1995). Material cost and availability should be considered based on effectiveness for a particular splint design.

Soft lightweight splint materials, such as neoprene or thickened closed cell foam are also available. These materials provide light restriction, which may be desirable for patients who do not tolerate hard thermoplastic splints. The disadvantages of these splints may be their bulk, lack of rigidity, and relatively short durability (Breger-Lee & Buford, 1991). *Safety Message: Sensitivity to various materials, such as an allergic contact dermatitis to neoprene has been reported in the literature (Stern et al., 1998).* The therapist should consider the patient's tolerance to any material being used in splinting.

Technological advances have allowed engineers to incorporate an antimicrobial agent into several splinting materials. Splints are often worn continuously against the skin; a moist environment can lead to bacteria and an unpleasant smell over time. Antimicrobial protection may make it easier to clean and maintain splints that are worn continuously. High-temperature thermoplastics are also available for rigid splinting. They require use of a band saw for cutting and an oven for heating (Fess et al., 2004). These high-temperature thermoplastics have high-impact strength but do not contour well, making them unsuitable for hand splinting.

PATIENT CONSIDERATIONS IN SPLINTING

As with any intervention, the therapist considers many patient factors in determining the appropriateness of splinting (see Procedures for Practice 16-1). The therapist should evaluate the patient's neurovascular status (sensation and blood supply), mobility, motor function, edema, tone, and cognition prior to splint design and construction. Sensory deficit in the hand creates a concern: the patient may not be able to feel pressure points or areas of irritation from the splint, which can lead to skin breakdown or injury. In the case of hypersensitivity, the use of a splint can protect the fingertip or hand from unpleasant stimuli. Edema may also indicate the need for close monitoring of splint fit and comfort. As edema diminishes, the splint requires modification or remolding to maintain proper fit. Deficits in mobility may change during the course of splinting, so the splint may have to be modified. Weakness may indicate the need for a dynamic assist splint to prevent muscle imbalance or deformity. As muscle strength improves, the force of the dynamic assist should

---

Procedures for Practice 16-1

Considerations for Designing a Splint

- What is the patient's provisional diagnosis?
- Is there a good reason to splint? If so, what should the splint accomplish?
- Does the benefit of splinting outweigh the benefits of not using a splint?
- Does the clinical evaluation support the provisional diagnosis and intervention of splinting?
- What are the implications of splinting for various anatomical factors (e.g., affected structures, number of joints, etc.)?
- Biomechanically should the splint be static, static progressive, or dynamic?
- What are the mechanical considerations? Forearm or hand based? Volar or dorsal design?
- Can the goals be achieved with a commercial splint?
- Does the patient understand the purpose and benefits of the splint?
- Can the patient don and doff the splint as required?
- What can be done to support patient adherence?

---

be adjusted to the patient's needs. Increased or decreased tone may indicate the need for splinting to maintain balance and prevent contracture. As tone changes, the therapist should modify the splint as necessary to meet the goals of treatment. Ongoing assessment helps the therapist identify any need for changes in the splint.

In designing a splint that includes functional positioning of the thumb, the therapist notes the position of the thumb for prehension to the index and middle finger (Fig. 16-20). Typically, the thumb is held in palmar abduction and opposition to these fingers for effective prehension. While forming the splint, the therapist may have the patient hold a pen or other object in the hand to test the ability of the thumb to achieve functional prehension. When designing a splint for the patient with carpal tunnel syndrome, the therapist should be aware of the position of the wrist that produces the lowest pressure in the carpal canal. The ideal position for the wrist is close to neutral, with $2 \pm 9°$ of dorsiflexion and $2 \pm 6°$ of ulnar deviation (Weiss et al., 1995).

Primary Reasons to Use Splinting as a Therapeutic Intervention

There are many reasons to introduce splinting into a patient's therapeutic program (see Definition 16-2). By understanding the body's response to trauma and the healing process, the therapist can better identify the patient's splinting needs. Trauma to the body creates

Figure 16-8 Functional position of the hand.

Definition 16-2

Reasons to Splint (Fess, 2002)

Reasons to splint include:

- to improve function
- avoid deformity
- to correct deformity
- to protect healing structures
- to limit motion
- to allow tissue proliferation and remodeling

During the **fibroblastic phase** of healing, splints may be used to mobilize healing tissues while protecting them. As the strength of the healing tissue increases, the scar tissue matures in the **maturation phase**. Low-load force may be applied with splinting as in the use of a static progressive splint, which is designed to lengthen contracted tissues through the application of incrementally adjusted static force. As maturation progresses, the tissues can tolerate an increased amount of stress (Schultz-Johnson, 2002).

A therapist must recognize these changes in healing tissues with appropriate changes in the splinting program. A splint incorporating the functional position may be considered in the later two phases of tissue healing (Fig. 16-8). This places the wrist in extension as in the intrinsic-plus splint, decreases the MCP joint flexion to approximately 20° and flexes the IP joints to approximately 10° each, while placing the thumb in palmar abduction with the MCP joint and the IP joint of the thumb in extension (Coppard & Lohman, 1996). Exercise programs for tissue preparation and functional activity must begin simultaneously with splinting to maximize therapeutic benefit.

an inflammatory response, creating increased capillary permeability that results in tissue edema (Hedman et al., 2009). To determine the most appropriate management technique, the therapist must understand the integrity of the tissue involved. If the integrity of the tissue involved is stable, motion can be used for edema reduction and functional recovery; the stress of active motion to unstable structures can cause edema production and delay the recovery process.

Tissue Healing

The therapist should be aware of the phases of wound healing when selecting the splint design for the patient with an injured hand. Splinting applies gentle stress to healing tissues to influence change (Fess & McCollum, 1998). During the **inflammatory phase**, the therapist may use a splint to immobilize and protect the healing tissues (Fig. 16-7). A splint in the position of safe immobilization, also known as the intrinsic-plus position, is considered during this phase to reduce risks of collateral ligament shortening at the metacarpal phalangeal (MCP) joints and tissue contracture throughout the area of insult. The MCP joints are placed in flexion, and the interphalangeal (IP) joints are in extension, whereas the wrist is placed in extension to the degree of function (Coppard & Lohman, 1996).

Influence of Splinting on Scar Remodeling

When immobilization is required to heal damaged tissue, collagen fibers develop increased intermolecular bonds, which result in dense tissue with relatively little mobility (Bell-Krotoski & Figarola, 1995). This response causes tissues to shorten, resulting in contracture. Such a limitation in mobility may be treated with splinting. Current research suggests that ideal tissue remodeling occurs with gentle elongation of tissues (Boccolari & Tocco, 2009). Tissues lengthen and grow if gentle stress is applied (Boccolari & Tocco, 2009). This process is not stretching but rather tissue proliferation to accommodate the stress placed on them (Bell-Krotoski & Figarola, 1995; Brand, 2002).

Patient Adherence to Splint Wearing

Patient adherence has a profound influence on the effectiveness of any intervention. Even the most expertly

Figure 16-7 Position of safe immobilization.

Procedures for Practice 16-2

Strategies to Advance Adherence

- Incorporate the patient's preferences (as able) in splint design.
- When possible, educate family members of the importance of splint use.
- Educate the patient in benefits of splint use and the possible outcomes if splint is not used.
- Instruct in proper splint wear and care to include splint hygiene.
- Make sure the splint fits properly and feels comfortable.
- Incorporate aesthetics into the splint design for improved cosmesis.
- Offer splint options to the patient if possible.
- Provide for easy application and removal of the splint.
- If feasible, collaborate with the patient on a wearing schedule.

designed and constructed splint will not benefit the patient if it is not worn. Adherence to a therapeutic program is influenced by intrinsic and extrinsic factors. Intrinsic factors are derived from the patient's perception of hand function, the seriousness of the injury, and the perceived efficacy of the treatment or rehabilitation (Sandford, Barlow, & Lewis, 2008). The therapist must understand that a patient's perception of the effectiveness of the splint in achieving the goals of rehabilitation can influence his or her willingness to wear a splint (McKee & Rivard, 2011; O'Brien, 2010). An informed patient takes ownership and adheres to splint use.

Extrinsic factors likely to influence adherence include time restriction, discomfort or pain, forgetting to perform the program or splint application, interference with family or social activities, and a lack of positive feedback (Sandford, Barlow, & Lewis, 2008). It is helpful to collaborate with the patient to identify effective options that are also acceptable to the patient (see Procedures for Practice 16-2 for strategies to advance adherence).

Education

Patients must be taught the goal and purpose of splinting. It may also be helpful to inform the patient of the consequences of failing to comply with splint wear. Provide written instructions on wear and care, which may include a diagram of proper application. If the patient has a cognitive deficit, instruct a caregiver in the proper application of the splint. Patients or caregivers also receive instructions to watch for pressure points, edema,

and excessive dynamic tension and on how to adjust the splint, if feasible. Make sure that patients know how to clean their splints and know to keep thermoplastic splints away from heat (so that splints do not lose their shape). Schedule a follow-up visit if you anticipate needing to modify the splint.

SPLINT CONSTRUCTION

Methods to construct splints from thermoplastic materials are described here. An overview of this process is provided in Procedures for Practice 16-3, as well as in the figures on the pages that follow. Figures 16-9 through 16-18 depict the process of making a resting splint, Figures 16-19 through 16-21 depict the process of making a thumb splint, and Figures 16-22 through 16-32 depict the process of making a dynamic extension splint.

Splint Design

As discussed above, the primary determination of a splint design is identified by the provisional diagnosis. Total design is multifactorial, requiring an appropriate assessment of the patient and clinical condition. Design decisions are also informed by relevant biomechanical and physiological factors and the therapeutic goals of the patient, therapist, and physician (Fess, 1995). The clinician weighs options by also considering costs related to custom splint construction. If there is a commercial splint that achieves the same purpose, it may be more cost effective to provide the commercial splint.

Material Selection

As discussed earlier, occupational therapists become familiar with the properties of various thermoplastics in order to select the material that best meets the patient's needs

Procedures for Practice 16-3

Steps in Splint Construction

1. Design splint.
2. Select material.
3. Make a pattern.
4. Cut splint material.
5. Heat splint material.
6. Form splint.
7. Finish edges.
8. Apply straps, padding, and attachments.
9. Evaluate the splint for fit and comfort.
Figure 16-9 Patterns. **A.** Resting splint. **B.** Hand-based thumb splint. **C.** Dorsal wrist splint. IP, interphalangeal; MCP, metacarpophalangeal.

and aligns with the purpose of the splint (see Table 16-2 for pros and cons of some commonly used materials).

Pattern Making

Once the splint design and material are determined, the splint should be well visualized, and you can create a pattern. A well-designed splint pattern leads to a functional, well-fitted splint. The pattern provides a two-dimensional guide for the three-dimensional splint that helps minimize waste of time and splint material. Three common splint patterns are illustrated in Figure 16-9. Paper towels provide an excellent moldable pattern, but any type of paper can be used for the pattern. Place the patient's hand directly on the paper and mark the anatomical landmarks according to the design being used (Fig. 16-10).

The pattern must extend beyond the lateral borders of the hand and forearm to allow the splint to form a trough, which will extend halfway around the surface being splinted for adequate support. When creating a forearm-based splint—dorsal, volar, or lateral—extend the forearm trough two-thirds the length of the forearm. Once drawn, cut out the pattern and place it on the patient in the design of the splint to assure it does not block joints unnecessarily (see Figs. 16-11, 16-19, and 16-23).

Modifications can be achieved by reducing the pattern, adding paper for extra length or width as needed. If the patient is unable to lay the hand flat for pattern drawing because of deformity or spasticity, use the uninvolved hand for pattern making and flip the pattern over for the contralateral side. A pattern can be adjusted for edema or other variations before transferring. When the pattern fits as designed, trace it onto the splinting material (Fig. 16-12).

A pen or pencil can be used to draw the pattern on the thermoplastic material. Cut away the marks as you cut out the splint. An awl can also be used to scratch the pattern onto the plastic.

Cutting

Cut the splinting material to a size that will fit the pattern; this provides a manageable sheet of plastic. Cut the full sheet with a utility knife by scoring it and bending it; turn the material over and score it again from the other side. Heat the thermoplastic once the pattern is marked (see Fig. 16-13).When the material is soft, cut the splint pattern out with sharp straight-edged scissors (see Fig. 16-14).

Cutting the material after heating eliminates rough edges, saving time in the finishing step. Minimize fingerprinting by maintaining the material on the work surface, handling it by sliding your flattened hand under the material, lifting as little as possible, and retaining the material horizontally while cutting to avoid stretching.

Table 16-2	Pros and Cons of Various Splint Materials
Splint Material	**Pros and Cons**
Rolyan® Polyform™ Patterson Medical	Pros: Stretches easily, conforms well for intimate fit, minimal handling, rigid, excellent self-bonding, used for hand-based splints, creating dynamic outriggers Cons: When overheated, it is difficult to control; no memory
Rolyan® Aquaplast® Patterson Medical	Pros: Stretches easily, excellent memory, excellent for serial splints or fracture bracing Cons: Additional work required to smooth edges
Orthoplast® North Coast Medical	Pros: Excellent for reuse in serial splints, good for forearm-based splints, edges smooth easily Cons: Limited long-term self-bonding
LMB Blend DeRoyal	Pros: Controlled stretch, good drape ability, excellent for reuse in serial splints, static positioning splints Cons: No self-bonding, additional effort to apply attachments

Heating Splinting Material

Electric fry pans, splint pans, and hydrocollators can be used to heat thermoplastic materials. If using a fry pan, the recommended depth of water is at least 1 inch. If using a hydrocollator, prevent material from stretching or dropping to the bottom; heat pan liners are helpful. Water temperature is usually kept at 150°F–160°F for most materials, but the recommended temperature varies among materials. Consult the manufacturer's recommendations for specific materials. Use a thermometer in the water to ensure consistent temperature. Heating time for most materials is about 1 minute. The therapist should check the material to make sure it is heated uniformly before forming the splint on the patient. The working time for splinting materials varies from 1 to 6 minutes depending on thickness or filler. Thin materials cool more rapidly than thick. Because heat guns do not uniformly soften splinting material, they are recommended only for spot heating when attachments are required, minor adjustment, and edge finishing.

Forming the Material into a Splint

Once the entire piece of material is heated, remove it from the water with a spatula or tongs, being careful not to stretch the pattern. The entire piece should feel soft and easily moldable. Lay the material on a towel to dry briefly. If you are rolling the edges to finish them, do so before forming the splint on the patient. If the material is too hot, let it cool slightly before placing it on the patient to assure tolerance and comfort. When using a material with draping qualities, it is best to let gravity assist the positioning.

Proper Positioning

Proper upper extremity positioning during splint construction can make the difference between use of the splint and noncompliance. If the splint is formed with the patient's forearm in supination, the trough of the splint may impose undue pressure on the forearm when it is moved toward the more common functional position of pronation. The problem is reduced when the splint is formed in neutral, creating enhanced comfort during splint use. The therapist must find a position that is comfortable for the patient to maintain. This may require some creativity, such as using a plinth so the patient can lay supine if he or she exhibits restricted shoulder or elbow motion.

After placing the patient's hand and forearm in the desired position, place the heated splint material on the patient. Avoid gripping or squeezing the thermoplastic (Figs. 16-15 and 16-20).

Finishing the Edges

Smooth edges are important to prevent pressure points. Cutting the material at the required temperature allows the edges to seal smoothly without requiring additional work (Fig. 16-16).

With some perforated materials or rough-cut thermoplastics, it may be necessary to smooth the edges by dipping the edge of the splint into the hot water and cutting it to produce a smooth edge or smooth it lightly with fingertip pressure. This technique yields the best results when the fingers are wet while smoothing. *Safety Message: The heat gun produces a very hot stream of dry heat. It should never be directed toward the patient's skin.*

Set the heat gun on a cool setting before turning it off to avoid damage to the motor. If edges remain slightly rough, apply a thin piece of moleskin along the edge to seal it for comfort.

Applying the Straps

Straps attach the splint to the patient. Their location must be planned to achieve optimal surface contact for pressure dispersion and positional stability. Apply adhesive-hook

Velcro® to the splint and use loop or foam strapping material to hold the splint securely on the patient. Hook Velcro® adheres well to the splint if the surface is prepared for the bond. Remove the nonstick finish on the thermoplastic by using a heat gun to spot heat the part of the splint to receive the Velcro® hook and press a cotton towel into the material. Then spot heat the sticky side of the Velcro® with a heat gun before applying it to the thermoplastic (Fig. 16-17).

Other techniques are to apply a solvent or scrape the plastic with the sharp edge of scissors. There are variations to the application of Velcro® hook. A full piece of sticky-back Velcro® can be used on the splint running the width of the trough or two pieces on the splint's edges for each strap. There are advantages and disadvantages to each technique. If the material has been properly prepared to accept the Velcro®, either technique will be adequate. Strapping materials include Velcro®, durable foam, neoprene, and elastic strapping in a variety of widths. It is best to round the corners of the strapping material to avoid bending and "dog ears."

Splint Attachments

Outriggers and pulleys can be attached to splints when the splint base is complete. An outrigger is best considered an extension to the splint base, providing the desired angle to direct a static progressive or dynamic force. An outrigger can be made by rolling or pressing thermoplastic into shape, by using prefabricated tubes, or by bending wire to the desired position (Coppard & Lohman, 1996) (see Procedures

for Practice 16-4). Commercial outriggers are also available. The therapist should consider the requirements of the outrigger, be it high or low profile (Austin et al., 2004), single or multiple finger, static progressive, or dynamic. If the requirements of the outrigger are of a very specific or complex application, it is best to custom construct it from thermoplastic. Begin with a splint base to support the outrigger.

Attach the outrigger or pulley by preparing the surface of the splint first for optimal bond. Use a heat gun to spot heat the material to receive the outrigger or pulley and press a cotton towel into the material, removing the laminate. Spot heat the post or area of the outrigger that will contact the base and attach it to the base while both pieces are heated (Fig. 16-30).

Bonding solvent or scraping the surface of the base can also remove the laminate. The outrigger or pulley attachment points should be treated similarly. Use a heat gun as described above and press them together. To increase the material bond, gently pull and push the base and outrigger enough to stress the material, gradually forcing them tighter together but not enough to separate or shift the position of attachment. As the material cools, hold the pieces together for adequate bonding. They can be cooled with cool water or a cold spray before starting the next attachment.

The described technique will omit the need for additional reinforcement. If an alternate technique is used, heat another piece of thermoplastic and apply it over the outrigger base attachment. Always prepare surfaces with dry heat for effective bonding. Dynamic splints may be prone to slide distally because of the traction on the splint. You can control this migration with appropriate strap placement and a friction-enhanced material that is in contact with the skin. Silicone gel or Microfoam tape (available through Patterson Medical) provides light friction to keep the splint in place. Rubber bands, coil springs, or elastic thread provide the tension to a dynamic splint. They can be attached to the splint with a thermoplastic hook, Velcro® tabs, or thumbscrews placed proximal to the outrigger on the splint base. Pulleys or line guides such as Velcro® hook and loop can redirect the line of pull as needed for dynamic or static progressive flexion splinting. Monofilament (fishing line) attached to the rubber band creates a smooth excursion for the rubber band tension as it pulls over the outrigger or under the pulley (Fig. 16-32).

The monofilament attaches to a finger sling, fingernail hook, or tab to provide the appropriate tension and angle of pull. Dynamic splints may incorporate hinges, which provide a movable axis at a joint. Hinges are available commercially or can be made from rivets (Byron, 1994), crimped thermoplastic tubing, or brass fasteners (Dennys, Hurst, & Cox, 1992). Static progressive splints use locking hinges and various types of inelastic components such as Velcro® strips, monofilament line, MERiT components,

Procedures for Practice 16-4

Process for Creating a Custom Outrigger

A technique to create a custom outrigger with thermoplastic material such as Polyform™ is described here. It is best to use the same material used for the splint base.

1. Heat a piece of material and place it on a cotton towel.
2. Cover the material on all surfaces with the towel and press the towel into the material (Fig. 16-24).
3. The impression of the towel indicates the removal of laminate from the material (Fig. 16-25).
4. Remove the material from the towel and press the warm material into the shape of a solid tube (Fig. 16-26).
5. The material can be reheated in the splint pan as needed and rolled into a tube and then flattened (Figs. 16-27 and 16-28).
6. Reheat the material to allow flexibility to conform it to the hand for precise construction (Fig. 16-29).

and Click Strips (Vazquez, 2002). Hinges and turn screws may also be used for static progressive splinting to provide adjustable positioning of stiff joints in the optimal position tolerated by the patient. These components allow for adjustments as the patient achieves increased mobility (Schultz-Johnson, 2002).

The Use of Padding

When padding a splint (static or dynamic), allow extra space in the design and molding phases to contour over a bony prominence, avoiding additional pressure in this area. Some padding can be applied before forming the splint. When applying the padding after splint construction, ensure that the material padding is measured to fit only the splint formed to accept padding (Fig. 16-33). Cut the padding before removing the pad backing, reducing damage to the scissors. Place padding over the splint area to be padded, assuring proper placement, then remove the backing, and apply padding to the splint (Fig. 16-34).

If the padding is applied to the thermoplastic before heating, the excess water should be squeezed out before applying the material to the patient. You can use stockinette liners instead of padding for light protection, or sticky-back moleskin is also available for a thin, soft padding material. Padding should never substitute for a well-fitting splint.

Evaluating Splint Fit and Comfort

Once the splint is completed, the therapist performs a checkout to verify its fit and comfort and to assure that the patient understands its use and care (see Figs. 16-18, 16-21, and 16-31 and Procedures for Practice 16-5).

In summary, orthotic intervention (such as splint construction) requires a client-centered approach by a skilled therapist. Splinting is an important component in

Figure 16-34 Placing padding on the splint.

the rehabilitation process to meet the occupational performance goals of the patient, not just the application of a device. By combining applicable knowledge, principles of splinting, skill, and creativity with the patient's needs, the therapist can meet the challenges imposed to meet the goals of rehabilitation.

Figure 16-33 Cutting padding prior to removing backing.

Procedures for Practice 16-5

Splint Checkout

Ask the patient to wear the splint for about 20 minutes, and then remove it. If redness or blanching is identified and does not readily resolve, it may be an indication that the pressure of the splint is too much (Brand, 2002). Modify the splint if signs of excessive pressure are present then reevaluate fit and comfort.

Prior to sending the splint home with the patient, consider the following questions:

- Does the splint achieve the purpose?
- Does the splint maintain proper position at rest and perform as required with stress?
- Does the splint contour to and fit the hand considering arches and bony prominences?
- Does the splint extend beyond necessary structures causing undue restrictions?
- Is the splint long enough to support splinted structures?
- Is the splinting finished with smooth edges and resolved pressure points?
- Can the patient apply and remove the splint?
- Does the patient understand wear and care instructions?
- Does the splint design have maximum patient acceptability for compliance?

case example

Mr. J.: Construction of a Resting Splint for a Patient with Hemiparesis

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mr. J. is a 67-year-old man who sustained a left cerebral vascular accident (CVA) 4 weeks ago resulting in right hemiparesis. He is medically stable. Hypertonicity of finger flexors limits grasp and release of his right hand. There is limited passive range of motion (PROM) in wrist and finger extension caused by mild hypertonicity. Mr. J. was referred for outpatient occupational therapy to address residual impairments impeding his occupational performance.	Obtain information about the patient	"Hemiparesis will limit the patient's strength, active range of motion, and endurance. Hypertonicity will affect grip strength, active and passive range of motion, gross motor coordination, and dexterity. Flexor inhibition will help weak extensors overcome flexion."
Interview Mr. J. is right-hand dominant, married and lives with his wife in a two-story home. He is retired but has remained socially active through hobbies, including golf and bridge. He misses the many close and supportive friends he has developed through his leisure activities. Currently, his wife assists him with basic activities of daily living (ADL) and community mobility.	Evaluate to identify the problem(s)	"The patient is highly motivated to retain his current hobbies, which require functional grasp and release."
Assessment The therapist tested upper extremity muscle tone, functional range of motion, and sensation during the initial assessment. Using the Modified Ashworth Scale, Mr. J. scored 3: considerable increase in muscle tone with full passive movement difficult to achieve (Bohannon & Smith, 1987). Mr. J. demonstrated right upper extremity active and passive range of motion (A/PROM) within functional limits with the exception of the right wrist and digits. He presented in Brunnstrom stage III: able to perform mass grasp, hook grasp, lateral prehension, but no release or voluntary extension of digits (Trombly, 2008). His right upper extremity sensation is normal.		"The patient values his roles as an independent person, husband, friend, and sportsman. Increased ability to participate in leisure activities will improve his occupational performance, quality of life, and self-esteem."
Mr. J. and his wife were provided instruction on splint purpose, precautions, wear and care, plus consequences of noncompliance. He stated the splint was comfortable and was able to don and doff it independently. Mr. J. received a home exercise program of tactile simulation, weight-bearing, A/PROM, strengthening, and functional activity.	Implement the intervention	"He will need a resting hand splint to help normalize muscle tone, maintain soft tissue length, and prevent painful contractures (Milazzo & Gillen, 2011). I will arrange follow-up appointments to monitor tone and make splint modifications as necessary."
Mr. J. exhibited decreased hypertonicity of the finger flexors and scored 1 on the Modified Ashworth Scale. Testing revealed improved right grip strength and full PROM of fingers. Patient had progressed to Brunnstrom stage V and demonstrated ability to voluntarily grasp and release objects (Trombly, 2008). Mr. J. was able to perform all ADLs to include leisure activities. He discontinued splint use at 6 months post CVA.	Evaluate the result	"I believe that the splint helped inhibit flexor spasticity and prevent contractures following his CVA. It likely helped that Mr. J. adhered to his splint wear schedule and home program."

Clinical Reasoning in Occupational Therapy Practice

Hemiparesis and Flexor Hypertonicity-Resting Hand Splint

What important factors must be considered in the construction of Mr. J.'s resting splint? What properties should the splinting material selected include? How should the therapist position the wrist and in the splint and why?

case example

Mrs. O.: Construction of a Hand-Based Thumb Splint for a Patient with Carpometacarpal Osteoarthritis

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mrs. O. is a 55-year-old right-hand–dominant female with carpometacarpal (CMC) osteoarthritis of the trapeziometacarpal joint of the right hand. Mrs. O. was referred to outpatient occupational therapy for conservative management to reduce hand pain and increase function.	Obtain information about the patient	"She can reduce pain by using thermal modalities, applying joint protection principles, wearing a hand-based thumb splint, modifying her activities, and using adaptive equipment when necessary."
Interview Mrs. O. lives alone in her one-story home. She is employed as a part-time librarian. Her leisure activities include reading and gardening. She is independent in all ADL. She describes pain with tasks like turning a key, grasping books, writing, and using gardening tools. She experiences swelling and redness at the base of her right thumb after prolonged use. Mrs. O. greatly values her self-advancement and self-enhancement roles of independent person, worker, and gardener. Her supervisor has revised her schedule to help lessen pain during work. She will spend more time at the checkout counter and less time shelving books. On her days off, Mrs. O. loves working on her favorite horticulture projects.	Evaluate to identify the problem(s)	"Mrs. O. values all her roles. She is highly motivated to make changes that will allow her to continue in these roles." "Mrs. O. gets so involved in her gardening that she works until her thumb pain is quite severe. She can find ways to manage her time and adapt her gardening." "Mrs. O. needs to work with her employer to find ways to manage her demands at work by rotating tasks and taking minibreaks."
Assessment Mrs. O. reported her pain was a 2/10 at rest and 7/10 with activity on the visual analog scale. Ligament stress testing revealed slight joint instability and tenderness with palpation at her right thumb CMC joint. Her sensation was intact, and there was no redness or inflammation present. Right-hand AROM was within functional limits (Biese, 2007).		
Mrs. O. is fitted with a custom-fabricated hand-based thumb splint made from a 1/16-inch thermoplastic. She received instruction on her program of splint wear, superficial heat or cold, pain-free thenar eminence strengthening, and AROM exercises. Joint protection, energy conservation, and the benefits of adaptive equipment use are introduced (Kurtz, 2006). She states her splint feels comfortable and is able to don and doff it without difficulty. A follow-up appointment is scheduled for a splint check and review of all instructions.	Implement the intervention	"She will benefit from use of a splint during her work day and as needed in the garden. She will modify her work day by taking minibreaks for exercises and alternating tasks that may be stressful to her thumbs. Setting a timer while in the garden to remind her to take breaks will help her pain awareness. Adaptive tools and joint protection techniques may be helpful in daily tasks as well as in the garden."
Mrs. O. tolerates the splint well and wears it as needed during the day. She is able to work and garden with the splint on. She is compliant with her home exercise program and has integrated joint protection strategies and adaptive equipment into her daily routine. Mrs. O. reports home paraffin baths help alleviate her joint pain.	Evaluate the results	"She may need splint adjustments over time as changes occur in her hand. She may require different splints for different activities: one for work and one for gardening."

Clinical Reasoning in Occupational Therapy Practice

Carpometacarpal Osteoarthritis and Hand-Based Thumb Splint Wear Compliance

During the assessment, Mrs. O. reveals that she does not understand how wearing a splint will decrease her thumb pain. In fact, she fears that it will be uncomfortable and interfere with her ability to use her hand. How can the therapist address Mrs. O.'s concerns and persuade her as to the effectiveness of the splint in helping her achieve her rehabilitation goals?

case example

Mrs. D.: Construction of the Dynamic Metacarpophalangeal Extension Assist Splint

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Mrs. D. is a 41-year-old, right-hand–dominant woman with a 12-year history of rheumatoid arthritis. Her surgeon performed left-hand metacarpophalangeal (MCP) arthroplasties with the surgical goals of restoring normal joint alignment and extensor tendon balance for improved hand function (Theisen, 2006). Mrs. D. was referred to occupational therapy 5 days postoperative for splinting, therapy, and activities of daily living (ADL) adaptations.	Obtain information about the patient	"Initially, Mrs. D. will have limited left-hand use; she will need assistance with ADL and must learn to perform many tasks one-handed. Her family will help with household tasks. She has taken a medical leave from work to devote the next month to therapy. The surgeon was pleased with the surgical result and wants her to follow his standard protocol. Mrs. D. is healthy and should do well."
Interview Mrs. D. lives in a two-story home with her husband and three teenage daughters. She is employed as a part-time receptionist and remarks that her hand deformity has made keyboarding extremely hard. Cooking is her favorite social and creative outlet, but her hand makes this hobby difficult. She cannot lay her hand flat, wash her face, or put her hand in her pocket. She has trouble turning keys, opening doors, and cutting with a knife. Mrs. D. values her self-advancement and self-enhancement roles of worker and cook. She will return to work but is happy her leave of absence will permit her to focus on her rehabilitation. Her daughters will assist with household chores.	Evaluate to identify the problem(s)	"Ms. D. values her roles as an independent person, wife, mother, friend, and worker. She wants to retain those roles." "During the recovery process, her activity requirements will be reviewed. Joint protection techniques and kitchen adaptations may be suggested."

Assessment

The patient's left-hand sensation is normal. Mrs. D. exhibits no signs of infection. There is mild edema localized to the dorsum of her left hand. Active range of motion (AROM) measurements are MCP extension of 0° and flexion 25°.

The therapist applies a light dressing and fabricates a dynamic extension splint for daytime wear and a resting splint for night use. Mrs. D. can actively flex her MCPs in the dynamic splint, and then the rubber bands passively return her MCPs to a neutral position. She and her husband are given verbal and written instructions to perform active MCP flexion exercises in the dynamic splint 10 times each waking hour, allowing the rubber bands to return her MCPs to full extension. Additional instructions describe splint wear and care, edema control techniques, wound care, and scar management. The surgeon told Mrs. D. that light ADL can be resumed while wearing the dynamic extension splint at postoperative week 3. She wears the dynamic splint for 4 weeks. She receives joint protection, energy conservation, work simplification, and adaptive device education to facilitate improved occupational performance.

Mrs. D. returns to work 4 weeks after surgery to answer phones with the use of a wireless headset and is learning to use a voice-activated keyboarding system. She gradually increases work demands and resumes full duties at 6 weeks after surgery. She continues to use the night resting splint for 3 months. Mrs. D. is very happy with her outcome. Her occupational performance is greatly improved because of her improved hand function and willingness to apply joint protection, work simplification, and energy conservation principles.

	"She must wear a dynamic splint during the day and a resting splint at night per postoperative protocol."
Implement the intervention	"Mrs. D. will follow a standard protocol for postoperative MCP arthroplasty. She needs review of joint protection, work simplification, and energy conservation principles. Information on adaptive devices that will enable her to perform daily tasks more efficiently will be provided; she should be open to any suggestions."
Evaluate the results	"Mrs. D. has had uneventful recovery and outstanding functional outcome."

Clinical Reasoning in Occupational Therapy Practice

Patient with Rheumatoid Arthritis: Ensuring a Positive Postoperative Outcome

Mrs. D. has had rheumatoid arthritis for 12 years. How does her diagnosis affect the therapist's splinting intervention?

Summary Review Questions

1. Name the steps of splint making in order.
2. Name the creases of the hand and describe their importance in splint construction.
3. What is the difference between the functional position of the hand and the position of safe immobilization in splinting? Give an example of when you would use each.
4. Describe the concept of dual obliquity as applied to splinting.
5. What does mechanical advantage mean in splinting?
6. What are some strategies to enhance compliance with splint wear?
7. What does a splint checkout include?
8. What are the top six cited reasons to introduce splinting as a therapeutic intervention?

Glossary

Dual obliquity—The difference, or variance between the length and the height of the metacarpals, with the radial side longer and higher than the ulnar side. This difference must be considered when designing splints for the hand.

Dynamic splint—A splint that applies a mobile force, applied with rubber bands or springs, in one direction while allowing active motion in the opposite direction.

Fibroblastic phase—Stage of wound healing that follows the inflammatory phase, during which fibroblasts proliferate and initiate collagen production in the healing of tissues.

Inflammatory phase—Phase of wound healing immediately following injury or surgery, characterized by edema and infiltration of leukocytes and macrophages to begin healing tissue.

Maturation phase—Stage of wound healing that follows the fibroblastic phase; characterized by wound contraction, remodeling, and maturation of the healed tissues.

Splint—A device applied to the body to provide protection, positioning, immobilization, restriction, correction, or prevention of deformity for the splinted part; an orthosis.

Static progressive splint—A splint designed to stretch contractures through the application of incrementally adjusted static force to promote lengthening of contracted tissues.

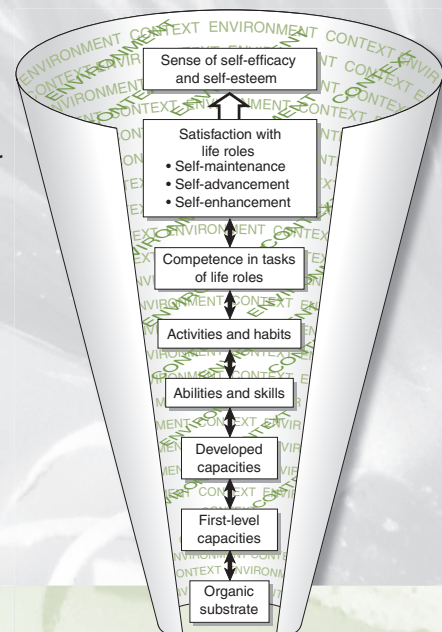
Wheelchair Selection

Brian J. Dudgeon, Jean C. Deitz, and Margaret Dimpfel

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the factors that should be considered in wheelchair selection and explain how they interrelate.
2. Describe the three basic types of wheelchairs and reasons for each to be chosen.
3. Specify measurements typically taken to determine wheelchair and related seating system configurations for a particular individual.
4. Demonstrate knowledge of the components common to many wheelchairs, and describe why each merits consideration in wheelchair selection.
5. Discuss the roles and responsibilities of the occupational therapist in wheelchair selection.
6. Suggest how the occupational therapist can acknowledge user preferences and facilitate the user's participation in wheelchair selection.


Mobility is a fundamental part of living. Being able to move about, to explore, under one's volitional control is a keystone of independence. (Warren, 1990, p. 74)

Mobility is a major part of daily living, facilitating participation in home, work, and community settings. Mobility difficulties are one of the most commonly reported functional difficulties, a problem that is commonly addressed by use of special devices or equipment (Dudgeon et al., 2008). Walking aids and wheelchair selection and use are also frequent needs arising for either short- or long-term adaptation to disability. As such, wheelchair selection and training necessitate consideration of the user's preferences and current as well as anticipated performance needs, capacities, and environments. The process of evaluating and choosing a wheelchair system involves the user, an interdisciplinary team, and equipment suppliers or vendors. Also, family members, primary care providers, and others from the user's work and leisure environments may contribute important information useful in choosing an appropriate wheelchair system to meet needs for mobility within and between environments. Such information could affect choices regarding seating and positioning, controls used, and supports for engagement in activities at home as well as mobility and transport in community settings.

Wheelchair selection has a functional orientation and involves multiple factors including the user's (1) needs and goals; (2) home, work, recreational, and other community environments; (3) physical and cognitive status and anticipated course of impairments; (4) financial and community resources; (5) views about appearance, maintenance, and social acceptability; and (6) needs for interface of the wheelchair system with other assistive technology and care provider or assistant requirements. A selection process includes issues, such as current and changing needs of the user and family, training needs for use and maintenance, and anticipated changes in technology. A wide range of wheelchair options are available, yet funding and community-based resources for training and servicing of mobility devices often limit choices for any given individual.

Some individuals use wheelchairs only occasionally to meet brief transportation needs, whereas others use them continuously to meet most day-to-day positioning and mobility demands. Especially in the latter case, the events that lead to the need for a wheelchair may be dramatic. For some, acquiring a wheelchair system may create stress or confusion, and this can hinder their contributions to the assessment of needs and selection of a system. Others view the acquisition of a wheelchair as a positive move toward greater independence and freedom and make substantial efforts to become informed about making choices. In either case, the needs of the user are central to the overall process of selection, prescription, and training, with the wheelchair viewed not just as a means for mobility but as

a highly personal device to be chosen with care and precision (Steins, 1998).

In contributing to the selection process, the occupational therapist must have a thorough understanding of the user's medical needs and personal factors, including environment, daily routines, goals related to activities and participation, and assistance or care provided by others. In addition, the therapist should understand the seating and positioning needs of the individual and wheelchair types, control mechanisms, features, and accessories. Knowledge of product resources and local area vendors is also important in creating device choice options. Although this information is presented as separate components, all of these factors interrelate in comprehensive planning for functional mobility through a clinical reasoning process.

EVALUATION OF THE INDIVIDUAL

During evaluation, primary attention is given to user and family goals for use of the wheelchair as part of a functional mobility system. Further, the therapist evaluates the skills of the user, the user's ability to develop new skills, and changes expected from the diagnosis (e.g., declining sensorimotor skills). How the user plans to transport the system is also an important consideration. Priorities of users should be considered and are likely to include concerns about both comfort as well as functioning with user satisfaction typically being most related to comfort and ease of use (Ward et al., 2010). Evaluation of needs should include interview, observation, and examination. Trials with seating simulators, trial seating systems, self-propulsion methods, and/or other control systems are often needed to confirm appropriate prescription of these systems. Figure 17-1 outlines evaluation needs; patient-specific information relates to Lisa (Case Example 17-1).

The evaluation typically involves both sitting posture and mobility needs. The therapist can best assist in seating and wheelchair selection by understanding the client's personal capacity and needs and medical conditions.

Personal Capacity and Needs

The evaluation of the client includes attention to factors such as age and stature, developmental status, living environment, educational or work routines and plans, recreational pursuits, other assistive technology needs or uses, and future anticipated needs. Special attention is given to seating and operation of the chair in both private and public environments. Specifically, the therapist should consider factors such as floor surfaces, outdoor terrain, climate, doorways, hall spaces, restroom dimensions, workspace design, transportability, and parking. If a client has already used an adaptive mobility device before, it is important for the therapist to determine

Sample Wheelchair Evaluation: Needs of the Individual

Client information: Lisa, 17-year-old high school senior with recent C7 level tetraplegia from traumatic SCI in MVC. Attends evaluation with mother during inpatient stay in acute rehabilitation unit.

Functional Needs and Goals

Environments of use (home, school, work, community at large): Full-time at home, at school, and in other community locations. Has interest in athletics, high school programs.

Seating needs (time, pressure relief, transfers): Postural support needs for trunk and thighs, cushioning for neurogenic skin, and armrests for upper limb support.

Able to perform push-up pressure relief and can do independent transfers to/from wheelchair to same level bed or other surface.

Control or propulsion methods (attendant, manual needs, power controls): With postural support and seat belt, self-propels using friction push rims and wheel brakes. May benefit from grade aids for propelling up inclines.

Methods of wheelchair transport (car, van, truck; ground travel, air travel): Family owns full-sized truck and minivan. Lisa has driver's license, but has not yet explored or been oriented to adaptive driving.

Physical Examination

Head control: Now using a Minerva brace for cervical spine immobilization that will be discontinued in several weeks with healing. Otherwise, no limitations in head movements when trunk is stabilized.

Sitting balance and spinal deformity: Propped wheelchair seating, enables good head control when neck immobilization is discontinued.

Pelvic rotation or obliquity: Symmetrical at this time, mobile pelvis, lumbar support through wheelchair seating back contour and lateral trunk supports.

Lower limb mobility: Full PROM, flaccid at rest with periodic spasms into hip adduction, knee extension and ankle plantarflexion. Neurogenic skin below C8 level.

Upper limb mobility: Full PROM, good to normal strength in shoulder, elbow flexion 5/5, extension 4/5, forearm rotation 4/5, wrist extension 4/5, flexion 3/5, finger extension 3/5. Neurogenic skin lateral hand, 4th and 5th fingers.

Sitting and Balance Needs

Postural support: Now using brace for stability, lateral trunk supports for midline positioning. Seat belt and chest harness necessary for support and safety. Explore back cushion contouring when brace is discontinued.

Cushioning: Solid base of support needed with cushion contour. Tried low-profile Roho and Jay Cushion. Lisa preferred latter for balance, good cushioning effects.

Wheelchair Training Needs

Control or propulsion: Manual propulsion with seating components in place. Enlarged and rubberized friction rim tried and preferred over plain rim or knobs. Wheel camber may assist in hand placement. Needs training for propulsion on level surfaces, maneuvering corners and doorways, all outdoor settings.

Transfers to and from wheelchair and chair, bed, toilet, bathing tub or shower, floor, car: Is beginning transfer training wheelchair to bed using sliding board. Removable armrests and swing-away footrests will enable independence. Will need car transfer training, tub transfer, and floor to wheelchair instruction later.

Wheelchair Maintenance Resources
Lisa expresses interest in learning maintenance routine; father willing to assist as reported by Lisa and her mother. Wheelchair vendor is within 15 miles from this family's home.

Figure 17-1 Evaluation overview. Clinicians address these issues by interview, observation, and physical examination. MVC, motor vehicle collision; PROM, passive range of motion; SCI, spinal cord injury.

the user's assessment of pros and cons regarding that mobility method or system. A blending of walking aids and wheelchair use may be planned. Therapists should recognize that uses of adapted mobility systems often conflict with personal spaces and public accessibility. Public accessibility is based in part on human factors design, in which the typical wheelchair user sits at a 19-inch height and propels a manual wheelchair through a 32-inch wide opening and turns around in a 5-foot open floor space. Many people are served well by environments that accommodate this type of user, but others continue to be constrained by the environment and need individual

guidance about making appropriate selection and accommodations. For example, some power mobility devices have a larger turning radius or excessive weight that puts limits on the user's access to some buildings, assistance that can be provided by others, and/or load limits of transportation systems.

Medical Conditions

Evaluation of a user's medical conditions includes a review of medical history and physical assessment. The therapist should be aware of the user's diagnosis and prognosis; that is, whether the medical condition is temporary, stable, or progressive (i.e., declining capacity). Such factors influence choices related to complexity of options and need for adjustment as well as preferences for rental, lease, or purchase. For example, if a condition is temporary, a chair may be selected with greater concern for cost factors. In contrast, if a client's condition is chronic, stable, and necessitates full-time use of a wheelchair, durability and individualization to meet needs are priorities. If a condition is progressive, a chair that permits a range of adjustments for both seating and wheelchair control may be indicated in order to meet a client's changing needs and maximize function and independence for as long as possible. The physical assessment should focus on neuromuscular status (e.g., muscle tone, postural control, reflexes, and coordination), musculoskeletal status (e.g., range of motion, deformity, strength, and endurance), sensory status (e.g., anesthetic skin and skin integrity), and physiological status (e.g., temperature regulation, respiration, and cardiopulmonary). Cognitive skills are also considered relative to capacity and safety in using and operating a wheelchair mobility system.

Wheelchair products are currently evaluated using standards put forth by the American National Standards Institute (ANSI) and the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), an interdisciplinary association for the advancement of rehabilitation and assistive technologies. Such standards enable direct product comparisons regarding features such as stability, safety, durability, and cost (Cooper et al., 1997). These standards are changing and call for uses of new terminologies as well as design elements that impact choices regarding seating and positioning options, wheelchair frame styles, and various control and equipment attachment options.

SEATING AND POSITIONING

Critical to selection of a wheelchair system is the attention given to the seating and posture needs of the user. Seating systems have a significant effect on the ability of the user to perform functional activities and on basic decisions about choice of mobility base types and components. Effective seating has several broad goals, including (1) enhancing posture, comfort, respiration, and skin protection; (2) preventing injury; (3) accommodating existing and preventing future deformity; (4) enabling vision readiness and limb use; (5) attending to cosmetic appearance and social acceptance; and (6) assisting with or enabling functional access and performance in specific settings or environments. Evaluation and intervention related to positioning often entails participation by team members, such as physical therapists to address postural supports, speech therapists to address augmentative communication, and family members and others to address daily routines and schedules. Occupational therapists may coordinate these concerns by incorporating the needs and goals of the user and family with medical care concerns in making recommendations and by analysis of functional issues so that recommendations optimize the individual's access to activities and participation. The roles of team members may vary somewhat in different locations and in different organizations.

Seating Principles: Solid Base of Support

Seating strategies and particular techniques can be specific to age groups and diagnoses, although some principles can be applied to meet a variety of needs. One such principle is the need to provide the individual with a solid base of support that begins with appropriate pelvic positioning. The sling seat, common to folding and unlocked wheelchair cross-brace frames, is a seating element that tends to promote pelvic instability and malalignment of the thighs. A solid seating base is accomplished by stabilizing the pelvis on a firm surface with pressure distributed throughout the buttocks and nearly the full length of each thigh. Seating pressure mapping can be used to assess distribution of pressure and peak pressure problems that may exist (Stinson, Crawford, & Porter-Armstrong, 2008). Although these systems give feedback to both clinicians and users, who can then visualize pressure difficulties and how effective pressure relief techniques may be, specific uses of such technology remain somewhat uncertain (see Fig. 17-2).

Postural Supports

Postural control is influenced by the seat and back contact surfaces and by orientation adjustments to the seat-back angle and the angle in space (Fig. 17-3). There are three commonly used seating positions. First is a sitting position with 90° hip, knee, and ankle positions. Second is a slight anterior (forward) tilt of the upper pelvis to distribute weight through the buttocks and thighs and, for some individuals, to inhibit abnormal reflexive responses (Fig. 17-4). Third is a 95° seat-back angle with a 3°–5° angle-in-space recline. Adjustable hardware that
Figure 17-2 **A.** Flexible pressure maps are placed over cushions to measure body contact pressures. High and low readings are displayed continuously and can be saved for record keeping. **B.** Pressures are shown in color, in grayscale, or graphed. Dynamic readings can be shown or summed over variable lengths of time.
Figure 17-4 Pelvic positioning with slight anterior tilt helps to distribute tissue pressure throughout the buttock and thigh.

secures the seat and the back components to the frame are often used to adjust these positions.

Seat Surfaces and Cushioning

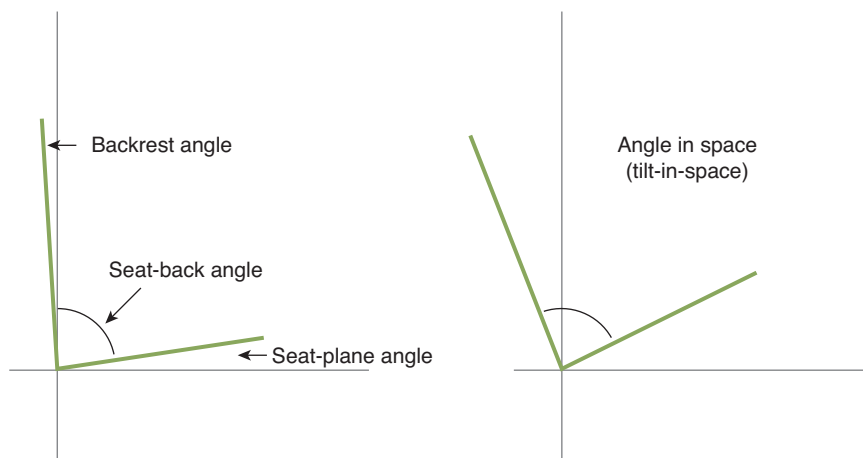
The seat and back contact surfaces can be planar, precontoured, or custom contoured. Single-plane or flat surfaces are typically appropriate only for those who need little


Figure 17-3 Adjustment of seat-back angle and angle in space helps to support posture and provide appropriate pressure distribution.

or no postural support and for those who can easily reposition themselves to maintain balance and comfort. Contoured designs are used to provide added contact for postural support and distribution of pressure. Custom contouring is often necessary for individuals who need accommodation for deformity of the pelvis or spine, those who have abnormal muscle tone, and those who have discomfort from lack of support at the lumbar spine. These customized cushions are individually fabricated by bead-seat molding, foam-in-place techniques, or other shape-sensing technology. Such devices are often fabricated and added to an existing wheelchair seating system, such as to improve seatback cushioning or enable better pelvic positioning for comfort and control.

Cushions are used to reduce peak pressures associated with bony landmarks and to distribute pressure evenly over a large area of skin contact. Shearing forces that compromise circulation also can be reduced by appropriately shaped cushions. Although cushioning relieves skin and soft tissue pressures, factors including postural stability and control, ease of transfers, ability to accommodate deformity, moisture, and maintenance may be as important for some users. Cushioning of the seat and back may call for use of one or more materials, such as variable-density foams, gels, air, and honeycomb-shaped plastics. Custom contouring and alternating pressure systems also may be

considered. Table 17-1 lists advantages, disadvantages, and examples of each. Selection of cushion coverings, for both contact with the user and contact with wheelchair seating surface, also should take into account factors such as heat and moisture, friction, durability, and cosmetic appearance. The actual pressure characteristics of cushions are being evaluated and compared with a focus on both compression and sheering forces that are encountered with use (Akins, Karg, & Brienza, 2011). Regardless of cushion types, the techniques of pressure relief described next are vital to consider as part of pressure management.

Skin should be monitored closely for tolerance when use of any new positioning or cushion system is started. Progressive sitting time schedules along with ongoing skin inspection routines are essential, because no cushion provides sufficient pressure relief during regular use. Properties of materials vary, yet no cushion is considered sufficient in relieving pressure enough to preserve capillary blood flow to compressed tissues while a person is seated. Pressure on sitting surfaces can be greatest during manual propulsion, and users should be informed about dynamic factors that may put at risk the health of skin tissues. Although cushions help to reduce skin pressures, other means of pressure relief are necessary. Assisted or user-performed wheelchair push-ups, side leans, or forward leans for pressure relief are typically

Table 17-1 **Cushion Types and Examples**

Classification	Advantages	Disadvantages	Example
Foam	Lightweight Easily sized, shaped Low cost	Uneven pressure relief Poor durability Hard to clean	T-Foam by Alimed®
Gel-filled	Self-contouring Posture control Sitting balance	Heavy to move Temperature sensitive Leaking, maintenance	Jay® Cushion by Jay Medical
Air-filled	Lightweight Even pressure relief Little shear	Reduced control/balance Requires attention to air-pressure tending Potentially requires repair of puncture/air leaking	High or Low Profile by Roho®
Honeycomb	Lightweight Easy to clean Low maintenance	Uneven pressure relief Difficult to shape Excessive thickness	Supracor Stimulite® Contoured
Custom-contoured foam	Surface area coverage Reduced shearing Better postural control	Expense Longevity with change Reduced weight shift	Contour U® Pindot by Invacare
Alternating pressure systems	Scheduled relief cycle Reduces user effort Self-contouring	Cost and availability Uneven pressure relief Unsteady sitting balance	Bellows Air Support Equipment™ by Talley Medical

Figure 17-5 Custom contouring. Specialty manufacturers make custom cushions and backrests from a direct cast molding of the individual, through an electronic sensing system or by foam-in-place methods. These systems are typically used with individuals whose unique postural needs cannot be well supported by premade cushions or backrests.

needed or recommended every 15–30 minutes. Alternatively, technologies for pressure relief include tilt-in-space mechanisms, use of alternating pressure cushions that continuously cycle varying pressure segments of a cushion, and custom contouring of cushions (Fig. 17-5). Options of powered tilt and recline systems are growing and available for lesser cost and impact on the weight of wheelchair systems (Dicianno et al., 2009).

Adding Seating System Components

A seat belt is often recommended because it serves an important role in stabilizing the pelvis as part of therapeutic positioning in the seating system. This anterior support is typically mounted on the wheelchair frame so that it pulls on the pelvis at a 45° angle to the base of the seat back, fitting just under the anterior superior iliac spines. Additional seating supports should be used as needed to improve posture, restrict abnormal movements, and promote head control and voluntary use of

the limbs. For example, if sitting balance and abnormal postures are problematic, lateral trunk and thigh supports may be suggested. Use of anterior supports, in addition to the seat belt, may be necessary across the upper trunk, knee, or ankle for balance and stabilization. Neck and head supports are used to promote head and neck alignment and are sometimes recommended for safety. Upper extremity positioning also may be a concern, in which case specialized armrests or lap trays can be recommended.

Justification of Seating Systems

Because sitting is a dynamic rather than a static state, seating devices should allow some element of pressure relief and freedom of movement. The principle of *less is more* is recommended when applying specialized seating systems because as more seating apparatuses are used, freedom of movement tends to diminish. Therefore, only components that maximize individuals' abilities to function, correct their positions, and maintain comfort should be applied. When considering additions to wheelchair systems, trade-offs between support and function need to be carefully considered.

Expense justification with a health insurance third-party payer must relate to medical necessity. Inappropriate seating and mobility base selection can exacerbate complications and result in decline for the user. Functional accessibility and protection of the user from secondary complications that come with immobility or physiological risks with seating may be cited as part of insurance justifications.

To justify specialized seating with users and families, the experienced therapist can employ clinical observation and literature evidence. Improved motor skills, comfort and participation, physiological supports, and functional independence are widely hoped for as part of specialized seating and wheelchair selection. Some goals should be viewed cautiously, however, because wheelchair and seating configurations can be considered specific to certain diagnostic groups and mostly provide a prosthetic effect, meaning that these benefits are largely limited to the time that the person spends in the seating system. Although more wheelchair seating research is now being conducted, methodological challenges and studies with small samples have led to calls for a more focused research effort. Geyer et al. (2003) assembled a variety of stakeholders who reviewed existing work addressing wheelchair seating and called for future research efforts aimed to address wheelchair transportation, postural control, comfort, and tissue integrity. Inclusion of the user in research regarding wheelchair uses and consequences of use should be considered (Sprigle, Cohen, & Davis, 2007) (see Evidence Table 17-1, which is related to selection and uses of powered postural controls.)

Evidence Table 17-1 | Best Evidence for Powered Seating Posture Features

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Monitoring of power seating activations	Tilt, recline, and/or height adjustments recorded and appraised for patterns of use	Eleven adult power wheelchair users, ages 18–70 years	Seating Function Data Logger used to monitor self-actuated seating functions over approximately 12 hours of use for a 2-week period of typical daily use	Description of seating activations and likely purposes of such self-actuated changes in sitting posture; Level: N	Users made frequent use of power seating adjustments, with >50 times in at least partial tilt or recline positions. This increased reported comfort but did not achieve pressure relief guidelines.	Descriptive statistics on each user's frequency and duration of seating posture change activations	Ding et al. (2008)
Tilt-in-space seating use and outcomes for nonambulatory users	Systematic literature review (19 studies) appraising use ot tilt by those children and adults with neurological impairment	Nineteen selected studies addressing neurological impairments (e.g., CP [n = 8] and SCI [n = 8])	NA	Systematic review with meta-analysis; citing level I and level II research studies. Level: I	Statistically significant reduction in pressure under ischial tuberosties when tilted backward (20°–45°); evidence lacking regarding effects of tilt on function and seating use	Varied per article reviewed	Michael, Porter, & Pountney (2007)
Participation and activity measurement approach used with wheeled mobility users	Nonintervention study; semistructured, prompted recall interview about wheeled mobility at home and in community; objective use measures and, satisfaction report as well	Five adult power tilt-in-space wheelchair users with various neurological disorders	NA; system use recall reported; 2 weeks of objective use measures	Descriptive study and systematic interview; Level N	Comfort was a common reason for tilt activation. Varied uses and places of use of tilt feature were part of participation in varied activities.	Descriptive summaries and satisfaction change reported.	Harris et al. (2010)
Relieving contact pressure & obtaining tissue perfusion with wheelchair push-ups or dynamic seating system	Contact pressure measurement changes and improve ischial tissue health with wheelchair push-ups or use of a dynamic seating system device	Twenty individuals with paraplegic SCI, 20 with tetraplegic SCI, and 20 nondisabled participants	Laboratory setting appraising hour-long sitting protocols and pressure as well as tissue health changes with use of push-ups or dynamic seating systems	Repeated measures design; Level IIIB	Contact pressure relief achieved with wheelchair push-up or dynamic device, but tissue recovery poor with push-up method; good with dynamic system device	Descriptive statistics on contact pressure reduction and tissue reoxygenization Skin contact pressure reduction $p \le 0.05$; tissue perfusion varied with poorer success for those with SCI who did not significantly improve $p \ge 0.05$	Makhsous et al. (2007)

Evaluate biomechanical responses in seated pressure and blood flow with body tilt	Eleven participants with SCI who used tilt-in-space wheelchairs and had no current pressure ulcers	Interface pressure reduction at ischial tuberosity and oxygenated blood flow with tilt sequences from upright to 45° tilt recline	Laboratory-based appraisal in different tilt sequences, single-session testing	One-group, repeated measures design. Level: IIIC	Highly variable responses to tilt, with increased blood flow observed only with maximum (45° tilt). Maximal (45°) tilt in wheelchairs can best assure peak and mean pressure relief and tissue health, although less than maximal tilt may have some benefit.	Varied success with 30° recline and better success with maximal 45° tilt recline ($p \leq 0.05$)	Sonenblum & Sprigle (2011)

WHEELCHAIR TYPES: MOBILITY BASES

Once the therapist has a full understanding of the user's personal capacities and medical issues, seating needs, and environments of expected use (Karmarkar et al., 2011), it is important to understand the types and uses of wheelchair systems. Wheelchairs used in everyday activity can be divided into three general categories: (1) attendant-propelled chairs, (2) manual chairs, and (3) power mobility devices. Special-use chairs and attachments to standard mobility bases for participation in recreation and sports also can be considered.

Attendant-Propelled Chairs

Attendant-propelled chairs are designed to be pushed by another individual because of the user's inability to propel or operate a manual or power wheelchair in a functional or safe manner. This may be necessary for some users on a temporary or circumstantial basis, for example, as a means to be mobile during community outings. Attendant assistance also may be a full-time need for individuals who have diminished cognitive capacities, severe judgment difficulties, or severely restricted physical capacities. These chairs may be full size (e.g., those used in skilled nursing facilities) or may be smaller and created for use in limited spaces (e.g., folding stroller types). Attendant-propelled chairs also are used as a substitute for power mobility when the individual's typical mobility system is being repaired or when space constraints preclude power mobility use. When assisting a user in selecting an attendant-propelled chair, it is necessary to consider not only the fit and comfort of the chair for the person who will be seated but also the sizing needs of the person most likely to be pushing it. As with all wheelchairs, attention to transportation of the user and the wheelchair device between environments needs attention and planning. In addition to chairs specifically designed to be attendant propelled, many manual wheelchairs (described next) can be propelled by an attendant. In both situations, the capacities of care providers, who may be family members, become important considerations. For example, it is important to consider needs of a partner assisting a patient in going to doctors' appointments, shopping malls, family events, and various other settings. If a chair must be lifted into the trunk of a car, consider the ability of the primary care provider to do this. Consider not only the weight of the chair but also the ergonomics involved in picking it up and positioning it in a specific vehicle.

Manual Chairs

Manual wheelchairs are for those who can propel and brake using the upper limbs (Fig. 17-6). These chairs have a variety of frame types, weights, and transport features. In general, manual wheelchairs have rigid box frames or

folding frames; folding frames are either free or locking lever–secured. Quick-release wheels can also be selected. Folding, locking-secured frames with quick-release wheels and detachable front rigging may offer the greatest flexibility for transporting the wheelchair. Rigid-frame chairs may provide greater energy efficiency with propulsion, and, with quick-release wheels, users can find this style to be either easier or more difficult to transport, depending on the type of vehicle used. Manual wheelchairs may be primarily user operated for most activities and many environments, but consideration of how others may help propel the wheelchair should be considered as well.

The conventional manual wheelchair frame has large rear wheels, which are used to propel the chair, with smaller caster wheels in the front. Wheelchairs of this design are highly maneuverable and easy to propel, and they allow freedom for tilting and wheeling pop-ups that can be learned for ascending or descending curbs (see Chapter 26). Standard designs, sometimes called depot or institutional wheelchairs (Cooper, 1998), weigh at least 50 pounds without specialized seating systems. A distinction can be made between multiuser chairs, often found in health care settings or places of public transportation (e.g., depot wheelchairs), and single-user or rehabilitation chairs, usually designated as lightweight and ultralight chairs. In recent years, sturdy lightweight metals and designs have been adapted from sport wheelchairs, resulting in lightweight and ultralightweight wheelchairs ranging from less than 25 to 40 pounds. Lightweight chairs are often used on a full-time basis. Many enable adjustable wheel positions and seat heights, which can help optimize biomechanical efficiency for the user. Along with reduced weight, these changes serve to enhance propulsion and ease transport and also may reduce strain on user's upper limbs.

Other types of manual wheelchair designs include the amputee frame for the person with loss of or severely reduced weight of the lower limbs. In this design, the rear axle is offset farther behind the seat back than is standard. This concentrates a person's weight farther in front of the rear axle, reducing the risk of the chair tipping backward. Another type of manual wheelchair, although not commonly recommended, is the indoor frame. It has large front wheels, which are used for propulsion, with smaller casters in back. This design rolls easily over door sills and rug edges, but larger barriers such as curbs are difficult to traverse; transfers may be awkward because of the forward placement of the large wheels; and access to tables and the use of lap trays can be more awkward.

In the conventional manual wheelchair, manual propulsion is typically accomplished through hand rims attached to the outside of each large wheel. The user is seated so that, with shoulders slightly extended and elbows partially flexed, each hand rests approximately at the 12 o'clock position of each hand rim. Contact with rims generally occurs between the 11 and 2 o'clock positions on

each side. Circular steel tube hand rims are common. For users who have difficulty with grip, hand rims can be covered with vinyl coating, knobs or other projections can be added as part of the rims so that grip is not required, and/or gloves or mitts can be worn for traction and to protect the hands. Hand rims vary in size. Small hand rims, often used on racing chairs, result in a slower and more difficult start but may provide for a high top speed that is sustainable with relatively little effort. For most users, the push wheel axle is in line with the fingertip of the middle finger with the arm at one's side.

Foot propulsion can also be considered as an option, particularly indoors, making seat height considerations important for foot placement on ground surfaces. This may also be a common consideration for steering and propelling with hemiparesis. Manual propulsion by a person with hemiplegia or unilateral upper limb use necessitates additional adaptations. Commonly, the person with hemiplegia uses the more capable side for the hand rim and the leg and foot to steer and provide additional propulsion and braking. This requires removal of the unused footrest and lowering the seat height or using small-diameter wheels to optimize foot contact with the floor. For the user who plans to propel the wheelchair using only one arm, a chair can be ordered with both hand rims on one side so that each wheel can be controlled independently or together. Learning to maneuver dual hand rims on the same side can be perceptually and mechanically difficult. Another option for unilateral control is the single-lever drive. This less commonly used device option uses a forward-and-backward motion to propel the chair and rotation of the lever to turn the chair.

Parking brakes are used on each large wheel and are engaged through a variable length single- or dual-action lever, depending on reach and force capabilities of the user. Such levers press on the tire to resist rolling and require that tires be fully inflated with periodic tightening after tire wear. Brakes restrict wheel turning when the chair is parked but are not typically recommended for slowing or stopping. In addition, antirotation locks also can be used on casters.

Augmentation of manual propulsion and braking systems is available. As an aid to propelling on inclines, hill climbers or grade aid devices restrict the rearward movement of wheels through a friction stop engaged by a lever on each tire. Speed control and braking to a stop simply depend on slowing wheel rotation by use of the arms or legs. New devices that augment propulsion through electrical or mechanical means can also be considered. Such devices provide supplemental power from an electric motor that amplify the user's effort (e.g., Superwheel™ and e-motion®) or give mechanical advantage through a gear system and wheel changes (e.g., HandMaster™ and Magic Wheels™). Another option for manual wheelchairs is to provide power through add-on devices (e.g., viamobil® and e-fix®). Such systems can be engaged and disengaged

to switch between manual and power mobility. Because a significant amount of weight is added to the chair and units are not easily taken on and off the frame, this option is most commonly suggested as a trial for a transition to a regular power wheelchair.

Power Mobility Devices: Motorized Wheelchairs

Power mobility devices are used by individuals (1) who cannot propel a chair using either the hands or the feet; (2) for whom the energy expenditure required to walk or propel a manual chair is contraindicated; (3) who have musculoskeletal complications, such as arthritis in upper limb joints; (4) who are prone to repetitive stress injury; and/or (5) who have neuromuscular dysfunction that may cause associated reactions in the lower extremities when the upper extremities are used for manual wheelchair propulsion. There are a number of types of power mobility devices. Selection of power mobility can be a complex task because of the variety of user needs and the many options for wheels, controls, and environmental designs.

Power Wheelchairs

Most power wheelchairs have a power-base design so that the wheels are, in effect, independent of the seating components. Such bases may have front-, middle-, or rear-wheel drive, with a variety of wheel diameters. For each type of design, the wheels may be coupled to motors through exposed or concealed chains or gear systems. Middle-wheel–drive chairs generally have a smaller turning radius, which improves maneuverability. Power-base wheelchair designs are noted for being sturdy and appropriate for the full-time user both indoors and outdoors. These designs generally allow for ease in changing seating dimensions, such as for a growing child or for an individual with changing seating system needs. Typically, the rear wheels are powered, but some designs have front wheel drive (e.g., Permobil) or, as noted, middle-wheel power (e.g., Invacare).

Several power-base chairs have options that enable the user to change seat height or elevate toward a standing position independently. Similarly, some manual wheelchairs have manual lever systems that allow the user to rise to a near standing position. These allow the person greater vertical flexibility in environmental accessibility, enabling face-to-face communication and easing performance in reaching books in a library, accessing a high counter, or reaching and operating controls. All environments of functioning should be considered as wheelchairs best for use outdoors may not work as well for indoor mobility (e.g., front wheel drive). Tilt, recline, and elevating leg-rest equipment are powered by wheelchair batteries and can be controlled by separate or integrated controls. Power seating controls enable users to sit more dynamically and can improve comfort and function (Dicianno et al., 2009).

The primary disadvantages of power wheelchairs are that (1) they can be large and heavy and may be difficult to maneuver in small spaces and transport from one place to another and (2) a 5 × 5–foot turning space, as part of standard barrier-free design, may not be sufficient for some power wheelchairs. Typically, van or bus transport of the individual sitting in a power mobility device requires special lifts or ramp devices, and the sizes of some chairs necessitate a raised roof in these vehicles. Alternatively, the user can transfer into the vehicle, and an attendant can load the chair separately by use of a lift or by breakdown into components. Some lightweight power wheelchairs are designed to be taken apart for automobile transport (e.g., the At'm Take-Along- Power Chair™). Some of these chairs are built on folding frames and/or have low-powered motors, making hill climbing and use on uneven surfaces more challenging. Assistance with taking apart and reassembling the chair often is required.

Scooter

Another popular power mobility device is the scooter. Scooters typically have three wheels, although four-wheeled designs are available, and may have either rear- or front-wheel drive. Most of these designs are characterized by tiller control, wherein the user steers the scooter by rotating the front wheel while using a lever-style switch for forward or reverse power. This type of chair is appropriate for the marginal walker and is often used to compensate for a person's inability to travel comfortably within the community. Scooters are sometimes modular and can be disassembled and loaded in and out of the trunk of a car or the back of a station wagon or van more easily. Steering and control of scooters can be difficult, so individuals with marginal control may be better served by use of a power wheelchair with a variety of control options. Scooters may also not be appropriate for individuals with significant posture control needs because special seating and other components are difficult to attach. In addition, scooters require a larger turning radius and may limit maneuverability indoors or not fit vehicle lifts and van and bus tie-down systems.

Power Mobility Considerations

Specific factors unique to power mobility require consideration. The therapist should determine whether the device will be used primarily indoors or both indoors and outdoors. A device that is to be used in both settings must have more stability, power, distance capability, and durability than an indoor-only model. User's planned operating distances, slopes, and outdoor conditions such as rain, temperature, and sunlight should be considered as part of selection and training. In addition, the therapist

should consider the use and maintenance of the batteries that provide power. Various sizes of deep-cycle lead-acid batteries and sealed cell gel types have different expense, longevity, and needs for recharging. Other power wheelchair characteristics to consider include noise, braking systems, ride quality, and portability, including ease of assembly and disassembly. If the device can be disassembled, the weight and size of each part should be carefully evaluated for transportability. Nonleaking sealed cell or gel batteries are preferred for added safety in airline transportation, with wet-cell lead-acid wheelchair batteries becoming somewhat obsolete. Such batteries require special handling as part of airline travel.

Selection of appropriate controls for driving is critical, and a graded approach to controls training is often needed. Wheelchair seating posture is key to determining the most reliable and effective motor actions for control. Programmable controls are most common and enable careful selection of torque and speed control based on wheeling surface resistance and safety. Power devices are driven using one of two types of options: proportional or discrete control. Most commonly, a proportional joystick is used, in which directions and speeds are linked to angle and magnitude of stick displacement. Proportional control also may be achieved through proximity-sensing devices that, for example, sense the position of the head. The user moves his or her head as a joystick, and the wheelchair's speed and directional control are proportional to the head displacement. Another alternative is discrete microswitch control activated with a joystick, a multiple-switch array, or a single-switch scan. Each switch activation engages a preset or programmed speed and direction. Microswitch systems require less skilled movement to achieve control, although control of the wheelchair is often less precise than that provided by proportional control. Also, learning to use microswitch control is not simple. Each direction may be controlled by activating a microswitch using a body part (i.e., hand, arm, chin, foot, head, mouth, lips, or tongue), and control may be organized through a combination of special techniques such as sip and puff, scanning, or switches imbedded in headrests (Fig. 17-7). For instance, breath may be used for forward and reverse control, and proximity-sensing switches may be used to activate turning control. When selecting controls, the therapist should consider adjustment options provided by various systems in relation to the needs of the individual. For example, clients with poor motor control may benefit from adjustment of programmable electronics that enable wheelchair speeds to be automatically restricted when turning or that enable several levels of control to be programmed for new learning and controls training in various environments.

Power wheelchairs and scooters electronically brake, meaning that drive wheels do not rotate except under power and with activation. Gears are then released by levers that allow the chair to roll freely.

Figure 17-7 College student uses a power wheelchair controlled with proximity switches in a head array. The display in front of right armrest provides feedback regarding drive selection, electronic aids to daily living (EADL) functions, and battery level. A switch on the right side of the head array permits selection of drive and EADL functions. (Courtesy of Adaptive Switch Laboratories, Inc., Spicewood, TX.)

Activity- or Environment-Specific Wheelchairs

For everyday use, attendant-propelled, manual, or power wheelchairs are selected. Many users may also need mobility to overcome unique barriers or for use in recreation and leisure activities that require activity- or location-specific technology. Special power-wheel configurations have been designed for ascending or descending stairs, although market availability for such models has been inconsistent. Other special designs for wheelchairs, including those for use at the beach and on other soft and uneven surfaces, are available commercially or may be custom made. For recreation, cycling configurations may be requested. Row cycles are large, low to the ground three-wheeled cycles propelled by a rowing action that activates chain-driven rear wheels. Cycling action also can be added to manual wheelchairs (Fig. 17-8) or be

Figure 17-8 A father uses a cycling apparatus attached to his everyday-use manual wheelchair for outdoor activity with his children.

configured as a separate chair for outdoor sport. Sport wheelchairs for racing, basketball, and other competitions are commercially available, but often they require customized sizing and expert instruction. For a thorough review of options for using activity-specific or sport and recreation chairs, see Cooper (1998) and _Paraplegia Sports 'N Spokes_ (Resources 17-1). As described later, health insurance funding for wheelchairs is most often restricted to one device purchased for up to 5 years or more of use, and so most second wheelchairs, for any purpose, are funded privately.

WHEELCHAIR SIZING AND ERGONOMIC CONSIDERATIONS

Modern wheelchairs are engineered as modular systems and are assembled to match the specific physical dimensions of the user. Measurements of the individual form the basis for determining wheelchair frame size, adjustable component parts, and other customization to meet special needs.

Sizing

Appropriate size determinations of the wheelchair frame, seat, back, leg rests, and armrests are based on measurements typically taken with the user in an optimally seated position. Alternatively, the therapist can evaluate the individual on a mat in a supine or side-lying position and take careful measurements of distances between key landmarks. These measurements are confirmed for accuracy with the user seated. The user's typical or specialized clothing needs should be considered during measurement. If thoracolumbar bracing or lower limb orthotics and prosthetics are likely to be used in the wheelchair, they should be worn during sizing measurements. Manufacturers of wheelchairs and seating systems have differing standards for measurement and sizing. Typically included are measures of pelvic or hip width; upper and lower leg lengths; midback, midscapula, and top of shoulder heights; chest and shoulder widths; elbow height; and overall sitting height (Fig. 17-9).

- Seat width: The therapist determines the widest point across the hips and thighs and may add a total of 5 cm (2 inches) for adequate clearance on the sides for clothing and positioning comfort. However, the seat width is kept as narrow as possible because overall wheelchair width is dictated by the seat-width measure. Wheelchairs should be as narrow as possible while allowing for comfort, easy repositioning, clothing needs, and transfers. For manual users, narrower wheelchairs are likely to improve ease of hand-rim propulsion and maneuverability.

- Seat depth: The therapist, for both the left and right sides, measures the distance from the most posterior part of the buttocks under the thigh to the popliteal fossa crease of each knee. About 5 cm (2 inches) is subtracted from the measure. This allows as much weight bearing through the thigh as possible without the front edge of the seat pressing into the back of the knee. Right and left leg length discrepancies can be caused by hip dislocation, pelvic rotation, or other anatomical factors. The shorter side may be used to determine seat depth, or if a greater than 1-inch discrepancy is found, the front seat edge may be offset to accommodate the length of each side. Individuals who use their feet to propel or steer will need greater front-edge seat clearance.
Figure 17-9 Seating measurements. For **B** to **G**, all measurements are taken on both right and left sides. **A.** Hip and thigh width. **B.** Thigh length. **C.** Leg length. **D.** Back height to below scapula. **E.** Back height to midscapula. **F.** Back height to top of shoulder. **G.** Elbow and forearm height. **H.** Chest width. **I.** Shoulder width. **J.** Sitting height.

Selected seat cushion height should be taken into account with further measurement of trunk, arm, and leg positioning components.

- Back height and width: The therapist generally takes three measures from the seat surface upward: (1) to the midback just under the scapula, (2) to the midscapula or axilla, and (3) to the top of the shoulder. Back height is affected by seat cushions, which should be considered in sizing decisions. Height of the chair back is based on the need for postural stability and freedom of arm movements for propulsion or other functions. For those who exclusively self-propel, a chair back height of 2–5 cm (1–2 inches) under the tip of the scapula may be preferred. For sporting activities, the optimal back height may be even lower. By contrast, for power wheelchair users, back heights to midscapula or the top of the shoulder may be necessary to allow use of postural supports for the upper trunk and the head. Chest and shoulder width should be measured in cases of deformity or to determine the space requirements for lateral trunk supports or other trunk-positioning devices. Alterations of the standard sling back may be necessary for improving trunk posture by using an adjustable or flexible sling back, curved backs, or additions of lateral trunk supports or custom-contoured backs.
- Seat height and leg rests: Seat height is based on positioning of the individual such that footrests have at least a 5-cm (2-inch) clearance from the floor. Use of seat cushions affects this measurement by raising overall seat height. Seat height is determined with the individual's knees and ankles positioned at about 90°.

Measurements are taken from under the distal thigh to the heel of the individual's commonly used footwear or shoe. Several inches of adjustment are typically available in leg rest lengths. Unusual leg lengths or hip or knee deformity may necessitate special ordering. Overall seat height may be determined and measured from the ground with considerations of needs for interactions with those who are standing, versus lower height to aid propelling, and considerations for transfer height surfaces.

- Armrest height: The therapist measures from under each elbow to the cushioned seating surface with the shoulder in neutral, the arms hanging at the sides, and the elbows flexed to 90°. Armrests must provide forearm support with neutral shoulder position but should not obstruct reach to hand rims for propulsion or to brake levers.

Common and Special Components

In addition to overall sizing and seat and back surface, the team and user should consider selection of head and neck rests, armrests, leg rests, and other options. Table 17-2 lists options for head, neck, arm, leg, and foot support. Users should consider armrest stability for performing wheelchair push-ups for pressure release. Detachable or swing-away styles may allow greater ease in sliding board and other sideways transfers and improve access to tables and desks. Guards can be used on armrests to keep clothes from coming in contact with wheels. Attachment of lap trays may require use of full-length armrests or other specialized hardware. The front rigging consists of

Table 17-2   **Head, Arm, and Leg Supports**

Component	Attachment to Frame	Adjustment	Style
Head and neck supports	Fixed or removable	Height, depth, and rotation	Flat, winged, lateral, occipital, or wedged
Armrests	Fixed, swing away, and/or removable	Same height or adjustable height	Full length or desk length, rigid or padded
Leg rests	Fixed rigid, swing away, and/or detachable	Fixed or telescoping length	Fixed angle or elevating
Calf pad and footplate	Rigid or flip up, flip away	Variable sizes in pads or straps	Plate, tubular, rigid, or padded

leg rests and footplates. Options are selected according to needs for elevation of the calf and foot, ankle position, and stabilization of the leg. Flip-down footplates or platforms are common and popular because they can reduce the overall length of the chair. Swing-away or detachable front rigging enables easy transfers, approach to tables and desks, and ease of transportability of the wheelchair in and out of vehicles.

Tires can be either pneumatic (air filled), semipneumatic (airless foam inserts), or solid-core rubber and are mounted on spoke or molded wheels. Air-filled tires are lightweight with low rolling resistance, providing a well-cushioned ride and shock-absorber function that tends to improve comfort and prolong the life of the chair, but they do require regular maintenance. Semipneumatics provide good cushioning and less maintenance, but tire wear may be more of a problem. Solid-core tires are noted for minimal maintenance and approach the weight and low rolling resistance of high-pressure pneumatic tires but without concerns for getting a flat and becoming stranded.

Casters, as either front or rear wheels, vary in diameter, and small ones better enable maneuverability. Pneumatic and semipneumatic caster tires provide some shock absorption for use outdoors and on rough surfaces. Solid-core caster tires are best for use indoors and on smooth surfaces. Special designs (e.g., Frog Legs™) for manual wheelchairs and power wheelchairs are promoted for shock absorption and enhanced maneuverability.

Seat belts, safety vests, and harnesses vary in design and are used for both safety and positioning. These devices should be considered for individuals who have severe neuromuscular impairments and need control for posture and safety. Restraints may be considered with individuals who have poor judgment but should be avoided whenever possible and be regarded separately from seating postural needs. Restraint reduction efforts in long-term care facilities may be enhanced by use of appropriate and comfortable seating, and because there are risks associated with wheelchair seating restraints, planning for client's control of releasing belts and straps should be considered (Chaves et al., 2007).

Frame and upholstery color and material options are numerous. Users can personalize their chair through selections of colors and other styling. Durability, cleaning, ease of repair, and compatibility of materials with temperature regulation, friction, moisture, and skin protection requires careful planning. Trial use of the wheelchair seat and back may be suggested with special consideration for surface stability and handling of moisture and heat.

Other special considerations are specific to different wheelchair mobility bases. On most manual wheelchairs, placement of the rear axles can be fixed or adjustable, especially with newer manual lightweight and ultralight styles. Backward placement of the axle tends to increase stability; by contrast, forward placement of the axle decreases stability but increases maneuverability and shortens turning radius. Sometimes rear wheels have a camber adjustment. This orients the hand rim for easier propulsion and slightly widens the wheel base for better stability. Although users often prefer a 6° camber, such configurations do not appear to impact ease of propulsion or handling (Perdios, Sawatzky, & Sheel, 2007). Antitipping extensions can be used on a wheelchair to prevent the chair from tipping backward or forward. Typically used on the back, these fixed or adjustable extensions can improve safety, particularly during mobility training.

Recline and tilt-in-space options, considered with attendant-propelled and power mobility, enable postural changes for rest and pressure relief. In attendant-propelled wheelchairs, semireclining up to 30° from upright or full reclining up to 90° from upright can be considered. In tilt-in-space systems, the seat and back assembly pivot together. This feature makes the use of postural seating components more stable because the angle between the seat and the back remains unchanged, reducing or eliminating the problem of shear. Power recline systems can be used with conventional or power-base designs. Such systems may involve tilt-in-space and/or low-shear back recline, both of which can be used to provide pressure relief and rest positioning. Tilt-in-space chairs that go back 45°–60° can achieve effective pressure relief

under the buttock and thigh and may have other benefits such as improved breathing These systems, however, add to costs and increase wheelchair size and weight.

Other considerations are accessories that optimize use and performance. Lap trays can be used for postural support of the upper limbs and serve a variety of purposes related to function. Other accessories include mounting bags or baskets for storage and carrying, cup or bottle holders for taking fluids, and storage attachments for a reacher or walking aids to enhance access and mobility. Communication devices or electronic aids to daily living may be mounted on the wheelchair and operated independently of wheelchair controls or can be integrated with power wheelchair controllers. Other medical equipment such as ventilators, oxygen tanks, or other devices need to mount within the wheelchair mobility system.

MOBILITY TRAINING

Mobility training with the wheelchair system can be essential and often involves interdisciplinary team members, such as the physical therapist. Most users benefit from instruction and practice beyond the training provided by vendors. Once the chair has been provided, a check should be conducted, and appropriate training of the user and attendants should commence. This includes review of the user's goals for mobility along with a check of the device for fit and adjustment. Instruction also should be provided regarding (1) use of the chair indoors and outdoors and on a variety of surfaces (e.g., level, carpeted, incline, and uneven), (2) transfers (e.g., bed, toilet, and car), (3) transport of the wheelchair (e.g., cars, trucks, vans, and buses), and (4) maintenance of the wheelchair (e.g., cleaning the chair, lubricating moving parts, monitoring tire pressure and wear, adjusting brakes, and caring for batteries). Troubleshooting with the wheelchair system ultimately becomes the responsibility of the user and equipment supplier or vendor, but the therapist may advise about problem-solving strategies and organization of maintenance routines and schedules. Throughout training, the therapist emphasizes safety issues because accidents during day-to-day wheelchair use do occur and are preventable (Chen et al., 2011).

For more than a decade, functional skill evaluation with wheelchair use has received increasing attention (Kikens et al., 2003). Manual wheelchair skills assessment (Fliess-Douer et al., 2010; Mortenson, Miller, & Auger, 2008) has received the greatest attention, and overall, increasing emphasis is also being placed on participation (Kikens et al., 2005).

Manual wheelchair users can benefit from instruction about propelling, braking, and transport. Hand placement and trunk lean for effective and efficient wheeling can be explored. General consumer use guidelines are available for the user and trainer (Axelson et al., 1998). Power wheelchair users also need guidance about power functions, such as controllers, batteries, and accessory devices. With all wheelchair users, the therapist should provide initial checks; periodic follow-up to address safety issues, fit, and adjustment; and updated information about new options to meet the changing needs of the user.

Transportability of the wheelchair system between environments can be especially challenging. Loading and unloading should be trialed with the vehicle most likely to be used. As noted, car transfers of the user and loading and unloading of the wheelchair need careful planning. Breakdown of the wheelchair for portability or the addition of special lift accessories to vehicles should be considered during selection. The weight of the wheelchair and its component parts may be limiting to users as well as care providers who assist with vehicle transfers. Lifts are often used with vans or buses. In these vehicles, wheelchair tie-downs are necessary as safety mechanisms to keep chairs stabilized when traveling. The style needed is determined by wheelchair design. Such devices secure the wheelchair to the base of the vehicle; the individual is independently secured in the wheelchair seat or in another seating device within the vehicle.

WHEELED MOBILITY AND PARTICIPATION

As part of the wheelchair selection process, the impact of devices on the users' roles and participation needs to be considered relative to home, work, and community contexts. User roles and social interactions have implications for positioning, speed of mobility, and ease of access within and between settings. For example, wheeling may necessitate using different routes of travel to gain access, and this may detract from user's or other's feelings of inclusion. Slow mobility speed may hinder shopping trips within and between stores or with movements at work. Armrest or other features of the wheelchair may preclude positioning with peers at dinner or meeting room tables. Professional rating tools that address needs (Miller et al., 2004) and consumer rating tools that address satisfaction with wheeled mobility devices are being proposed and address issues and interactions among the person, the technology, and the environment (Mills et al., 2002).

Greater success in matching devices with environments of participation is needed. Although wheelchair mobility can lead to successful independence, challenges continue regarding integration of wheelchair users in various settings. For example, data on disability and workplace accommodation (http://www.infouse.com/disabilitydata/workdisability/2_1.php) reveal that less than 25% of wheelchair users are employed. Studies involving wheelchair users often indicate that obstacles created by use of wheeled mobility devices are seen as a major reason for lack of community participation and as a source

of frustration (Chaves et al., 2004; Hoenig et al., 2003). Nevertheless, use of wheelchairs, and powered mobility devices in particular, is often credited with enhancing occupational performance and participation (Buning, Angelo, & Schmeler, 2001; Davies, DeSouza, & Frank, 2003). Although the built environment is a major reason for obstacles, attention also should be given to associated factors, such as wheelchair user fitness and health, use of assistants and other assistive technologies, social interactions in the community, and the natural environment's weather conditions.

FINAL DETERMINATION

In making a final determination regarding seating components, style, size, and control systems, the user and team take a comprehensive and functional view, simultaneously considering the current and future needs, desires, and resources of the user; environments of participation; and anticipated changes in technology. This can certainly be a challenge in matching a client's current needs with a wheelchair mobility system, as well as forecasting future needs in the weeks and months and years ahead in terms of independence, participation, and well-being.

Decision Making and Justification

Costs and related funding issues are critical components of the decision-making process. Expensive technology and options should not be ordered unless justifiable for increased function, health, user satisfaction, or safety. When expensive choices are being considered, it is important to rule out the feasibility of using less costly alternatives. For example, before selecting power mobility, it is important to rule out the feasibility of using a manual chair because the cost of providing and maintaining a powered system may be much more costly than getting and using a manual system. In such cases, appropriate justification must be clearly delineated for users and third-party payers. Some users decide to purchase devices or features on their own or seek funding through other sources when the feature is denied by the third-party payer.

A comprehensive functional mobility system for an individual often includes more than one means of mobility and selective use in different environments (Hoenig et al., 2002). For example, an individual may use limited walking skills within some settings (e.g., walking from the kitchen table to the refrigerator), benefit from a manual chair for traveling longer distances within indoor environments (e.g., moving from room to room within the home), and use a power chair for traveling longer distances in the community and at school or work. Funding sources will typically pay for only one of these options, but with mobility being unique to different activities, negotiation of options may be explored with health insurance providers as well as educational and vocational support programs. In many cases, the expected term of use for a wheelchair by medical insurance funding policies is 5 years, although expected uses and benefits for that period of time may be difficult to predict. Private pay for assistive technology, including wheelchairs, is common (Carlson & Ehrlich, 2006).

The Clinician's Responsibilities

Therapists have a responsibility to keep abreast of new technology, new products, and new product evaluation research. They must be able to provide users with appropriate and updated information on the advantages and disadvantages of wheelchair options and components. In addition, they must have current knowledge of issues related to availability, serviceability, and performance of various wheelchairs and options. Professional and consumer sources of information about wheelchairs, related options, and manufacturers of mobility systems, controls, and seating systems are useful for product information (see Resources 17-1). Therapists also are encouraged to explore wheelchair standards developed by the ANSI, the RESNA, and the International Standards Organization (http://www.wheelchairstandards.pitt.edu/). These voluntary standards for wheelchair developers and manufacturers provide guidelines for product specifications based on uniform measurements and testing. Use of these standards facilitates product comparisons. In addition to being aware of wheelchair standards, the therapist also is responsible, along with the interdisciplinary team, for developing relationships with appropriate vendors of seating and wheelchair systems in order to make trial equipment available.

Wheelchairs, selected through a user-led team, can facilitate participation in multiple environments. Selection of an appropriate wheelchair system results from a clinical reasoning process that considers multiple variables, particularly best fit, function, and the user's preferences. Consumers' satisfaction with seating and mobility systems can be incorporated in critical program evaluations that address outcomes. Ragnarsson (1990) stated, "Ultimately, the most important factor in the success of a wheelchair prescription is the user's total level of acceptance and satisfaction with [the] chair as it combines looks, comfort, and function" (p. 8).

case example
Ms. Lisa: Wheelchair Selection for a Student Who Has Tetraplegia

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information	Appreciate the context	See Chapter 38 for a review of SCI rehabilitation.
Lisa is a 17-year-old high school senior with C7-level tetraplegia from a traumatic spinal cord injury (SCI) that she experienced in an automobile crash. She is expected to be a long-term wheelchair user. In the hospital, she demonstrates the ability to propel a manual ultralight wheelchair using coated push rims. Lisa previously was active in soccer and other sports and would like to match her school colors with her wheelchair frame. She was intrigued to learn about competitive wheelchair sports but is inexperienced with independent mobility.	Develop intervention hypotheses	"Lisa may not endorse her need for long-term use of a wheelchair but may agree to the interim reality and specific wheelchair choices related to return to home and school."
	Consider the evidence	"My recommendations to Lisa are based on prior experiences with this level of SCI and supported by literature regarding manual versus power mobility uses with SCI (Hastings et al., 2011) and skills obtained with manual wheelchair uses (Lemay et al., 2012)."
		"Ultralight wheelchair styles have good longevity and can be customized in various ways for her size and needs. A vendor and options for wheelchair choices from such a vendor should be introduced to Lisa and her family."
	Select an intervention approach	"A rehabilitative approach matches her adaptive capacities and skills with training for use of appropriate assistive technology, environmental accommodations, and care providers."
	Reflect on competence	"My own knowledge of wheelchair needs is strong, but my awareness of currently available products will be augmented through the vendor and product representatives. Accessibility needs at home, in school, and in the community will need to be explored specifically for Lisa and her support network."
Recommendations	Consider the patient's appraisal of performance	"Lisa may regard the wheelchair as a short-term versus a long-term strategy but seems interested in resuming independent mobility, as seen in her use of a loaner wheelchair. Helping her learn about customization of size, cushioning, colors, and other features may encourage her use of the wheelchair."
The care team is preparing a wheelchair prescription and considering these features:		
Wheelchair	Consider what will occur in therapy, how often, and for how long	"Her new wheelchair may not be available until after inpatient hospital discharge."
• Manual ultralight cross-brace folding frame		
• Purple frame with black upholstery		
• Adjustable axle position with camber control		
• Lift-off desk-length tubular armrests	Ascertain the patient's endorsement of plan	"Options to review with her for selection of chair include frame type, cushioning, arm and leg rest features, frame and upholstery color, and a variety of hand rim and brake features."
• Swing-away fixed-angle foot rests with heel loops on flip-up footplates		
• Vinyl-coated push rims with pneumatic tires and nonpneumatic front casters		
• Grade aids and standard rubber-coated brake levers		"Gel cushion is encouraged for sitting balance and pressure relief. Air cushions demonstrated good pressure relief but can impair sitting balance and necessitates tending to air pressure. Foam or silicone cushions have less even pressure distribution but are lighter weight and do not need regular maintenance. Gel has the precaution of cooling/freezing with low outdoor temperature and could puncture and leak."
Seating		
• Cloth-covered Jay seat cushion with flexible sling back, midscapular height		
• Seat belt and chest strap		

Summary of Short-Term Goals and Progress

A loaner rehabilitation wheelchair has been provided to Lisa, and she makes use of this self-propelled device to go to and from therapy and other appointments. When she is with visitors, she is often pushed to other locations on the hospital campus.

Sitting tolerance times have been increasing daily with skin inspection performed by Lisa with nursing or therapy supervision and guidance. Sitting tolerance and travel distances are being staggered and staged to increase time and range of mobility. By discharge, up to 6 hours of wheelchair time is expected before bed rest relief. Indoor mobility independence is expected, including use of doorways and elevators. Outdoor mobility is supervised initially to assure safety with ramps, curb cuts, and cross-slopes.

Wheelchair-to-bed transfer training is proceeding with use of a lightweight sliding board and standby supervision for safety. Toilet and tub transfer skills are being introduced, and she currently receives moderate assistance. Independence in wheelchair transfers is expected with standby supervision anticipated.

Assess the patient's and family's comprehension	"Trial use of a loaner wheelchair has Lisa experiencing transfers, self-propulsion, and environmental access on hospital grounds. She is taking responsibility to go to and from therapy sessions but is seen being pushed by family and friends at other times."
Compare actual to expected performance	"Staging of wheelchair sitting time is scheduled, and Lisa seems willing to observe this precaution and is accepting of reminders to attempt pressure relief routines. She does not appear to attend to time of day on a regular basis, so she will likely need an external cue of some sort."
Know the person	"Lisa monitors her progress carefully in both occupational and physical therapy with high hopes of regaining strength. Nevertheless, she also is aware of her functional mobility and capacity to self-propel and transfer."
Appreciate the context	"Self-initiated goals for functional mobility in and around the hospital campus are being suggested by her. These are being encouraged with use of appropriate standby supervision."

Next Steps

Lisa will be using the wheelchair full-time at home, at school, and in other community locations. Her own wheelchair is being ordered and will be available at discharge or soon after her return home. Accessibility at home and school need to be assessed with Lisa and her family.

Loading her wheelchair into a personal vehicle as well as public transportation need to be considered. Driver retraining with adaptive hand controls also is being explored.

Anticipate present and future patient concerns	"Lisa has become aware and has concerns about accessibility at home and school, where stairs are an issue to enter and move between levels."
Analyze patient's comprehension	"An accessibility audit of home and school through interview will be conducted, and a home visit with Lisa and family members is anticipated before inpatient discharge. School access may be appraised in conjunction with the school therapist."
	"Lisa continues to hope that she will again be able to walk, but as weeks progress, she has focused increasingly on her wheelchair skills."
Determine what referrals may be needed to appropriate community-based services for advice regarding community mobility and driving	"Referral to and follow-along in community-based therapy or outpatient visits to the SCI program are anticipated. Goals will be safe mobility; community transportation; and full participation in school, work, and community settings. Consideration for airline travel and sports participation might be anticipated in coming years."

Clinical Reasoning in Occupational Therapy Practice

Wheelchair Selection with a Student Who Has Tetraplegia

What else should be considered related to wheelchair selection and mobility training with Lisa? Consider uses of wheelchair accessories, capacity to carry items, performance in transfers, transportation with the wheelchair, and maintenance of the wheelchair. Under what circumstances might power mobility be considered?

case example
Mr. R.: Dependent Mobility with Amyotrophic Lateral Sclerosis

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information	Appreciate the context	See related assessment and intervention in Chapter 35 regarding adults with neurodegenerative disorders.
Mr. R. is a 48-year-old husband and father with amyotrophic lateral sclerosis (ALS). He is near the end of his ability to walk safely and has quit driving a car. He teaches in a public school and expects to retire at the end of the month. He coaches his children's youth baseball teams. He lacks sufficient strength in his arms to self-propel a wheelchair. To address his needs now for mobility at home, at work, and in the community, a prescription for a wheelchair is being written. Family financial resources are limited.	Consider the evidence	"Power wheelchair prescriptions for those with ALS appear to address needs (Ward et al., 2010), yet a full spectrum of equipment and devices is likely needed in the latter half of this disease process (Bromberg et al., 2010)."
		"Mr. R.'s walking difficulty combined with upper limb weakness will necessitate power wheelchair mobility and/or dependent wheelchair use. Use of power mobility in homes is problematic for maneuverability and will likely necessitate a dependent wheelchair for function and care."
		"Medicare funding would address wheeled mobility for at-home use and perhaps transportation to and from medical appointments. Other community mobility needs should be addressed separately."
	Select an intervention approach	"A rehabilitative approach will attempt to match devices and environments with abilities to address Mr. R.'s family goals. Wheelchair use will take place along with uses of other assistive devices and environmental accommodations planned for home."
	Reflect on competence	"As a therapist, I am familiar with dependent mobility devices and need to carefully match size and adjustment options for the client's home environment. Loaner equipment or used devices are sometimes preferred for cost savings. The ALS Association or other assistive technology recycling programs could be explored."
Recommendations	Consider the patient's appraisal of performance	"Mr. R. is knowledgeable about his condition but is reluctant to give up walking. Presenting the wheelchair as an option rather than an exclusive device for mobility might be best."
To address needs within the home, an attendant-propelled wheelchair is needed. A tilt-in-space manual chair that permits full upright position to 45° recline is selected, along with a foam seat cushion and flexible sling back with a winged headrest. A lap tray is added to enable positioning of the arms and for attachment of communication devices. This chair is requested through health insurance, and once Mr. R. is unable to walk safely, it will be used at home and for attending medical appointments. Community mobility may be served by this device, but other options will need to be explored as well.	Consider what will occur in therapy, how often, and for how long	"Selecting, fitting, and brief training are specifically needed with the wheelchair device. Operation of brakes, recline mechanism, and other features should be reviewed with Mr. R. and his care providers."
	Ascertain the patient's endorsement of plan	"Mr. R. is in agreement but views the wheelchair as being a further indicator of his decline."

Summary of Short-Term Goals and Progress

Mr. R. needs consumer education about wheelchair products and options that he could use. Funding mechanisms need careful review in terms of requirements, dollar allowances, and costs of options.

Client and family training in use of the wheelchair is a service goal, with Mr. R. having informed options about wheelchair use and the family being educated about community mobility with wheeled mobility devices.

Assess the patient's comprehension	"Mr. R. recognizes his mobility needs and is aware of and concerned about costs and access within his home, such as installation of ramps and widening of doorways."
Understand what the patient is doing	"Adjustable cushioning for comfort and function should be devised. Foam cushions are likely the most cost-effective and flexible option, both for seating and transport. He will likely adjust his position easily on his own at first. With more static seating later on, air cushioning could be considered. This will then necessitate adjustment and tending of the cushion relative to air pressure. Gel cushions could be considered, but they are heavy and may make Mr. R.'s own adjustment of his position more challenging."
Appreciate the context	"Resting and functional settings at home are likely to include his bed, wheelchair, and another chair or couch location. Transfer training with family care providers should take place soon."

Next Steps

Mr. R. obtains and uses the mobility devices, which appear to meet his present needs. Occupational therapy is put on hold, with plans for reassessment in 6 weeks.

Anticipate present and future patient concerns	"Monitoring of wheelchair operation and use, along with other assistive devices, should occur as part of outpatient follow-up, perhaps every 6 weeks depending on the speed of Mr. R.'s decline. Coordination with home-health or hospice care also may be considered."
Decide if patient should continue or discontinue therapy and/ or return in the future	

Clinical Reasoning in Occupational Therapy Practice

Selection of Other Mobility Options

Mr. R. and his family also recognize his need for functional mobility outside the home. His extended family are discussing pooling resources to purchase another mobility device he can use outdoors for coaching baseball, shopping, and other activities. Given the progressive decline expected with ALS, what might you suggest in terms of powered mobility? What kind of comprehensive mobility system would you recommend, and why, if financial resources were not an issue?

Summary Review Questions

1. Who should participate in the wheelchair selection process?
2. What are the three basic types of wheelchairs, and why would each be selected?
3. What factors should be taken into consideration in wheelchair selection and use by adults and older adults?
4. Describe a situation in which the optimal decision for an individual might involve the selection of more than one mobility device.
5. What are the six broad goals of wheelchair seating and positioning?
6. In determining wheelchair and related seating system sizes for a particular individual, what measurements typically are taken?

7. Contrast the benefits and limitations of various manual and power mobility frame types.
8. Name and describe two types of controls for power mobility devices. Which would be preferable for a person with cerebral palsy and extremely poor upper extremity control? Why?
9. How can an occupational therapist keep abreast of new product development and research related to these products?
10. How can the occupational therapist facilitate the client's participation in wheelchair selection?

Glossary

Angle in space—Angle of the seat back in relation to the true vertical when the seat and back are rotated counterclockwise as a unit. Sometimes called tilt-in-space or orientation, this position may be altered for postural control.

Camber—The amount of angle on the wheels, creating flare-out at the bottom. A 6° camber is recommended for push-rim convenience and wheelchair width.

Locking lever–secured—A locking mechanism on the frame that holds folding frame parts in place for smoother ride with less frame migration and reduced wheel and caster flutter.

Pelvic rotation—Asymmetrical position of the pelvis with forward position of one side, typically because of low back rotation, muscle asymmetry, or spinal deformity.

Proximity-sensing devices—Devices or systems that remotely sense the position of a body part (e.g., head) and use that position to control the wheelchair without

physical contact between the part of the body used for control and the switch.

Scanning—Control option that presents choices one at a time, grouped or singly, until the desired choice is offered for the user to select by switch activation.

Seat-back angle—The angle of the seat surface relative to the back surface. This angle is typically 90°–100°. Backrest angles and seat-plane angles may be designated separately.

Sip and puff—A system typically involving a dual-action switch, in which one action is controlled by the user sipping on a tube held in the mouth and the second action is controlled by puffing on the same tube. (In wheelchair operation, the chair functions can be controlled by patterns of switch closures.)

Third-party payer—Individual or organization (i.e., insurance company) other than the person receiving services that pays for services or equipment.

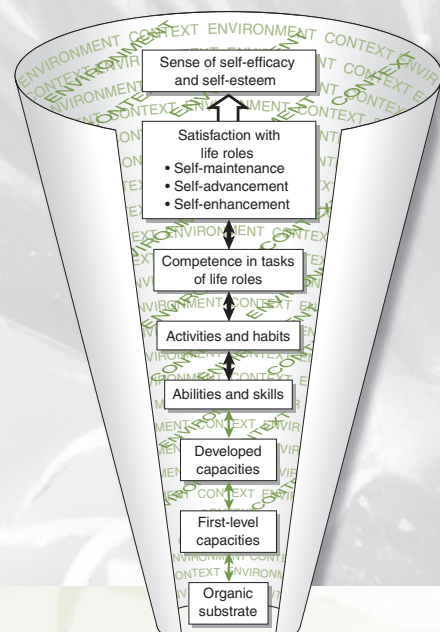
Technology for Remediation and Compensation of Disability

Mary Ellen Buning

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Apply occupational therapy concepts and skills for evaluation, planning, and treatment to the process of incorporating digital technologies for treatment-as-means for remediation and treatment-as-end as compensation for impaired or missing body structures and functions.
2. Understand the interdisciplinary nature of assistive technology (AT) assessment and treatment, the roles of other professionals, and the unique contribution of occupational therapy to the process.
3. Use knowledge of unimpaired abilities and features of digital technologies to determine the required features of a user interface and to optimize settings and use of digital devices to accomplish therapeutic goals.
4. Recognize clients who should be referred to AT experts.
5. Define primary categories of AT and give examples of AT use to support occupational functioning.


Occupational therapists use assistive technology (AT) to remediate and/or compensate for disability. Descriptions of assistive devices and various adaptations are given throughout this text. This chapter focuses on digital technology. Computerized technology is a central reality in society today because it underlies most of the tasks of modern life and increasingly influences human communication and transactions. Computer technologies are rapidly changing societal patterns around the world. In the developed world, it is difficult to find a school setting or a job that does not incorporate computer-based technology. Microprocessor technology underlies so many aspects of life today that it is almost impossible to think of a way that it does not affect human occupations. It is found in home appliances, shopping, banking, learning and acquiring information, transportation, and all types of business and commerce. People now carry Wi-Fi–enabled smartphones that have features far beyond those found in expensive computers 5 years ago (Mack, 2011).

In many ways, technology has significant advantages for an individual with a disability. In addition to managing many of the tasks of daily life, technology has the additional capacity to support compensation. AT brings an array of options for alternate access in addition to new technologies that increase capacity and enable occupations in new ways. The rapidly increasing availability and creativity of consumer technology is expanding the application of AT by occupational therapists beyond adaptation for disability. Occupational therapists use this technology to remediate impairment, prevent disability, and maintain health.

THE ORIGINS OF TECHNOLOGY IN OCCUPATIONAL THERAPY

OT as a profession has been using technology as a treatment modality since its earliest days. Wikipedia (2011) describes technology as making, using, and knowing about tools, machines, techniques, crafts, systems or methods of organization in order to solve a problem or perform a specific function. Further, humans have always used technology to control and adapt to their natural environments. Early therapists used technology to adapt looms, build bicycle jigsaws, and teach leather crafts to develop eye–hand coordination. Using technology, they facilitated emotional expression and improved problem solving and sequential task behavior. These outcomes can occur with digital technologies.

Today's technologies include microprocessors and sensors that increasingly influence employment, education, human interactions, and all types of instrumental activities of daily living (IADL). These technologies enable human capacity in ways that range from instant access to information and communication to real-time feedback on movement trajectory, speed, and accuracy. This capacity can support group interaction in virtual or simulated environments and motivate users to stay engaged as they repeat and refine their movements. This ability to generate multisensory environments can be used to customize therapeutic amounts of visual, auditory, kinesthetic, and proprioceptive input while challenging a patient to learn new skills in an emotionally stimulating activity. These digital interventions demand that occupational therapists use and be comfortable with microprocessor-based or digital technologies. Such occupational therapists will then learn to apply activity analysis and treatment planning skills combined with critical thinking and creativity to successfully incorporate digital technologies into therapy. When knowledge of technology and media tools are combined with knowledge of a patient's pretreatment occupations and interests, therapists will easily bring digital technologies into occupational therapy practice.

OVERVIEW OF THIS CHAPTER

Several challenges arose in attempting to organize the content of this chapter. Some occupational therapists have been intrigued by the potential of technology and quickly embraced it as a modality for treatment and remediation. This is a key characteristic of the diffusion of innovations (Rogers, 2003). Innovators incorporated digital technologies into their practice because they recognized its potential for motivating patients with fun, "just right" challenges and the ability to provide knowledge of results. Now that evidence of positive outcomes is appearing in the literature (see Evidence Table 18-1 for examples), other early adopters who are comfortable with technology will adopt it and lead more therapists to acknowledge its usefulness.

For this reason, it seems important to create some common language and categories and provide some organizing concepts that will help to guide increased interest and usage of technology for remediation. Because this topic will be emerging as you read this chapter and begin to practice, it is also important to offer suggestions for staying current with developments.

TECHNOLOGY AS A TOOL FOR REMEDIATION: OCCUPATION-AS-MEANS

The core occupational therapy treatment skills (evaluation, goal-setting, selecting activities based on task analysis to help a patient achieve a treatment goal, and evaluating the outcome) will also guide therapists as they incorporate digital devices into occupational therapy treatment. Therapists have quickly recognized the potential of home entertainment devices such as Nintendo's Wii®, Sony's PlayStation®, and Microsoft's Xbox 360 with Kinect® as treatment activities. Using activity analysis to recognize

Evidence Table 18-1	Best Evidence for Occupational Therapy Practice Using Technology for Remediation and Compensation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Remediation: Robot-assisted (RA) upper limb therapy following CVA in acute rehabilitation settings	Mirror Image Movement Enabler (MIME) robot combines bimanual movements with unilateral passive, active-assisted, and resisted movements of hemiparetic upper limb. Both RA groups could see their limbs, used physical objects, and did goal-directed tasks. Control received conventional therapy to improve the paretic upper limb plus 5 minutes of exposure to the robot without forces applied. FMA (for randomization) plus FIM™, WMFT, Motor Power, and Ashworth at intake, completion, and at 6-month follow-up	Fifty-four subjects at three VA Medical Center sites randomized to three groups: low dose, high dose, and control. Acute ischemic CVA with some upper extremity sensory or motor recovery. Exclusion: joint pain on movement, no proprioception, scored <22 Mini Mental Status Exam, and other comorbidities that preclude exercise. First, stratified by FMA score into high, medium, and low impairment and then randomized to high- or low-dose RA or conventional therapy.	All three groups got 5 minutes of preparatory and terminal (undescribed) therapy. Low-dose therapy. Low-dose group = 8.6 hours; high-dose group = 15.8 hours of RA therapy. Control group = 9.4 hours of conventional therapy.	Randomized, controlled, multisite study; Level: IC2b	Yes. RA training is equal to or better than conventional therapy. RA can increase intensity and dose at lower cost.	Randomization created equivalent groups. Analysis of covariance (ANCOVA) used to control for scores, age, and chronicity. Robot high-dose group improved significantly more than control ($p = 0.04$) on FIM™. No group differences in any other outcome measure. Dose of RA therapy positively correlated with gains in FMA ($r = 0.34$, $p = 0.04$), possibly because of intensity (intensity and FMA: $r = 0.45$, $p = 0.005$).	Burgar et al. (2011)
Compensation: Use of automatic speech recognition (ASR) as a means of computer access	Collected performance data via interview and task measures from experienced ASR users on (1) computer use, (2) type of ASR, (3) reasons for ASR use, and (4) measures of performance on six ASR tasks (e.g., file management, transcription rate, etc.). For 18 users who had a choice: comparison between ASR and alternative method.	Twenty-four users of ASR with >6 months experience; 5 participants could use ASR only, and 19 used ASR plus keyboard.	Exploration of the ASR experience for variety of experienced users. Results varied widely because of (1) limitations of the technology and (2) limitations in user's ability to maximize effective use of ASR.	One group, descriptive statistics; Level: VC3a	Of participants with choice, 48% used ASR for ≤25% of computer tasks, and 37% used ASR for >50% of computer tasks; 63% reported overall satisfaction with ASR. Text entry rate ranged from 3 to 32 words per minute with accuracy of 72%–94%. Best users had best correction strategies. Typists with speed >15 words per minute got less benefit from ASR.	Those with higher recognition accuracy had higher satisfaction scores, $p = 0.027$. For non-text-entry tasks, ASR plus keyboard was 61% slower, $p < 0.05$. For study participants, more agreed with (1) can enter text more quickly with ASR than with any other method, (2) ASR is easy to use, and (3) I can enter text more accurately ($p < 0.05$).	Koester (2004)

Conventional therapy included soft tissue mobilization, joint mobilization, use of reeducation strategies, isolated progressive resistive exercises, and progression to functional activities of daily living (ADL).
CVA, cerebrovascular accident; FMA, Fugl-Meyer Assessment; FIM™, Functional Independence Measure; MMSE, Mini-Mental State Exam; WMFT, Wolf Motor Function Test.

task characteristics, they use these technologies to motivate patients for purposeful movement within interesting and satisfying goal-directed activities that allow self-challenge and tracking of progress. Clients are drawn to the novelty of these forms of digital play and are motivated to interact with technology to restore function and maintain health.

All indicators point toward even greater use of technology within the realm of occupation-as-means (i.e., use of Wii® bowling to develop tolerance for standing and simple balance and progressing to adding dynamic balance paired with the need for eye–hand coordination). Additionally, quantitative data gathering is within the capability of a digital device to measure frequency, accuracy, and duration. Robotic arm devices such as the Rice Robot (Fig. 18-1) sense increasing strength and accuracy and escalate the task demands for range or complexity to further challenge developing strength and coordination. Even digital media such as video cameras in cell phones and the face-to-face communication enabled on tablets and laptops make it easier to document progress, substantiate the need for a device, or provide a remote home accessibility consultation.

Digital devices even find a role in wellness or prevention. With GameWheel®, a computerized arm ergometer attached to a video game, hand-cycling motion on a pivoting base translates into racecar control. Faster cycling speeds one's car, and pivoting the crank arm in the frontal plane translates into right and left steering motions. Soon, the user is absorbed in cycling to avoid other cars or barricades on the track as he engages in bilaterally integrated activity and gets a moderate aerobic workout (O'Connor et al., 2000).

With this new domain for applying task and activity analysis skills, occupational therapists can help with the selection of entertainment platforms based on the types of user controls offered by particular platforms. These

Figure 18-1 The Rice Robot, a fully articulated exoskeleton for spinal cord injury (SCI) rehabilitation, mimics upper extremity joints from shoulder to hand. (Courtesy of the Mechatronics and Haptic Interfaces Lab, Department of Mechanical Engineering & Materials Science, Rice University, Houston, TX.)

same skills may even enable occupational therapists to collaborate on the design of games and activities or on improved or customizable user interfaces. The next generation of activities and games could help improve carryover of skills performed with digital devices into the actual performance of activities of daily living (ADL) in the real world. Occupational therapists who are comfortable with technology will be ready to use it in their practice both as a means and as an end—both to treat and support recovery and as a compensation to enable return to performance of the activities that comprise valued roles. The next section of this chapter focuses on use of computerized technology for remediation (technology as means).

Early Visions of Technology for Remediation

Older therapists can visualize their first exposure to virtual reality (VR) innovations. Humans, strangely outfitted with goggles or helmets and special gloves, worked in special settings or immersive environments in which they felt like they were actually opening doors or trekking on a challenging pathway. This technology of the mid-1990s motivated some rehabilitation researchers to actually conduct trials to determine whether VR environments could be used to create situations that were dynamic and interactive and provided opportunities for challenge to motor and sensory systems (Sveistrup et al., 2003). In their study, using a new commercially available rehabilitation product with 14 individuals with traumatic brain injury (TBI), Sveistrup and colleagues (2003) demonstrated that those who used VR had greater improvement in functional balance and mobility than the conventional exercise or control groups. These researchers even wondered whether someday VR might provide a tool for rehabilitation at a distant location or a motivating tool for maintaining the gains of rehabilitation (Sveistrup et al., 2003). This research article actually discusses many of the positives that therapists using technology for treatment today consider as advantages for this approach, which are discussed next.

Ability to Control the Level of Stimulus

VR can offer characteristics of good therapeutic intervention: repeated opportunities for tasks using multiple sensory modalities (vision, touch, and manipulation or haptics, proprioception, and audition) with a focus on function (Sveistrup, 2004). Because parameters can be set ahead of time, therapy can be provided within a context that provides just the right challenge and stimulus to support recovery of performance skills. Therapeutic activities need to be engaging and rewarding at the same time that they require patients to repeatedly move weak limbs or increase ranges of motion or strength. Novel, multisensory environments are adept at this. Therapists and users benefit from the ability to grade challenge and document the outcome of intervention in various scenarios.

Control of the Environment

Digital or virtual environments can simulate a functional or realistic context while presenting a purposeful task or goal. For example, walking on a treadmill can increase endurance—a reasonable goal in therapy—but the activity could be more realistic and motivating if it were set to simulate walking a sidewalk to the corner store to get eggs and milk for breakfast. Meanwhile, the client is not actually dealing with weather, outdoor temperature, or risk of falls on uneven sidewalks. Activities in VR can be repeated and additional components or interactions added to increase the level of challenge or complexity as endurance and problem-solving skills develop.

Environments and activities that exist in VR allow a therapy team to preplan and modify treatment activities in interesting ways to maintain motivation. Solo activities can become group activities. The visual interface can range from a desktop monitor to a head-mounted display that creates a 180° sense of actually being in the middle of an environment. Gloves and controllers can provide a haptic interface that allows users to interact with virtual objects in real time. Opportunities for object manipulation and movable platforms challenge body movement in variable degrees that are perceived as real-world situations.

Fine Motor and Eye–Hand Coordination

A key feature of all VR applications is purposeful interaction within the surroundings. Virtual environments not only use spaces and surfaces to challenge a user's balance responses and coordination but also to interact with virtual objects within that space. This can occur when the user sees a representation of her hand that is linked to her own movement pattern as she reaches for and touches objects or even as she watches her movements as if she were a third person observing her body in action.

Repetition with a Level of Novelty

Technology-based interventions do not fatigue! They can vary tasks within parameters or at the direction of the therapist. Reaching into a cabinet to put away dishes is a common activity that changes in important ways when the dish is a cup versus a plate or whether the dish goes on a high or low shelf. In the natural environment, opportunity to practice this movement is limited by cabinet space, but in a virtual environment, the cabinet can always accept more dishes. Playing Wii® tennis offers opportunities for repetition of variable responses because the path and speed of the oncoming ball are different with each play, similar to the variation that is an important characteristic of similar activities in natural environments.

Data Collection

Digital technologies because of their very nature require precise settings, require specific amounts of time, and are set to count or measure the behavior or response for which they are designed. This makes it easy to see progress and display results in formats that motivate patients with evidence of progress—such as increases in strength, speed, or time. This, of course, frees the therapist to coach on quality of movement or optimal use of a body segment.

Transferability

Some worried that skills learned in VR would not transfer to the real world. To test this concept, Zhang et al. (2003) developed an immersive virtual kitchen in which patients with TBI could cook. Her researchers asked subjects to prepare a multistep meal both in a VR kitchen and in an actual kitchen twice over a 3-week period. Performance in the VR environment was actually a good predictor for performance in the actual kitchen assessment ($r = 0.63$, $p < 0.01$). The VR system showed adequate reliability and validity as a method of assessment in persons with brain injury (Zhang et al., 2003). This study shows the role that occupational therapists can play in contributing to the design of tasks for emerging VR tools. Activity simulations relating to common therapeutic goals and containing task elements that can be graded to increase challenge and complexity will be even more useful to occupational therapists.

Home-Based Activities

Because so many of these technology-based interventions are based on mass-marketed home entertainment systems, it becomes easier to encourage activity carryover as part of a home program or postdischarge activities. Older adults are often pleased to learn that being savvy about video games elevates their status with children and younger family members. Wii® golf, for example, recreates the experience of golf games shared with others but occurs within the safety and environmental predictability of the family room.

Range of Therapeutic Virtual Reality Activities

Given the nature of digital enterprise, there will always be new and improved products and interfaces for games and activities. A laptop computer purchased 5 years ago may have cost $1,500, but spending the same amount today buys one with faster processors, better graphics, more storage, etc. Observing the explosion of "apps" to entertain and support tasks on various smartphones and tablets suggests that there will be no shortage of software developers interested in working with therapists to develop therapeutic games and activities. The demand for apps appropriate for rehabilitation outcomes will only increase, so developing for this market will create opportunities for both entrepreneurial therapists and developers.

Digital Technologies for Cognitive Remediation

Compensation has always been an emphasis in treatment for cognitive impairment. We already know that compensatory

strategies and devices are very helpful for functioning in the presence of memory and executive function impairments (Gentry, 2011). We know that individuals with TBI often cannot remember to use calendars or notes nor attend to a task through to its completion. Digital devices have some key advantages over low-technology strategies. They have interactive multisensory user interfaces that are well designed and so intuitive that task sequences are easy to learn. Most devices allow easy customization for user needs so that once set up, retrieving data or responding to reminders can be made consistent and predictable.

Knowledge gained from perceptual or neuropsychological testing can be very helpful in setting up these devices for a specific client. Interfaces on smartphones and tablets offer features such as text-to-speech, distinctive icons/sounds, and immediate knowledge of results in a nonjudging interaction. Thus, mainstream, "cool looking" products can offer reminders for medications or appointments with one or more alert sounds, offer a map and directions, a photo of a landmark, the list of four steps in a task, or a phone number linked to help. Remediation is supported by repetition of steps for setup or response to device prompts. This new learning stimulates the development of neural pathways and opens the door to even more opportunities for learning and restoration (Dowds et al., 2011).

As personal mobile technology becomes more and more part of daily life and a tool used for all kinds of IADL, the tasks that support device management will be even more imbedded in common procedural memory. However, professionals specializing in cognitive rehabilitation seem clear that considering context is essential when retraining cognitive processes, skills, or functional abilities (Sohlberg & Mateer, 2001). Individuals who used devices in one way prior to TBI will need individualized instruction to reestablish patterns of use, develop new strategies for seeking help, and get consistent reinforcement for appropriate response to cues.

With high interest in neuroplasticity and recovery, there is new interest in determining whether digital technologies support remediation. Evidence from well-designed studies must show whether using today's digital technologies can stimulate dendritic regrowth and actually support repair and improved motor function following acquired or TBIs.

Motor Recovery with Electrical Stimulation
