Forty years of research with functional electrical stimulation (FES) has led to the development of a number of interventions and devices for treatment, although most are in the realm of neuroprostheses (Peckham & Knutson, 2005). Efficacy in the remediation of neuromuscular deficits is still preliminary. Electrical stimulation is being used in combination with goal-oriented repetitive movement therapy to augment motor learning in hemiplegia, and it has been helpful for treatment of shoulder subluxation and pain in hemiplegia (Sheffler & Chae, 2007). Neuromuscular electrical stimulation is effective in strengthening muscles, preventing muscle atrophy (see chapters 15, 19 and 21), preventing deep vein thrombosis, improving tissue oxygenation and hemodynamics, and facilitating cardiopulmonary conditioning (Sheffler & Chae, 2007). Current outcomes research on using FES in activity-based therapy for treatment of spinal cord injury (SCI) suggests that even when FES was withdrawn, there was evidence of sustained improvement when FES was used along with other interventions to elicit adaptability within a damaged nervous system (Behrman & Harkema, 2007).

Therapeutic Robots

Robots have been part of future fantasy for years but were only considered useful for rehabilitation starting in the early 1990s (Dijkers et al., 1991). Initially, developers thought robots could serve as intelligent assistants for those with high levels of impairment. High cost, regulation policy, and reluctance were effective barriers (Seelman, Kelleher, & Grindle, 2010).

Rehabilitation of stroke has been the area of first focus for robotics researchers. Stroke is prevalent, and helping individuals to achieve maximal recovery is very labor intensive, generally involving one-on-one interaction with an occupational therapist for a prolonged episode of care. Because rehabilitation for stroke recovery had always used this model of care, it is interesting to note that patients, once introduced to the idea of a robot helper, were enthusiastic about its use in treatment (Dijkers et al., 1991). Robots are novel and clearly report progress, which can increase patient motivation (Fig. 18-2). In the past 10 years, there have been many studies to demonstrate efficacy. An early, randomized clinical trial (RCT) showed significant differences in motor outcome when comparing conventional therapy with a robotic intervention. However, investigators could not report whether greater strength and motor control led to improved functional ability (Volpe et al., 2000). Since then, many studies have demonstrated that robotic stimulation leads to improvements in movement patterns that can be trained so that motor patterns are regained and the improvement is sustained over time (Hogan & Krebs, 2011; Krebs et al., 2008; Volpe et al., 2008).

Not all studies to date have had rosy reports. The most comprehensive clinical trial to date regarding the effectiveness of robot-assisted therapy reported mixed evidence for the use of robot-assisted therapy for upper arm rehabilitation after stroke (Lo et al., 2010). The main conclusions indicated that following 36 1-hour high-intensity robotic therapy sessions (with horizontal, vertical, wrist, and hand modules), stroke survivors 6 months post with moderate to severe upper limb impairment and with lesions caused by single and multiple strokes did not improve significantly more than nonrobot control groups of usual care or intensive therapy. They did have modest improvements over 36 weeks.
Figure 18-2 **A, B.** Patients recovering from cerebrovascular accident (CVA) like accuracy-challenge games presented by a computer and robotic arm.

A review of RCTs on the use of robotics suggests that motor improvements are greater when used earlier in post-stroke treatment and that research should focus on whether upper limb robots should be used in place of, or in addition to, standard of care interventions (Masiero, Armani, & Rosati, 2011).

Looking for ways to increase the improvement attributed to robotic devices has led to adding other modalities to robotic interventions, such as FES. The goal of therapeutic FES is to improve voluntary function by inducing physiological changes that remain after the stimulation is discontinued (Kowalczewski & Prochazka, 2011; Peckham & Knutson, 2005; Sheffler & Chae, 2007). Newer studies of robotic treatment are introducing pharmaceuticals as well. As we learn more about the biochemistry of neurological dysfunction, researchers look to pharmacology to modify blocked receptors and speed recovery following neurological trauma (Aravamudhan & Bellamkonda, 2011).

Researchers are looking, too, at the importance of attention, emotion, novelty, or reward in the recovery process. Often, incoming stimuli are reduced as a consequence of neurological loss and resulting inactivity. This makes increasing stimuli in the ascending brainstem pathways even more important so that learning is enhanced. It appears that combining robotics and highly stimulating interventions is essential to creating neuroplastic changes. These stimuli can range from engagement in highly valued tasks, to VR or FES, or the addition of neuromodulating drugs; their specific combination is the focus of current research (Volpe et al., 2009). Initial RCTs have yielded promising results (Knecht, Hesse, & Oster, 2011).

Occupational therapists have always associated recovery of function with the use of meaningful, repetitive, and task-specific activities that provide strong sensory input to the nervous system. It is affirming that research studies in

SCI, with both animals and humans, show that this kind of intervention is very effective in the treatment of SCI. Using the intrinsic physiological properties of the nervous system in combination with frequent, intensive sensory input to spinal networks is facilitating the recovery of function below the level of injury (Barbeau, Nadeau, & Garneau, 2006; Behrman & Harkema, 2007). The neurological system responds with plasticity as the spinal cord integrates supraspinal and afferent information arising from repetitive practice to improve motor output within the central pattern generators of the spinal cord. Training interventions based on the innate processing capacity of the spinal cord are leading to recovery of ambulation and improved respiratory function (McKay et al., 2011). The SCI recovery model has increased expectations for recovery of upper extremity (UE) functions for those with cervical injuries as therapeutic robots designed for SCI work to maintain normal range of motion (ROM), augment weak muscles, and gradually add resistance to increase strength to start, stop, and touch targets. In tandem with UE robotics and FES orthotic devices, outpatient occupational therapists use intensive, focused repetitive grasp and release tasks. Publications on development of robotic devices and case studies on outcomes for SCI are just beginning to emerge (Kadivar et al., 2011; Pehlivan, Celik, & O'Malley, 2011). YouTube videos of robot demonstrations are found with a search for "rehabilitation robot."

There are several reasons why research and development are so intensely focused on digital strategies to support functional motor recovery. Health care reform is seeking better treatment outcomes at lower costs. Robotic technologies have already helped to identify fundamental properties of brain function. This success is attributed to the fact that robots are able to control the position of, or forces applied to, limbs while having the ability to easily, objectively, and reliably quantify sensorimotor behavior (Loureiro et al., 2011; Scott & Dukelow, 2011). Robots

do not fatigue or give up and through variability in tasks and modifiable resistance and movement parameters help maintain focus and interest.

Researchers recognized that robots had potential to reduce cost of stroke rehabilitation (Dijkers et al., 1991). Since then, forces for change—the coming flood of aging baby boomers, the rising cost of health care, and the remarkable advances in neuroscience and computer technology—have increased the interest in robotics for improved economic and health outcomes. The success with stroke recovery has also increased the interest in robotics for treatment of other significant conditions too—multiple sclerosis (MS), cerebral palsy (CP), peripheral nerve injuries, burns, etc.

Telerehabilitation and the Portability of Therapeutic Activities

The development of these digital tools and interventions that support recovery or remediation are also creating greater interest in consultation with experts or therapy that can be provided remotely with central oversight through telerehabilitation. It is an extension of the use of wireless audio and video communication technology (with secure signal transmission to protect health care information) that allows rehabilitation services to be delivered in client's homes. A document on telerehabilitation from the American Occupational Therapy Association (AOTA) cites many studies in which this technology is used for evaluation and intervention (AOTA, 2010a). Because digital technologies enable data collection and assessment with computer-based tools, therapists can measure progress even at a distance. They are using VR techniques with computer-based simulations and telemonitoring with real-time video and using apps on smartphones to take advantage of digital motion sensors imbedded in them. The quality of data collected via telerehabilitation has been shown to have excellent correlation with in-person assessment (Kim et al., 2008). Therapists save the time and expense of travel, and clients receive remotely supervised, individualized care in the comfort of their home or local environment. After all, performing ADL safely and effectively within the daily context is precisely the goal of occupational therapy care.

Being engaged in the therapeutic process does not necessarily require use of telerehabilitation. Many people with disabilities live in small communities far from the accessible health club facilities or resources of larger towns. They can also use digital technologies to maintain health and wellness. The sedentary lifestyle of many with SCI makes cardiovascular disease a major health concern, whereas a suitable exercise program could improve their cardiovascular fitness level.

One such concept is a hand-crank ergometer linked to a computer and its display. The individual controls a computer game with the direction and intensity of arm rotations. In the research that led to its development, physiological data were collected, and the subjects' oxygen consumption and heart rate were analyzed. Analysis showed that the system enabled nine subjects to reach their training zone, defined as 50%–60% of their maximum O_2 consumption and heart rate, respectively (O'Connor et al., 2001). Using this digital exerciser, now sold as GameCycle™, which is fun yet enables an effective training response, individuals can take a greater role in health self-maintenance.

The Big Question: Evidence of Effectiveness

These new digital technologies for treatment will challenge tomorrow's OT practitioners to develop the critical thinking skills and decision algorithms needed to select, modify, and use them appropriately with their clients. The current complexity of setup and adjustment of rehabilitation technologies will be refined and improved just as the human technology interface has for all digital technologies. Evidence of effectiveness will be easier to measure, yet occupational therapists will need to be clear in their treatments goals, choose appropriate tools, and ensure that measurable gains demonstrated on devices translate to real improvements in everyday tasks that are part of life in natural and desired environments. The chapter focus will now transition to another role of technology in OT.

ASSISTIVE TECHNOLOGY FOR COMPENSATION: OCCUPATION-AS-END

Occupational therapists have been interested in "high tech" AT, since the early 1980s when the Adaptive Firmware Card and Unicorn Board showed up to modify input for the Apple IIe computer (Bates et al., 1993). Early adopters recognized the ability of a modified computer to compensate for absent or impaired abilities and enable occupational performance. A consumer with significant physical or sensory limitation could suddenly create a document, a spreadsheet, or "speak" text using a home computer. In addition, therapists quickly recognized the value of computer technology to speed documentation and establish peer networks for their own sharing of information and resources.

Now that computers are more powerful, AT supports even more sophisticated activities. Today, a consumer with tetraplegia can use a hands-free interface to make video phone calls, design and distribute documents, or control the environment. AT enables consumers with limitations to participate in activities and make choices based on their goals and desired roles that motivate them. AT clearly fits within the model of occupation-as-end (i.e., an alternate way to complete an activity).

As stated in Chapter 1, competent role performance leads to life satisfaction; this is a prime goal of AT. Occupational

therapists interact with the clients to identify current and future life roles and the tasks and activities those roles require. They analyze the individual's skills and abilities to build on strengths. They use their knowledge of intact body structures and functions to identify categories of AT with features that offer user interfaces and have functions that can replace missing capacities. They recognize that training as well as human and environmental supports are necessary to learn to use AT and integrate it into the tasks and activities of life roles. AT devices that match consumers' goals and abilities help them assume or return to meaningful roles and lives even in the presence of physical, sensory, or cognitive disabilities. Let us look at some specific examples of ways that ATs help individuals perform the activities and tasks of occupations and roles to support self-maintenance, self-advancement, and self-enhancement roles.

Self-Maintenance Roles

Enabling ADL performance is a familiar reason for OT referral. Simple technologies such as electric toothbrushes and shavers can increase efficacy and safety in personal care ADL tasks. However, IADL clearly benefit from AT solutions. Video relay services that use smartphones and video devices to enable remote American Sign Language (ASL) interpreters to speak to the recipients of phone calls are quickly replacing the text telephones and relay operator previously used by those who are deaf. Bluetooth headsets enable voice dialing on cell phones for those with paralysis who need to schedule a paratransit ride, shop for groceries, or request technical assistance over the telephone. Closed-circuit televisions (CCTVs) that enlarge objects help those with low vision pay bills and balance checkbooks. Even more IADL, such as banking, shopping, and e-mail, are supported with adaptations to computers and tablets.

Individuals with significant impairment can independently control lights, fans, or the TV volume within their living space with electronic aids to daily living (EADL) or even with smartphones equipped with apps and add-on transmitters that enable smartphones to function like universal remotes. The signaling technologies used in EADL are the same as those used in typical remotes: radio frequency (RF) and infrared (IR) light. Figure 18-3 illustrates the concept for categorizing simple and complex EADL.

Simple EADL

Each device uses one type of
signaling technology or controls
a separate type of appliance.

Complex EADL

One base unit
controls many kinds
of appliances.

Appliance Modules
Appliances plug into X-10™ or Insteon™ modules. They accept IR, RF, or Wi-Fi input and use house wiring to send a control signal.

X-10

One system is capable of controlling all of the simple EADL devices by means of IR, RF, or Wi-Fi or combinations as needed by the device. Controls vary: speech recognition, direct selection, or scanning.

TV

IR Transmitter:
controlled by large button remote, scanning remote, Relax II, AAC device, power wheelchair controller, and Wi-Fi-enabled handheld devices

VCR

CD/Tape

Bed:
controlled by remote or switch interface

Base unit

Intercom:
controlled by remote camera or wall unit, Wi-Fi-enabled handheld devices

Intercom

Examples:
Insteon™ Home Control Systems, IR-enabled smartphones and tablets, AAC devices, computer-based systems, Pilot Pro™, and Primo™/ Sero™

Telephone:
controlled by voice-activated smartphones and Bluetooth headset, computer phone dialer software, switch-activated phone, or IR phone dialing device

Figure 18-3 EADL devices are classified as simple or complex and use a variety of signal transmission methods that now include Wi-Fi and the internet. AAC, augmentative and alternative communication; EADL, electronic aids to daily living; IR, infrared; RF, radio frequency.

Powered mobility, for those who cannot propel a manual wheelchair, contributes greatly to self-maintenance tasks. Independent mobility not only communicates curiosity, interest in participating, or the wish to be alone, it also supports independence with basic ADL such as eating, toileting, and bathing, and instrumental activities such as shopping for groceries. Powered mobility can increase the capacity of individuals to engage in the activities of role performance, although the availability of accessible environments is a key requirement (Buning, Angelo, & Schmeler, 2001). Home modification is usually necessary for using a wheelchair to cook a meal in a kitchen or approach a toilet in the bathroom. Universal design, which offers seven principles to guide inclusive design, considers the needs of a broad range of individuals by creating people-friendly spaces that are safer and more easily modified for those with severe impairment (Center for Universal Design, 2012). (See further discussion of powered mobility in Chapters 17 and 26 and more information regarding universal design in Chapter 31).

Augmentative and alternative communication (AAC) devices can incorporate synthesized or digitized speech devices for those who are unable to speak or whose speech is difficult to understand. Some AAC devices support the capacity to engage in full conversations; others store only a few messages. AAC devices allow consumers who have been taught to use them to socialize, call for assistance, direct caregivers, inform health care providers about health issues, initiate plans for activities, make food or clothing choices, and even gain employment.

Self-Advancement Roles: Work, School, or Community Volunteer

AT enables self-advancement roles for those with disability that range from volunteering by retirees to working full-time in paid employment or to students acquiring education. Wheelchairs and scooters allow travel on neighborhood sidewalks, commuting on accessible public transportation, and access to schools, stores, and workplaces with accessible entrances. Four-wheel drive wheelchairs give mobility on farms, on ranches, and in the backwoods.

Wireless internet communication technologies make information exchange easier and faster for everyone. When clients with sensory, motor, and language impairments can use these technologies, they reap huge benefits. Desktop and tablet computers commonly enable listening to text, writing, searching the Internet, managing finances and data, working remotely, and making video phone calls for work or leisure. Real-time closed captioning of a speaker's words at a conference and captioned multimedia and distance learning software create access for those with sensory impairment.

AAC devices are an essential part of communication and participation in school or workplace. Making choices, demonstrating knowledge, asking questions, forming peer relationships, and getting the job done all occur when alternative or augmentative communication devices are used.

Self-Enhancement Roles: Recreation and Leisure

Recreational choices often have symbolic meaning and clearly reveal our interests and our tolerance for challenge (Kielhofner, 1997). Recreational choices, made for their intrinsic and symbolic qualities, allow individuals to take on valued images of self as adventurer, connoisseur, or creator (see Chapter 29). AT enables activities ranging from alternate controls for video games to adapted reels for one-handed fishing. Recreational AT includes wheelchairs designed for beaches, tennis courts, or mountain trails. Water sit-skis and adaptive snow skis like mono- or bi-skis allow full participation and agility in mainstream recreations.

Many enjoy using home computers for leisure. Adapted computer access allows browsing sites on the Internet, pursuing interests like genealogy or collecting, and engaging in creative art activities and puzzles. The Internet allows researching destinations, finding accessible accommodations, and renting accessible vans. With this increased accessibility, even traveling is now a form of recreation and play.

THE ASSISTIVE TECHNOLOGY ASSESSMENT PROCESS

The potential contribution of AT devices is remarkable. However, the real contribution of AT only occurs as a result of a skilled, thoughtful, and thorough assessment that centers on the client's goals. A discussion of the elements of this process follows. Figure 18-4 is an overview of the AT assessment and intervention sequence.

Assessments are driven by the consumer's goals and needs (Bain & Leger, 1997). Family members or caregivers, speaking on behalf of a consumer with communication impairment, may also identify goals and needs. Occupational therapists, because of their knowledge of functional impairment and adaptations, are often an entry point for exploring the possibilities created by ATs (Hammel & Smith, 1993). As a member of an AT team, the occupational therapist attempts to understand the reason for the client referral, seeks to recognize the role that AT might play in compensating for impairment, and assists individuals in forming realistic expectations.

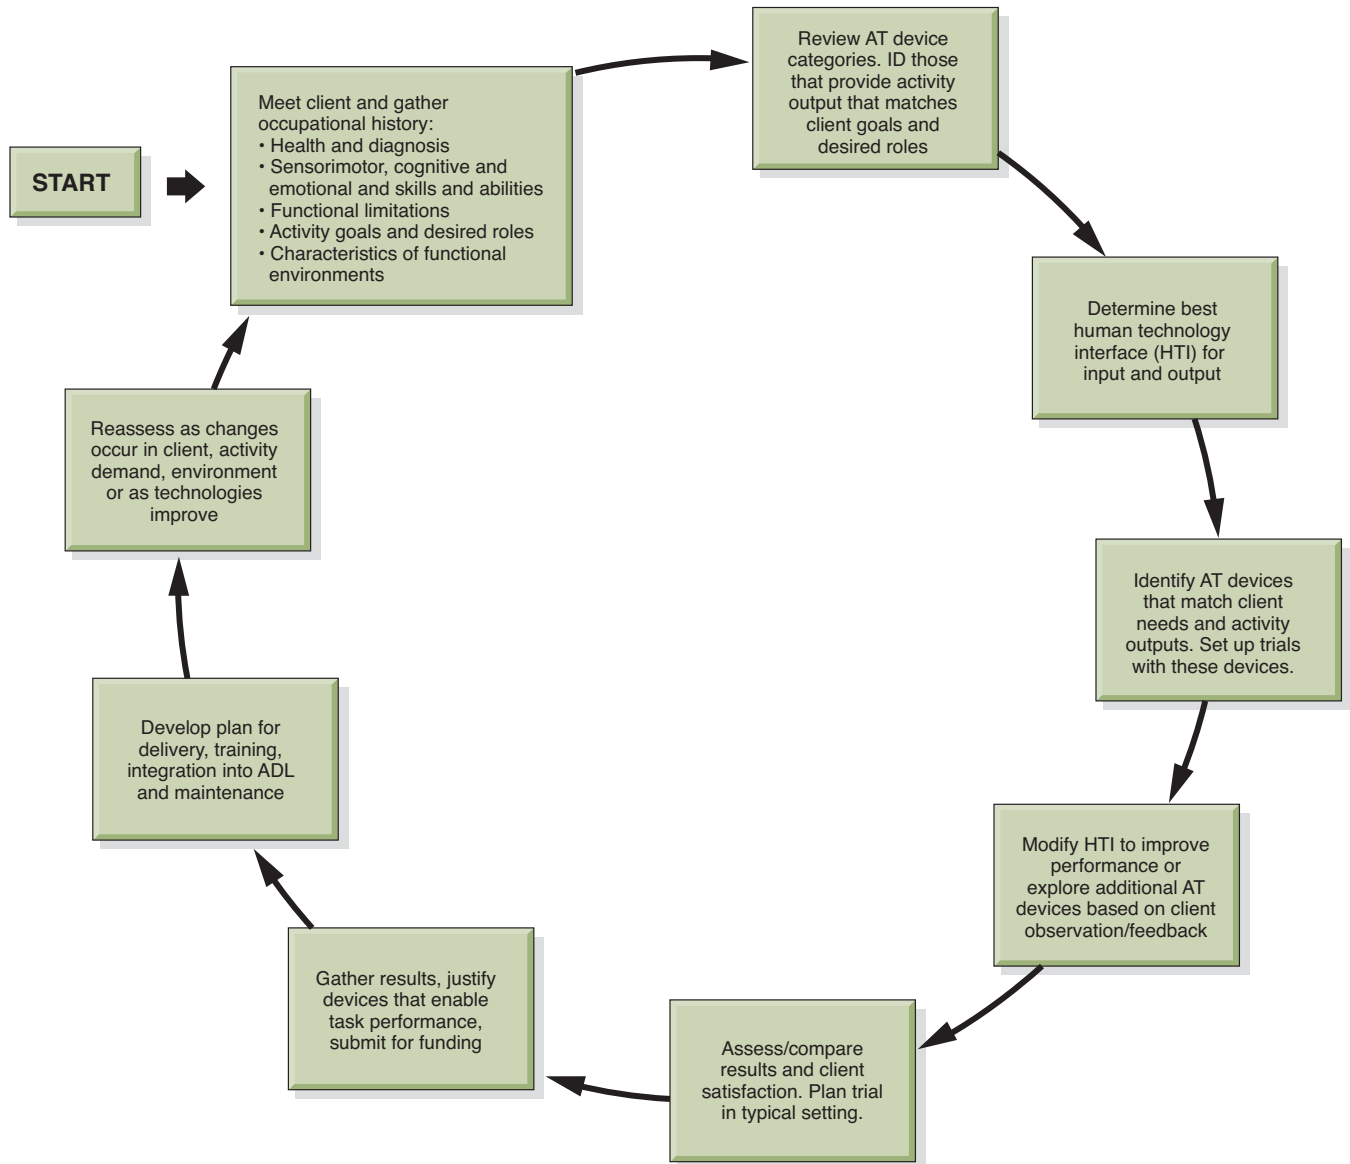
Consumers, family members, and caregivers come to an OT assessment with various needs and motivations. For example, a young adult transitioning to college may need computer technology and training in order to more efficiently complete assignments and participate in online class discussions or project development. A working adult


Figure 18-4 The AT assessment process. ADL, activities of daily living; AT, assistive technology; ID.

with a newly acquired motor impairment may need to learn about technologies, such as a trackball or speech recognition in order to return to work.

In addition to their goals and priorities, the assessment focuses on consumer and family attitudes toward AT. Some people easily adopt technology and incorporate it into tasks and routines; others resist and even fear it. Some feel that the latest high-technology equipment is not necessary and prefer simpler, more familiar devices. Consumers' religious and cultural background and personal tastes may also influence their choice of devices. Devices that fit within the personal, social, and cultural context of the consumer are more likely to be used than those outside the consumer's comfort zone.

Multiple factors need to be considered because consumer dissatisfaction leads to AT abandonment (Batavia & Hammer, 1990). Putting aside personal values, the therapist concentrates on addressing the consumer's goals and preferences.

As new occupational therapists who have grown up with technology and are already comfortable with a variety of digital devices and the internet begin to practice, digital solutions will become more common in OT practice. Some therapists will discover that they enjoy a more specialized focus on technology and will seek opportunities to work with an AT team in order to meet the needs of clients who would benefit from more specialized types of AT devices.

Team Members

Because of the wide variety of AT devices available, AT services are often delivered with the help of a multidisciplinary team that consists of a variety of professionals and stakeholders. The consumer, family, and caregivers have key roles because they will use the equipment on a daily basis. Professionals on the team vary according to the consumer's needs.

- A seating expert, an occupational or physical therapist, understands maximizing fine motor function when sitting. With the consumer's activities in mind, this expert assesses posture and ROM and specifies seat, back and foot support angles, and cushion type (e.g., support or pressure relief or accommodation to abnormal posture). If the consumer uses a wheelchair, assessment includes a trial with his or her wheelchair. The decision to use a manual or powered wheelchair can affect selection and use of other AT devices (see Chapter 17 for information on wheelchairs and assessment).
- An access specialist, typically an occupational therapist, focuses on finding the best method for controlling an AT device. The access specialist works with the rehabilitation technology supplier (RTS) and/or the rehabilitation engineer in selecting and developing control for specific devices, such as computers, AAC devices, and EADL.
- A teacher or special educator, if the consumer is a student, describes schoolwork tasks and helps ensure that AT solutions support educational tasks and school participation.
- A vocational rehabilitation counselor, if the consumer works or is preparing for work, will approve AT solutions and help with funding.
- A speech–language pathologist (SLP) with expertise in AAC leads the team when communication is the focus. The SLP evaluates a consumer's potential for verbal and written communication, determines the symbol set to be used (alphabet, pictures, etc.), and collaborates with the access specialist.
- A rehabilitation engineer may be on the team if the consumer has complex needs and off-the-shelf solutions are not likely to be effective. The engineer may integrate several types of AT when consumers have few options for control. For example, a consumer with reliable control of only a finger would need an integrated control system that allows this small movement to drive a wheelchair, operate a computer, and control an AAC device.
- A social worker may help locate funding sources or provide counseling as consumers and significant others come to terms with disability.
- RTSs (often called vendors) are equipment experts. Because they sell devices, an RTS may be able to provide demonstration equipment for evaluations.

The RTS knows product features and can help with selecting components, customizing products, and handling warranty issues following delivery. Suppliers with specialty certification have advanced training, skill with assessment, and commitment to ethical practices.

The Assistive Technology Assessment

Prior to an AT assessment, the team needs to understand the consumer's goals related to roles and the performance of activities to support roles. This client-centered approach, a key feature of OT assessment, can be accomplished either through a structured interview or an intake questionnaire (AOTA, 2008). For some clients, goals are actually expressed by family members or caregivers. Once goals are established, the door is open for focusing on a particular area of AT and categories of solutions and for assessing current skills and abilities to determine potential access methods. During this part of the assessment, it is important to gather a realistic picture of the consumer's motor control, social skills, and cognitive and sensory abilities, as well as the environments where the consumer will use the devices. Areas commonly addressed in AT assessments follow.

Seating

Optimal seating is mandatory to achieve the best results during the rest of the assessment. If the client uses a seating system that does not provide adequate support, the performance observed during subsequent AT evaluation activities will not accurately show the consumer's ability.

Sometimes it is not possible to address seating issues before the rest of the assessment. When this happens, a seating simulator with an adjustable back, sides, armrests, and lateral trunk and foot supports can be used to meet a broad range of postural support needs. The optimal solution is to assess consumers in their own appropriately fitting seating system.

Another important factor to determine early in the assessment is where and in what positions the consumer spends the most time. Asking these questions at the beginning of the assessment avoids recommending access methods that the consumer can use with accuracy in their wheelchair only to find out that, at home, the consumer spends the most time in bed or a lounge chair. Once seating issues have been resolved, motor control for access is addressed.

Motor Control

Ideally, an access method (e.g., touch-typing on a keyboard) is effortless. Effortlessness comes after practicing and refining a skill and allows attention to be directed to

thoughts rather than to keystrokes. To reach effortlessness, access methods that the consumer is able to activate consistently, reliably, and with endurance are needed.

To plan for physical control of an AT device, the therapist needs to identify optimal body segments usable for reaching, touching, turning, tapping, etc. This leads to a functional evaluation of ROM, coordination, and endurance. Often, consumers and their family members and caregivers know a consumer's best controlled body segments and can provide this information. Usually, the hands and fingers are assessed first because humans prefer them for interacting with objects (Cook & Polgar, 2007). If not hands or fingers, assess head movement next. Consumers with limited control over their UEs sometimes have excellent control of head movements. If the head is only partly successful, consider use of eye movements. Some find best or preferred control through the feet or knees. The best two or three sites should become the focus at this point in the assessment (Cook & Polgar, 2007).

Evaluating accuracy, ROM, and endurance helps to determine the active range a consumer has for accessing a keyboard, a switch, or other input devices. It is helpful to quantify this function. Using a vertical or horizontal checkerboard or a spare computer keyboard can be very useful when assessing this capacity. It may be necessary to do a series of trials with various body parts in order to determine which one moves reliably with the least effort. This serves to narrow options for access devices that can be explored further. For example, overshooting or dragging a finger on a typical computer keyboard indicates a need for bigger targets or the use of keys with less sensitivity. Conversely, if the consumer has good accuracy but can only reach targets close to the midline, consider small keyboards or a joystick to reach all keys or to control a cursor. Coordination can also be assessed in this simple manner by asking the consumer to point to specific squares on a board. If precise pointing is not possible, the occupational therapist may add a control enhancer (to be discussed) or a more specialized control interface to ensure accuracy.

Once pointing and reaching trials are completed with several body segments, compare the results to determine which body segment offered the best control. It is important to ask the consumer whether he or she agrees. If the consumer feels more comfortable using another body part despite less accuracy, the therapist and consumer should discuss this and come to agreement about the primary access site. Skill can develop in time.

Having said all of this, it seems important to note that speech recognition and eye gaze technology have improved greatly in the last few years. These technologies create the possibility that a consumer may need no physical contact with an input device in order to control it. Depending on a consumer's cognitive abilities and goals,

it may be possible to use speech recognition, eye gaze, or scanning to move past the need for good motor control.

Direct versus Indirect Selection Methods. With motor skill assessed, the occupational therapist is ready to determine whether direct or indirect selection will be used (Definition 18-1). If a consumer can point, touch, or move accurately, direct selection is appropriate. Target size and device placement will still be factors. Use indirect selections only when some form of accurate pointing to select from a set of options (e.g., keyboard or number pad) is not possible or is too inefficient. Indirect selection is very demanding. The consumer must be able to plan a sequence as well as anticipate the choice and activate the switch at exactly the right time.

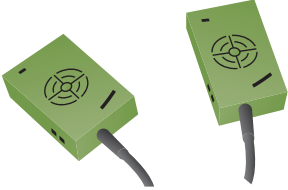
Switch Assessment. Selecting and mounting the optimal switch is critical for success with indirect selection, Morse code, or other controls (Table 18-1 for options and sources). Consistent, comfortable, and reliable switch pressing increases accuracy. The body segment that is most reliable guides switch choice. A consumer with muscular dystrophy who has finger weakness should be offered a small, sensitive switch. In contrast, someone with CP may need a rugged foot switch mounted on a wheelchair footrest. For an anatomical site that is bony, such as the back of the hand, a padded or pillow switch is appropriate.

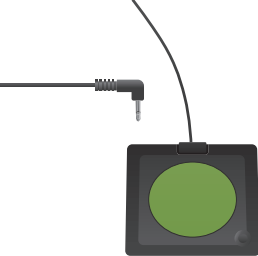
Definition 18-1

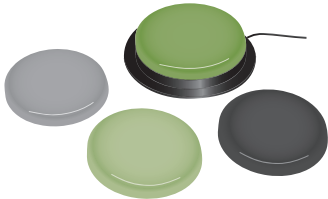
Direct and Indirect Selection

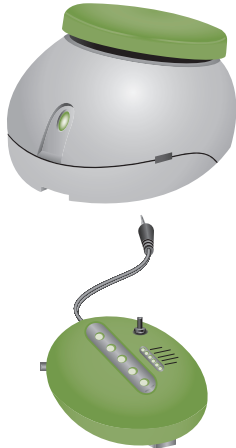
Selection set refers to the universe of options from which an individual can choose. In *direct selection*, all of the items in the selection set are available all the time. Examples of direct selection are computer keyboards, telephone keypads, and calculators. Direct selection is very intuitive; if K is pressed on a keyboard, K will appear on the display. The disadvantage is that direct selection demands hand–eye coordination, range of motion, and endurance.

If the consumer is unable to reliably press the desired keys even with a performance enhancer, the option often becomes *indirect selection* or scanning. In this mode, only a subset of all possible choices are available at a given time, for example, setting the time on a digital clock and waiting for the correct number to appear. The advantage of indirect selection is that a consumer needs only one reliable movement (i.e., an eyebrow, elbow, or toe) to activate a switch indicating choice. However, this process is demanding because a user must wait for an item to be presented, accurately time switch activation, have the cognition to focus on an objective, and sequence the steps to achieve it. Additionally, error correction is frustrating and very time consuming.

Table 18-1 Common Switches and Activation Methods








Category and Switch Name	Image	How and Where It Works
No Physical Contact (requires battery or external power source (e.g., power wheelchair battery)		
Self-Calibrating Auditory Tone Infrared (SCATIR) switch from AbleNet		Activates with small movement (i.e., eyelid, facial muscle, or finger) that interrupts an IR beam. Provides auditory feedback.
Proximity switch from Adaptive Switch Laboratory		Activates when body part moves into a preset but adjustable range. Does not provide sensory feedback.
Physical Contact, No Pressure		
Pneumatic (or sip and puff) from AbleNet and others		Activates as a dual switch with minimal force; internal membrane detects in or out air pressure delivered through closed lips. Gives no feedback.
Physical Contact with Pressure		
Micro Light switch from AbleNet		Activates with minimal force; for use with small or weak body part. Gives auditory and tactile feedback.
Ribbon switch from AbleNet		Activates with minimal force; moisture proof for use at chin, hand, or other body part. Gives no feedback when the flexible ribbon is bent >10°.
Plate switch from AbleNet		Activates with minimal force; thin and moisture proof for use by hand, arm, knee, or foot. Gives no feedback when touched.
Pillow switch from AbleNet		Activates with moderate force; soft foam padding makes it best for bony areas. Gives auditory and tactile feedback.

Table 18-1 **Common Switches and Activation Methods** *(continued)*

Category and Switch Name	Image	How and Where It Works
Big Red (5 inches), Jelly Bean (2.5 inches), and Spec (1.4 inches) switches from AbleNet		Activate with moderate to maximum force; match size to finger, hand, arm, knee, or foot. Gives auditory and tactile feedback.
Big Beamer or Jelly Beamer switches from AbleNet		Activates with moderate to maximum force; sends wireless signal 30 feet to the receiver plugged into target device; can be pressed by hand, arm, or foot. Gives auditory and tactile feedback.
Rocker switch from AbleNet		Activates as a dual switch with moderate force; use with small body part for row/column scanning or Morse code. Gives auditory and tactile feedback.

Switches need to be mounted so they remain in place and in line with the angle of activation. Wheelchair and desk mounts with solid, one-way connections are far more likely to be used correctly than those that are adjustable. A switch mount must also be easily removable so it does not interfere with transfers or eating.

Regardless of the type of switch selected, it should give the consumer feedback about successful movement. Usually, this feedback is auditory or tactile, but it can also occur through the instant response of the device being controlled. Switches activated with head movements need less auditory feedback, because a noisy switch mounted near the ear can be annoying. Six occupational therapists with expertise in AT participated in a focus group to develop a list of the 10 most important considerations for switch access (Angelo, 2000). In the control category, the therapists indicated that the most important considerations were reliability of response, ability to perform timed responses, ability to activate and deactivate the switch within

a given time frame, and endurance (the ability to sustain a force and to apply that force repeatedly over time). In the ease of movement category, therapists said that tasks should be performed volitionally, easily, and efficiently and that past performances with positive outcomes should be considered. Because context was considered important, assessments should occur in the environment where tasks are routinely performed. Finally, switch safety should be considered. Switches should have rounded corners, and all wires should be secured or avoided so that they do not become entangled with fingers, pointing devices, or other equipment (Procedures for Practice 18-1).

Cognition

Cognition is usually evaluated informally during AT assessment (Cook & Polgar, 2007). During the assessment activities and interaction, it is possible to estimate the consumer's attention span, reading level, short- and long-term

Procedures for Practice 18-1

Switch Assessment

1. Identify the anatomical sites over which the consumer has most control for switch activation. No timing is involved in this step. Cause-and-effect software games can make this a fun activity.
2. Evaluate the consumer's ability to wait a specific length of time before activating the switch. This skill is critical for effectively using indirect selection. Errors in selection occur when the switch is released too soon or too late. Cause-and-effect games that introduce timing (e.g., Frog and Fly) are useful for determining this ability.
3. Evaluate the consumer's ability to maintain contact with the switch and to release the switch on command. This information will help to identify the best scanning mode, for example, automatic, inverse, or step scanning.
4. When one or more anatomical sites have been identified for accurate switch activation, the AT team determines which body part and type of switch is most appropriate and how and where to mount the switch. This concept is further described by Cook and Polgar (2007).

memory, and ability to follow instructions and sequence tasks. A neuropsychological evaluation can also be very helpful. Knowing more about cognitive functioning helps the AT team determine which devices have the features and performance characteristics that will match the consumer's cognitive ability (see Chapter 6). A consumer with a learning disability or an intellectual disability associated with cerebrovascular accident (CVA) or TBI should be assessed for visual perception. Knowledge about figure-ground problems or form constancy helps the team ensure that a visual display is usable. Icons, words, or symbols may need to be placed farther apart or the background may need to be simplified to reduce visual stimulation.

Visual Acuity and Visual Perception

The AT evaluation team should always consider vision because many impairments affect acuity, occulomotor skills, or visual perception. Visual acuity will affect the size of symbols used for communication boards and the sizes of letters and icons on a computer display. Decreasing the distance from the eye to the display (typically one arm's length) can help. It is also possible to use options in the computer control panel to alter brightness or screen resolution or add magnification or change contrast.

Eye ROM, conjugate eye movements, visual field cuts, and tracking should be noted (see Chapter 5). Knowing the extent of eye movement and whether the eyes work together is especially important when consumers are using indirect selection methods. This method requires the eye to track or follow a cursor and scan options to find a specific item. If imbalance is noted, then eye preference should be established, and this information should be used during the assessment and later during equipment setup. Information about a visual field loss helps to determine the location of visual displays and may influence choice of font, font size, or contrast to help compensate. If visual tracking is impaired, remedial work with single switch and cause-and-effect software may help to develop this skill for users who have limited experience with controlling their environment.

Finalizing the Match between User and Technology

By this time in the assessment, an AT team has a clear idea of the consumer's motor, cognitive, visual, and visual perception abilities. The AT team should have begun to narrow the range of options down to a few devices with activity outputs, user controls, mounts, and control enhancers that match the consumer's needs and abilities.

Once options are narrowed to two or three, it is time to conduct a more extensive trial with each. Trials of two to three devices with the control interface and control enhancers allow the consumer to become familiar with the equipment and determine level of comfort when using it. As previously mentioned, this trial, if not the entire assessment, should occur in the environment where the consumer will use the equipment. Using the system in the actual or intended environment—home, workplace, or school—uncovers problems that may not emerge during center-based trials (Angelo, 2000). Noise, desks that are too small for devices, tables that are too low for rolling under with a wheelchair, and lights that are too dim or that glare on the display can be addressed and resolved. Trials should occur before making recommendations and submitting a final equipment list because this increases the likelihood that the devices will actually be used and not abandoned. With the reauthorization of the Tech Act of 1988, each state is required to develop an AT device-lending library. AT teams should make use of this resource (Bailey, Weber, & Meidenbauer, 2012).

THE ASSISTIVE TECHNOLOGY INTERVENTION PROCESS

An AT device recommendation is guided first by a consumer's activity goals with the AT device features based on the consumer's abilities, capacities, and preferences. The broad categories of AT solutions include control enhancers, computer modifications, AAC devices, and EADL, and each of these will be briefly discussed in turn.

It may be helpful to think of an AT solution as a complex assistive device. Because of its complexity, four critical components must be considered: (1) a user interface (how the client will interact with it), (2) a processor that converts the user input into the desired action, (3) the product or activity output, and (4) an environmental interface that influences its adoption and effectiveness. The environmental interface includes the physical, social, and cultural environments in which a device will be used.

Occupational therapists, by their education and interest in human function, are already familiar with this kind of consideration, because they have already learned a process for recommending assistive devices to their clients. However, interdisciplinary AT team members are usually acquainted with a service delivery model called the HAAT (Human Activity and Assistive Technology) model (Cook & Polgar, 2007). The HAAT model is based on systems theory, in which a change at any point in the process requires readjustment in other components of the system to rebalance and ensure continuity (von Bertalanfy, 1968). This model (Fig. 18-5) will look familiar to occupational therapists. Because AT practice demands greater knowledge of devices with processors, more customizable user interfaces and activity outputs, occupational therapists with an interest in AT must typically invest additional time and effort in continuing education or self-directed learning with a mentor to develop competence with specific elements of the HAAT model.

Hierarchy of Access

When consumers with impairments cannot use digital devices in standard ways, a principle called hierarchy of access is used (Schmitt, 1992). This principle reminds us that simple solutions should be considered before those that are complex. Less complex solutions are less costly and easier to implement. The goal is to optimize control without burdening consumers with more technology than they need.

Control

One of the key approaches to reducing complexity is to consider how typical or mainstream user interfaces can be enhanced using low-tech aids or assistive devices that consider the consumer's limitations and address barriers to use. This concept has been referred to as control enhancers. This term refers to aids that enhance or extend a consumer's physical control (Cook & Polgar, 2007). Control enhancers include head pointers, handheld pointing devices (pencils, pointers with built-up handles, and typing sticks), mouth sticks, wrist rests, and arm supports (Fig. 18-6). Control enhancers also include devices that modify placement of user interfaces such as easels, flexible switch mounts, and flat-panel monitor arms. For example, a lever-adjustable keyboard tray can increase keyboarding comfort or an easel can position a regular keyboard for a consumer using a mouth stick and eliminate the need for a special keyboard. Control enhancers also support using devices efficiently with less fatigue. Comparing outcomes with several control enhancers helps determine the best fit between the consumer and his or her AT device.

Figure 18-5 The HAAT (Human Activity and Assistive Technology) Model helps to conceptualize factors in an assistive technology (AT) device system.

Figure 18-6 Often performance or control can be enhanced by repositioning an assistive technology device or the orientation of the person using the device (Photo courtesy of Blue Sky Designs, Inc., Minneapolis, MN).

Adaptive Computer Access

In general, adaptations for computer use fall into two categories—changing how information is put into a computer (input) or changing how a computer's information is delivered (output). Depending on impairment, consumers who want to use computers may have difficulty with one or the other or even both input and output. Typically, input is accomplished with keyboard, mouse, or trackpad, and output is accomplished through computer display, sound, or a printer. However, technology continues to offer new modes of input and output such as automatic speech recognition and soon, brain-computer interface (BCI).

Adapting access to a computer should always start with the accessibility options (Fig. 18-7) in the control panel of the computer operating system (OS). Because these options are included in all computers at no additional cost, they are the first step in the "hierarchy of access." Accessibility or universal access options allow any user to modify input and outputs such as setting the size and speed of the mouse cursor, latching modifier keys on the keyboard to aid one-handed typing, reducing keyboard sensitivity to reduce errors caused by tremor, increasing the contrast or size of fonts on the menus and icons, and controlling basic computer functions with speech. Both Microsoft and Apple websites offer extensive tutorials and step-by-step guides for these features.

Modifications to Computer or Device Input

There are a variety of ways that specialized and even mainstream software and hardware can modify computer input. Because the goal of this chapter is to acquaint occupational therapy practitioners with the range of possibilities for adapting computers, the descriptions that follow will serve as encouragement to search and learn more about specific products.

Keyboarding. A standard keyboard should be the first device tried. Using accessibility options or a keyguard to reduce unintended key hits may be all that is needed. If not, then consider alternative keyboards. Most alternative keyboards provide transparent computer access; that is, the computer thinks the input is coming from a standard computer keyboard. Additionally, most of these keyboards are equipped with Universal Serial Bus (USB) connectors so they can be exchanged without rebooting and will work on either Windows or Macintosh platforms.

Several commercial products are included in this category. Some are adaptable and can be used in a variety of ways; others have narrow applications. One keyboard, shown in Figure 18-8, crosses computer platforms. It comes with a set of standard overlays that are instantly detected by the keyboard via bar code readers. The layouts of these overlays range from simple enough for those with low cognitive ability to those for advanced computer users. Key press acceptance rates are easily adjusted, and keyguards can facilitate key pressing accuracy. The keyboard also allows arrow keys to control mouse movements. The keyboard is 11 × 17 inches, so good ROM is needed to reach all of the keys. These features make this a good device to use in an OT setting where therapists are providing basic adaptive access for a variety of diagnoses.

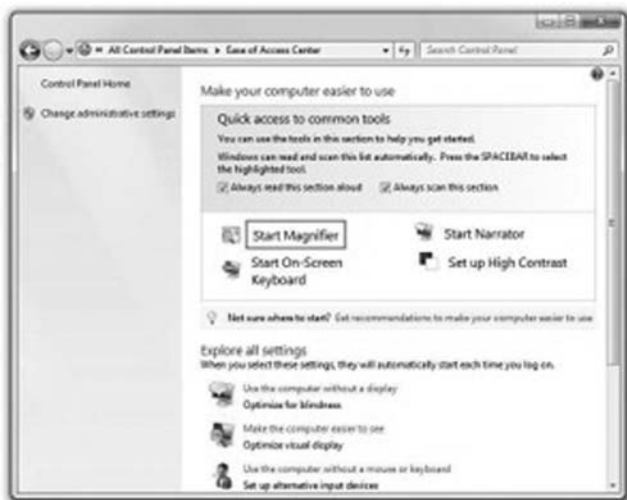
Another option that is available on all computers is an on-screen keyboard. In this adaptation, a physical keyboard is not used. Rather, a keyboard is represented on the computer display and the consumer uses a device that can move an arrow cursor to point to keys on the virtual keyboard (Fig. 18-9). This method is the equivalent


Figure 18-7 First, consider accessibility options within a computer operating system.

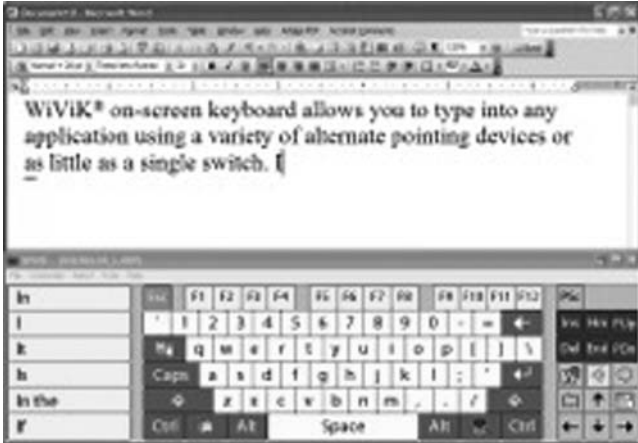
Figure 18-8 Intellikeys keyboard allows easy modification when the user needs large keys or decreased sensitivity.


Figure 18-9 A resizable, on-screen keyboard with word prediction allows text entry by mouse, trackball, or any device that moves the cursor on a computer display.

of one-finger typing, but it makes typing possible for someone without the endurance to hold fingers over a keyboard. On-screen keyboards are usually packaged with word prediction and abbreviation expansion software. Word prediction software uses rules of recency, frequency, and grammar to anticipate the next word. Optimally configured, word prediction saves keystrokes, but it works especially well with the on-screen keyboard because the consumer's eyes are looking at the screen where the predicted words are displayed. A second click or dwell chooses a whole word and enters it into the text document. Abbreviation expansion lets the consumer establish shortcuts to represent frequently used phrases or personal information, such as BTW for "by the way." As you will see shortly, there are many mouse pointing options.

There are also variations in keyboard layout that can help a one-handed typist be more efficient. Balance the usefulness of this approach with the time needed to relearn a keyboard layout. The ability to electronically select an alternate keyboard layout is much easier now because of the sophistication of control panels or system preferences that are part of today's computer OS. Keyboard keys can be relabeled with stickers or popped off and rearranged on a spare keyboard. In this approach, the hand stays in a home position and uses reaches from the home row to type all letters and numbers.

The process for determining a best option for a keyboard modification is to determine existing skill and familiarity with keyboarding and the places where keyboarding will need to occur. Then expose the consumer to use of some adaptive options that consider his or her activity and task needs, determine a keyboard rate for comparison, and then discuss the usability of each approach across settings. Remember unlearning a familiar skill is not easy, and success in use of all new methods will be slow in the beginning.

Mousing. A mouse is still the most common pointing device, and pointing is still an essential means of directing a computer's action. The actions of pointing and clicking can be completed with a range of devices. One mainstream product with features that make it useful for consumers with limitations is a trackball. A trackball offers both the advantage of remaining stationary in a base as well as separating the actions of pointing and clicking. This allows more accurate cursor control and reduces the frustrating movement that can occur when initiating a mouse click. The ability to rest the wrist on the base of the trackball increases proximal stability for the fingers. Many consumers with poor coordination who cannot control a mouse can control a trackball. Furthermore, a trackball is sturdy enough for control via elbow, wrist, or foot movements. Trackball software allows adjusting the ratios between ball movement and cursor speed and clicks and double clicks can be linked to buttons on the right or left side of the trackball base.

Trackpads are common on computers. They can be customized to change the number of fingertips or the direction of their movement required to scroll or flip through pages in a photo collection. This mainstream customization can function to simplify computer input for some.

A touch screen is also a mouse substitute. Selecting or interacting with a touch screen is as simple as touching an icon to select it or dragging a finger to draw in a paint program. This reality is basis for the revolution created by touch screen devices. Some touch screen devices work by creating contact between two membranes with the pressure of touch. Other touch screens work because the screen is coated with a material that detects the small electrical charge in human skin. The device processor translates the *xy* coordinates of the consumer's touch or the mouse location on the screen for conversion to action outputs.

Mouse Emulation. When hands or feet cannot control a mouse or cursor, more complex AT devices are used. These specialized AT devices can emulate or imitate the function of a mouse. One category is a joystick operated by mouth to provide for quick and precise cursor movement. Usually, the joystick is mounted on an adjustable mount attached to the edge of the desktop. Once adjusted, a consumer simply pulls up to the computer and gets to work. A built-in sip and puff switch substitutes for mouse buttons or allows sending Morse code. Text entry is achieved either through code or through software for an on-screen keyboard.

Another category of mouse emulators use either a reflective dot worn on the forehead or the reflected light from the curve of the eyeball at the pupil to indicate pointing. Solid-state photo sensors in a camera attached to a computer or AAC device detect small movements

and convert them into *xy* coordinates. Selecting or mouse clicking and dragging are produced with an external switch or with associated software. Another means of selecting occurs through the use of dwell. This feature allows choice making by floating the cursor over an icon or key for a predetermined amount of time. Mouse emulation enables typing with an on-screen keyboard or using computer-aided design (CAD) or illustration software. This technology allows pixel-to-pixel accuracy and smooth cursor movement.

Of course, using a mouse or any other pointing technology is very challenging if not impossible for a consumer without vision. With a touch screen device, they will, at a minimum, need auditory feedback through a speech synthesizer to know what they are touching on the screen and the associated function of that position. For most other devices that commonly use a mouse for pointing, an entirely different user interface will be needed.

Automatic Speech Recognition. Automatic Speech Recognition (ASR) technology, a mainstream technology developed to enable data entry in settings where hands were busy, was quickly recognized as valuable for those with motor impairment (Koester, 2001). Consumers with significant motor limitations but with speech were able to write independently using a computer. Although early versions required each word to be spoken separately, the technology now works with continuous speech. The leading product, Dragon Naturally Speaking™ (Simpson & Koester, 1999) uses sophisticated algorithms to compare speech sounds with likely or logical phrases, a process that requires a computer with sufficient RAM and processor speed. Most ASR applications require good literacy skills, because the user must compare the displayed text to the text he or she intended to write. Auditory playback, however, make this much more feasible for most users. SpeakQ™, another speech recognition application, removes this obstacle for individuals with learning disabilities or low literacy skills. Its user interface is easy to customize and tends to work well with users whose voices have unique characteristics.

With ASR technology, it is important to consider both the user and the environment. This technology requires learning and using a very different approach to writing. The user must mentally compose a sentence and then speak it without "ums" or incidental comments. Users who cannot use their hands or a mouse must recall specific command phrases, although on-screen help has reduced this cognitive load. The user needs to be able to work in an environment that is tolerant of someone speaking at conversational volume; that is to say not in a classroom or a typical office cube environment. Also, loud environmental sounds can interfere with ASR. Individuals should use a high-quality, noise-cancelling microphone connected to the USB port rather than the sound card.

Good instruction in proper correction strategies is essential for continuously improving recognition accuracy and the efficiency of ASR (Koester, 2006).

At present, speech recognition offers good access to well-designed Internet websites, launching applications, and performing general computer tasks. Computer OS and handheld devices are rapidly moving in the direction of allowing individuals to have voice control over complex processing tasks.

Optical Character Recognition. Optical character recognition (OCR), a mainstream technology that converts pages of print into computer documents, can also serve as an adaptive input method. OCR uses a page scanner to capture text and software to analyze the image and recognize it as text. This creates a significant compensation for those with visual impairment or learning disability because this text can be read with a speech synthesizer as text-to-speech, converted to large print, or sent to a Braille printer. OCR is used in stand-alone products such as the SARA™ (scanning and reading appliance) or with software on a personal computer. Naturally, recognition accuracy is critical for success, but excellent accuracy is achieved with high-quality printed materials.

Use of Single Switches for Input: Morse and Scanning. Single switches can be used for direct selection. The consumer needs control and endurance at one motor site (e.g., a finger or eyebrow) and the cognitive ability to learn and recall codes, which can be sent via one or two switches. Those with the motor ability to send both long and short signals use one switch. Those unable to vary switch closure must use two switches, one for dit and one for dah. Once the code is sent, computer software converts signals into alphanumeric characters, keyboard shortcuts, or OS macros. Morse code supports writing, using spreadsheets, and Internet browsing. Using a body part that can be moved quickly, it is possible to text at 30 words per minute. No other input method for a person with severe motor limitation allows writing at this rate of speed (Anson, 1997). Higher word-per-minute rates are claimed for ASR, but Koester (2006) found that those with motor impairment rarely achieve these rates.

Scanning is the input method of last resort and has already been described. When a consumer lacks the ability to accurately choose one item from a set of all options (e.g., a key on a keyboard or touch screen), an array with subsets of options is offered. The individual chooses by activating a switch, but the time spent waiting makes it very inefficient. This delay increases further when the consumer cannot see. In this case, auditory scanning is used, and the consumer listens for an announcement of each choice just before it is available for selection. Scanning arrays can be used to control computers, EADL, and AAC

Definition 18-2

Basic Scanning Modes

Automatic—The consumer presses the switch to initiate scanning and bring up an array of choices. The cursor highlights items in the selection set one at a time. The consumer presses the switch to choose when the desired item is highlighted.

Inverse—The consumer presses the switch to initiate scanning. The consumer must maintain pressure or switch activation to enable the cursor to move through the selection set or array of choices. When the desired item is highlighted, the consumer releases the switch to choose it.

Step—The consumer presses the switch to bring up the array and to move the cursor to the next item in the selection set or array. The highlighted area moves to the next item each time the switch is pressed. A selection is made when the cursor dwells on an item for a preset amount of time and the consumer refrains from pressing the switch.

devices. Information on scanning modes is provided in Definition 18-2.

New Input Technologies. Work continues on development of a BCI. This topic is related to neural prosthetics in which an artificial device replaces the function of an impaired nervous system or sensory organ, for example, a cochlear or retinal implant. Currently, BCI occurs primarily through noninvasive techniques that capture brain signals through electroencephalogram (EEG) or with sensors located with the help of functional magnetic resonance imaging (MRI) or magnetic encephalography. Products suited for consumers have begun to appear but rely on extensive training for any level of reliable performance. Successful BCI would aid those locked in as a result of brainstem stroke or the late stages of motor neuron diseases such as amyotrophic lateral sclerosis (ALS) or MS.

Modifications to Computer Output

Once a computer receives input, the central processing unit (CPU) and the OS software perform the requested task. The CPU delivers output as words, images, or video on the display, as a printed page, or as a sound. Output can be a dialogue box, a finished product, or an alert sound. Individuals with sensory impairment are most affected by computer output, and this leads to the other broad category: adaptations to computer output for sensory or learning disabilities.

Screen. For most, output via the computer display is interpreted quickly via the visual system; those with impairment will need adaptation. Visual impairments range from field deficits and color blindness to low vision and the inability to perceive light; likewise, there is a range of adaptations. Some are as simple as reducing the amount of light coming from the display. Use the accessibility options in the control panel or preferences to reverse screen contrast so that letters are light on a dark background. Likewise, increase the size of objects on a display by reducing monitor resolution. To illustrate, if the resolution on a 17-inch display is set to 1280 × 1024, then changing it to 640 × 480 will make text and icons appear twice the size.

Those with more significant vision issues will need screen enlargement software that can magnify the screen 2 to 16 times. One product, ZoomText™, shown in Figure 18-10, creates a virtual magnifying glass for a section of the screen. The user shifts between the normal display and a magnified area to see parts of the screen that are of interest, for example, a radio button. Screen enlargement software offers the option of highlighting words as a speech synthesizer reads them. Listening while seeing larger text allows hearing to support weak vision. Software also allows users to set up default colors for text and background, which supports usable vision.

When consumers have no usable vision, they need software to completely substitute for seeing, not just in application software but also in the OS. Specialized software, generically called a screen reader (e.g., JAWS™, WindowEyes™), allows a consumer to send the cursor around the display as they listen to a speech synthesizer

Figure 18-10 ZoomText™ (here with 3× magnification) offers customizable enlargement of part of the screen, with or without text-to-speech option. (Courtesy of Ai Squared, Manchester Center, VT.)

read menu choices, dialogue boxes, and paragraphs in word-processed documents. All cursor and reading functions are controlled via the keyboard's number pad or by a separate keypad. Consumers can set up preferences for speech rate, pronunciation of proper nouns, etc. Similar adaptations are used when consumers have learning disabilities. Solutions include text-to-speech tools that highlight text as it is spoken and extensive resources for writing organization, spelling, and grammar.

Refreshable Braille Display. Braille is an important tool for literacy, although audio recordings and speech synthesis are increasingly common. Today, few learn Braille, although it is highly correlated with literacy and academic achievement. Refreshable Braille on a computer lets a user "see" information on a display and read and correct errors (Cook & Polgar, 2007). The Braille display sits beneath a computer keyboard, extending beyond its front edge. Movable pins rise and fall, making tactile dots that change as the cursor moves. Proficient users easily move between keyboard and Braille display. As adaptive output, a Braille display gives access to text in web pages, numbers in a column, text in a table, and notation in a math formula. A Braille embosser prints documents by pressing dots into heavy paper, which makes it easy to make Braille resources, restaurant menus, etc.

Large Print. Consumers with low vision often use large print. Computers make it easy to change font size. Some fonts are considered easier to read. Serif fonts (with a small cap or foot) are considered better than sans serif fonts. However, OCR devices more accurately recognize sans serif fonts. Luckily, it is easy to select text in a document and change a font or size before printing.

Auditory Signals. Hearing impairment requires modification to computer output such as flashing menu bar instead of alert sounds. Otherwise, users with hearing loss usually do not require other adaptations. It is important that multimedia videos, ads, and distance learning software offer captioning and text descriptions of sound features—especially when they convey meaning.

Augmentative and Alternative Communication Devices

AAC intervention is the process of facilitating functional communication across all types of activities and environments. AAC intervention should be considered when *motor* impairments such as CP, ALS, and apraxia or when *language* impairment such as aphasia, autism, and TBI affect speech production or communication. Using an AAC device is very different from speech because it requires learning a language representation system and mastering a complex user interface.

Augmentative and Alternative Communication Intervention

SLPs with specialized training are responsible for this form of AT. Successful use requires device selection, a user interface designed to maximize speed and efficiency, extensive teaching, and practice in retrieving and using language in ADL (Beukelman & Mirenda, 2006; U.S. Society for Augmentative and Alternative Communication [USSAAC], 2012).

Occupational therapists will also encounter consumers who use *unaided* communication systems, such as sign languages, gestures, facial expressions, and looking up for yes and down for no, as well as *aided* communication systems. Aided systems use physical objects such as picture and letter boards and voice output devices such as dedicated AAC devices or apps on tablets or smartphones to convey thoughts, needs, and wants. Both types are useful depending on setting and communication partner familiarity. There are situations when paper and pencil and alphabet, symbol or picture boards and books are very appropriate. However, speech output devices allow a user to get the attention of others and communicate easily with voice output—especially to unfamiliar partners.

Most complex, dedicated AAC devices offer speech output along with a microprocessor-based storage and retrieval system. This allows messages to be prepared ahead of time, stored, retrieved, and then delivered as either synthesized or digitized speech as needed. Dedicated AAC devices have highly adaptive user interfaces and many options for customizing vocabulary for various users. They allow Internet access, use of computer applications, and control of IR devices in the environment.

Reimbursement for AAC devices has greatly improved. The Centers for Medicare and Medicaid Services (CMS) pays for them as speech-generating devices, a type of durable medical equipment (Kander, 2012).

The Occupational Therapy Practitioner's Role in Augmentative and Alternative Communication

Occupational therapists are key partners with SLPs because they often recognize individuals who could benefit from AAC evaluation and work with SLPs to identify the best access method. In addition to pointing with a finger, access methods include use of a performance enhancer, head or eye pointing, joystick, or scanning. Occupational therapists can advise on best motor patterns and on device layout. The most frequently used items should be located where the consumer has the

best accuracy because this facilitates success with the device and speeds communication. Occupational therapists can advise on single-switch selection, placement, mounting, and design of scanning arrays. Arrays should be designed so that the most commonly used items are offered as the first or second choice. Finally, occupational therapists often help with placement or mounting of an AAC device and the configuration of environments and interactions to encourage AAC device use. Occupational therapists are often the lead advocates for setting up AAC devices so patients can control IR devices in home as EADL.

Future Trends with Augmentative and Alternative Communication

There has been tremendous interest in the use of Wi-Fi–enabled touch screen tablets and handheld devices for AAC. They are attractive and not associated with disability. Additionally, they are much less expensive and available without professional assistance. Care in selection is needed because of the highly variable quality of the software for language representation, storage, and retrieval. Do-it-yourself enthusiasm can overlook the expertise of an SLP for teaching device use, developing language and literacy skills, and the pragmatic skills needed for social communication.

Electronic Aids to Daily Living

EADLs create independent control of electrically powered devices in a home environment. The name changed from environmental control unit (ECU) to EADL because it is a more accurate description of adaptive function (Lange, 2002). Instead of emphasizing the item controlled (i.e., television, telephone), the focus is the outcome (i.e., increased independence, safety, communication, leisure). EADL create access to lights, telephones, home entertainment, beds, intercoms, thermostats, door locks, and window curtains.

EADL have clearly benefitted from the surge of interest in home automation and mass-marketed technologies designed to save effort or money by remotely regulating lights, security, thermostats, and sprinklers. These same products with or without an adaptive user interface increase the capacity for independent living and safety for those with disability. Good examples are products that turn on lights in response to a clap or a house robot that vacuums and washes floors while conserving energy for those with chronic illness or pain (Drew, 2012).

New home automation products let Wi-Fi–enabled devices and tablets function as control centers when loaded with free apps and hardware that can send IR signals (Fig. 18-11). Operating an iOS or Android device with a finger or with a special stylus or mouth

Figure 18-11 The Gear 4 Unity Remote is an example of a wireless link between tablet and IR emitter that enables customized control of entertainment appliances and other X-10™ or Insteon™ devices. (Courtesy of Disruptive USA, Inc., Seattle, WA.)

stick gives control of most household systems. There may always be a need for specialized EADL systems that allow advanced customization of the human technology interface for those with complex needs, but it is clear that EADL technology is more within reach than ever before.

Characteristics of Electronic Aids to Daily Living Control Technology

Occupational therapists often see consumers who are unable to reach or manipulate knobs, dials, and buttons or who are limited by pain or fatigue. Like other forms of AT, EADL can be controlled either through direct (speaking a command or pressing a button) or indirect (scanning) methods. Most direct-selection devices are developed for the mass market and therefore are inexpensive and found in electronics stores. If direct selection is not possible, even with control enhancers, a specialized AT product may be needed. The same criteria previously discussed for computers or AAC devices apply to choosing an access method for EADL.

Appliances vary in complexity of the control signals they require. For example, turning on a light requires only an on/off signal, but reshuffling the songs on the CDs in a five-disc player requires a complex control signal. Control signals can be transmitted by several methods: through the electrical wiring in a house, by IR or RF, or by a combination of these. Transmission technologies are often associated with control of specific types of devices.

Using a building's electrical wiring for control of electrical appliances is excellent for controlling appliances, such as lights or fans, which require only simple on/off or dimming signals. Technology called X-10™ has long been used for this function. X-10™ transmits a signal through the pathway of the house wiring. A newer technology, Insteon™, uses the same approach but is faster and more reliable while still compatible with X-10™. Both types offer command centers that plug into the house wiring and receiver modules that are controlled by IR or RF signals.

Both types send a coded signal that is intended for a module with a specific address, for example, a light at the far end of the house. Insteon™ modules offer an important additional feature because they respond to Wi-Fi or internet communication. This allows control of modules in its home automation system via Wi-Fi–enabled smartphones and tablets or even from a remote location outside the home.

IR signals are invisible to the human eye and are used to control things within line of sight. Television remote controls use this technology because the user is typically sitting directly in front of the television. The IR signal is interpreted by an IR receiver, which translates the signal into an output or function. Various patterns of IR light are coded for various devices and functions. IR tends to be used in applications that require multiple adjustments, such as television sets, DVRs, and CD players. Insteon™ and X-10™ have receivers that can convert IR signals into house wiring signals for control by AAC devices, power wheelchair controllers, etc.

RF signals, another transmission technology, do not require line of sight and are not affected by obstacles such as walls. Devices using RF offer consumers a choice of bands in order to bypass heavily used channels. That is, the consumer can change the frequency band so as not to turn on devices in the neighbor's house. RF signals are typically used to open garage doors and unlatch front doors. They are also used in Insteon™ or X-10™ systems equipped with an RF receiver that converts the signal for transmission through house wiring.

Simple or Complex Electronic Aids to Daily Living

A simple EADL gives alternate control over one electrical device. It can take the form of a large-button remote control or a household appliance plugged into an AbleNet PowerLink®4 (Fig. 18-12). This type of EADL

Figure 18-12 The redesigned PowerLink®4 gives customizable, single-switch control of any plug-in device such as a blender, fan, etc. (Courtesy of AbleNet, Inc., Roseville, MN.)

is useful for teaching cause and effect, increasing personal control, or developing responsibility. Simple EADL can be set up to work in momentary mode (i.e., work only as long as the switch is activated) or latched mode (i.e., stay on until the switch is pressed again to turn off the device). A device like the PowerLink®4 appliance interface can be easily incorporated into a group participation activity. Similarly, an AAC device that sends an IR signals to an Insteon™ module can turn on a bedroom light and give control over personal space. Picture phones with large buttons and speed dial or phones that scan phone numbers give modified phone access with simple interfaces. AbleNet offers an EADL selection guide that provides an overview of options (Resources 18-1).

Consumers with a desire for control over more devices within their environment will need a system that offers complex EADL functions (see Fig. 18-3). These systems exist as dedicated EADL devices, as a feature of an AAC device, and through computer-, Internet-, or Wi-Fi–enabled systems. Dedicated devices perform complex adjustments to multiple systems within a consumer's environment. Some use voice commands; others use scanning input to take commands. They respond to user input and use a combination of transmission technologies based on what is best for the appliance being controlled.

The rapid development of home automation devices has created the potential for the same AT device that enables speech or powered mobility or use of a Wi-Fi–enabled tablet to monitor security cameras, change the thermostat, and turn on the home theater. Of course, those relying on home automation must plan for power loss with an uninterruptible power supply for safety.

Sensory Accommodations

Many therapists find opportunities to suggest technology for vision loss because of the older adults they treat for hemiplegia, movement disorders, and orthopedic impairments. Often, these adults are unfamiliar with digital technologies and so are not necessarily ready to adopt the microprocessor-based aids that are available. Simpler forms of AT devices are needed.

Closed-Circuit Television

Consumers with low vision and limited interest in computer-based adaptations may benefit from CCTV systems. CCTVs use a camera mounted downward facing so it focuses on a surface where the individual places the item of interest—greeting card, recipe, invoice, or magazine article. The camera sends the image to a flat-panel display positioned at eye level for which the user sets magnification, color, and contrast. This same

---

technology exists as small, portable handheld units that are easy to use for reading a menu or a price tag when shopping.

Reading Appliances

OCR technology (previously described as computer input) is offered for those who are not interested in or ready for computer use. These "reading machines" provide an extremely simple user interface with bright, textured buttons that control the process. A camera photographs the image of a page of print placed on top of the device. Using amazingly intelligent OCR, the internal processor recognizes the text on the printed page and immediately begins to read it. A speech synthesizer reads at a user-selected speed and volume in the language of the text.

For consumers with visual impairment, portable microprocessor-based note takers function like personal digital assistants (PDAs). Consumers can choose between models with a six-key Braille keyboard or a full **QWERTY** keyboard. Some models offer speech feedback via earphone; others allow review via a refreshable Braille display. Consumers can record notes from class or a meeting and later upload them to a computer or print them directly to a paper or Braille printer. These devices function as smartphones with calendars, contacts, and reminders, with the ability to access the Internet.

Closed Captioning

Real-time closed captioning is an important technology for those with hearing impairment who do not understand ASL. Early systems required a stenographer who could capture spoken language and a computer to process and display the text. A speaker's words then appeared as they were spoken. Speech recognition technology has advanced to the point that a stenographer is not always needed. This makes it more useful

when groups need to accommodate those with hearing impairment.

ENVIRONMENTAL ACCESS AND UNIVERSAL DESIGN

AT devices enable participation and control only when the human and nonhuman environments create access for consumers and their devices. Independent power mobility is only an advantage in places with ramps and doorways that are wide enough to allow entry. Consumers using AAC devices can only communicate if people will take the time to interact with them. Within AOTA, this philosophy is evident in the skills and practice document produced for technology and environmental interventions (AOTA, 2010b). If architects and product designers truly consider human variability, many barriers can be eliminated. This concept, universal design, means that products and environments are designed to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design (Center for Universal Design, 2012).

LEGISLATION AND FUNDING FOR ASSISTIVE TECHNOLOGY

At times, inexpensive solutions can be found to enhance the consumer's occupational performance, but sometimes AT equipment is costly. Although cost should be considered, the consumer's abilities, needs, and specific occupational goals should drive the assessment, and the compelling need for an AT device or service should drive the search for funding (Table 18-2). If the best solution facilitates the consumer's occupation but is expensive, the AT team needs to document its contribution and present a strong case to the funding agency or to a community nonprofit or advocacy group.

Justification Letter

This documentation is an important component of getting AT devices and services funded. Occupational therapists use the knowledge gained from the consumer-centered assessment, trial use of a device, interviews with significant others, and, possibly, a home visit to justify the need for AT devices. In medical settings, a physician's prescription is needed for all requests and generally accompanies the

Table 18-2 Sources of Assistive Technology Funding for Adults

Funding Source	Available to	Notes
Private health insurance	Employees and dependents	Vary by policy benefits
Medicaid	Those with low income or with a waiver, for example, for brain injury	Limited devices, may pay for services
Medicare	Those who qualify for disability or older than 65 years of age	Limited devices, may pay for services
PASS Plan (Plan to Achieve Self Sufficiency)	Individuals receiving Social Security Disability	Social Security benefits can be sheltered and saved for AT
Public/private agencies	Vary by community but are often diagnosis related	For example, ALS Society, Muscular Dystrophy Association
Grants/trust funds/legal settlements	Applicants, beneficiaries, and plaintiffs	Must meet funding or inclusion criteria
Friends, relatives	Families with resources who can organize an appeal	AT devices and home modifications are tax deductible
Clubs, churches, service organizations	Members or individuals who match fund-raising focus	For example, Lions Club's interest in visual impairment
Vocational rehabilitation	AT devices and training needed to prepare for or return to work	Vocational rehabilitation services are available in all 50 states
Worker's compensation	Employers insurance that covers those injured at work	Restore independent living and possible return to work
Veterans' Administration	Covers in service-related injuries for military	Generous benefits, also covers recreational AT
Low-interest consumer loans and device lending libraries	Available through Tech Act Projects located in all 50 states and U.S. territories	(Bailey, Weber, & Meidenbauer, 2012; U.S. Congress, 1988/1998, 2004)

therapist's letter of justification. For work-related funding sources, another form of "prescription" may be needed.

To develop a report, the occupational therapist uses knowledge gained in clinical assessment, knowledge of product features, and the expected outcomes for the consumer. Clear writing, case data, and sometimes photographs or videotape footage of the consumer using the device are used to show that the cost of AT devices will be offset by an increase in function, employability, and/or greater independence. The report needs to be tailored to the funding source; for example, Medicaid requests must use medical necessity to justify AT devices and services.

A denial letter does not always mean "no" as a system of appeals is used to weed out groundless requests. Always get a denial in writing, and then prepare an appeal letter while honoring deadlines. The mandate to pay for AT is clear, but payers still raise objections to avoid obligations. A clear, logical letter of appeal can win payment for AT devices and services.

ROLES OF OCCUPATIONAL THERAPISTS IN ASSISTIVE TECHNOLOGY INTERVENTION

AOTA (2010b) has published a specialized knowledge and skills document for the practice of AT and environmental interventions that provides the foundation for this section. The document presents guidelines for entry- and advanced-level skills that define minimum levels of knowledge and skills for practice in the area of technology. Of course, therapists have an ethical responsibility to do no harm and be aware of their level of competence. Novice therapists should seek supervision, mentoring, and continuing education opportunities to build their level of skill and competence.

Most occupational therapists should be able to assist with AT for common needs or topics covered in this chapter such as modifications to accessibility settings in the computer OS, trials with performance enhancers, and knowledge of general categories of AT intervention. They should also be able to discuss and describe the benefits of AT with their clients and give them hope for regaining occupations by means of AT solutions available through specialized AT evaluation and service delivery. Consumers with complex needs and goals should be referred to an occupational therapist with advanced practice skills or to an interdisciplinary AT center such as one supported by a university, Easter Seals, or a Tech Act project. Referrals can also occur via telerehabilitation. Telerehabilitation research has demonstrated equivalence between remote and in-person services (AOTA, 2010a; Schein et al., 2011). Referring to experts creates an opportunity for OT practitioners to increase their knowledge about AT. Additionally, they can contribute to the process with in-depth knowledge of consumer skills, abilities, and needs and position themselves to collaborate in follow-up as the consumer

begins to integrate an AT solution into everyday tasks and routines. We discussed roles for the professionals within the AT assessment team, and now we present possible roles for occupational therapists.

Assistive Technology Specialist

Occupational therapists with AT service delivery expertise usually strive for the assistive technology professional (ATP) credential. This certification, offered through the Rehabilitation Engineering and Assistive Technology Society of North America (RESNA), sets a standard for entry-level expertise for AT knowledge and experience. RESNA is an interdisciplinary professional association of those with a desire to improve the potential of people with disabilities to achieve their goals through the use of technology. Professionals with the ATP credential adhere to a code of ethics, practice within their scope of knowledge, practice in a consumer-centered manner, and stay current in their area of AT specialty. RESNA now offers a specialty credential for seating and mobility and anticipates offering specialty credentials for other types of AT (RESNA, 2011).

Product Development Team and Product Testing

Occupational therapists contribute significantly to engineering and research teams because of their broad clinical knowledge of impairment and their comfort with functional tasks and environments. They can help engineers conceptualize consumer needs as well as the device's output features and user interfaces. Occupational therapists are also excellent partners for testing prototypes and measuring the efficacy of devices for treatment and compensation.

Continuing Education for Keeping Current

AT for remediation and compensation will be constantly changing, so occupational therapists practicing with technology must commit to continuing education. Device manufacturers and professional organizations continuously offer education (see Resources 18-1). University courses, sessions at annual conferences, weekend workshops, online courses, journal articles (Research Note 18-1), and thoughtful consideration of the application of consumer and entertainment electronics allow practitioners to gain the knowledge and skills needed to incorporate technology into a range of practice settings. Listservs, like those offered by AOTA, RESNA, and university programs, allow novice practitioners to use the expertise and help of experienced AT practitioners to solve practical problems or develop effective plans for referral.

Research Note 18-1

Abstract

The successful motor rehabilitation of stroke patients requires early intensive and task-specific therapy. A recent Cochrane review, although based on a limited number of randomized controlled trials (RCTs), showed that early robotic training of the upper limb (i.e., during acute or subacute phase) can enhance motor learning and improve functional abilities.

Purpose

To determine whether training with the Neuro-Rehabilitation-roBot (NeReBot) resulted in comparable reductions in motor impairment and enhancements of upper limb function as compared to conventional upper limb exercise (control).

Method

Twenty-one patients, aged 18–85 years, within 20 days of a first, single ischemic or hemorrhagic cerebrovascular accident with paralysis or paresis and with sufficient cognitive and language capacities to understand directions were randomized to the experimental or control group. For the experimental group ($n = 11$), NeReBot was used as an alternative to standard treatment 35% of the total treatment time. NeReBot assists movement of the upper limb in three-dimensional space, simulating hand-over-hand therapy. The patient is told to anticipate the trajectory to add the necessary active contribution to the movement of the limb. The NeReBot provides visual and auditory feedback. Each session lasted 20 minutes; number of sessions per day or week are not reported; total treatment lasted 5 weeks. Therapy for the control group ($n = 10$) was not described.

Results

An evaluator, blind to group assignment, evaluated each patient at the end of the 5-week treatment period and at 3-month follow-up. Before-after training improvements in motor and functional scales within each group were all statistically significant at the 5-week mark, indicating that both groups improved. However, because of ethical considerations, a no-treatment group to control for spontaneous recovery was not possible, so it cannot be said for certain that therapy, with or without robotic enhancement, was responsible for the improvement. The between-group comparisons revealed no significant differences between groups either at the end of therapy or at follow-up. All patients in the experimental group voiced favor of including NeReBot training in the post-stroke rehabilitation program.

Implications for Practice

- Therapy appears to enhance recovery that is occurring spontaneously post stroke.
- Patients enjoy engaging in therapy that involves novelty (robot assistance).
- Repetitive, active movement therapy for 20 minutes per day for 5 weeks results in improvement of motor impairments and function as measured by the FIM™ and the Box & Block Test.

case example
Mr. S.S.: Using High-Technology Adaptations

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	**Examples of Internal Dialogue**

Patient Information

Mr. S.S. is a 29-year-old male who is 4 months post-traumatic brain injury (TBI) sustained in a bicycle crash with injury to his right motor cortex. He is left-hand dominant and has worked hard in rehab to regain strength, range of motion (ROM), and fine motor skills. He has a positive attitude and is eager to return to his work as a civil engineer and reduce his dependence on his wife. Although very eager to return to work, Mr. S.S. is concerned that continued limitations in his left hand prevent writing and keyboarding and that he has occasional gaps in task sequencing and recall of recent events. Mr. S.S. is being referred for an assistive technology (AT) assessment to identify compensations for these remaining deficits and to support his return to work. Mr. S.S. and his wife both like technology and use computers intensively at work and to manage their household.

Objectives	Examples of Internal Dialogue
Understand the patient's diagnosis or condition	"I can see that Mr. S.S. is eager to change his focus from rehab to getting back to work. It is great to have a client who had an active healthy lifestyle and is so well supported by his wife, his vocational rehabilitation counselor, and his employer. His desire to return to work definitely links him to vocational rehabilitation funding."
Know the person	"Both Mr. S.S. and his wife use and like computers, so 'talking computers for work' is a nice change from rehabilitation topics."
Appreciate the context

Develop provisional hypotheses | "AT devices and environmental modifications can help him **compensate** for motor and cognitive impairment. I expect there will be **remediation** of cognitive deficits through graded return to familiar work tasks. Computers are predictable and sequential, and reengaging in work-related tasks could support recovery." |

AT/OT Intervention Process

Based on this information, it is clear that AT should focus on finding an adaptive computer-access strategy so that a keyboard and software could help support compensation for and remediation of memory and sequencing skills. Although his task sequencing for self-care skills has progressed, a computer-access assessment will show his ability to retain and use new learning. Mr. S.S. and his wife were pleased that the occupational therapist will make a workplace visit to identify barriers or needed modifications to increase the possibility of success. With Mr. S.S. and his wife, these AT goals were agreed on:

1. Return to productive computer use with an adaptive computer-access method
2. Use Outlook® calendar, tasks, and contacts synched with his smartphone as a cognitive support for work events and tasks
3. Determine need for workplace modifications to optimize safety, independence, and social supports

Mr. S.S. and his wife like this plan, which begins to move their life back toward "normal."

	"It seems like Mr. S.S. and his wife are grateful for his recovery to this point. Although they expect more, they are willing to compensate now."
	"I'm not sure that Mr. S.S. and his wife know what is ahead, but at this point both are relieved to be moving beyond treatment to achieve medical stability and into activities that focus on return to function."
Consider intervention approach and methods	"I think an intensive approach is needed so a return to work can happen as soon as possible. I would like to increase the amount of time at work and the complexity of tasks, but we will go ahead and get started."
Consider what will occur in therapy, how often, and for how long	"I have tried to devise a plan that will allow one skill to build on another. I want to avoid overwhelming him. The emphasis will be on developing one skill at a time and taking one day at a time."

"Occupational therapy (OT) sessions will need to happen about three times a week to ensure continuity and sufficient opportunities for teaching, learning, and practicing." |

Computer-Access Assessment

They returned for a 2-hour computer-access evaluation that allowed the occupational therapist to observe common computing tasks for reach, finger isolation, pointing accuracy, text entry, and success with three-step instructions and to introduce several hardware and software adaptations. The occupational therapist recorded results of task trials and Mr. S.S.'s opinion of the computer adaptations presented. The results pointed to three strong tactics: learning to use a trackball with his left hand to include his impaired side yet increase pointing accuracy, learning to use the HalfQWERTY™ keyboard for simple text writing, and learning Dragon Naturally Speaking™ (DNS™) speech recognition for writing reports and longer e-mails. The plan will involve 3 weeks of AT sessions for learning and skill development, followed by another 3 weeks of transition into the workplace as direct services fade to direct services only as needed.

Because Mr. S.S. reported during the assessment that his work desk is in a cube environment, the occupational therapist needs to consult with Mr. S.S.'s supervisor before finalizing use of DNS™ or proceeding with training. A noisy environment can affect recognition accuracy. Training will begin with a trackball and HalfQWERTY™. With this decided, Mr. S.S will have occupational therapy training in these adaptations three times per week for 3 weeks with follow-up activities for practice and learning at home. AT devices will be loaned for home use to support continuity and practice. This will assure confidence when asking purchase approval from vocational rehabilitation. His wife will attend as many sessions as possible so that she can help bridge between occupational therapy and home practice.

Computer Access Results

In his first training session, Mr. S.S. really liked the four-button trackball. He realized immediately that a trackball separates the actions of pointing and clicking. His earlier efforts at mouse use were frustrating because trying to click the mouse button with his left index finger caused an involuntary arm movement that moved the mouse cursor off its intended target.

The occupational therapist introduced him to the trackball with computer solitaire, where he used new movement patterns to point, click, and drag cards to appropriate locations. The occupational therapist observed the intense effort he made to isolate his little finger for left button clicks. The occupational therapist moved the function of the left-sided button to the lower thumb side button, which reduced his distraction and increased his efficiency.

Once confident with this new skill, he appeared to transfer it directly to more accuracy with desktop and file management activities.

The occupational therapist sent Mr. S.S. home with a loaner trackball to practice the new motor skill with a simple graphics application on his home computer. She knew that concentrating on a game would help increase his attention span and make demands on his procedural memory.

Select an intervention approach	"Wow, he is actually doing better than I expected. That reminds me of the power of motivation and a personally meaningful goal."
	"I must remind Mr. S.S.: Be sure you have the right tool before you proceed. DNS™ is a powerful tool for text entry, but there are just some contexts where it is doomed to failure!"
	"I am so glad his wife is a willing partner in this process. That will help Mr. S.S. be successful. His vocational rehabilitation counselor is really pleased with his enthusiasm and focus, too."
Interpret observations	"I think the fact that Mr. S.S. is an engineer makes him a good AT client and problem solver. He likes using technology to solve problems. This is a familiar concept to him and one that he uses to solve his client's problems, too."
Select an intervention approach	"I hope that he and his wife have fun with this trackball approach. I whispered to his wife the suggestion that she help him find a practical goal for using the drawing app. Could he draw up plans for a ramp for their garage door?"
	"Can you believe he was able to draw up the plans for a simple 1:2 sloped ramp for the 4-inch step up in their garage?"
	"Motor learning theory in action! I am so glad that I took the time to explain the concept underlying HalfQWERTY™. I think that I really liked the idea that he had this basic motor pattern in his brain and that he just needed to modify it."
	"It is so important to remind clients about the complexity of what they are trying to accomplish. A bright perfectionist like Mr. S.S. needs encouragement to be focused on process and not solely on results."
	"I am really starting to feel confident that I am on the right path with Mr. S.S. Each person with a TBI is so unique. He has an amazing ability to self-assess, and this is a skill so often missing in the presence of TBI. This bodes well for his future."

In the second training session, the results of home practice were reviewed prior to starting work with HalfQWERTY™. The occupational therapist recorded how well he used the trackball in a 5-minute demonstration with solitaire. She knew he had practiced, retained skill, and regained confidence with his new abilities.

The recommendation for using HalfQWERTY™ was based on the fact that Mr. S.S. was a strong touch-typist. During the AT assessment, he had shown that he understood the concept of using his right hand to type assigned keys and using his right hand as it held down the space bar to type keys on the left side of the keyboard. During this session, Mr. S.S. began formal instruction in using the software. The occupational therapist used the tutorial that comes with HalfQWERTY™ to introduce the new motor patterns needed for letters previously typed with the left hand. Repetition of motor patterns, gradual introduction of new letter combinations, and avoiding any concern for speed allowed Mr. S.S. to end the occupational therapy session typing at a rate of 8–10 words per minute—as fast as writing long hand.

The occupational therapist gave his wife instructions so she could download the demo software to enable home practice before his next visit. The goal was to return with two approximately 100-word paragraphs typed by his right hand alone.

At the next visit, Mr. S.S. met the goal but reported that it had gone very slowly. The occupational therapist praised and reassured him that he was doing extremely well. The occupational therapist reminded Mr. S.S. to pursue accuracy over speed, assuring him that new motor patterns would develop and speed would return.

The next two sessions were spent with more focus on a "drill and practice" approach intended to develop proficiency and speed. Each session ended with a home assignment to start writing a personal journal about his recovery.

On the fifth session, Mr. S.S. was able to type 17 words per minute and was pleased to have more than met his goal of 15 words per minute. He reported he was expending less cognitive effort and had started pressing the correct keys without conscious thought.

Just prior to his sixth session, Mr. S.S.'s supervisor responded to my questions about the noise level in the cube. The company will not only move his desk to an enclosed office space but reported that the IT manager will integrate any needed software into his computer system.

This allowed training to begin in use of DNS™. His success with the trackball and strong progress with HalfQWERTY™ gave him tools that he would be able to use instead of having to learn voice commands. Many editing actions can be done by keyboard or mouse.

Select an intervention approach

"Great, I am very relieved that I can proceed with teaching DNS™. His interest in learning and adopting other adaptive computer-access methods gives me assurance about his potential for success with this application. The cube environment was my major worry."

"I am so pleased that Mr. S.S. is grasping the big picture and is able to see how these adaptive strategies work together for a comprehensive approach."

"I'm really starting to see progress. Each time Mr. S.S. comes in with a finished assignment, I see his confidence grow too. He has used my incremental approach, and that makes me feel good too."

"Who knew that engineering firms commonly encourage team problem solving? Mr. S.S. even seemed to appreciate Joe's presence and exceeded my expectations."

"Many people have ended up rejecting automatic speech recognition because of this issue. I hope he can adopt this trackball strategy."

The occupational therapist used the next four sessions to introduce DNS™ and develop his confidence with using his voice to write. First, they created a voice file and then, using a quick-start menu, started writing text using speech and voice commands. The occupational therapist showed that the keyboard and trackball can substitute for a voice command. The trackball gives access to menus and HalfQWERTY™ allows typing (rather than speaking) to correct recognition errors. The occupational therapist focused intervention on training recognition accuracy and building vocabulary. These skills actively build voice files and refine recognition accuracy. The next session was focused on developing a pattern that is important when using DNS™—"preparing to write" or silently developing an idea before speaking it.

During prior conversations, the occupational therapist had learned that a coworker and friend, Joe, also used DNS™. Mr. S.S. really liked the idea that Joe could be a DNS™ resource at work. He agreed to have Joe come to one of their DNS™ training sessions so that he could understand how Mr. S.S. used DNS™. By the end of the session with Joe, Mr. S.S. had written 200 words and corrected six recognition errors as Joe watched. Mr. S.S. had learned to pause and think before speaking and had adopted a speech pattern that is clear and deliberate when using his voice for writing.

"Hmmm, what about his pal, Joe? Would Mr. S.S. allow a colleague at work to give him some assist?"

The occupational therapist had given Mr. S.S. the home practice task of using DNS™ to dictate 100 words per day in his daily journal documenting his recovery.

"He is so proud that his journal is growing in pages and that his sentences are longer . . . like they used to be."

Synch Outlook® with Smartphone

The occupational therapist knew that when DNS™ got installed on Mr. S.S.'s workstation that it would integrate well with Microsoft Office® and Outlook®. The DNS™ version selected for Mr. S.S. includes commands for immediate use with Microsoft Office®. As a first action, the occupational therapist directed DNS™ to import the vocabulary and the names stored in Word and Outlook® documents. This instantly customizes DNS™ and makes it more powerful for writing and managing daily tasks and calendars. Mr. S.S. will be able to add new information either with DNS™ or with HalfQWERTY™ based on which is more suited to the task.

Select an intervention approach

"Now the process gets a little more complicated as I start to transition him back to the work site from our weeks of AT sessions. I am going to need people at the firm to help me with the systems issues there. I should better make a list."

Mr. S.S. had been using a smartphone for several years but had not put any effort into synching with his work computer. His situation was suddenly different, now that he was dealing with the consequences of a TBI. He needed to have calendars, contacts, and tasks synched to his smartphone. The occupational therapist will record the steps for the synching process and create a step-by-step guide in the notes section of Outlook®.

Appreciate the context

"I need the IT manager to confirm that Mr. S.S.'s phone is compatible with the network, and I need help with passwords and access to directories. I need the DNS™ and HalfQWERTY™ software loaded onto his workstation. His smartphone needs to have proper security for synching with the network and using the office Wi-Fi connection."

"Mr. S.S. does not need the challenges of learning or resolving these issues right now, he just needs it all to be ready to go! He will learn more as he is ready and as recovery becomes more solidified."

The occupational therapist will recruit his wife to create medication reminders and set up other personal reminders like birthdays or holidays and scheduled appointments for the household.

"It is great that technology that helps so much at work will help in his personal life, too."

"Oops! I need to remind his wife to create a personal calendar for home events so they do not get imported to his work calendar."

The occupational therapist looked for Joe while at the engineering firm and told him that Mr. S.S. would soon be starting a daily schedule but for only 4 hours per day. The occupational therapist gave Joe AT center contact information and asked him to call if he saw that Mr. S.S. was having unexpected problems with new computer skills.

"Glad to know that Joe already synchs his smartphone with the firm's Outlook® calendar, contacts, and task lists. Another resource for Mr. S.S."

Assess the Workplace for Accessibility

The occupational therapist was pleased with the results of the workplace visit. The engineering company is located in a fairly new building, which brought several benefits:

- Handicapped parking and accessible bathrooms are available.
- The new enclosed office space made available to Mr. S.S. is close to Joe's cube. This office is one that was previously used by visiting staff so Mr. S.S. will have to share this office space occasionally. This will allow him to measure the interference created by others' conversations and perhaps lead to returning to a cube as microphones and recognition continue to improve.

Vocational rehabilitation has agreed to pay for future occupational therapy visits to address changes in his access method or office software. The vocational rehabilitation counselor will also be checking on Mr. S.S. and will alert the occupational therapist if more intensive support is needed. Mr. S.S. and his wife will return to the AT center for a follow-up visit in 6 weeks to assess progress and any new issues.

Understand the patient's diagnosis or condition	"Mr. S.S. has regained so much of his mobility that his mobility issues are now actually pretty minimal. He will be adequately served by standard Americans with Disabilities Act (ADA) accessibility accommodations for bathroom and parking."
Appreciate the context	"Mr. S.S. must really be a valuable employee because his company really went out of the way to meet his needs and reintegrate him into the office."
	"With three vocational rehabilitation-approved AT visits remaining, I know I have approval for follow-up to help him succeed."
	"It is hard to see my collaboration with Mr. S.S and his wife come to an end. We have all worked hard, and it feels great to see his progress."

Clinical Reasoning in Occupational Therapy Practice

Assistive Technology Related to Self-Maintenance Roles

Claire, a 65-year-old widow, is increasingly frustrated by the effects of macular degeneration on her activities of daily living (ADL) routines. She has become dependent on her daughter, Jean, to stop by her apartment daily to assist her with visual tasks. Claire is upset because Jean's husband has taken a new job in another state, and they will be moving soon. Jean has heard that there are low-vision aids that might help restore her mother's confidence and self-sufficiency and wants to help her mother find resources. Claire's goals include restoring her independence with food preparation, bill paying, and reading correspondence; feeling safer at home; and feeling better about herself.

1. What kind of assistive technology (AT) solution might allow Claire to regain some of her self-sufficiency and ease her daughter's mind about moving away?
2. What pieces of equipment would assist Claire in her apartment?
3. What would help ensure a better "fit" between Claire and this equipment?

Clinical Reasoning in Occupational Therapy Practice

Assistive Technology Related to Self-Advancement Roles: Return to Employment

Charles is a 55-year-old psychologist discharged 2 weeks ago from an acute inpatient rehabilitation stay. He has made a significant recovery from his second Guillain-Barré syndrome (G-B) episode, an acute polyneuropathy that affects the peripheral nervous system. In his work as a counselor, he always makes session notes at the end of each patient visit and for efficiency uses a laptop computer. Actually, he explored Dragon Naturally Speaking™ (DNS™) following his first episode of G-B but did not have the confidence to adopt it as a tool without support. This episode, his hands have been more affected, and he has not yet recovered quick, independent finger movements like those used in keyboarding. His outpatient occupational therapist, Jeanne, has experience with DNS™ because she used it when writing long documents back in college. She immediately recognized the value of automatic speech recognition as an adaptive strategy for Charles. Not only would it allow him to return to work more quickly and help to restore his professional identity, but it would also enable him to log his recovery from this second G-B episode and restore his ability to communicate with friends and colleagues by e-mail.

1. What environmental characteristics of Charles's office space make automatic speech recognition a good AT solution?
2. How should Jeanne set up her outpatient occupational therapy (OT) treatment sessions so that she can charge for instruction in the use of an AT solution?
3. How long should treatment persist, and how will Jeanne know when she has met a treatment goal for this activity that affects both Charles's professional and personal lives?

Summary Review Questions

1. What social, reimbursement, and scientific factors have driven interest in using technology for remediation?
2. What is a key challenge for occupational therapists using VR and robotic interventions in rehabilitation for neurological diagnoses?
3. What is a minimal level of AT competence needed by a therapist providing services to adults with physical dysfunction?
4. How do occupational therapy activity analysis skills guide a therapist in exploring AT solutions for a particular consumer?
5. For adaptive computer use, list two input and two output devices (other than a keyboard or standard mouse or display), and describe consumers who might need these modifications.
6. What are the differences between RF and IR control interfaces that make them more suitable for one EADL versus another?
7. Where and how can occupational therapists learn more about recommending AT devices and services?

Glossary

Abbreviation expansion—Software designed to decrease keystrokes, increase efficiency, and decrease errors. For example, OT is the abbreviation for occupational therapy. The abbreviation is entered instead of the words, and software expands the abbreviation into the words or phrases it represents.

Array—When indirect selection is used, the array is the set of options that are presented in sequence. The user selects from an array by waiting until the desired item is offered and then activates a switch. Some items in an array may branch to a secondary array, for example, when a punctuation array is opened from an alphabet array.

Augmentative and alternative communication (AAC)—A communication system that requires using something external to the body. Examples include pen and paper, letter or picture communication boards, and communication devices. Gestures and vocalizations are often used to enhance communication when using an AAC device. Devices may be manual or electronic. AAC devices use a language representation system, for example, letters grouped into words or picture symbols.

Automatic Speech Recognition (ASR)—Software that enables recognition of spoken words through a sophisticated process of sound pattern recognition, predicting the likeliest phrase or pair of words, and analysis of user writing style and vocabulary; sometimes called speech-to-text.

Bluetooth—The short-range wireless interconnection of cellular phones, computers, and other electronic devices.

Brain-computer interface (BCI)—Technology that creates a pathway between neurological signals and an external device to enable direct control of impaired sensorimotor functions such as vision, hearing, and movement; also referred to as neuroprosthetics.

Computer-aided design (CAD)—Software used to design, draft, or lay out technical projects ranging from home design and architecture to manufacturing. CAD makes modifications and estimating construction costs much easier.

Digital—Continuous data or signals represented by digits. Digital devices rely on microprocessors, which express data in binary code as a series of 0s and 1s and offer output in ways that are useful for analysis, storage in databases, and entry into electronic medical records.

Digitized speech—Speech that is converted from sound wave to digital form for playback at a later time.

Dwell—This input method interprets hovering over a key or an object for a user-adjusted amount of time. It is equivalent of a mouse click and allows selection without needing an external switch.

Electronic aids to daily living (EADL)—Devices that give consumers control of appliances in their environment. This term is favored over the alternative, environmental control unit (ECU), because it focuses on the task (i.e., safety, communication, and independence) rather than the device (i.e., television, telephone, and lights). The term EADL accurately describes the technology and has helped acquire funding, both here and in Europe.

Home automation—Using digital devices to enable remote control and/or monitoring of entertainment appliances, lights, heating, sprinkler systems, security cameras, etc.

Infrared (IR) light—Light wave outside of (longer than) the spectrum normally detected by the human eye. Sequences of IR signal are interpreted as unique instructions by an IR receiver, which executes the associated instruction, for example, power on, volume up.

Microprocessor—Integrated circuit board that processes digital signals to complete a set operation and are common in all of today's technologies including AT devices.

Pixel—The smallest unit of visual display on a computer screen; a dot. These dots combine to form words and images. Pixels-per-square-inch is a measure of resolution or pixel density, for example, 640 × 480. Higher numbers indicate more pixels thus more information shown on a display.

Pneumatic—Refers to control activation by changing the amount or direction of air pressure. Sip n' Puff switches commonly are pneumatic switches.

QWERTY—Common layout for computer keyboards in which the letters in the top left row are QWERTY. This layout originated with mechanical typewriters when it was important to slow down typists so that the strike arms that printed each letter had time to avoid each other.

Radio frequency (RF)—A signaling technology that uses private radio bands to control appliances, open doors, or communicate with other AT devices.

Rehabilitation engineer—This term includes those with various engineering degrees who develop, test, customize, and support use of sophisticated digital devices by rehabilitation teams for remediation or compensation of impairment.

Scanning—A selection method in which the consumer watches an array and waits for a choice to be offered rather than actively choosing. Activating a single switch indicates choice.

Universal design—A concept used to make built space or consumer products accessible or highly usable for most people. For example, a universally designed airport considers not only persons using wheelchairs but also those who have auditory or visual impairments or who do not speak English.

Universal Serial Bus (USB)—A standard interface commonly used for connections between two or more devices (e.g., mouse, printer, or keyboard) connected to a computer. USB II supports high-speed data transfer and works on Windows and Apple computers.

Wi-Fi—An abbreviation for wireless fidelity, which is a group of technical standards enabling the transmission of data over wireless networks.

Word prediction—Software that uses rules of recency and frequency to anticipate the word the consumer is beginning to spell. It is designed to decrease keystrokes and errors but does not increase typing speed.

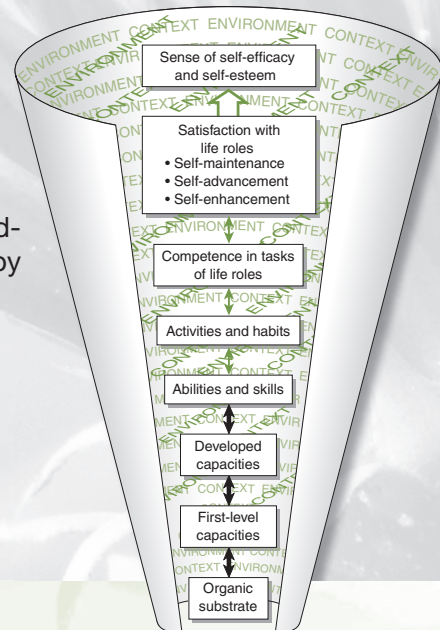
Physical Agent Modalities and Biofeedback

Christine M. Wietlisbach and F. D. Blade Branham

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the phases of tissue healing.
2. Identify the professional and regulatory issues related to physical agents.
3. Describe the appropriate indications for use of superficial thermal agents, deep thermal agents, and electrotherapeutic agents.
4. List the precautions and contraindications in the use of select physical agents.
5. Discuss the current evidence and its implications for using physical agents as part of a comprehensive occupational therapy treatment plan.
6. Describe how surface electromyography (EMG) biofeedback can be used as an adjunct to occupational therapy to restore motor control.


Physical agent modalities are interventions or procedures that produce a response in soft tissue through the use of light, water, temperature, sound, electricity, or mechanical devices. They are applied to modify specific client factors and prepare clients for engagement in occupations when neurological, musculoskeletal, or skin conditions limit occupational performance. Physical agent modalities are used in preparation for or concurrently with purposeful and occupation-based activities (American Occupational Therapy Association [AOTA], 2012). There are four primary classifications of physical agents: superficial thermal agents, deep thermal agents, electrotherapeutic agents, and mechanical devices. Superficial thermal agents include hydrotherapy/whirlpool; cryotherapy; Fluidotherapy®; hot packs; and paraffin, water, and infrared heating. Deep thermal agents include therapeutic ultrasound, phonophoresis, and short-wave diathermy. Electrotherapeutic agents include biofeedback, neuromuscular electrical stimulation (NMES), functional electrical stimulation (FES), transcutaneous electrical nerve stimulation (TENS), high-voltage galvanic stimulation (HVGS), high-voltage pulsed current, direct current, and iontophoresis. Mechanical devices may include vasopneumatic devices and continuous passive motion devices (AOTA, 2012).

The overall purpose of occupational therapy is to support health and participation through engagement in occupation (AOTA, 2008). Physical agent modalities are used as part of a comprehensive occupational therapy treatment plan as preparatory interventions to facilitate outcomes in our clients as quickly and as cost effectively as possible. The focus is always on helping our clients engage in their occupations. Physical agents can help increase soft tissue extensibility, reduce pain and inflammation, and improve muscle performance to help clients more successfully engage in occupational activity. Although other health professions may also use physical agents as part of their treatment, the occupational therapy profession's distinct approach always focuses on occupational performance.

This chapter provides a broad overview of the physical agents most commonly used by occupational therapists. This chapter reviews superficial thermal agents, such as hydrotherapy, hot packs, paraffin, and cryotherapy; and deep thermal agents, such as ultrasound, along with their biophysiological effects. A discussion of the principles and clinical application of electrotherapy and surface electromyographic biofeedback is included. This chapter also discusses tissue healing. This information, often overlooked by therapists, is vital to determine which type of agent would be most efficacious and at which point in treatment and healing it should be applied.

It is beyond the scope of this chapter to present all of the information needed to use physical agents safely and effectively. The intent of this chapter is to provide a basic description of the most commonly used physical agents and their potential for incorporation into clinical practice to facilitate engagement in occupation.

COMPETENCY AND REGULATORY ISSUES

The profession of occupational therapy has a long and colorful history, adapting and changing in response to internal and external issues and challenges. The use of physical agent modalities in clinical practice has not always been embraced within the occupational therapy professional community. However, when the new accreditation standards for occupational therapy education programs went into effect in 2008, all entry-level occupational therapy and occupational therapy assistant students were, for the first time, required to demonstrate some knowledge of physical agents upon graduation (AOTA, 2007a, 2007b, 2007c). The implementation of this educational requirement symbolized the widespread acceptance of using physical agents in occupational therapy practice. Physical agents are now an accepted tool for preparing clients for occupational performance.

Although physical agents are now accepted in occupational therapy, the use of this intervention is associated with some risk in terms of both client safety and professional liability. Occupational therapy practitioners must carefully consider three issues when deciding whether or not to use a particular physical agent modality in clinical practice: (1) the American Occupational Therapy Association's (AOTA) position on the use of physical agent modalities; (2) personal competency in the specific physical agent; and (3) federal, state, and institutional rules and guidelines surrounding use of physical agents in occupational therapy practice.

AOTA asserts that physical agents are preparatory and are to be used by occupational therapy practitioners before or during therapeutic activities that ultimately enhance engagement in occupation (AOTA, 2008, 2012). AOTA clarifies this point by stating, "The exclusive use of (physical agents) as a therapeutic intervention without application to occupational performance is not considered occupational therapy" (AOTA, 2012). Therefore, an occupational therapist who uses a physical agent modality must always do so relative to an occupational outcome. Occupational therapists who use physical agents without any application to occupational performance could be viewed by regulatory agencies as practicing outside the scope of occupational therapy (Definition 19-1).

Personal competency in using specific physical agents is another consideration for clinicians who want to use this type of intervention. AOTA states that physical agents may only be applied by occupational therapy practitioners who have documented evidence of possessing the theoretical background and technical skills for safe and competent integration of the modality into an occupational therapy intervention plan (AOTA, 2012). This sentiment is echoed

Definition 19-1

Is It Occupational Therapy?

Consider the following scenarios: Because there is evidence that electrical stimulation helps reduce post-stroke spasticity in the upper extremity (Hardy et al., 2010; Sahin, Ugurlu, & Albayrak, 2012), a therapist decides to use electrical stimulation when treating a client with stroke-related hand spasticity.

Scenario A: The therapist applies electrical stimulation to reduce spasticity and then works with the client on using the hand for grooming. The client is pleased because she is more successful using the hand for grooming if spasticity is first reduced through electrical stimulation.

Scenario B: The therapist applies electrical stimulation at the end of a treatment session to reduce hand spasticity. The client is pleased because the electrical stimulation helps reduce spasticity, and she leaves the clinic with less hand pain.

Question: Which scenario is considered an appropriate occupational therapy intervention using a physical agent modality?

Answer: Scenario A meets the criteria established by the American Occupational Therapy Association (AOTA) to be considered an occupational therapy intervention. Physical agents should always be used in preparation for, or concurrently with, purposeful and occupation-based activities. Scenario B would not be considered occupational therapy because although the client did receive some benefit (pain relief) from using electrical stimulation to reduce spasticity, the physical agent was applied without any application to occupational performance.

in the Occupational Therapy Code of Ethics and Ethics Standards, which states, "Occupational therapy personnel shall provide occupational therapy services that are within each practitioner's level of competence and scope of practice (e.g., qualifications, experience, the law)" (AOTA, 2010). Although occupational therapy programs educate students about physical agents, each institution has discretion about the depth and breadth of instruction in this area. Entry-level therapists are advised to seek additional education and training, as needed to supplement their knowledge basis, in each modality they plan to use in clinical practice. Education and training in these interventions can be accomplished through in-service training or professional education, such as continuing education or accredited higher education programs and courses.

Occupational therapists that use physical agents as part of their clinical practice also need to know federal, state, and institutional rules and guidelines, which may restrict or limit the use of physical agents. Many states have statutes and regulations related to the use of physical agents by occupational therapy practitioners. It is illegal to apply physical agent modalities without meeting the regulatory requirements outlined in a particular state's laws. Some state guidelines may also regulate or limit specific applications by occupational therapy assistants. It is the responsibility of all occupational therapy practitioners to stay up to date concerning any regulatory issues related to practice in one's state. All occupational therapy practitioners who anticipate using physical agents should contact their respective state regulatory board to obtain the most current information and should be able to document and defend their education and training in meeting regulatory requirements.

EVIDENCE-BASED PRACTICE, PHYSICAL AGENT MODALITIES AND CLINICAL DECISION MAKING

In its Centennial Vision (AOTA, 2007d), the American Occupational Therapy Association has identified evidence-based practice as a key component in linking education, research, and practice. It is imperative that we occupational therapists substantiate the efficacy of our interventions to preserve the long-term viability of our profession. Our professional literature has seen a rise in the number of research reports, including randomized controlled trials and systematic reviews, over the past 10 years, but there is still much work to be done. Many interventions used in clinical practice still need to be studied and validated. The use of physical agent modalities is one such area that requires more research. For the most part, the evidence in peer-reviewed literature is contradictory when it comes to the efficacy of most physical agents. In the absence of definitive external evidence, however, we must remember that the founders of the evidence-based medicine movement never intended for high-level research to be the *only* evidence upon which we base clinical decision making.

David L. Sackett, a pioneer in the evidence-based medicine movement, and his colleagues clarified the widespread misconception that evidence-based medicine is some sort of "cookbook" approach to patient care. In fact, evidence-based medicine is the integration of *three* distinct components: (1) current best evidence, (2) clinical expertise, and (3) patient choice (Sackett et al., 1996). It is important to note that the founders of evidence-based medicine embraced clinician expertise and patient choice as valid components of sound clinical decision making. Effective clinicians combine knowledge of the best published evidence with their own clinical skills and judgment, as well as patient preference, to develop the most appropriate plan of care for each individual patient. Therefore, it is perfectly acceptable, in the face of contradictory literature, for a clinician to use a physical agent to prepare a client to more successfully participate in an

occupation-based activity if, in the therapist's experience or anecdotal knowledge, the agent has been successful with another similar client. The therapist must carefully observe the client's reaction. Improved performance is evidence of treatment efficacy.

This chapter contains both external evidence from peer-reviewed journals and expert clinical opinion. The chapter presents evidence supporting the use of physical agents when that evidence exists and could be located by the authors (see Evidence Table 19-1). Critical consumers of this information would do well to remember that contradictory evidence abounds. We make a plea to our colleagues to conduct more high level research in this area.

TISSUE HEALING

High-level evidence supporting the use of physical agents for tissue healing is mixed. Definitive guidance will require considerably more research. However, many occupational therapists do use physical agents for this purpose, and there is widespread opinion by experienced therapists that physical agents are effective for tissue healing. Occupational therapists that choose to use these modalities need a basic understanding of normal tissue healing and an appreciation for the sequence of events that follows an injury to determine the appropriate physical agent to facilitate healing at each stage of the healing process.

Tissue healing is a complex series of events affected by both physical and psychological components. In the healthy individual, the body's attempt to heal itself in response to an injury is well ordered and sequenced. Factors such as advanced age, the presence of foreign objects, infection, poor nutrition, and medications may slow the healing process (Mulder, Brazinsky, & Seeley, 2010). Traditionally, tissue healing is thought of in terms of healing damaged epithelial tissue in the form of an open wound on the surface of the body. However, understanding tissue healing is also important in the case of internal soft tissue traumas that occur with musculoskeletal overuse injuries causing tissue inflammation and degeneration, or after surgical repair of internal soft tissue structures. In both internal and external tissue healing, the healing sequence is similar (with some minor differences depending on the internal structure and tissue involved). A basic understanding of the phases of tissue healing and how physical agents may influence each phase is helpful when addressing tissue injuries, both internal and external. The stages of healing and repair may overlap, but they consist of three primary phases: inflammation, proliferation, and maturation/remodeling.

Phase I: Inflammatory Phase

Inflammation is the initial response to tissue injury; it is both vascular and cellular. At this point, the body is working to control blood loss and to clean the wounded area.

The inflammatory response may be associated with changes in skin color (red, blue, or purple), temperature (heat), edema (swelling), sensation (pain), and loss of function. The inflammatory phase begins from the moment the injury is sustained and continues until the injured area is free from debris such as bacteria, foreign matter, and dead tissue. It is a normal and necessary phase of tissue healing. The acute inflammatory phase lasts a couple of days to a couple of weeks. Physical agents that help manage pain and control excessive edema are cryotherapy and pulsed wave ultrasound. It is important to remember that elimination of all inflammation and edema in the acute phase of tissue injury is not only unrealistic but unwarranted. Some amount of inflammation and swelling are needed to prepare the wound for the proliferative phase of healing. Inflammation becomes an issue only when it is unrelenting. Chronic inflammation indicates an abnormality in the body's healing response, and the cause of this abnormality must then be identified by a physician. Edema becomes a problem when it is excessive because it is painful and can reduce blood flow, which is critical for bringing nutrients to healing cells. *Safety Message: The use of heat during the acute inflammatory phase of healing is contraindicated because it causes physiological responses that increase edema.*

Phase II: Proliferative Phase

Once the injured area is clean, the body starts working on repairing the damaged tissue site. This repair stage is known as the proliferative phase of tissue healing. Proliferation consists of granulation, angiogenesis, wound contraction, and epithelialization. Granulation occurs when the body forms a matrix of connective tissue, including collagen, in the wound bed. This tissue is known as granulation tissue and builds on itself to fill the tissue defect, or "hole" of the wound.

Angiogenesis is the growth of new blood vessels. Very small capillary networks are formed in the matrix of connective tissue in the wound bed and give healthy wounds their distinctive reddish color. Wound contraction occurs when specialized cells in the wound bed act to pull the edges of the wound together. Finally, the wound is covered with epithelial cells that migrate across the top of the wound bed. This is known as epithelialization. The proliferation phase may take up to a few weeks to complete. Physical agents that help speed new tissue formation (proliferation) are therapeutic ultrasound and electrical stimulation.

Phase III: Remodeling/Maturation Phase

Newly healed tissue is still quite fragile and must go through the remodeling (also called the maturation) phase of tissue healing. During this final phase, collagen fibers in the wounded tissue are produced, broken down, changed,

Evidence Table 19-1 | Best Evidence for Use of Physical Agent Modalities

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Functional electrical stimulation (FES)	Use of FES to supraspinatus and posterior deltoid muscles in addition to conventional therapy versus conventional therapy only. Active electrode placed over the posterior deltoid (see the article for specifics of FES parameters).	Fifty hemiplegic patients with shoulder subluxation and shoulder pain. Mean age 60.7 years in study group, 62.0 years in control group; no statistically significant difference for age, gender, etiology, hemiplegic duration, or side affected; randomized to group	FES to affected extremity five times per day, 1 hour daily for 4 weeks for a total of 20 sessions	Randomized controlled trial (RCT) Level: 1B2a (greater intensity of therapy to control group)	Yes. FES treatment to the supraspinatus and posterior deltoid muscles, in addition to conventional treatment (not described), reduced subluxation in hemiplegic patients more than conventional treatment alone. No significant change in pain in the study group after treatment as compared to before, but the control group experienced significantly less pain after treatment ($p < 0.016$).	Statistically significant difference between the pre- and postrehabilitation shoulder subluxation values of the study group (10-mm subluxation reduced to 5 mm; $p = < 0.001$) but nonsignificant in the control group (10 mm both pre- and postrehabilitation; $p = 0.077$). Between-group comparison of change from pre- to postrehabilitation indicated a significant difference ($p = 0.025$) in favor of the study group.	Koyuncu et al. (2010)
Iontophoresis	Iontophoresis with dexamethasone sodium phosphate compared to a saline solution (placebo) for the treatment of epicondylitis	One hundred ninety-nine patients from 11 centers with diagnosis of acute elbow epicondylitis; mean age = 49.9 years (17–70 years) in study group and 50.9 years (21–70 years) in the placebo group; symptom duration ranged from 3 to 150 days. All patients had prior treatment and medications; randomized to group	40 mA-minute dosage at a maximum current of 3–4 mA of either active medication or placebo for six treatments, 1–3 days apart within 15 days	Randomized, double-blinded, placebo-controlled study (RCT) Level: 1A2a	Yes. Iontophoresis treatment was effective in reducing symptoms of epicondylitis at short-term follow-up. Dexamethasone produced a significant 23-mm improvement on the 100-mm patient visual analog pain scale (VAS) ratings compared with 14 mm for the placebo at 2 days and 24.5 mm compared with 19.5 mm at 1 month	Statistically significant ($p = 0.012$; effect size $r = 0.16$) difference between the groups in pain reduction at 2 days but not at 1 month ($p = 0.249$). Patients completing six treatments in 10 days or less had better results than those treated over a longer period. Mild adverse effects were reported for both the study ($n = 12$) and the placebo ($n = 11$) groups.	Nirschl et al. (2003)

Ultrasound and Phonophoresis	Comparison of effect of ultrasound, phonophoresis, and placebo ultrasound therapies in the treatment of myofascial pain syndrome	Sixty subjects (48 females, 12 males; 20–73 years) who had a diagnosis of myofascial pain syndrome with at least one active trigger point in the upper trapezius and symptom duration for 1 month; randomized to three groups	Groups received either (1) phonophoresis (diclofenac gel), (2) ultrasound, or (3) placebo ultrasound over trigger points. Dosage = 1 MHz, 1.5 watt/cm² for 10 minutes per day, five times per week for 15 treatments in 3 weeks. All groups received a home-based neck exercise program.	Randomized, double-blind, placebo controlled study Level: 1B1a	Yes. Both the ultrasound and phonophoresis were effective in treatment of patients with myofascial pain syndrome.	Both groups showed statistically significant improvements in the VAS for pain ($p = 0.000$; $r = 0.80$, a large effect); number of trigger points ($p = 0.000$, $r = 0.80$); pain pressure threshold ($p = 0.007$; $r = 0.55$, a large effect); cervical ROM ($p < 0.05$); neck pain disability index NPDI ($p = 0.000$, $r = 0.80$). There was no difference between the ultrasound and phonophoresis groups. Significant improvement in the placebo group was limited to increased cervical rotation and lateral flexion ($p \leq 0.0456$) and improved pain pressure threshold ($p = 0.000$). No adverse effects observed.	Ay et al. (2011)
EMG biofeedback to learn relaxation	Comparison of the effect of EMG biofeedback and sham biofeedback on pain reduction and number of tender points in patients with fibromyalgia	Thirty subjects (21 females, 9 males) with diagnosis of fibromyalgia; average age 39 years; randomized to group	Both groups received six 45-minute sessions of treatment to forearm extensors, upper trapezius and frontalis. One group received EMG biofeedback. The other group received a sham treatment that provided visual feedback to the participant irrespective of muscle activity. Both groups were taught relaxation techniques.	RCT Level: 1C1b	Yes. EMG biofeedback as a treatment modality reduces pain in patients with fibromyalgia.	There was a significant decrease in pain ($p = 0.09$; $r = 0.24$, small effect) and number of tender points ($p = 0.002$, $r = 0.53$, large effect) for the EMG group as compared to the sham group. EMG group mean change for VAS was −4.3 (CI: −5.3, −3.3); for the sham group, −2.6 (CI: −4.4, −1). Group mean change for number of tender points for the EMG group was −8.6 (CI: −10.9, −6.3) and for the sham group was −4.4 (CI: −5.9, −2.9).	Babu et al. (2007)

CI, confidence interval; VAS, visual analog scale, often used to measure pain. EMG, electromyography, recording of the electrical signal generated by muscle when it contracts.

and reoriented to become what we know as scar tissue. Gradually, the wound cover—a combination of scar tissue and epithelial tissue—gets stronger. The maturation phase can take up to 2 years to complete. Even when it is fully remodeled, this new wound covering is only about 80% as strong as the original tissue's strength. Additionally, this new tissue is relatively inelastic and "tight" compared to the original tissue. Physical agents that help improve connective tissue extensibility in preparation for tissue stretch and ultimately improved function are superficial heating agents and the use of continuous wave ultrasound that provides deep heat.

INCORPORATING PHYSICAL AGENTS INTO A TYPICAL OCCUPATIONAL THERAPY TREATMENT

Physical agents are used as a precursor to, or during, functional activity to facilitate occupational performance. The therapist determines which physical agents will help achieve the patient's goals. Physical agents address pain and other biophysiological client factors that interfere with engagement in occupation. For example, a patient with osteoarthritis of the hand may have joint pain. Any physical agent that relieves the pain of hand osteoarthritis may help improve function (Barthel et al., 2010). Therapeutic ultrasound, for example, has been shown to have beneficial effects on pain and functional outcomes in patients with osteoarthritis (Srbely, 2008). An occupational therapist might use ultrasound to alleviate the patient's hand pain prior to training with adaptive equipment for self-care activities.

Patients with lateral epicondylitis report pain at the elbow that interferes with grip strength and function. The cause of this condition is degeneration of the common extensor tendon fibers where they originate on the lateral epicondyle, and it is closely associated with overuse and inflammation. A number of studies support using a specialized type of electrical stimulation—called iontophoresis—to reduce pain and thus improve grip strength and function in patients with lateral epicondylitis (Nirschl et al., 2003; Stefanou et al., 2012). Iontophoresis uses electrical charges to drive medication through the skin and into the body. Occupational therapists might use iontophoresis to deliver anti-inflammatory medication to chronically inflamed tissues in the elbow to reduce pain and promote healing in preparation for return to work activity.

Patients who have experienced a stroke may struggle with increased spasticity that interferes with functional use of the arm and hand. There is evidence to support the use of electrical stimulation to reduce spasticity in the hemiplegic upper extremity (Hara et al., 2008; Sahin, Ugurlu, & Albayrak, 2012). An occupational therapist could use electrical stimulation to reduce spasticity in the patient's arm in preparation for having that patient perform a dressing activity. Before administering any

Procedures for Practice 19-1

Documenting Physical Agent Interventions

Documentation of physical agent interventions should include the following:

- Physical agent applied and treatment parameters
- Site of application or placement
- Treatment duration
- Physiological responses elicited from treatment
- Subjective responses from the patient, such as tolerance, reaction, and clinical effectiveness
- Reason for using the physical agent with respect to the ultimate functional goal

modality, the therapist should question the patient about any negative response to physical agents applied in previous treatment and review whether the patient has any contraindications for the selected agent. Prior to administering the physical agent, the therapist should inform the patient as to the procedure, expected outcome, and subjective sensation that the patient may feel during the treatment. Skin integrity should always be evaluated prior to administration of physical agents and immediately following the intervention. Documentation should be clear and concise (Procedures for Practice 19-1). Therapists should also assess the effectiveness of the modality on a session-by-session basis. If the modality fails to provide the desired outcome or if the patient has discomfort or negative results, the modality should be discontinued.

THERMOTHERAPY

Thermotherapy is the term used to describe the therapeutic application of heat. A thermotherapy agent is any modality applied to the body that increases tissue temperature. These agents are further classified as either superficial-heating agents or deep-heating agents. Superficial agents heat tissues at depths of up to 1 cm (Kaul, 1994). Commonly used superficial-heating agents include warm whirlpool baths, Fluidotherapy®, hot packs, and paraffin. Deep-heating agents heat tissues at depths up to 5 cm. Therapeutic ultrasound is commonly used to deliver deep heat.

The four primary biophysiological effects of thermotherapy are analgesic, vascular, metabolic, and connective tissue responses.

- The analgesic effect reduces pain symptoms. Heat acts selectively on free nerve endings, tissues, and peripheral nerve fibers, which directly or indirectly reduces pain, elevates pain tolerance, and promotes relaxation.

- Vascular effects aid in pain relief and in decreasing muscle spasm and spasticity. As the temperature of tissue elevates, substances such as histamines are released into the bloodstream, resulting in vasodilation. This increased blood flow reduces ischemia, muscle spindle activity, tonic muscle contractions, spasticity, and pain.
- Metabolic effects influence tissue repair and aid pain relief. In addition to the vascular effect of increased circulation, thermal agents affect inflammation and healing because of chemical reactions. Increases in blood flow and oxygen within the tissues bring a greater number of antibodies, leukocytes, nutrients, and enzymes to injured tissues. Pain is reduced by the removal of by-products of the inflammatory process. Nutrition is enhanced at the cellular level, and repair occurs.
- The connective tissue response to heat refers to the fact that biological tissues are more easily stretched after heating. Collagen is the primary component protein of skin, tendon, bone cartilage, and connective tissue. Those tissues containing collagen can become shortened because of immobilization or limited range of motion (ROM) as a result of weakness, injury, or pain. Improvement in the properties of collagen and extensibility of tissues occurs when heat is combined with passive or active mobilization and/or engagement in occupation. This ultimately results in reduced joint stiffness and increased ROM.

Selection of Superficial Thermal Agents

Thermotherapy is used when an increase in tissue temperature is the intended effect. General dosage guidelines provide a starting point for selection of an agent and for application parameters. Dosage refers to the amount of heat applied to the tissue that then elevates the tissue temperature. A positive therapeutic effect occurs when the temperature of soft tissue is increased to the range of 102°F–113°F (38°C–45°C). If the soft tissue is heated to a temperature less than 102°F (38°C), cell metabolism may not be stimulated adequately enough to elicit a therapeutic response. If tissue is heated to a temperature greater than 113°F (45°C), tissue damage may occur.

Application of a mild dose of heat elevates tissue temperature 4°F–5°F (2.2°C–2.78°C). For example, if the average skin surface temperature is 91°F (32.8°C), a change of 4°F would elevate the skin temperature to 95°F (35°C). The primary benefit of a mild application of heat is relaxation and pain relief. Many conservative home remedies (for example, a dry heating pad) provide this mild dosage. A moderate dose of heat causes an increase in tissue temperature of approximately 6°F (3.3°C) and a moderate increase in blood flow. A vigorous dose elevates the tissue up to 14°F (9.78°C) and results in a marked increase in blood flow. Moderate to vigorous doses of heat are needed to cause vascular, metabolic, and connective tissue responses. The therapist should

be especially vigilant with moderate and vigorous doses of heat by monitoring skin color and the patient's reported perception of comfort during the heating process. Patients can be burned during the application of therapeutic heat. This usually occurs when tissue temperatures have been elevated beyond 113°F (45°C). However, individual sensitivity to heat varies from patient to patient. ***Safety Message: It is important that heat be applied only to patients who can feel the sensation of heat and only to patients who can understand and communicate to the therapist if the heating process becomes uncomfortable.*** Therapeutic heating should always be discontinued if a patient reports pain or burning during application. Safety Note 19-1 lists precautions and contraindications of thermotherapy.

Regardless of the type of heating modality applied to the tissue (paraffin, hot pack, etc.), the biophysiological effects will be the same. However, the choice of heating modality determines *how* the heat will be transferred. There are three primary mechanisms of heat transfer within the body: conduction, convection, and radiation. Conduction occurs when heat transfers from a stationary heat source that has direct contact with body tissue, such as hot packs and paraffin baths. Convection occurs when heated particles or molecules continuously move across body tissue causing a

➕ Safety Note 19-1

Superficial Thermal Agents

Precautions

- Edema
- Diminished sensation
- Compromised circulation
- Use of anticoagulant medications

Contraindications

- Impaired sensation caused by skin graft or scar
- Tumors or cancer
- Advanced cardiac disease (body inadequately dissipates heat)
- Acute inflammation or acute edema
- Deep vein thrombophlebitis
- Pregnancy (systemic effects of circulating blood on fetus are unclear)
- Bleeding tendencies
- Infection
- Primary repair of tendon or ligament
- Semicoma or impaired cognitive status
- Rheumatoid arthritis: vigorous dosages of heat can exacerbate joint inflammation

Adapted from Schmidt, K. L., Ott, V. R., Rocher, G., & Schaller, H. (1979). Heat, cold, and inflammation. *Zeitschrift fur Rheumatologie, 38*, 391–404.

heat transfer, such as with the use of whirlpool baths and Fluidotherapy®. Radiation occurs when there is a transfer of radiant energy through the air from a warmer source to a cooler source, such as with the use of infrared lamps.

The therapist must remember that the temperature of the heating agent is not necessarily the temperature to which the body tissue will rise. For example, setting the Fluidotherapy® to 118°F (47.7°C) will not increase tissue temperature to 118°F (47.7°C). The ultimate rise in tissue temperature depends on the mechanism of heat transfer (conduction versus convection versus radiation), the dosage of heat applied, and the time period tissue is exposed to the heating agent. More research is needed to identify the optimal combination of dosage, mechanism, and timing guidelines for reaching specific tissue temperatures. However, the guiding principle for heating tissue is that deeper tissues require longer periods of heat application to reach therapeutic temperatures. When heat must be applied for longer periods, it cannot be so intense as to overheat the skin layer before tissues at greater depths (i.e., muscle, tendon) are adequately heated. Also, we know that adipose tissue is an excellent insulator, so heating tissue located below body fat requires a longer application of heat. Likewise, heating more superficial body structures that are generally devoid of adipose tissue (such as the hand) will require shorter time periods of heat application for tissue to reach therapeutic temperatures.

The choice of a superficial heating agent depends on the treatment objective, the location of the involved structure, and the desired ultimate tissue temperature. Other considerations include whether moist or dry heat is desired, the positioning of the extremity in a nondependent or intermittently dependent position, and whether active or passive participation by the patient is desired (Earley, 1999). The acuity or chronicity of the patient's condition is also an important factor. It is important to understand that while heat can be beneficial to tissue healing in the case of a prolonged inflammatory phase (for example, as the body tries to reabsorb a large hematoma), heat tends to worsen acute inflammation and edema. Injuries in the early inflammatory phase should be treated with cryotherapy, not heat, to avoid increased edema. Tissues in the remodeling stage of recovery would be treated with heat to facilitate the remodeling process of collagen alignment and differentiation.

Common Superficial Heating Modalities in the Occupational Therapy Clinic

Whirlpool Baths

Whirlpool treatment is performed in a tank equipped with a water circulating mechanism that draws water out and pushes it into the tank at varying speeds (whirlpool bath). Water temperature is usually set between 99°F and 104°F (37.2°C–40°C) and should never exceed 110°F (43.3°C).

Treatment time is approximately 20 minutes. Advantages of whirlpool use are that the client can actively exercise the extremity as the tissue heats up, the therapist has easy access to the extremity for providing active-assistive and passive mobilization, and the degree of agitation of the water can be controlled to act as a soft tissue massage or resistance for exercise. *Safety Message: However, the use of whirlpool is contraindicated when significant edema is present. The heat as well as the unavoidable and prolonged dependent position of the extremity in the whirlpool bath almost always increases edema. Additionally, whirlpool is contra-indicated when open wounds are present. Cross-contamination and risk for infection is significant because it is difficult to adequately disinfect all parts of the whirlpool bath between patients.*

Fluidotherapy®

Fluidotherapy® uses fine particles of organic cellulose blown around in a hot air stream inside a containing unit to heat an extremity. The force of the air and particles circulating within the machine can be graded via the blower speed. It is like a dry whirlpool bath. Temperature is controlled by a thermostat and is generally set between 105°F and 118°F (40.5°C–47.7°C). Treatment time is approximately 20 minutes. The advantage of Fluidotherapy® is the ease of implementation, the client can actively exercise the extremity as the tissue heats up, the therapist has easy access to the extremity for providing active-assistive and passive mobilization, and the dry cellulose particles can provide desensitization therapy during the heating process. *Safety Message: Extremities with open wounds should not be placed in the Fluidotherapy® machine and all clients should wash the area to be treated with soap and water prior to using this modality.*

Hot Packs

Hot packs are canvas cases of material stored in a thermostatically controlled container of hot water called a hydrocollator. Water temperature is kept at approximately 165°F (73.8°C). When the pack is removed from the water, its temperature is typically between 104°F and 113°F (40°C–45°C). The pack is then wrapped in dry padding with appropriate towel use and applied to the body to provide moist heat. Treatment time is approximately 20 minutes. The advantages to hot packs are that they are simple to use, are widely available, and can heat large surface areas. Disadvantages include the heaviness of hot packs—which can be uncomfortable for the patient—as well as their difficulty in conforming to small multisurface body parts such as the hand. Another disadvantage to hot packs is that the area being treated must be nonmobile and covered. This limits active and active-assistive mobilization during the heating process, although a joint can be placed on passive stretch while being heated with a hot pack. *Safety Message: It is important to ensure that six to eight layers of dry*

padding is used between the hot pack and the skin to avoid burns. Toweling is commonly used to cover hot packs. Commercially available terry cloth "hot pack covers" are also available and are the equivalent of three to four layers of toweling. If toweling and hot pack covers become damp from repeated use throughout the day, more heat is transferred from the hot pack to the body. Therefore, padding should be rotated and allowed to dry, or more layers of moist padding will be needed to avoid tissue burns. The therapist should also remember to rotate the hot packs inside the hydrocollator because packs cool during use. It takes approximately 30 minutes to adequately reheat a hot pack to a therapeutic temperature between uses.

Paraffin

Therapeutic paraffin baths consist of a thermostatically controlled heating unit filled with a commercial mixture of paraffin wax and mineral oil. Mineral oil is used to lower the melting point of the paraffin. Paraffin baths are kept at temperatures between 120°F and 130°F (48.8°C–54.4°C). Paraffin is often the heating agent of choice for occupational therapists working with hand dysfunction. This is because paraffin easily conforms to the contours of the hand and therefore provides even distribution of heat to all surfaces. The patient immerses the hand in the bath for 1–2 seconds and withdraws it to allow the paraffin to harden. This gloving process is repeated 8–10 times, and then the hand is wrapped in a plastic bag followed by a towel to retain the heat. The paraffin, bag, and towel are left on for 20 minutes (Fig. 19-1). At the end of treatment, the paraffin is removed and discarded. A disadvantage to this
Figure 19-1 Application of paraffin to increase pain-free AROM of the digit interphalangeal joints. The extremity will be wrapped in a plastic bag and then a towel.

form of paraffin treatment is that the hand needs to remain still during the heating process, and this limits active and active-assistive mobilization. *Safety Message: The therapist should always check the temperature of the paraffin before each use to ensure a safe temperature and avoid burns. Paraffin is not appropriate to use when open wounds are present at the treatment site, and the client should wash the entire extremity with soap and water before using the paraffin bath.*

CRYOTHERAPY

Cryotherapy–also called "cold therapy"—is the therapeutic application of physical agents to lower tissue temperatures. Cryotherapy is classified as a superficial thermal agent because it moves heat out of the body. Cold therapy agents can affect tissue temperatures to a depth of 2 cm (Bracciano, 2008). Commonly used cooling agents include commercial and homemade ice packs and ice massage. The primary biophysiological effects of cryotherapy are analgesic, vascular, metabolic, and neuromuscular.

- The analgesic effect influences pain symptoms. Cold elevates the pain threshold through counterirritation and by reducing nerve conduction velocity in the more superficial sensory nerves (Algafly & George, 2007; Herrera et al., 2010).
- Vascular effects include both vasoconstriction (when cold is applied for less than 15 minutes) and vasodilation (when cold is applied for longer than 15 minutes) (Bracciano, 2008). Short-term application of cold therapy can help reduce edema.
- Metabolic effects influence inflammation and tissue repair. Application of cold therapy slows down the metabolic processes of tissue repair and should therefore be used thoughtfully. We do not want to interfere with the normal healing process, but cold therapy can be useful to control excessive inflammation and edema in the very early stages of healing.
- Neuromuscular effects influence muscle tone. Cold therapy can temporarily reduce spasticity in patients with upper motor neuron lesions (dos Santos & de Oliveira, 2004).

Selection of Cryotherapy Agents

Cryotherapy involves the application of a cooling agent to cause heat to move *out* of the body. As with superficial heating agents, where the goal of therapy is to transfer heat *into* the body, heat energy can be transferred out of the body for the purposes of cooling through conduction and convection. Application of a cold pack is an example of conduction cryotherapy. Immersing an extremity in a cold water bath is an example of convection cryotherapy. In addition to these methods of application, heat can also be transmitted out of the body through evaporation.

Therapeutic cold sprays applied to the body in the form of liquid absorb heat from the skin and then evaporate.

The temperature of the cooling agent is certainly not the temperature to which the body tissues will fall. Tissue temperature change and biophysical effects of cooling are related to the specific cooling agent used, the time of exposure, and the conductivity of the tissue. It is important to ensure that target tissues are completely covered by the cooling agent in order to achieve the desired results. The location and size of target tissues will help guide the selection of an appropriate cooling agent. A large area of target tissue is more effectively cooled with a large cold pack or cold water immersion, whereas a smaller area of target tissue might be best cooled with an ice massage.

Another guiding principle for cooling tissue is that deeper tissues, and tissues located under body fat, require longer periods of cold application to reach therapeutic temperatures. When deeper tissues need to be cooled, the method of applying cold therapy must be adjusted to reduce the intensity of cold against the skin so that longer treatment times can be tolerated. In the case of a conductive cold agent like a crushed-ice cold pack, this can be achieved by covering the cold pack with dry material. Ice packs covered with wetted material will cool superficial tissues at a faster rate and may not be tolerated well by patients who need deeper tissues cooled (Dykstra et al., 2009). *Safety Message: Care must be used when applying cold agents because changes in skin temperature occur quickly, and tissue may be damaged before the desired biophysical effects are achieved. As with superficial heating agents, monitoring of the skin for tissue damage is essential, and caution is advised for patients with decreased sensation or mentation. Cold therapy normally turns the skin a pink or light red color. It should be immediately discontinued if the skin turns bright red, white, pale, or grayish yellow or develops welts.* Safety Note 19-2 lists contraindications to cryotherapy.

Common Cooling Modalities in the Occupational Therapy Clinic

Cold Packs

Cold packs come in a variety of shapes and sizes. They are commercially available as cold therapy machines and gel packs, or they can be homemade. Cold therapy machines circulate cold water through an insulated cooler and special sleeve that covers the body part (Fig. 19-2). Commercial gel packs are generally made from gel covered with a type of plastic. They can be kept in a standard household or industrial freezer between uses. Cold packs can also be made from crushed ice wrapped in toweling or placed in a plastic bag. An unopened bag of frozen peas can serve as a cold pack and works well to conform to small rounded areas like the hand. Cold packs can also be made by combining three parts water to one part isopropyl alcohol in a plastic zip-seal bag and freezing. The alcohol will keep the mixture from fully freezing, resulting in a slushy soft cold pack similar in consistency to some commercial gel packs. Cold packs should always be covered with a material such as toweling or a pillow case. A dry covering will make the initial contact with the patient more comfortable and slow the cooling process. Wetted cold pack covers cause more rapid cooling of tissues. Treatment time can be up to 20 minutes, but the patient should be monitored for signs of cold intolerance or tissue damage.

The advantages of cold packs are that they are inexpensive, are easy to find or make, and can cover large areas. A disadvantage of some cold packs is that they can be difficult to conform to smaller, multisurface areas such as the hand.

Ice Massage

Ice massage requires holding ice directly against the skin and moving it in slow circles over the target tissue. This technique is normally used for cooling small areas such as

Safety Note 19-2

Cryotherapy

Avoid cryotherapy with patients who exhibit the following:

- Peripheral vascular disease or any circulatory compromised area
- Cold sensitivity or Raynaud's phenomenon
- Multiple myeloma, leukemia, or systemic lupus (cryoglobinemia is a disorder of abnormal protein formation that can lead to ischemia in these individuals)
- Cold urticaria/intolerance; can occur with rheumatic diseases, or following crush injuries or amputations

Figure 19-2 Application of cryotherapy for distal extremity edema and inflammation.

tendon insertion sites and hyper-irritable muscle spots to produce an analgesic effect. Because tissues are cooled so rapidly during ice massage, this treatment generally takes no longer than 10 minutes, and treatment time should be guided by how the patient feels. The patient can expect to experience the sensation of cold, then burning, then aching, and finally numbness. Once the patient experiences numbness, the ice massage should be discontinued.

It can become uncomfortable for the therapist to hold a piece of ice in his or her bare hands for the duration of the treatment, so ice cubes can be held with a folded wash cloth. Alternatively, small Styrofoam or paper cups can be filled with water and frozen. Prior to starting an ice massage, the top rim of the cup is peeled off to expose the ice tip. The therapist then holds the cup part while performing the massage. This protects the therapist's hands from the ice. As the ice melts during the massage, more cup can be peeled away to expose more ice.

Advantages to ice massage include ease of use, little expense, and quick inducement of analgesia in appropriate tissues. A disadvantage to ice massage is that it is not tolerated well by people who do not want to endure the sensations of burning and aching prior to reaching the stage of numbness. Additionally, ice massage can be messy as the ice melts, so protect your patients' clothing with dry toweling during this procedure.

THERAPEUTIC ULTRASOUND

Ultrasound is acoustic energy (sound waves) used in medicine for diagnosis and in rehabilitation to help restore and heal soft tissues. Therapeutic ultrasound is classified as a deep-heat modality. Ultrasound is inaudible high frequency acoustic vibration that produces thermal and/or nonthermal (mechanical) physiologic effects on tissue. Thermal effects refer to those biophysiological changes produced by cellular heating, whereas nonthermal, or mechanical effects, refer to biophysiological changes produced by the cellular effects of cavitation, microstreaming, or acoustic streaming. Both thermal and nonthermal ultrasound can be used to facilitate healing and ultimately improve occupational function.

Physical Principles

Standard ultrasound units consist of a power supply, generator, coaxial cable, transducer, and crystal. The generator produces a high frequency alternating current at 1–3 million cycles per second (MHz). The alternating current travels through the coaxial cable into the transducer. The transducer houses the vibrating crystal and converts electrical energy into ultrasonic or acoustic energy (Fig. 19-3). The vibration of the crystal generates the sound waves, which are transmitted to a small volume of tissue, causing molecules within the tissue to move. Ultrasound travels poorly
Figure 19-3 Production of ultrasound.

through air, so a lubricant is used to maintain contact between the transducer and the tissue, ensuring that the energy is dispersed into the tissue (Draper, 2010) (Fig. 19-4).

When the sound waves are generated rapidly and dispersed into the tissue, the molecules in the waves' path are pushed back and forth by the alternating phases of successive waves until the wave runs out of energy. This type of wave, moving in one direction and compressing and decompressing the molecules in its way, is termed a *longitudinal wave*. When the wave encounters bone, the sound energy is transferred along the periosteum and is then deflected up at a right angle causing a *shear wave*. Shear waves occur when the sound energy strikes a solid substance. This may cause heating of the outer covering of the bone but is negligible in terms of tissue temperature elevation (Bracciano, 2008; Cameron, 2012). A *standing wave* occurs when the sound head is not moved adequately enough, and the incoming sound waves encounter the reflected sound waves moving back up toward the surface,

Figure 19-4 Application of nonthermal ultrasound for acute elbow lateral epicondylitis.

creating hot spots and potential overheating of tissue. Each tissue in the body transmits and absorbs ultrasound energy according to its unique properties, known as absorption coefficients. The rate at which the sound wave travels depends on the density of the molecules of the tissue, with body fluids such as blood and water having the lowest impedance and lowest acoustic absorption coefficient. Bone, along with other protein-dense structures, such as scars, joint capsules, ligaments, and tendons, possess high impedance and absorption coefficients, making them good absorbers of ultrasound energy (Kimura et al., 1998)

Energy Distribution

The spread of ultrasound waves into tissue is affected by the frequency (produced by the generator) and size of the crystal (mounted inside the transducer head). The frequency of the ultrasound (the number of times per second that the crystal changes shape) determines the depth of penetration and rate of heating. At 1 MHz, the depth of penetration is 2.5–5 cm, and at 3 MHz, the depth is surface to 2.5 cm. Three MHz will also heat three times faster than 1 MHz (Draper, 2010).

The intensity of the beam of energy varies within the sound wave; this phenomenon is called the beam nonuniformity ratio (BNR). The BNR is a measure of the homogeneity of the therapeutic ultrasound wave (Venes, 2009). The BNR of a transducer refers to the ratio (ideal is 1:1) between its spatial peak and the average intensities in the output wave. Higher areas of intensity are in part responsible for hot spots, which can be prevented by moving the sound head during treatment. Smaller ratios refer to a more uniform ultrasound beam (Johns, Straub, & Howard, 2007). The intensity of the beam of energy is a significant factor in determining tissue response. In general, there is greater tissue temperature elevation with higher intensities. Intensity is documented as watts per square centimeter (W/cm^2). Ultrasound energy will decrease as it passes through different layers of tissue. This is related to the absorption of energy by tissue and the scattering of the beam.

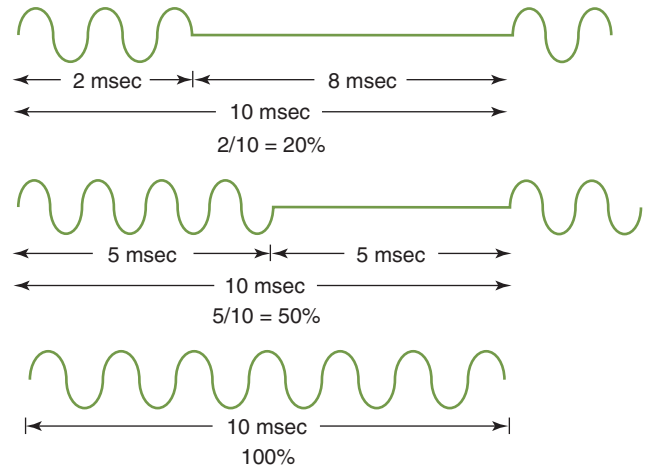
To simplify, ultrasound is absorbed into tissue, causing tissue molecules to rotate and bounce, resulting in heat or nonthermal effects depending on parameter settings (frequency, intensity, continuous or pulsed, and time), treatment goals (thermal/nonthermal), and the area being treated. The duty cycle determines the overall amount of acoustic energy a patient receives and plays a role in determining tissue response (Fig. 19-5). The duty cycle (refers to pulsed or continuous) is a percentage or ratio of time that the ultrasound energy is actually being introduced into the body. A 50% duty cycle provides twice as much acoustic energy as a 25% duty cycle because the on-time is twice as long (Kollmann et al., 2005). When the sound wave is on 100%, the sound wave and energy are constant.


Figure 19-5 Duty cycles determine the on time of the ultrasound.

When the sound energy is turned on and off rapidly, the sound wave is pulsed and is described in terms of a ratio of the cycle. Whether to use continuous or pulsed ultrasound depends on the pathology, stage of wound healing, and the area being treated (Bracciano, 2008).

Effects on Tissue: Thermal Versus Nonthermal Ultrasound

In the thermal mode, ultrasound is a deep-heating agent capable of elevating tissue temperatures to a depth of 5 cm. Thermal effects are typically achieved with continuous sound waves (as in a 100% duty cycle). Nonthermal ultrasound exerts mechanical effects at the cellular level such as increased cellular permeability and diffusion but does not elevate tissue temperature. It typically involves delivering the ultrasound at a 20% duty cycle (on 20%, off 80% of each cycle) (Fig. 19-5). Clinicians may use ultrasound to achieve thermal or nonthermal effects and must select the effect considering a patient's given problem and the therapeutic effect that is desired. Table 19-1 summarizes the thermal and nonthermal effects of therapeutic ultrasound (Draper, 2010).

Table 19-1	Thermal and Nonthermal Effects of Therapeutic Ultrasound
Thermal Effects	**Nonthermal Effects**
• Increases extensibility of collagen fibers • Decreases muscle stiffness • Reduces muscle spasm • Alters nerve conduction velocity/diminishes pain perception • Increases metabolism and blood flow • Provides all of the effects of nonthermal ultrasound	• Increases phagocytic activity of macrophages/attracts immune cells to tissue • Increases protein synthesis • Increases capillary density • Regenerates tissue • Heals wounds

Nonthermal effects of pulsed ultrasound occur at the cell membrane because of stable cavitation, acoustic streaming, and micromassage (Apfel, 1982; Hauptmann et al., 2012). Acoustic streaming occurs with the unidirectional movement of the body fluids that cause currents that exert force and structural changes in the cell membrane along with increased permeability. Second-order effects of nonthermal ultrasound are due to the destabilization of the cellular membrane. With destabilization, more molecules are able to enter the cell and facilitate increased intercellular calcium and protein synthesis and the release of histamine. All this contributes to the enhancement of the inflammatory response to accelerate tissue healing.

Clinical Use of Ultrasound

A thorough evaluation of the patient is necessary to determine the location, stage of healing, depth, and anatomical location of the injury and the area and type of tissue to be treated. Superficial conditions, for example epicondylitis, are best treated using a frequency of 3 MHz. Deeper conditions, such as adhesive capsulitis, are better treated with a 1-MHz frequency. This will allow the ultrasound to be more effectively and efficiently absorbed into the desired tissue.

The thermal dose of the ultrasound should be set according to treatment goals. When treating subacute inflammation, the thermal effect should be mild, that is an increase in tissue temperature of approximately 1°C (1.8°F). A moderate thermal effect is used for pain modulation/altered nerve conduction velocity, muscle relaxation/stiffness, muscle spasm, and chronic inflammation. A vigorous increase in tissue temperature (approximately 4°C [7.2°F]) is used when the goal is to heat in order to stretch collagen (positional stretch, splinting, manual therapy) and increase blood flow. It is important to respect the stretching window following high intensity applications as the tissue temperature will cool approximately 2°C (3.6°F) within 5–10 minutes (Draper, 2010).

Patients should feel gentle warmth with thermal treatments. Remember that 3 MHz heats faster than 1 MHz, so treatment times will be longer (at the same intensity level) with 1 MHz in order to obtain the same desired increase in tissue temperature. Because application of the ultrasound requires a medium or lubricant between the sound head and the skin to avoid interference of the transmission from air, water immersion is appropriate for small areas when the sound head cannot lie flat (bony prominences). With water immersion, the sound head should be held approximately 0.5 cm away from and perpendicular to the area being treated. The water temperature should be warm and close to body temperature.

With application of ultrasound in general, the size of the treatment area should be limited to twice the size of the sound head. Transducer movement should cover approximately 4 cm per second using back and forth or circular strokes. The goal is to keep the face of the sound head flat. The treatment duration (time per application) and number of treatments depends on the treatment goals, size of the area treated, and the intensity, frequency, and efficacy of the modality. Preset intensities should be avoided because they will likely not be as effective in generating desired treatment outcomes and benefits of therapeutic ultrasound (Draper, 2010).

Phonophoresis

Phonophoresis is the use of ultrasound to facilitate the delivery of topically applied drugs or medication to selected tissue. Although it is used by some practitioners, there are questions as to its effectiveness because of variability in outcomes associated with inconsistent treatment parameters, such as intensity of sound waves and transmission characteristics of the conducting medium (typically hydrocortisone cream or a dexamethasone sodium phosphate sonic gel mixture). Therapists should review current literature prior to selecting phonophoresis as the treatment modality of choice (for example, see Evidence Table 19-1).

Precautions for Use of Ultrasound

Patients should be monitored during ultrasound, and any pain or discomfort may indicate that the intensity is too high or that there is an inadequate amount of gel. When using ultrasound as a thermal agent, one must follow general contraindications and precautions for any thermal modality. Safety Note 19-3 lists precautions and contraindications specific to ultrasound.

ELECTROTHERAPY

The growth of the use of electrical stimulation in recent years is due to advances in technology. Electrical stimulation is used in the clinical setting to increase muscle strength, decrease muscle spasm, decrease swelling, improve tissue healing, decrease pain, and provide an option for longer lasting analgesia. Frequently used applications include NMES, TENS, electrical stimulation for tissue repair (ESTR), FES, electrical muscle stimulation (EMS), interferential current therapy (IFC), and iontophoresis. Surface electromyography biofeedback monitors the level of electrical activity in muscles (helps determine how well somebody is able to recruit muscle activity on their own) and is often paired with NMES. The various applications will be described now, and certain clinical applications will be discussed later.

- NMES uses pulsating, alternating current to activate muscles through stimulation of intact peripheral nerves to cause a motor response. Stimulation of the nerve is used to decrease muscle spasm, to strengthen muscle,

Safety Note 19-3

Ultrasound

Precautions

- Unhealed fracture sites
- Early stages of tendon or ligament repair
- Marked demineralization/osteoporosis
- Plastic and metal implants
- When using phonophoresis, be aware of drug allergies

Contraindications

- Suspected deep vein thrombophlebitis
- Bleeding and edema; areas with tendency to hemorrhage
- Where sensation is reduced or if a person cannot report heat sensations accurately
- In the very old and very young, because of compromised body temperature regulation
- Skin or lymphatic cancers; tumors or malignancies
- Over a cardiac pacemaker or surrounding adjacent tissue
- Pregnancy
- Infected areas
- Epiphyses of growing bone (high intensity, needs to be less than 1.0 W/cm^2)
- In conjunction with radium or radioactive isotopes treatment for cancer within 6 months
- Over the heart, eyes, or testes
- Over carotid sinus and cervical ganglion
- Over the spinal column or where there is inadequate protection over the spinal cord, such as after laminectomy

Effects of continuous therapeutic ultrasound growth and metastasis of subcutaneous murine tumors. *Physical Therapy, 75*, 3–13.

and to cause muscle pumping that can reduce edema. NMES stimulation applied directly to innervated muscle is used for muscle reeducation and to prevent atrophy.

- FES is electrical stimulation used to activate targeted muscle groups for orthotic substitution or to facilitate performance of functional activities or movements (Fig. 19-6). FES is often used with individuals who have shoulder subluxation or foot drop after a stroke (see Evidence Table 19-1).
- TENS operates on the gate theory (to be discussed later in this chapter) and describes the wide variety of stimulators used for pain control. TENS uses surface electrodes placed strategically over regions of pain to stimulate specific afferent nerve fibers with the goal of sensory analgesia rather than a motor response.
- EMS is electrical stimulation of denervated muscle to facilitate viability and to prevent atrophy, degeneration,

Figure 19-6 FES for the extrinsic finger flexor and extensor muscle groups to facilitate grasp for self-feeding.

and fibrosis of the fibers. EMS facilitates nerve regeneration and muscle reinnervation.

- IFC utilizes two channels (four electrodes placed in a vector pattern) simultaneously with different frequencies. This allows for a more comfortable surface and deeper tissue penetration to help with pain reduction and edema management.
- Iontophoresis is the use of low-voltage direct current to ionize topically applied medication into the tissue. Iontophoresis is often used in the treatment of inflammatory conditions or for scar formation and management.
- ESTR, also known as high-voltage galvanic stimulation, has been used for tissue healing. Because of its complexity, use requires highly advanced training, and therefore it is not reviewed in this chapter.

Principles of Electricity

To use electrotherapy in occupational therapy practice, clinicians need working knowledge of the principles of current, duration, frequency, duty cycle, and current modulation and ramp time.

Current

Electric current is the movement of ions or electrons, which are charged particles, from one point to another to equalize the charge. Current, measured in amperes, occurs when there is an imbalance in the number of electrons in two distinct locations. Voltage is the potential or electromotive force that drives the current and is measured in volts. Current flows from an area of high electron concentration (cathode, or negative pole) to an area of less concentration (anode, or positive pole). Opposition or resistance to current flow is measured in ohms. Ohm's law states that

Figure 19-7 Commonly used electrotherapeutic current wave forms. **A.** Direct current. **B.** Monophasic pulsed. **C.** Biphasic pulsed. **D.** Interferential beats. **E.** Russian bursts.

(sinusoidal wave form). The current is uninterrupted and bidirectional, without any true positive or negative pole. Household electricity uses AC.

Pulsed Current. Pulsed current is the term used when the electron flow is periodically interrupted for very short periods of milliseconds or microseconds. These interrupted currents can flow in one phase (monophasic), two phases (biphasic), or in many phases (polyphasic). Most current modulation output is pulsed DC or continuous repetitive series of AC pulses.

- Monophasic waveforms have a single phase to each pulse, with the current flow being unidirectional and either negative or positive.
- Biphasic currents have two opposing phases in a single pulse, and the current flows in both directions.
- Polyphasic waveforms consist of a burst of three or more phases, a series of pulses delivered as a single charge. IFC and Russian NMES currents are examples of polyphasic waveforms. There have been many claims as to the uniqueness of this type of current, although there are no confirmed physiological advantages to this type of waveform.

Duration

For monophasic current, phase and pulse duration are synonymous and refer to the length of time between the beginning and end of one phase of the pulse. For biphasic currents, the pulse duration is equal to the total of the two phase durations, including the intrapulse interval. As pulse width increases, more muscle fibers are stimulated because the current is available for longer periods of time. Short pulses are less than 150 microseconds, and longer durations are greater than 200 microseconds. A narrow pulse width is typically better for pain control (Draper, 2010).

Stimulus Frequency

The number of pulses or wave forms repeated at regular intervals is the pulse or stimulus frequency. The pulse frequency consists of the number of cycles or pulses per second (pps) delivered to the body. Low frequency is less than 1,000 pps, and high frequency is greater than 10,000 pps. Low frequency is typically used for pain management, but skin resistance may require higher intensities. Frequency controls the strength of the muscle contraction (number of motor units being stimulated in the muscle) and relative recovery time before the muscle can be stimulated again. The higher the intensity and frequency of pulses, the stronger the muscle contraction will be.

Duty Cycle

Duty cycle is the proportion of time between the stimulation period and the rest period. That is, it is the ratio of the time the current is on to the time the current is off. For

voltage (V) is proportional to both current (I) and resistance (R), such that $V = I \times R$. Three specific forms of current: direct current (DC), alternating current (AC), and pulsatile current, are used in clinical applications (Fig. 19-7).

Direct Current. Direct current (DC) is unidirectional, with the electrons moving continuously in one direction, and the electrodes maintaining their polarity. DC flow, characterized by the square wave, can cause chemical reactions in the body and facilitate the ionization of medication through the skin (iontophoresis).

Alternating Current. Alternating current (AC) is characterized by periodic changes in the polarity of the current flow

example, a treatment protocol in which electrical stimuli are delivered for 10 seconds followed by a 50-second off period is expressed as a 1:5 duty cycle. Duty cycle is important in determining muscle fatigue because muscles need recovery time. As the patient's condition improves, the duty cycle can be gradually increased so that the stimulus delivery is a greater proportion of the duty cycle.

Current Modulation and Ramp Time

Changes to the current or to the pulse characteristics are referred to as modulation. Current can be modulated by modifying the frequency, amplitude (intensity), or duration. Ramping is a change of the pulse intensity or duration of the current. Ramp time is the time required for successive current stimuli to reach the desired amplitude and plateau. Ramp-down, the gradual decrease of the intensity, describes the movement of the peak amplitude back to zero. Ramp time is important for muscle comfort during recruitment of fibers, contraction time, and recovery time. A gradual ramp is usually more comfortable and effective with general strengthening applications, but a steep ramp may be necessary when the desired plateau needs to be accomplished more quickly with functional activities.

Physiology of Nerve and Muscle Excitation

In addition to a working knowledge of electrical principles, clinicians using electrotherapy must understand the physiology of nerve and muscle excitation. The application of electrical current causes physiological changes at both a local and a cellular level; these changes can occur segmentally or systemically. The application of electrical current modifies the body's physiological response and has physiochemical effects (Hess, Howard, & Attignger, 2000).

Human tissue is either excitable or nonexcitable. Excitable tissues, such as nerves and muscles, can initiate and propagate an action potential if the stimulation parameters are sufficient. Stimuli must be sufficiently intense and last long enough to cause the ions to shift across the resting cell membrane to depolarize the cell. Depolarization of a neural or muscle cell occurs quickly, and the sudden alteration in the cell membrane's electrical potential is known as an action potential. Action potentials are an all-or-none occurrence and, once started, are carried along the cell membrane to depolarize it. Following depolarization, a period of hyperpolarization occurs, making the cell briefly unable to be stimulated.

Following stimulation and generation of an action potential in a nerve cell membrane, the membrane needs a short period to recover its excitability. This recovery time is known as the absolute refractory period.

Propagation

Tissues with high water content, such as muscle and nerve, transmit electricity better than those with lower water
Figure 19-8 Strength-duration curve of an electrical stimulus. MST, maximum sensory threshold.

content, such as bone, fascia, and adipose tissue. The diameter of the fiber and degree of myelination are also factors affecting the rate of propagation of action potentials. Conduction is faster in myelinated fibers and in large-diameter fibers, which offer less resistance to the conduction of current. More intense stimuli, which are achieved by increasing the stimulus duration and amplitude, are needed to depolarize smaller diameter nerves, unmyelinated nerves, and denervated muscle membrane (Hecox, Mehreteab, & Weisberg, 1994). Nonnoxious cutaneous sensory modalities and large motor units are served by large diameter, myelinated nerves. Pain pathways are served by small-diameter, sparsely myelinated sensory nerves.

As the current amplitude and pulse duration increase, so do the number of nerve fibers recruited. The strength-duration curve in Figure 19-8 describes the relationship between the amplitude and duration of the stimulus needed to depolarize the membranes of various types of nerves to achieve a response (Hecox, Mehreteab, & Weisberg, 1994). Sensory nerves are stimulated first, followed by motor nerves, then pain fibers, and finally muscle fibers. Although pain fibers are superficial in relation to motor nerves, they also have a smaller diameter and a greater resistance to electrical current flow.

When the cell membrane or tissue receives an unchanging stimulus over time, the cell membrane begins to adapt to the stimulus and requires higher levels of stimulation to trigger an action potential; this is termed accommodation.

Electrically Stimulated Movement

The diameter of the nerve, depth of the nerve, and duration of the pulse affect a nerve's response to electrical stimulation (Baker, Bowman, & McNeal, 1988; Bennie et al., 2002). If there is sufficient intensity of electrical stimulation to cause the motor nerve to reach threshold, contraction of all muscle fibers attached to that nerve (motor unit) occurs. If the stimulus frequency is sufficient, the muscle twitch contractions become fused in synchronous rapid succession,

and the contraction becomes tetanic, leading to a complete contraction of the muscle and movement at the specified joint. In a voluntary contraction, smaller motor units are recruited first, followed by the larger motor units as contraction strength increases. This gradual, asynchronous sequence allows for fine motor control, with larger fibers recruited as increased strength or speed is needed. This type of recruitment allows smooth, controlled movement. In electrically stimulated movement patterns, however, the reverse occurs, with larger motor units recruited first in a synchronous pattern. This causes electrically stimulated muscle to fatigue more rapidly and limits the finely controlled quality of functional movement.

Treatment Planning Specific to Electrotherapy

Before incorporating electrotherapy into treatment, clinicians make decisions about the type of electrical stimulator to use and placement and size of electrodes.

Parameters of Electrical Stimulation Devices

Because research has been equivocal, the clinician must critically evaluate the claims made for various outcomes of electrotherapeutic interventions. Prior to use, the therapist should be familiar with the specific capabilities of the available stimulators and their stimulation parameters (types of current offered, frequencies, intensities, treatment guidelines, etc.).

Electrodes

Electrodes are the contact point providing the current flow from the stimulation device to the body. The electrode interfaces with the skin surface at the point where the electron–ion conversion occurs. Electrodes should offer little resistance to the current flow. A variety of electrodes are commercially available (see Resources 19-1). Commonly used electrodes include carbon-rubber electrodes, which are silicon rubber impregnated with small

carbon particles; metal- or foil-backed electrodes; sponges over metal plates; and self-adherent polymer electrodes (Draper, 2010). The self-adhering electrodes may be reusable and do not require strapping or taping, making them convenient to use. Full contact with the skin is crucial, which is facilitated by use of electrode gel.

Electrodes should be examined before each use and changed when necessary. Electrodes degrade with use and become unable to conduct the current efficiently. Therapists should look for cracking and worn spots in the carbon-rubber electrodes or excessive dryness in self-adhering electrodes and replace them as needed. With frequent use, carbon-rubber electrodes may develop nonconductive areas because of the absorption of dirt, skin oil, or electrode gel and depletion of the carbon rubber. This may cause "hot spots," areas of high current density that may be uncomfortable for the patient and cause skin burns. When uneven conductivity causes a biting or stinging sensation during electrical stimulation, the electrodes should be replaced.

Regardless of the type of electrode used, it is necessary to prevent skin irritation or breakdown. This factor becomes critically important for patients who are using the stimulators on a home program or when there is prolonged placement and use of the electrodes.

Electrode Size. Current density is inversely related to the electrode size. As the electrode size decreases or the contact area of the electrode decreases, the current density increases, which can cause hot spots, as mentioned earlier. As the current density increases, there is a greater perception of the stimulation beneath the electrode along with a greater physiological response because of the charge transfer. The inverse relationship between electrode size and current density means that smaller electrodes require less current to stimulate tissue. Electrode size is therefore determined by the size of the targeted tissue.

Electrode Placement. The distance between the electrodes also influences the depth of the current flow. When the electrodes are close together, the current passes superficially, and when the electrodes are farther apart, the current penetrates deeper. Care should be taken when applying and selecting location of the electrodes because closely spaced electrodes may increase discomfort. Size of electrodes must also be considered when stimulating muscles. Small electrodes can be used to obtain an isolated contraction from smaller muscles, such as those of the hand. Larger electrodes are less specific in stimulating isolated muscles.

There are three primary methods of electrode placement for electrical stimulation: monopolar, bipolar, and quadripolar. Simply put, the terms identify whether one electrode (monopolar) is placed over the targeted tissue or if all electrodes (bipolar and quadripolar) are placed over the area. The monopolar technique uses one stimulating (active) electrode, which is placed over the targeted area. The other (dispersive) electrode completes the electrical circuit and can be placed away from the target area in the same region. The dispersive electrode is often larger, minimizing the current density and perception of sensory stimulation. Monopolar placement is used for iontophoresis, acupuncture, and trigger point stimulation.

The bipolar technique consists of both electrodes placed over the targeted area. Because both electrodes or sides of the circuit are in contact with the targeted area, the current flow is more local, and the stimulation is perceived under both electrodes. Most often, the electrodes are the same size, and this technique can be used to stimulate muscle contraction. Bipolar techniques are often used to activate muscles atrophied because of disuse, for muscle reeducation, or to obtain stronger contraction (neuromuscular facilitation) to increase limited movement.

Quadripolar placement refers to two sets of electrodes, each from its own channel. Electrodes generally surround the targeted area in a parallel or criss-cross pattern. Interferential current (IFC) is delivered via quadripolar placement and is commonly used for pain management and circulation (Draper, 2010).

Clinical Use of Electrotherapy

The unique applications and indications for each type of electrotherapy are discussed in turn. Safety Note 19-4 lists precautions and contraindications for electrotherapy.

Safety Note 19-4

Electrotherapy

Precautions

- Monitor patients with epilepsy
- When used in or around healing tissue, avoid muscle contraction
- When using iontophoresis, be aware of drug allergies
- Where sensation is reduced
- Pregnancy
- Early stages of tendon repair or tenolysis

Contraindications

- Cardiac pacemaker
- Active cancer/tumor
- Transcerebral, transcranial, or transthoracic stimulation
- Danger of hemorrhage immediately following injury
- Overdamaged or denuded skin

Adapted from Draper, D. (2010). *Syllabus for enhancing treatment outcomes with therapeutic modalities: Electrotherapy and ultrasound.* Brentwood, TN: Cross Country Education.

Electrical Stimulation. Electricity has been advocated in the treatment of a variety of body systems and for a plethora of conditions, including joint swelling and inflammation, joint dysfunction, tissue healing, muscle reeducation, circulatory disorders, postural disorders, fracture healing, and pain management. There are a number of claims for electrical stimulation along with a variety of protocols and applications; some are objective, but many are unsubstantiated or anecdotal. The clinician should take a systematic and objective approach to the use of electrical stimulation.

Neuromuscular Electrical Stimulation. NMES has a variety of clinical uses as an adjunct to occupational therapy treatment. NMES is the electrical stimulation of an intact or partially intact peripheral nerve to evoke a muscle contraction (Bracciano, 2008). NMES is often erroneously referred to as "functional" electrical stimulation. Functional electrical stimulation, or FES, is a subcategory of NMES and refers to the use of NMES as a substitute for an orthosis to assist with a functional activity, such as standing or holding an object, or as a substitute for a sling.

NMES can be used for strengthening and endurance, ROM, facilitation of muscle function, management of muscle spasms and spasticity, edema reduction, and orthotic substitution (Cahe, Yu, & Walker, 2004). Clinical use of NMES requires a partially intact or intact peripheral nerve, and its use with primary muscle disease or muscular dystrophy is unwarranted.

Maintain Muscle Mass. NMES can be a successful adjunct to conventional treatment in individuals with limited traumatic or orthopedic injuries. There is a relationship between intensity and strength gains; improving muscle strength is based in part on the overload principle. The overload principle refers to the fact that the body must be subjected to greater levels of stress than it is accustomed to for strength gains to occur. To accomplish this, the therapist must increase the load, frequency, or duration of the exercise or activity. Patients who are deconditioned or have areas of weakness may benefit from NMES to improve endurance of the targeted muscle. Isometric strengthening using NMES produces better results than conventional isometric exercises alone but is most effective when paired with functional goals and movements (Baker et al., 2000).

Maintain or Gain Range of Motion. Neurologically impaired patients often develop spasticity as a consequence of their injury. Hemiplegic patients with chronic moderate spasticity in the wrist or finger flexors may be appropriate candidates for this intervention (Rosewilliam et al., 2012). For these individuals, the stimulus applied to the antagonist muscle should ramp up slowly and be sufficiently intense to allow for a slow stretch without increasing spasticity caused by a quick stretch or jerk (Baker et al., 2000). Ramp-up times should be extended to 6–8 seconds or longer. Proper positioning or blocking of other muscles should be considered. Serial casting or splinting of the extremity can be an effective adjunct to NMES. The use of NMES is effective as part of a home program because it allows the caregiver to carry out passive ROM several times daily.

For the orthopedic patient, ROM may be limited by contractures secondary to immobilization or pain. NMES may be used to improve joint ROM if the limitation is due to intrinsic soft tissue shortening as opposed to a bony block or biomechanical limitation. The technique should maintain a low-intensity stretch for a few seconds.

Management of Spasticity. The effectiveness of NMES for the treatment of spasticity depends in part on the underlying disease causing the spasticity. The response of NMES in a patient with a spastic spinal cord injury may be different from the response in a patient with a brain injury or multiple sclerosis. The variability of abnormal tone may only result in a temporary interruption of the motor neuron excitability, with short-term treatment effects. Stimulation of a spastic muscle in the neurologically impaired client using high frequency pulses causes a tetanic response that fatigues the muscle (Vodovnik, Bowman, & Hufford, 1984).

NMES also affects spasticity by stimulating the muscle antagonistic to the spastic muscle, which inhibits the spastic muscle, allowing ROM exercise (Sabut et al., 2011; Wang, Tsai, & Chan, 1998). Heat or ice and serial casting or splinting paired with functional movements and activities may enhance the therapeutic response.

Orthopedic patients may have pain–spasm cycles caused by local spasm of a particular muscle or group. Decreasing the pain–spasm cycle through the application of NMES to the area improves and enhances ROM and occupational performance.

Facilitate Voluntary Control. NMES has been used frequently for muscle reeducation and facilitation, particularly with neurological injuries and orthopedic injuries after surgery. Facilitation and retraining can be effective for patients suffering from disuse atrophy, muscle weakness, and pain (Lewek, Stevens, & Snyder-Maackler, 2001). In neurologically involved patients, the sensory feedback loop becomes distorted or impaired.

The goal of NMES for facilitation and reeducation is to incorporate the stimulation with voluntary contraction, functional movement and activity, and sensory feedback (Bracciano, 2008). The intent of NMES for facilitation and reeducation is to flood the central nervous system with sensory and kinesthetic information linked to an anticipated motor response. A variety of functional activities incorporating the desired motor response should be used to ensure adequate carryover of the response. For example, a patient who has had a stroke who is working

on grasp and release should practice a meaningful activity that requires picking up and placing a variety of objects of various shapes, sizes, and weights to various heights and locations.

Functional Electrical Stimulation. FES, the use of NMES as a replacement for orthoses, has been an effective adjunct in facilitating occupational function, most notably positional stability and mobility. Stimulation of innervated paretic or paralyzed muscles can decrease dependence on slings, splints, or other orthoses through the development of increased strength and endurance of the paretic musculature.

FES has been effectively used with hemiparetic patients who display shoulder subluxation during the flaccid phase of recovery and also to facilitate grasp-and-release activities (Thrasher et al., 2008). In the hemiplegic patient, gravity stresses the shoulder capsule, stretching it. When muscle tone and voluntary control develop at the shoulder, normal glenohumeral alignment may not recur when the arm is at rest because of this ligamentous laxity (Yu et al., 2001). Slings may be helpful to establish glenohumeral alignment, but stimulation of the posterior deltoid and supraspinatus muscles may be more effective in improving normal shoulder integrity (Koyuncu et al., 2010; Lin, Granat, & Lees, 1999; Wang, Chan, & Tsai, 2000). Use of FES for maintaining shoulder integrity can be an effective adjunct to splinting and facilitate occupational function. Clearly outlining and teaching the client and caregivers in a home program is vital to ensure continuity and carryover.

Transcutaneous Electrical Nerve Stimulation. Pain is one of the most common complaints that cause patients to seek medical care. Adequate pain management facilitates occupational function (Fig. 19-9). TENS can be used to manage pain in musculoskeletal disorders. The two primary theories on which the modulation of pain with TENS is based are the gate control theory (Melzack & Wall, 1965; Robertson et al., 2006) and the endorphin theory (Bonica, 1990). Basically described, the gate theory is the stimulation of afferent nerves to block pain by closing the gate in the spinal column to pain signals coming from slower conducting nerves. The endorphin theory specifies that natural beta endorphins are released with the application of intense beat frequency of TENS that inhibits pain signal transmission and decreases chemical irritants in the central nervous system (Draper, 2010).

Treatment applications using electrical stimulation for pain control employ pulsed or alternating current in a variety of stimulation patterns. The type of stimulation is based on the neurological response to the stimulation with the goal being pain relief and comfort. The four levels of stimulation used include subsensory level, sensory level, motor level, and noxious level. Stimulation sites

Figure 19-9 Application of transcutaneous electrical nerve stimulation (TENS) to the shoulder for acute pain.

for electrode placement are based on the problem areas. Optimal electrode placements should correlate with the structures and sources of pain and include motor points, trigger points, and acupuncture points. TENS units are often used at home, and the therapist should explain the purpose of the equipment and instruct the patient in its operations and precautions, with written and pictorial instructions. Through application of TENS for sensory analgesia, the patient may better perform functional activities and movements that foster independence and function because they are in less pain.

Iontophoresis. Iontophoresis is a method of topically delivering a medication or ionized drug to an area of tissue by using direct electrical current. Occupational therapists frequently use iontophoresis in the treatment of inflammatory conditions such as epicondylitis, carpal tunnel syndrome, glenohumeral bursitis, ulnar nerve inflammation, and wrist tendinitis and tenosynovitis (see Evidence Table 19-1). Therapists using iontophoresis should thoroughly understand the pathophysiology of the condition, the tissue healing process, the medications being used, and any potential drug interactions. *Safety Message: Caution must be used whenever using iontophoresis because medications may cause an allergic or*

anaphylactic reaction, which is a life-threatening condition and medical emergency. Patients should always be asked for a list of current medications and whether they have any known allergies, sensitivities, or reactions to foods or medications. Documented orders should always be obtained from the patient's physician prior to using iontophoresis (Bracciano, 2008).

SURFACE ELECTROMYOGRAPHIC BIOFEEDBACK

Feedback is an important element in motor learning (Molier et al., 2011). Occupational therapists often use verbal feedback to provide encouragement and direction to patients who are performing a task. For example, the therapist may comment on the speed or accuracy of a feeding task and offer suggestions to improve functional outcomes, such as, "Good, you got the spoon to your lips without dropping anything. Now open your mouth wider." This type of therapeutic feedback is beneficial in rehabilitation, but it is limited by the therapist's ability to comment only on a result that has already occurred ("Good, you got the spoon to your lips without dropping anything.") or a result that the therapist hopes will occur next ("Now open your mouth wider.").

Biofeedback—which means biological feedback—refers to the process of using instrumentation to feed back to the patient immediate information about what the body is doing. Feedback is provided to the patient before the patient is even consciously aware of the body's action. This allows the patient to make small alterations in body functions *during* performance in order to improve the actual functional outcome. When occupational therapists use biofeedback technology, they most commonly use surface electromyographic biofeedback. This type of biofeedback helps make the patient more aware of muscle activation and is used for muscle reeducation and training. When the term "biofeedback" is used in this chapter, the authors are referring to surface electromyographic biofeedback. Biofeedback has been used to treat urinary incontinence (Herderschee et al., 2011), motor dysfunction and spasticity following stroke (Dogan-Aslan et al., 2012; Woodford & Price, 2007), chronic pain (Babu et al., 2007) (see Evidence Table 19-1), muscle dysfunction and myoclonus following spinal cord injury (De Biase et al., 2011; Sugimoto et al., 2007), focal hand dystonia (Byl, Archer, & McKenzie, 2009), and motor dysfunction in children with cerebral palsy (Bolek, 2006).

In biofeedback, small electrodes are attached to the patient's skin to detect the tiny electrical signals that are generated when skeletal muscle contracts. When the onset of a muscle contraction is detected, the biofeedback unit will alert the patient with, typically, an auditory or visual stimulus. As the muscle contraction progresses and strengthens, the auditory tone will become louder, and the visual display will become larger. Because electrical signals from skeletal muscle are detected as soon as motor units are recruited in the target muscle—before movement even occurs—biofeedback provides the patient with immediate information about desired or unwanted muscle activity.

In patients with motor dysfunction who need to relearn voluntary control over impaired muscles, biofeedback provides an early signal to the patient that his current muscle activity is either leading to the desired movement or not. The patient can then try to improve the effectiveness of muscular effort *during* activity. If a patient's arm is paralyzed, biofeedback is the only way to inform the patient who is trying to move that appropriate muscle motor units are being recruited, even if no movement in the arm can be seen yet. When chronic pain is a result of unconscious forceful or prolonged muscle contraction, biofeedback can signal the patient to relax those muscles.

Biofeedback Equipment

Biofeedback units have three major components to detect, measure, and report activity in the body: the transducer, the processing unit, and the output mechanism. The transducer is what detects the target activity in the body. In surface electromyographic biofeedback, the transducers are electrodes attached to the patient's skin to detect muscle contraction. The electrodes are placed over the muscle belly and aligned parallel to the muscle's line of pull. The electrodes are spaced according to the goal of treatment but must always stay within the margins of the target muscle. Widely spaced electrodes pick up signals from a wider area of the muscle and should be used initially to reeducate a weak muscle. If the goal is to reduce spasticity, placing the electrodes more closely together will reduce the pickup area and make it easier for the patient to relax the muscle enough to influence the biofeedback system (see Procedures for Practice 19-2 and 19-3) .

Procedures for Practice 19-2

Electromyography Biofeedback Session for Muscle Reeducation

- Begin with large, widely spaced electrodes over the muscle belly.
- Initially set the threshold at an attainable level.
- During a 10- to 15-minute treatment session, the patient voluntarily contracts the muscle to reach the threshold level.
- When possible, incorporate purposeful activities to facilitate the muscle activity desired.
- Gradually raise the threshold during the treatment session to challenge the patient to contract the muscle more strongly.

Procedures for Practice 19-3

Electromyography Biofeedback Session to Decrease Spasticity

- Begin with small, closely spaced electrodes over the muscle belly.
- Initially set the threshold at an attainable level.
- Place the limb in midrange, and keep the environment free of distractions.
- During a 10- to 15-minute treatment session, the patient attempts to maintain relaxation of the muscle below the threshold level.
- Gradually decrease the threshold as the patient learns to relax the muscle.
- In subsequent sessions, challenge the patient to maintain relaxation of the spastic muscle while contracting the antagonistic group and then while performing a functional task.

The processing unit contains electrical circuits that amplify, integrate, and otherwise prepare the messages from the electrodes for an output signal. Biofeedback units in occupational therapy departments generally have output mechanisms that give off visual, auditory, or both types of feedback. The processing unit will send a signal for visual or auditory output once a certain amount of electrode messages are received. As more motor units fire and more messages are received, more electricity flows through the circuits. When more electricity flows through the circuit, the processing unit will send a signal to increase the visual or auditory output. If the number of electrode messages is reduced, the signal for output will reduce or stop altogether. The threshold at which the output signal is initially set can be raised or lowered depending on the patient's ability. This allows the therapist to grade the level of activity the patient must achieve before he or she receives feedback. As the patient's performance improves, the threshold is set higher so that an output response is not obtained until more input signals are received. If the goal is muscle inhibition, the threshold is set so that the device will deliver the feedback response when the level of motor activity decreases below the specific setting.

Biofeedback units come in the form of small handheld devices, as well as larger units attached to video display screens. In small units, the visual output may be as simple as a red dot that turns on when an electrode signal is first detected—signaling muscle firing in the targeted muscle. The red dot might then turn into a red line that grows longer if the electrode detects more muscle firing. Audio output on handheld devices will likely be a soft "beep" that grows louder or faster as muscle firing is increased. Larger biofeedback units often come with interesting graphic visual displays and auditory tones that respond to muscle activity. On larger units, multiple electrodes can be used to simultaneously gather information about muscle activity in different areas. These multichannel units can provide a variety of visual and auditory stimuli that can be programmed in the form of a video game with sound. Some biofeedback instruments can be connected to radios, DVD players, electronic toys, etc., which provide the feedback reward for achieved muscle activity or relaxation. For example, if the patient achieves muscle inhibition to a certain preset level, his audiobook player will turn on and stay on as long as the inhibition is maintained.

Some biofeedback equipment can be synchronized with NMES to increase motor unit recruitment and movement. Biofeedback paired with NMES can be used for patients who are, for example, unable to fully complete a movement through full desired ROM. The therapist can set the threshold so that the patient receives auditory and visual feedback with activation of a selected muscle, which, when achieved, activates the NMES to complete the movement, thereby reinforcing and strengthening the response (Pullman et al., 2000; Seo et al., 2005).

Incorporating Biofeedback into the Occupational Therapy Treatment Plan

When choosing a therapy intervention for a patient, it is important to choose wisely for a successful outcome. Successful biofeedback treatment requires that the patient be able to understand the relationship between his effort and the feedback. Additionally, patients with some visible movement tend to do better with biofeedback than patients who are completely flaccid, and patients who have less spasticity tend to do better than those who are severely spastic. However, biofeedback success is not dependent on the age or sex of the patient, the side affected by injury, or the duration of injury. Biofeedback can be successful when used with both peripheral and central nervous system injuries (Bloom, Przekop, & Sanger, 2010; Vedsted et al., 2011). Because biofeedback is essentially a learning process, if the patient fails to benefit after just one session, another session is justified.

Biofeedback treatments should be conducted in a quiet environment so that the patient can concentrate on his muscle activity and the biofeedback unit's response without distraction. The first session should start with an orientation and a trial run with the biofeedback unit. The trial, using an intact limb, allows the patient to understand how muscular contractions influence the equipment's audio or visual feedback. Then the electrodes are placed over target muscle(s) in the dysfunctional extremity or area. The feedback unit is set so that no signal is produced with the baseline level of muscle activity present

in the target muscles. The threshold level is then set by the therapist so that the patient must achieve that preset level of muscle contraction or relaxation to receive the feedback signal. The patient then attempts to relax or contract the target muscle (depending on the goal). Biofeedback treatment sessions are generally about 15 minutes (see Procedures for Practice 19-2 and 19-3).

Biofeedback is motivating for patients because they are provided instantaneous feedback in the form of visual and auditory modes. As the patient gains some control over target muscles, occupational therapy sessions should incorporate simple functional tasks and activities to reinforce the muscular contractions (or relaxation) relearned with biofeedback. As muscle function continues to improve, more complex movement patterns can be added to the therapy program. As with all physical modalities used in occupational therapy, biofeedback is to be performed in preparation for or concurrently with purposeful and occupation-based activities. The goal is always eventual engagement in occupation.

case example

Laura S.: Iontophoresis

Clinical Reasoning Process

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Laura S. is an active, and athletic, 47-year-old female who was referred to occupational therapy by her family physician. She relates that she was "painting her kitchen and family room" in the "new house" they recently purchased. After three days of painting, she developed pain in her right elbow (dominant hand), increasing inability to hold onto objects such as a gallon of milk, and further difficulty with cooking and self-care activities requiring her to use her right hand in static hold positions. She reports the pain being "constant 5 out of 10" and increasing to "8 out of 10" with use. The patient displayed pain on the lateral epicondyle with resisted wrist extension. Patient also displays point tenderness over the right lateral epicondyle. Grip strength is significantly decreased in the right hand (20 pounds) compared to her left hand (80 pounds). The patient also displays an extension lag at the elbow of 25° and lacks full elbow flexion by 20° (pain in both end ranges).	Appreciate the context	"It seems that Laura's signs and symptoms are consistent with a diagnosis of lateral epicondylitis. Her symptoms developed quickly after 3 days of repetitive use of the right upper extremity to paint her house."
	Develop intervention hypotheses	"Because of the rapidity with which her symptoms developed, the quick referral by her physician, and the lack of previous difficulties in her right upper extremity, Laura's condition is considered an acute episode. I know that the root cause of lateral epicondylitis is tendinosis—a degeneration of the tendon fibers. However, right now, Laura's elbow is inflamed and painful—a true epicondylitis. I believe that she will require a multifaceted approach to treat her condition. We will first need to reduce her inflammation and pain, and then we need to strengthen her muscles and tendons to reduce the likelihood of a recurrence in the future."
	Select an intervention approach	"Laura's problems and clinical presentation are consistent with a diagnosis of acute lateral epicondylitis. I expect that her physician will recommend some form of nonsteroidal anti-inflammatory drugs (NSAIDs) or other anti-inflammatory medications. I will be recommending static splinting of the right wrist in 30° of extension, physical agent modalities to reduce her inflammation and pain, gentle range of motion (ROM)/stretching, and modification of her daily activities until her pain and inflammation subside. Then I will introduce gradual strengthening of the upper extremity starting with isometrics and then progressing to concentric and eccentric strengthening exercises."
	Reflect on competence	"I am familiar with a number of therapeutic approaches that can be used with lateral epicondylitis. I have advanced training in iontophoresis and am permitted to use it by my state's practice act. I will need to consistently monitor Laura's response to the interventions used and modify the treatment as needed. I will also want to monitor her compliance with the splint wearing schedule and modifications to her daily routine to prevent further exacerbation of her condition."

Recommendations

The occupational therapist recommended three treatment sessions per week for 4 weeks. The following initial goals were established:

In 1 week, Laura will report:

1. Understanding of and use of activities of daily living (ADL) modification techniques to reduce stress on her elbow
2. Compliance with her splinting program

In 2 weeks, Laura will report:

1. Decreased pain at the right elbow during rest from a score of 5 out of 10 to a score of 1 out of 10
2. Decreased pain at the right elbow during daily activities from a score of 8 out of 10 to one of 3 out of 10

In 2 weeks, Laura will demonstrate

1. 25° improved elbow extension
2. 20° improve elbow flexion

Consider the patient's appraisal of performance	"From the beginning, it was apparent that Laura would follow through on all recommendations. She is highly motivated and has been very active and participated in a number of athletic activities prior to her injury. Because her children are older, I am confident that she could ask her family members to help her with those activities that require heavy lifting or static hold and release patterns. She is anxious to return to her premorbid activities, and there is a slight concern that she might 'overdo it' as she progresses in treatment and her pain begins to subside. I will ask her to come for therapy three times weekly to closely monitor and upgrade her program."
Consider what will occur in therapy, how often, and for how long	
Ascertain the patient's endorsement of plan	"Laura agreed with the goals and is eager to begin treatment to decrease the pain and loss of function in her right upper extremity. Once she understood the importance of strengthening after the pain and inflammation subsided, she was agreeable to not 'overdoing' her activities until she was stronger."

Summary of Interventions and Progress

The treatment approach and intervention will include:

1. Static extension splinting of the right wrist
2. Iontophoresis with dexamethasone to decrease the inflammatory process and pain
3. Gentle A/PROM to the right elbow
4. Education in modification of ADL and specific movements to prevent exacerbating her condition
5. Progressive upper extremity strengthening

Laura was instructed in different methods of modifying activities that required her to lift or manipulate objects as part of her daily activities. She was also provided with a static extension positioning splint for her right wrist that she was to wear at night and also initially during the day. She was aware of skin and splint care and her wearing schedule.

Laura's condition responded to the iontophoresis, and she reported a decrease in pain after the fourth treatment. As she responded to treatment, her iontophoresis dosage was increased from 40 mA/min to 60 mA/min and finally to 80 mA/min.

Assess the patient's comprehension	"I noticed that Laura was apprehensive about asking for assistance at home, but after we talked about the importance of initially resting the wrist and elbow, she allowed her family to take an active role in assisting her with her activities and responsibilities. As her pain subsided and her elbow ROM increased, I recommended that she begin wearing her wrist splint only at night, but to resume wearing the splint during the day if she noticed any return of her symptoms or pain. I know how important it is for me to monitor Laura's condition closely and to note any changes in pain or symptoms during each treatment visit, modifying the treatment and interventions as needed. If she reports a reversal back to earlier levels of pain and symptoms, I will have to figure out whether the interventions are effective or whether she is impacting the injury somehow in the performance of her daily occupations and activities."
Understand what the patient is doing	
Know the person	
Appreciate the context	

Next Steps

Revised goals (at week 2)
By week 4, Laura will report

1. Decreased pain in the right elbow during rest from 1 out of 10 to 0 out of 10
2. Decreased pain in the right elbow during activity from 5 out of 10 to 2 out of 10
3. Complete weaning from wearing the wrist splint
4. Proper understanding of resistance progression in her home strengthening program

By week 4, Laura will demonstrate

1. Proper technique for her home strengthening exercises
2. An increase in right grip strength from 20 to 50 pounds

Anticipate present and future patient concerns	"I am pleased with Laura's response to the initial 2 weeks of treatment. She was compliant with her splint wearing and modified her routine and activities to avoid overusing the right upper extremity. She noticed a marked decrease in pain (from 5 out of 10 to 1 out of 10 at rest and from 8 out of 10 to 5 out of 10 with activity) and an increase in elbow ROM to 'normal' by the end of 2 weeks. Because she responded so well to the treatment, I recommend that we continue with the iontophoresis and also begin gentle isometric strengthening exercises. If she tolerates isometrics without an increase in pain, we can wean from the iontophoresis treatments and wrist splinting and progressively strengthen with concentric and eccentric exercises. If I can strengthen Laura gradually and avoid any 'flare-ups,' Laura will be much more likely to withstand her normal activities without a recurrence of pain and inflammation in the future. I plan to transition Laura to a home strengthening program once I am sure she understands her exercises and how to upgrade the resistance cautiously. I will have her demonstrate her home exercises in the clinic so I can ensure that she understands."
Analyze patient's comprehension	
Decide whether he or she should continue or discontinue therapy and/or return in the future	

⊘ Clinical Reasoning in Occupational Therapy Practice

Determining Progress in Physical Agent Modalities

Laura's injury occurred following her engagement in a rather "normal" activity, painting her house. The signs and symptoms that she exhibited were pain in her elbow, difficulty holding onto objects, and difficulty performing activities of daily living (ADL). These symptoms are clues that an occupational therapist would use to select an appropriate treatment plan and physical agent modality. Establishing a realistic "starting point" based on the evaluation provides a mechanism for determining progress and efficacy of the therapeutic interventions, which guides modifications to the treatment.

Based on Laura's objective and subjective presentation, what physical agent modality—other than iontophoresis—could be provided in the clinic to achieve the same results of decreased pain and inflammation? If ultrasound was the modality that the therapist selected, should the therapist use a frequency of 1 or 3 MHz? Why? If Laura starts to feel better after a couple of treatments and asks to return to painting her house, what should the therapist's response be?

case example
M.J.: FES

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
	Clinical Reasoning Process	

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information M.J. is a 36-year-old female who suffered a stroke affecting her left, nondominant, side. The stroke occurred while she was camping with her two sons (ages 12 and 9 years) and her husband. When her condition stabilized, she was referred to an inpatient rehabilitation program, where she stayed for 4 weeks. She was discharged home with the recommendation for outpatient occupational and physical therapy. Prior to the cerebrovascular accident (CVA), she was employed as a surgical nurse. She was independent in all her activities of daily living (ADL). She was accompanied by her husband for the initial evaluation. She was alert and oriented, but somewhat apprehensive and subdued. The following problems were identified during the occupational therapy assessment:	Appreciate the context	"M.J. seems to be a young, vibrant woman. All of her occupational roles have been affected by her CVA. She has gone from total independence to one of greater dependence on her family and husband. She seems apprehensive and concerned over whether she will regain function in her upper extremity. She is also in a lot of pain when she moves her arm, so is not very motivated to try to use the arm for functional activities." "M.J. seems worried about whether she will be able to return to work and was also concerned about the financial impact her disability would have on the family. Her husband and family seem extremely supportive of her, and I am pleased that they are very engaged in her rehabilitation and in facilitating her independence."
1. Decreased initiation of instrumental activities of daily living (IADL) 2. Decreased functional use of the left upper extremity (active shoulder flexion/abduction limited to 95°) 3. Subluxed left shoulder (two finger widths) 4. Painful (8 out of 10) shoulder range of motion (ROM) and use	Develop intervention hypotheses	"Despite M.J.'s encouraging family, pain is a powerful deterrent to movement and use of her left arm. I know that trying to use her left arm is extremely important in M.J.'s recovery. If I can help reduce her shoulder pain, M.J. is much more likely to participate in therapeutic activities geared toward improving function in the left arm. Shoulder subluxation is associated with shoulder pain in patients who have suffered a stroke. If I can reduce the subluxation in her left shoulder, then the pain is likely to decrease."
5. Increased tone in the left upper extremity with active grasp and weak release 6. Dependent for transportation and community mobility	Select an intervention approach	"I am proposing an intervention plan that emphasizes compensatory techniques, pain reduction strategies, remediation, and neuro-reeducation techniques to facilitate the return of function in the upper extremity. M.J. is in a lot of pain right now and not very motivated to move her left arm. However, she says she wants to 'try everything and anything to get better.'"

"I have to admit that M.J. is a challenging case because she is about my age and was extremely active prior to her CVA. She wants to try to return to work, but cannot imagine regaining use of her left arm because she is in so much pain. I know that we can use functional electrical stimulation (FES) to help reduce the amount of shoulder subluxation, and this will likely reduce M.J.'s pain. If we can reduce her left shoulder pain, M.J. will be less reluctant to move her left arm, and this will allow her to more fully participate in other treatment approaches aimed at improving left arm use."

Reflect on competence	"I have experience treating patients who present as M.J. does. Additionally, my state's occupational therapy practice act allows me to use electrical modalities. However, even though I learned about FES in school, this will be my first application of this knowledge to a patient, so I will ask my supervisor for guidance at first."

Recommendations

The occupational therapist initially recommended three outpatient treatment sessions per week for 4 weeks. In collaboration with M.J. and her family, the occupational therapist established the following long-term treatment goals:

In 6 months, M.J. will demonstrate

1. No subluxation of left shoulder joint
2. No pain in left shoulder
3. Active range of motion (AROM) in the left upper extremity within normal limits
4. Active grasp and release patterns of the left hand to manipulate large objects
5. Independence in IADL
6. A return to work
7. The ability to drive independently

Consider the patient's appraisal of performance Consider what will occur in therapy, how often, and for how long Ascertain the patient's endorsement of plan	"M.J. seems highly motivated to attempt to return to work, and her family is supportive of this goal. In addition, because of the school and church activities that her sons are involved in and the fact that public transportation is negligible in the county that she lives in, M.J. really wants to return to driving independently. I know that this goal would strengthen her independence and ability to engage in those IADL that are so vital to an active and involved family. However, to keep her focused on these goals, even M.J. admits we need to get her shoulder pain under control." "M.J.'s husband is agreeable to driving M.J. to therapy three times each week for 45-minute sessions. In therapy, M.J. and I have decided to first work on compensatory strategies for self-care and pain reduction. We will use FES in the clinic, and I will also teach M.J. how to use the FES unit at home. She agrees to follow through with using the FES at home five times each day for an hour because she is very motivated to reduce her shoulder pain."

Summary of Short-Term Goals and Progress

In 4 weeks, M.J. will demonstrate

1. Decreased subluxation of the left shoulder joint to one finger width
2. Decreased pain in the left shoulder from 8 out of 10 to 3 out of 10
3. Increased AROM of the left shoulder to 110° of flexion and abduction
4. The ability to actively grasp a plastic cup with her left hand

The therapist began treatment using FES to the supraspinatus and posterior deltoid muscles in order to decrease shoulder subluxation. FES was used both in the clinic and as part of M.J.'s home program. The therapist ordered M.J. a home FES unit and instructed M.J. in the use of the modality five times per day for 1 hour daily. When the FES unit was stimulating the muscles, M.J. was instructed to work with the stimulation in reaching for objects. She engaged in a variety of reaching activities that initially required active shoulder movement slightly below the point that would cause her pain. The amount of shoulder subluxation was monitored weekly by the therapist for 4 weeks. Gradually, the subluxation was reduced to about one finger width. As the subluxation reduced, M.J. experienced less pain. As her pain decreased, she was able to reach further and higher for objects.

Assess the patient's comprehension Understand what she is doing Compare actual to expected performance Know the person Appreciate the context	"In the initial evaluations and subsequent visits in the first week of therapy, I showed M.J. how to use the FES machine. She understood how to apply the electrodes and turn on the machine, but she needed her husband's help in placing the electrodes appropriately, so her husband was instructed in helping M.J. with her FES setup. I had M.J. and her husband demonstrate to me the proper FES setup a few times over the first week of therapy." "M.J. is a perfect candidate for this kind of intervention. She quickly learned how to use the FES unit, and so did her husband. He will be a good support for M.J. and a source of motivation for her to follow through with her daily FES sessions." "I am monitoring the subluxation in M.J.'s shoulder, as well as her pain levels and shoulder AROM each week. After the first week, there was not much change, despite M.J.'s compliance with her program. I encouraged her to continue. By the end of the second week, M.J. said she was able to raise her left arm further without as much pain, and I noticed a little decrease in the shoulder subluxation. By the end of 4 weeks, M.J.'s shoulder subluxation was down to about one finger width. Her shoulder pain level was tolerable at 3 out of 10. Additionally, her active shoulder flexion was greatly improved to 110°. M.J. is getting better at grasping objects, but she still has a lot of difficulty releasing her grasp on these objects. However, she is starting to use her left arm more during self-care strategies, and I can now add some other treatment techniques to the therapy plan that will focus on further left arm improvement."

"I am pleased to see M.J. translate her gains in upper extremity function into expansion of her IADL. She recently began testing to determine whether she could resume driving independently and ultimately succeeded. This will further her independence and resumption of IADL and eventually enable her to attempt to return to her work."

Next Steps	Anticipate present and future patient concerns	"Because of the patient's background as a nurse, M.J. seems well aware of challenges and potential limitations based on her initial prognosis. She has always been highly motivated to 'try almost anything' if it would 'work.' I am impressed at her insight into the possible risks and difficulties she would face returning to her career as a surgical nurse, and she is starting to prepare herself for other options that might require less fine motor dexterity and endurance as her condition improves. I expect that she will work closely with her employer and physicians to adapt her work site and work requirements."

Continue outpatient occupational therapy for 1 month but with declining contact. Intervention will focus on weaning M.J. away from the FES and ensuring that she continues to use the extremity for functional movements. Focus will be on function and imparting the importance of a home program of exercise and movement as crucial to ensure continued progress toward the established long-term goals. The patient will also be assisted in resuming many of her social and religious activities and reintegrating into meaningful community organizations and activities. Thought will be given to potential for return to work.

Analyze patient's comprehension

Decide whether he or she should continue or discontinue therapy and/or return in the future

"In-clinic therapy will transition to a home-based program when M.J. has received maximum benefit from the skilled services of a therapist. Once I have taught M.J. and her family all they need to know, and they are able to follow through independently, M.J. will be discharged and continue to work toward her long-term goals."

Clinical Reasoning in Occupational Therapy Practice

Identifying Appropriate Therapeutic Goals and Interventions

M.J. was a young, active, healthy individual prior to her devastating stroke. Overnight, her life and roles changed, impacting her immediate family and employer. She was highly motivated to return to some semblance of her premorbid activities and life. The difficulty she faced, and that the therapist had to assist her prioritize, was in determining short-term, realistic goals and objectives and expanding those into long-term functional goals. As pain decreased and functional return and movement occurred in her upper extremity, refining and

strengthening the motor patterns and movements available to the patient became a motivating factor for her. There are a variety of neuromuscular facilitation techniques that can be used as part of neuromuscular reeducation.

Other than FES, what other physical agent modalities could the therapist use to address M.J.'s shoulder pain? Why is FES the *best* modality choice to help manage shoulder pain associated with subluxation? What are some key points to remember when training M.J. to use the FES unit at home?

Summary Review Questions

1. Identify and discuss the three phases of tissue healing. Why is the phase of tissue healing a significant factor in selection of a specific physical agent modality as an adjunct to treatment?
2. What are the superficial and deep thermal agents discussed in this chapter?
3. List the different types and the most frequent uses of electrotherapy.
4. Discuss AOTA's position on physical agent modalities and how each modality can be used as a precursor to functional performance tasks.
5. Define and discuss therapeutic ultrasound, both its thermal and nonthermal effects.
6. List precautions and contraindications for superficial heat and cryotherapy.
7. List precautions and contraindications for use of ultrasound and electrical stimulation.
8. Why would an occupational therapist use surface electromyographic biofeedback?
9. How do licensing/regulatory issues affect an occupational therapist's use of physical agent modalities?
10. Discuss how the push for evidence-based practice may or may not influence the use of physical agents in clinical practice.

Glossary

Absorption coefficients—The ability of biological tissue to absorb and transmit energy relative to the tissue's unique properties.

Acoustic streaming—The physical forces of sound waves capable of displacing ions and small molecules.

Angiogenesis—The biological process of developing new blood vessels.

Biofeedback—Procedures or techniques that are used to provide an individual with an auditory or visual cue or "feedback" to learn and gain volitional control over a physiological response.

Cavitation—The physical forces of sound waves causing gas bubble formation, expansion, and contraction within fluid or tissue.

Conduction—Exchange of energy (for example heat or cold) when two surfaces are in direct contact with each other.

Convection—Conveyance of heat by the movement of heated particles, such as air or water molecules, across the body part being treated, creating temperature variations.

Cryotherapy—Application of a superficial cold agent to part of the body. Often used for pain relief, reducing edema, and decreasing inflammation following trauma.

Deep thermal agent—Therapeutic application of any modality to the skin and underlying soft tissue structures to cause a temperature elevation in tissue up to a depth of 5 cm.

Duty cycle—During the delivery of electrical stimulation or ultrasound, the duty cycle refers to the time that the electrical current or sound energy is on versus the time the electrical current or sound energy is off.

Electrotherapeutic agents—Therapeutic application of an electrical current to selected tissue or monitoring of endogenous electrical activity in tissue. Includes biofeedback, neuromuscular electrical stimulation, functional electrical stimulation, transcutaneous electrical nerve stimulation, electrical stimulation for tissue repair, high-voltage galvanic stimulation, and iontophoresis.

Epithelialization—The biological process of tissue healing in which a wound is covered by the proliferation of epithelial cells over the wounded area.

Impedance—Resistance of tissue to the passage of electrical current or ultrasound waves or the resistance of the electrodes used in biofeedback to detection of electrical signal generated by muscle activity.

Inflammation—Cellular and vascular response in affected tissue that follows injury or abnormal stimulation; the initial phase of the healing process; the body's attempt to rid itself of bacteria, foreign matter, and dead tissue and to decrease blood loss.

Iontophoresis—The use of electrical current to actively deliver drug ions through the skin.

Microstreaming—The microscopic fluid movement caused by cavitation.

Overload principle—In terms of gaining muscle strength, this principle refers to the fact that the body must be subjected to greater levels of stress than it is accustomed to for strength gains to occur.

Phonophoresis—The use of ultrasound to deliver topically applied medications to selected tissue.

Physical agent modality—An occupational therapy intervention, considered preparatory, that uses heat, light, sound, cold, electricity, or mechanical devices to modify specific client factors when neurological, musculoskeletal, or skin conditions may be limiting occupational performance.

Proliferation—Formation of new collagen tissue and epithelium in the intermediate stage of wound healing.

Remodeling—Third phase of tissue healing; dynamic process with maturation of new collagen tissue within the wound.

Superficial thermal agents—Therapeutic application of any modality that raises or lowers the temperature of skin and superficial subcutaneous tissue to a depth of 1–2 cm.

Thermotherapy—The therapeutic application of heat to increase tissue temperature.

Ultrasound—Deep-heat modality; application of sound waves to soft tissue, causing thermal and nonthermal effects; sound having a frequency greater than 20,000 Hz.

Wound contraction—The biological process of tissue healing where wound edges are drawn toward each other as the body attempts to heal and close the wound.

Optimizing Abilities and Capacities: Range of Motion, Strength, and Endurance

Andrew Fabrizio and Jose Rafols

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. State the biomechanical and physiological mechanisms that underlie therapeutic exercise and occupation.
2. Apply the methods for decreasing edema, minimizing contracture, and mobilization to prevent limitation of range of motion.
3. Apply biomechanical and physiologcial prinicples of the biomechanical approach to the selection of occupations as a means for treating range of motion, strength, and/or endurance problems as needed for occupational performance.
4. Design treatment goals and therapy for clients who have problems with range of motion, strength, and/or endurance to enhance occupational performance.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate
An assumption of the occupational functioning model is that the ability to carry out one's roles and activities depends on an individual's basic capacities (see Chapter 1). Three capacities necessary for performing physical activity are range of motion (ROM), strength, and endurance. Occupational therapists help clients improve these basic capacities as a preparatory means for developing higher level skills needed for the performance of everyday activities or occupations (American Occupational Therapy Association, 2008). The underlying biomechanical and physiological principles that pertain to motion, strength, and endurance are the building blocks upon which treatment for physical dysfunction is built. The principles are applied to the remediation of impairments from acute injuries; the prevention of illnesses and conditions caused by repetitive motion, cumulative trauma, or poor biomechanics; and as compensation for or adaptation to chronic disability.

MUSCULOSKELETAL SYSTEM

The following is a simple overview of the biomechanical and physiological elements of the musculoskeletal system that underlie ROM, strength, and endurance. This basic understanding enables occupational therapists to analyze and prescribe therapeutic occupations and exercise to promote occupational function. Table 20-1 illustrates the linkage between various biomechanical capacities needed for a common military activity (see Activity-Focused Case Example later in the chapter).

Biomechanical Aspects

Although mechanics is a branch of physics that deals with the study of motion produced by force, biomechanics involves taking those principles and applying them to the structure and function of the human body. Biomechanics is broken down into static (nonmoving) and dynamic (moving) systems, and the dynamic systems can be further broken down into concepts described as kinematics and kinetics.

Kinematic analysis describes human motion in relation to the location and direction of the movement, the magnitude and velocity of the motion, and the type of motion that is occurring such as translatory motion or rotary motion (Levangie & Norkin, 2011). Researchers use these quantitative kinematic descriptors to describe the act of grasping with reachers (Maitra, Philips, & Rice, 2010), the effect of elbow angles in manual wheelchair propulsion (Goins et al., 2011), and the way the three joints of the thumb move during different activities of daily living (Lin et al., 2011).

Kinetics is a description of motion with regards to the forces that cause motion (Lippert, 2006). The forces that provide movement or stability are both internal and external to the body. Internal forces consist of muscle contractions that enable us to engage in our daily occupations or the elasticity of structural and connective tissue that prevent unwanted movement. The wind that pushes against the body, the friction of a sock on the floor, or the weight of a hammer held by a construction worker are all examples of external forces on human movement. Gravity is another example of external force. Gravity is constant and unnoticeable to most of us, but it affects all human movement. It is the gravitational pull on the body and body segments that gives them weight and can be a challenge to patients who have lost the strength to overcome this weight. Researchers are studying kinetics when they measure the influence of gravity during reach and retrieval activity for subjects with spinal cord injuries (Kloosterman et al., 2010), when they study the maximum load, stress, and elongation of different tendons used for tendon grafting (Mazurek et al., 2011), or when they look at the force on the wrist and thumb during jar opening activities (Chang, Ho, & Su, 2008).

Nearly all purposeful activity can be broken down into a series of coordinated movements. Understanding the different types of movement and forces behind the motion helps therapists design the most efficient exercise programs and structure therapeutic occupation. The following is an example of force, stability, and motion in occupation. While dining, a person grasps a glass filled with a beverage and lifts it to take a sip. This task requires both stability and motion. Initially, muscles in the trunk and shoulder girdle (internal forces) co-contract to provide proximal stability, allowing for controlled distal mobility. To raise the glass, the forearm flexors contract causing rotary motion, or flexion of the elbow joint. When rotary motion occurs, each point on the bone segment (ulna and radius) moves through an arc at the same time at a constant distance from the axis (elbow joint). To cause rotation, the forearm flexors must have enough strength to overcome the external forces created by gravity and the weight of the glass.

Torque

When analyzing the movement in this scenario, one must also consider torque. Torque is the tendency of a force to produce rotation about an axis (Lippert, 2006). In rotary movements, torque depends on (1) the amount of force applied and (2) the distance of the force from the axis of movement, also known as the moment arm. Thus, in mathematical terms, torque is equal to the magnitude of a force times the perpendicular distance between the line of force and the axis of rotation $[T = (F)(D)]$ (Levangie & Norkin, 2011). In relation to the example of taking and raising a glass, the torque produced by the biceps at the elbow (effort force) is equal to the force the muscles can produce times the distance between the bicep's insertion on the radius and the axis of motion or elbow joint (Fig. 20-1A).
Figure 20-1 **A.** Torque of effort force. *a,* Line of pull of effort force (elbow flexors). *b,* Perpendicular distance between the insertion of the elbow flexors and the axis of rotation. **B.** Torque of resistance force. *a,* Line of pull of resistance force (weight of glass and forearm). *b,* Perpendicular distance between the resistance force and the axis of rotation.

The torque of resistance force (the glass, forearm, and hand) is equal to the resistance force (weight of the glass, forearm, and hand) times the distance between the glass and the axis of movement or elbow joint (Fig. 20-1B). For a person to flex the elbow and take a sip, the torque of the biceps has to be greater than the torque of the glass, forearm, and hand.

The concept of torque also explains why the placement of an object either closer to or farther from the axis of rotation changes the effort needed to make the movement, even though the object's weight remains constant. Therapists use this concept in a number of situations. Teaching clients to lift objects closer to the body's center of gravity, thereby reducing the moment arm and the amount of stress on the back and shoulders, is one example. Likewise, when assisting a patient to perform a stand-and-pivot transfer from the wheelchair to the bed, a therapist stands close to the patient as they both pivot, and the therapist lowers the patient to a sitting position. The patient provides less resistance torque (the weight of the patient times the perpendicular distance between the patient and the therapist's back) when he or she is close to the therapist. This in turn requires less effort force by the therapist's back muscles for raising, maintaining the position during the pivot, and lowering the patient to the bedside. Similarly, therapists use this concept to help clients increase productivity while minimizing effort. For example, by using longer tools, which increase the moment arm and thereby increase the amount of torque that is placed on the nut or bolt, manual laborers decrease the muscle force needed to turn the tool (see Research Note 20-1 for further information regarding torque and safe rehabilitation).

Lever Systems

Another way to evaluate torque in angular movement is through the description of levers. A lever system consists of a rigid bar (such as a bone), an axis of rotation (such as a joint), and two forces: effort and resistance. Effort is the force that causes movement, and resistance is the force that tends to keep an object from moving. There are three classes of lever systems.

A first-class lever is a system where the axis of rotation lies between the effort and resistance forces (Levangie & Norkin, 2011). A common example of a first-class lever is the seesaw (Fig. 20-2A). As one can see, a seesaw would remain in balance, with no movement, if two children of the same weight sat the same distance from the axis. This balance, or equilibrium, is maintained because the torque (weight of child 1 times the perpendicular distance from child 1 to the axis of rotation) on one side of the seesaw equals the torque (weight of child 2 times the perpendicular distance from child 2 to the axis of rotation) on the opposite side of the seesaw. In essence, they balance, and there is no movement. If one of the children is heavier, he or she must move closer to the axis to maintain that balance (Fig. 20-2B).

In second- and third-class levers, the effort and resistance force lie on the same side of the axis (Lippert, 2006). A second-class lever system, such as a bottle opener or a wheelbarrow used to carry compost in a garden, is a system in which the resistance force lies closer to the axis of rotation than does the effort force (Fig. 20-3). With a bottle opener, the resistance force is the force of the cap that is tightly connected to the bottle. The effort force is a person's hand lifting the end of the opener to release the cap. This lever system allows a relatively small amount of force to overcome strong resistance. Second-class lever systems explain the type of tools used frequently in occupations when mechanical advantage is required, such as an extended handle on a faucet.

In third-class lever systems, the effort force lies closer to the axis than does the resistance force (Levangie & Norkin, 2011) (Fig. 20-4, top). The example of bringing a glass to one's mouth represents a third-class lever. The elbow joint is the axis; the biceps is the effort force; and the combined weight of the forearm and glass is the resistance force (Fig. 20-4, bottom). In contrast to the stability of first-class levers and the mechanical advantage of second-class levers, third-class levers produce greater velocity and ROM. Most body segments that are moved

Research Note 20-1

Abstract

Background: Forces on the ulnar collateral ligament of the elbow after reconstruction are measured during a rehabilitation protocol that includes passive range of motion, isometric muscle contraction, and varus and valgus torques to help develop guidelines for safe and productive rehabilitation.

Methods: Eight cadaveric elbows underwent ulnar collateral ligament reconstruction using a gracilis tendon graft. Strain on the anterior and posterior bands of the ligament were measured with differential variable reluctance transducers during passive range of motion, isometric flexion and extension contractions, and varus and valgus torques with the arm at 90° of flexion.

Results: Range of motion from maximum extension to 50° of flexion produced 3% or less strain in both bands of the reconstructed ligament. Forearm rotation did not significantly affect strain in the ligament. Strain at 90° approached 7% in the posterior band. Isometric muscle contractions had no measurable effect on strain. Varus torques decreased and valgus torques increased strain significantly.

Conclusion: In the immediate postoperative period, full extension is safe, whereas flexion beyond 50° may place deleterious strain on the reconstruction. Isometric flexion and extension exercises do not increase ligament strain but may be unsafe at 90° of flexion, whereas valgus exercises (internal rotation at the shoulder) can increase strain in the reconstructed ligament.

Implications for Practice:

A unique expertise of occupational therapy is the design and prescription of purposeful and meaningful activity (occupation) to enhance and promote health. Along these lines, occupational therapists frequently use therapeutic occupation to improve an individual's ROM, strength, and endurance. In this example, the ulnar collateral ligament is often repaired to enable athletes who use overhead motions to return to competition. However, this study highlights the need to use biomechanical principles to design therapeutic programs that are safe and effective for patients.

Whether therapists are designing exercise programs to increase motion or strength or prescribing purposeful and meaningful activities that do the same, it is important to analyze the forces that are put on the body, as to not injure or debilitate a person who is recovering. Through activity analysis, an educational background steeped in kinetics and kinematics, and knowledge of human anatomy, occupational therapists are able to design the most appropriate methods for rehabilitation.

---

by muscular effort are third-class lever systems where the muscles provide the effort force and the joints are the axis (Hamilton, Weimar, & Luttgens, 2012). However, the potential work capacity of the various muscles of the body also depends on the amount of force they can generate and the distance over which the muscles can shorten. In other words, the ability to fully function, move, and engage in occupation depends not only on the biomechanics of the musculoskeletal system but also the physiologic principles of the muscles themselves.

Physiological Aspects

Skeletal muscle provides the power to produce movement of a bony lever around its joint axis. A muscle's strength and endurance to perform this activity depend on multiple factors including the size and type of muscle fibers, the number and frequency of motor units firing, and the length-tension relationship of the muscle. Before this discussion, it is important to understand the basic contractile elements within muscle.

The sarcomere, made up of actin and myosin, is the main contractile portion of skeletal muscle and is located within the myofibrils of the muscle. A nerve impulse sent to a motor unit, which consist of a motor neuron, an axon, and the muscle fibers supplied by the neuron, initiates a chemical reaction and the release of calcium throughout the muscle fibers. The calcium ions release the inhibition that prevents actin and myosin filaments from combining. When these thin and thick filaments are allowed to combine, **cross-bridges** are created. According to the sliding filament theory, muscle contraction occurs when these cross-bridges are broken, actin is pulled over the myosin, and new cross-bridges are formed (Cooke, 2004; Levangie & Norkin, 2011) (see Fig. 20-5). As this sequence continues, tension is generated, and the muscle shortens (concentric contraction). In a lengthening contraction (eccentric contraction), cross-bridges are broken and reformed as the actin is pulled away from the myosin filaments (see Definition 20-1).

The strength of a contraction depends on the number and type of muscle fibers found in a motor unit (MacIntosh, Gardiner, & McComas, 2006). Muscles that produce large contractions typically are composed of motor units that have large axons, large cell bodies, and many muscle fibers. These fibers are also typically type II fibers, which are fast twitch fibers capable of producing more power and
Figure 20-2 A. First-class lever system. Balanced equilibrium depicted by children on a seesaw. Both children weigh 60 pounds, and they are equidistant from the axis. **B.** First-class lever system. The heavier child must be closer to the axis of the seesaw to maintain the equilibrium.

are usually recruited first, but if they cannot complete the task, larger motor units are recruited to complete the action. The frequency of a motor unit's firing also affects the force modulation. For small distal muscles, there is more of a reliance on an increased frequency of motor unit firing than for larger proximal muscles that may rely more heavily on recruiting more motor units (Levangie & Norkin, 2011).

Finally, a muscle's ability to produce force depends on the length of the muscle. This is tied directly to the length and number of sarcomeres in a muscle fiber. When a muscle

a higher rate of contraction (Levangie & Norkin, 2011). Muscles that contain a majority of these types of motor units, like the bicep or hamstring, are often responsible for activities that call for large movements. On the other hand, muscles that contain motor units with small axons, smaller cell bodies, and fewer muscle fibers are more adept at smaller movements, stabilizing actions and fine motor activity. Smaller motor units typically have more type I slow twitch fibers, which are capable of prolonged activity because they do not fatigue as rapidly (see Fig. 20-7).

Other contributing factors for regulating the force of a muscle contraction are the number of motor units that are recruited and the modulation of firing rates of active motor units (Contessa, Adam, & De Luca, 2009). As the need for force increases because of the load or if motor units fatigue because of duration of contraction, other motor units are recruited (Hall & Brody, 2005). Small motor units that produce less tension and thus require less energy

is at its optimal length, the actin and myosin filaments are positioned in such a way that the maximum number of cross-bridges are formed (Levangie & Norkin, 2011). If muscle fibers are lengthened, there is less overlap of the actin and myosin filaments, resulting in fewer cross-bridges and less tension, and when muscle fibers are shortened, the filaments do not slide as far, resulting in decreased force.

Definition 20-1

Types of Muscle Contractions

Concentric—Muscle shortens to move a limb section in the direction of the muscle pull. In a concentric contraction, the internal force of the muscle overcomes the external resistance.

Eccentric—Contracted muscle lengthens to act as a brake against an external force to allow for a smooth controlled movement.

Isometric—External and internal forces are in equilibrium, and the length of a contracted muscle remains the same.

Example

In Figure 20-6, raising the flag involves concentric contractions of the shoulder abductors and flexors to raise the arm and then the finger flexors, the biceps, and latissimus dorsi to pull down on the rope. Lowering the flag involves eccentric contraction of the shoulder flexors and biceps to slowly release the rope allowing the weight of the flag to descend in a controlled manner. Holding the flag at half mast while the rope is being tied off is an example of isometric contraction of the biceps and triceps and shoulder flexors and extensors.

Figure 20-6 Raising, lowering, and securing a flag on a flagpole requires concentric, eccentric, and isometric muscle contractions.

BIOMECHANICAL APPROACH TO TREATMENT

Having an understanding of the biomechanical and physiologic principles of ROM, strength, and endurance helps occupational therapists design the most effective treatment programs aimed at enabling performance.

Figure 20-7 Typing or computer work is a fine motor task that uses muscles with smaller motor units that contain more type I slow twitch fibers for prolonged activity.

Remediation or prevention of limitations in these three capacities prepares an individual to fully engage in purposeful and occupation-based activities that support health and participation in life.

Maintaining or Preventing Limitation in Range of Motion

ROM is the maximal distance that bones move about a connecting joint. It involves the length and excursion of muscles as well as the extensibility of connective tissues that cross the joint. There are assessments that provide guidelines for the typical ROM available at various joints in the human body, but an individual's actual ROM at any joint is directly affected by the structures surrounding the segments that are moving. Occupational therapists are concerned with the total range allowed by these structures, but more importantly, they are concerned with functional ROM, which is the range necessary to perform daily activities. To this end, it is the therapist's responsibility to provide treatment that helps clients maintain functional motion or to help patients gain motion when there are limitations that interfere with occupation.

Factors That Limit Range of Motion

There are numerous reasons for limited ROM such as systemic, neurological, or muscular diseases that impair muscle performance (Kisner & Colby, 2007). Joint diseases such as arthritis that create pain and inflammation decrease motion, and surgical or traumatic insults that produce edema and scarring may also limit motion. Finally, simple inactivity or immobilization affects ROM.

Forces that act across a joint during motion determine the quantity, alignment, length, and structural organization of the collagen fibers that make up the majority of connective tissue around a joint (Glasgow, Tooth, & Fleming, 2010). When a joint is not put through its full ROM because of either internal factors such as pain and inflammation or external factors such as casting, splinting, or bed rest, physiological changes in the connective tissues occur. For muscle, this includes changes in the length and numbers of sarcomeres, thickening of the tissue, a loss of fibers, and potential atrophy, resulting in a muscle's inability to exert force on the bony lever. For ligaments, joint capsules, and tendons, a lack of motion results in a decrease in collagen fibers, which results in weakness, and when new collagen is formed, it is done in a shortened, disorganized fashion that results in stiffness (Levangie & Norkin, 2011). In the joints themselves, a loss of motion results in the breakdown of articular cartilage because synovial fluid is no longer moving to carry the necessary nutrients to the joint surfaces (Kisner & Colby, 2007). This in turn creates further loss of motion because of pain, inflammation, and edema.

Edema, defined as the accumulation of excessive fluid in intercellular spaces, is a natural result of trauma or injury (Guyton & Hall, 2011). The fluid (made up mostly of water and dissolved electrolytes) usually dissipates as the healing process progresses (Priganc & Ito, 2008). However, if the edema persists over time, the content of the fluid changes to a highly viscous, protein-laden material, which if not managed can increase circumference of a joint, cause fibrosis and thickening of tissues, and result in adhesions and contractures that restrict motion and limit a person's ability to engage in purposeful activity (Glasgow, Tooth, & Fleming, 2010; Hall & Brody, 2005; Kisner & Colby, 2007).

Intervention Methods

Many ROM limitations can and should be prevented. Limited motion creates a pathological cycle where the loss of motion results in pain, edema, and shortened structures that result in further loss of motion. It is important for occupational therapists to help patients break the cycle in order to remain as functional as possible. This is done by providing therapy that is aimed at decreasing edema, helping patients prevent contractures through proper positioning and/or splinting, and facilitating joint movement through as much range as possible if motion is not contraindicated.

Decreasing Edema. In order to prevent ROM limitations secondary to edema, occupational therapists commonly use techniques of elevation, cryotherapy, compression, massage, and at times electrical current (see further information on physical agent modalities in Chapter 19). The use of these techniques is dependent on the stage of the injury, the vascular status of the patient, and the desired clinical effect. During acute injuries or right after surgery, patients who do not have any arterial compromise are instructed to slightly elevate injured extremities above the heart in order to use gravity to improve venous and lymphatic flow and decrease swelling (Villeco, 2011). Cryotherapy or the use of cold application is helpful in managing edema by producing vasoconstriction, which reduces blood flow, slows down metabolic activity, and decreases the inflammatory response that causes edema (Capps, 2009). Compression limits edema by restricting the accumulation of subcutaneous fluid in tissues through external pressure. The pressure is provided by form fitting compressive garments like gloves or hosiery, tubular sleeves such as Tubigrip™ (Mark One Health Care Products, Philadelphia, PA), or elastic wraps such as Coban™ (3M, St. Paul, MN) (see Procedures for Practice 20-1 for the proper use of elastic wrap compression). There are various techniques of massage to reduce edema, including retrograde massage, which involves a constant stroking massage from the distal portion of the extremity back proximally toward the heart, and a newer technique called manual edema mobilization (discussed further in Chapter 37). Finally, although the effectiveness of high-voltage pulsed current at reducing edema has not

Procedures for Practice 20-1

Applying Self-Adhesive Elastic Bandages for Compression

- Choose the appropriate width of bandage, understanding that the narrower the bandage, the greater the pressure.
- Start at the distal end of the limb or digit and wrap proximally, keeping the tension constant at about 50% of the stretch of the material.
- Wrap in a spiral motion overlapping 50% so that the fluid can flow evenly back toward the body and not be trapped in pockets of unwrapped tissue.
- If wrapping a digit, leave the tip open to observe skin color and preservation of circulation.
- Instruct patient on amount of wear (nighttime, hourly, or multiple hours).
- Instruct patient to remove bandage periodically to inspect skin for color and maceration.

been established, some therapists use this technique in the belief that it helps decrease edema that may be limiting ROM. Note that use of many of these intervention techniques require specialized training and/or licensure.

Minimizing Contractures. Contractures are defined as static shortening of muscle and connective tissue that result in reduced joint mobility and an increase in resistance to passive joint movement (Fergusson, Hutton, & Drodge, 2007). People suffering from hypertonicity caused by a stroke or traumatic brain injury may develop contractures in the upper extremity when elbow or wrist flexors continually fire, resulting in a shortening of the flexors and lengthening of the extensors. Even without hypertonicity, patients with paralysis often rest with their affected arm in the lap, which predisposes the shoulder muscles and tissues to shorten. Patients with burns or deep wounds as a result of trauma may develop contractures when normal skin is replaced by scar tissue (Dewey, Richard, & Parry, 2011). As stated before, patients who are immobilized for a long period of time may also develop contractures when their soft tissues begin to shorten because of lack of movement. To counteract tissue shortening and prevent contractures and subsequent loss of motion and function, occupational therapists may use therapeutic positioning and splinting. Therapeutic positioning is designed to help with edema resolution when limbs are elevated, to help preserve function by holding limbs at a proper muscle length, and to help patients avoid positions that result in tissue shortening or contracture. For example, patients often develop tightness in the shoulder extensors, adductors, and internal rotators after stroke. Therefore, positioning the patient with the arm in shoulder flexion, abduction, and external rotation helps prevent that tightness from developing (Ada et al., 2005).

Splinting, which is an extension of positioning, is indicated when there is a need to prevent unwanted motion or when a patient does not have the capability to assume postures and positions that prevent tissue shortening (see Chapter 16). Splints can be used to hold joints in a position with optimum tissue length, and in the case of burns, they are used to prevent or limit scar contracture (Selvaggi et al., 2005). In spite of prevention, sometimes contractures and consequent ankylosis are unavoidable because of the disease process. In these instances, positioning and splinting patients in a safe, functional position that allow the patient to manage self-care and other functional tasks, is necessary. The functional position of the hand and wrist is slight (20°–30°) extension of the wrist, opposition and abduction of the thumb, metacarpal-phalangeal joints in 40°–60° of flexion and semiflexion of the finger joints (Haines & Cooper, 2007). Then, if a patient's hand contracts in that position, the person can still hold objects. If, however, the hand or digits were to contract in a fully flexed or fully extended posture, function is lost. When positioning and splinting a patient, the occupational therapist must be vigilant in anticipating eventual outcomes of prolonged immobilization that may compromise occupational performance.

Movement through Full Range of Motion. Immobilization is often necessary to protect structures such as bone and skin while they heal, but prolonged immobilization can lead to decreased strength, shortened tissues, contractures, and loss of motion (Glasgow, Tooth, & Fleming, 2010). Controlled motion applied early in the rehabilitation process helps minimize the negative effects of immobilization (Levangie & Norkin, 2011). The method used for movement through full ROM, referred to as ranging, involves teaching the patient to move the joints that are injured, immobilized, or edematous or passively moving the joints if the patient is unable to actively move the joint themselves. In active range of motion (AROM), the patient actively moves the joint through full range with their own muscle power, and in passive range of motion (PROM), the patient's limb is moved through the desired motion by an external source. If a patient has some strength but is unable to fully move a joint through its desired ROM because of weakness, a therapist may use active-assistive ROM (AAROM) to provide just enough assistance to help the patient achieve the desired motion. AROM or AAROM is preferred to PROM because the contraction of the muscles helps pump the fluid out of the extremity helping with edema and stiffness. However, if AROM is not possible, PROM and in particular the use of a continuous passive motion (CPM) machine, which electronically moves a joint through a set ROM, also reduce stiffness and edema (O'Driscoll & Giori, 2000). The extent of effectiveness of CPM versus PROM has been studied and debated (see LaStayo and Cass [2002], O'Driscoll and Giori [2000], and Schwartz and Chafetz (2008) for additional information on the use of CPM with the upper extremities).

Whatever kind of motion is being applied, therapists must pay attention to the plane of motion a joint is moving through, the structures involved with the movement of the joint, and joint biomechanics. For example, the therapist pays special attention to the scapulohumeral rhythm when ranging the shoulder girdle. By moving the scapula with one hand and the humerus with the other, the therapist ensures that they are moving in synchrony (Fig. 20-8). Attention to this alignment during movement of the scapula and humerus eliminates injury to the glenohumeral joint, bursae, capsule, and ligaments.

To maintain ROM, joints must periodically be moved through their available ranges (Kisner & Colby, 2007). As for the frequency of AROM or PROM when trying to maintain motion, there is no set protocol. Therapists constantly monitor a patient's response to any intervention and adjust treatment accordingly. The amount of motion is dependent on the patient's status (inpatient versus outpatient), time constraints during treatment, and the patient's own abilities, both physical and cognitive. If a patient has the physical and cognitive abilities, occupational therapists use activity to promote the AROM and PROM needed to

Figure 20-8 Facilitation of glenohumeral rhythm during passive ROM.

prevent loss of motion. For example, using a Wii™ golf or tennis program during therapy encourages a patient who has either of those interests to move at the shoulder, elbow, and wrist. Another example is having a patient use his or her hemiplegic upper extremity in weight-bearing activities for balance and postural stability while passively stretching the wrist and fingers in extension.

Increasing Range of Motion

If limitation in ROM impairs a patient's ability to function independently or is likely to lead to joint deformity, skilled intervention to facilitate and improve ROM is warranted. Whereas some significant limitations of ROM can be improved or corrected through the use of occupation and exercise, others cannot. Problems that can be changed include contractures of soft tissues, such as skin, muscles, tendons, and ligaments. Occupational therapists may treat ROM limitations using several time-tested interventions such as moist heat, PROM with prolonged passive stretch at the patient's end range, CPM, and various splinting techniques. However, therapists universally recognize the importance of stretch in helping patients develop the capabilities needed to perform occupations. Some problems cannot be changed through these means including ankylosis or arthrodesis, long-standing contractures in which there are extensive fibrotic changes in soft tissue and severe joint destruction. If ROM limitations cannot be overcome, occupational therapy facilitates functional mobility by providing compensatory techniques through the use of equipment to enable participation in life occupations.

Stretching

Stretch is a process by which the target tissue is lengthened by an external force, usually through manual therapy or through the use of splinting, casting, or external equipment. Stretch is used to eliminate tightness that has the potential to cause contracture, even in periods of brief inactivity. Stretch produces change in the extensibility of soft tissue that dissipates when the stress is removed, so to make lasting gains, the stretch needs to be repeated or sustained over time (Katalinic, Harvey, & Herbert, 2011). Factors that determine the effectiveness of stretching are the duration, the intensity, the speed, and the frequency of the stretch being applied (Hall & Brody, 2005; Kisner & Colby, 2007).

The duration of a stretch refers to the amount of time tissues are held under an external force. According to the total end range time principle outlined by Flowers and LaStayo (1994), the longer a joint is held at the end range under adequate tension, the greater the gains will be in ROM. However, there are different types of stretching such as ballistic stretching or joint mobilization techniques that incorporate shorter stretches. It is clinically recognized that maintained stretching is more effective; however, gains are also noted using the briefly held stretches (Kisner & Colby, 2007; Michlovitz, Harris, & Watkins, 2004).

The intensity of a stretch is determined by the amount of force put on the tissues that are being stretched. Gentle, controlled stretching that achieves small increments of gain over time is thought to be more effective than vigorous stretching aimed at large, rapid gains. *Safety Message: Residual pain after stretching indicates that the stretch was too forceful and caused tearing of soft tissues or blood vessels.* The method of moving gently to the point of maximal stretch and holding that position allows connective tissue to gradually adapt to its new elongated state over time. This is the principle behind static progressive stretching. In static progressive stretching, shortened tissues are held comfortably in a lengthened position until a degree of relaxation is felt by the patient or the therapist. Once this is achieved, the newly lengthened tissues are lengthened again, and over time the accommodated tissues lengthen to a functional position.

As for the velocity of a stretch, it is generally thought that the speed should be slow to allow the tissues to adjust gradually to the forces being applied. As a protective mechanism, connective tissue resists quick vigorous stretching by evoking a stretch reflex that increases the tension in the contractile structures of muscle, thereby opposing the purpose of the stretch (Kisner & Colby, 2007).

The frequency of stretching refers to the number of sessions during a day or week that the tissues are stretched either at home, by a therapist, or during occupation. There is little evidence to define the optimal frequency of stretching, but it is known that there needs to be adequate time between stretching to allow for tissue healing and to prevent inflammation. In the case of low-load, prolonged stretching to lengthen contracture found in static progressive splinting, frequency is not an issue as much as the duration of splint wear.

Intervention Methods

There are two types of stretching: active and passive. In active stretching, contraction of muscles opposite to the direction of limitation is the source of the force, and in passive stretching, an external force is applied.

Active Stretching. An occupational therapist's clinical expertise lies in using occupation as a treatment medium and in this case, as a means for reaching the goal of increasing ROM in a given joint or mobility within a given extremity. The use of occupation for stretching is empirically based on the idea that a person involved in an interesting and purposeful activity will gain greater range because he or she is relaxed, is not anticipating pain, is motivated to complete the task, and therefore is likely to move as the activity demands (Colaianni & Provident, 2010; Earley & Shannon, 2006.)

The therapist and patient choose a life occupation that has significance to the patient. Occupations can be performed using a number of muscle patterns. Therefore, through the use of activity analysis, the therapist must determine how the patient completed the activity prior to injury. If the activity, as naturally performed by the patient, requires stretching of the soft tissues that are shortened, it can be used as a form of active stretching. Occupations used as a means to increase ROM must provide a gentle active stretch by use of slow, repetitive isotonic contractions of the muscle opposite the contracture or by use of prolonged passive stretched position of the contracted tissue. In both types of stretch, the requirement is that the range be increased slightly beyond the limitations. Grading of the task or subtasks can also be seamlessly integrated into the activity and is of great therapeutic benefit. Techniques, such as, slowing down the sequence of the task or event, increasing or decreasing the placement distance from the patient's center of gravity, and increasing the weight of the object being transferred to and from the various levels all address active stretching with ROM. These techniques not only facilitate active stretching, but also promote gross motor control, trunk balance, and weight shifting, which are all used in performing occupational tasks (Holmes et al., 2008). People move in individually characteristic ways and frequently compensate by using available ROM in adjacent joints, so the therapist must carefully monitor the patient's motions. The therapist cannot assume that the activity itself will evoke the desired response in all persons. Reasonable adaptations of the occupation may sometimes be used to elicit desired motions. Examples of adaptations include adjusting the size of a handle to stretch finger flexors or by placing an object that has to be reached up higher to increase the amount of shoulder ROM during the activity (Fig. 20-9). The Activity-Focused Analysis Case Example incorporates active stretching involved in the aforementioned task. Table 20-1 details the biomechanical capacities involved in this activity.

Another technique that increases the range of shortened tissue is the proprioceptive neuromuscular facilitation

Figure 20-9 Putting together an army uniform with all decorations with the jacket hanging from a hanger will achieve more shoulder ROM than if the jacket was laying on a table.

Activity-Focused Analysis
Assembling an Army Uniform

Task Analysis Process			Example
Describe the task demands	Objects used	Properties of the utensils, tools, and materials and their locations relative to the person	U.S. Army Service Uniform jacket 8 Army ribbons and 21 decoration clasps 1 name plate, unit crest, combat service badge 2 U.S. Army insignia, branch insignia, skill badges 2 rank epaulettes Ruler Decorations placed on a table, the uniform jacket on a hanger, and the person doing the activity between the table and the uniform
	Environmental demands	Characteristics of the environment in which the activity is usually carried out, including possible environmental barriers and enablers	Indoors Decorations positioned on the table top surface within reach No obstacles between the table and uniform
	Social demands	Nature of and extent to which the activity involves others and/or holds particular meaning associated with social roles	Does not require participation of others; may hold personal meaning to those in the military or for those who wear a uniform to work such as police officers or firemen
	Contextual demands	Nature of and extent to which the activity or the way it is carried out holds particular meaning to certain cultures or age groups	Appropriate for individuals who are of work age and any cultural background
	Sequencing and timing	Monological task (requiring a singular sequence in order to be performed correctly) or a multilogical task in which a variety of sequences will work Extent to which the task involves temporal requirements or timing requirements	Assembling the decorations on the uniform jacket can be multilogical where the order of placement of the decorations on the jacket can be alternated. If working on memory or following directions, the order of placement can be written out to create a monological task. The activity can be completed within one therapy session (no specific temporal requirements).
	Required actions	Steps that comprise the activity	1. Hang the uniform jacket on a hanger at eye level. 2. Set out decorations including rank and name plates on the table. 3. Place name plate on flap of the right pocket between top of button and top of pocket. 4. Place unit awards 1/8 inch above right pocket and regimental crest 1/4 inch above awards. 5. Place combat service identification badge in the center of the right pocket. 6. Assemble ribbons on a ribbon rack according to military order of importance. 7. Place ribbons 1/8 inch above the top of the left pocket. 8. Place skill badges 1/4 inch above the ribbons and centered between sides of ribbons.

			9. Place U.S. insignia 5/8 inch above the notch on both collars with centerline of insignia parallel to the edge of the lapel and branch insignia 1 and 1/4 inch below the U.S. insignia.
			10. Place epaulettes of rank on shoulder clasps.
	Prerequisite capacities, abilities, skills necessary to successful task performance	Sensorimotor: range of motion, strength, motor control, postural control, endurance, coordination/dexterity	See Table 20-1 for biomechanical analysis of Steps 3 to 10.
		Vision-perceptual: visual acuity, visual scanning, visual perception, awareness of extrapersonal space	Visual proficiency with small objects that are within arm's reach.
			Ability to differentiate color, figure-ground perception, position in space
			Adequate spatial relations to move between table and uniform
		Cognitive: attention, memory, executive functioning, problem solving, self-awareness	Ability to sustain attention for ~20 minutes
			Ability to follow directions for sequence of placement of decorations and ribbons or ability to memorize steps
			Able to problem solve to achieve correct spacing between decorations
		Emotional, relational	Varies based on patient background with activity; can be performed with or without social interaction
	Safety precautions	Nature of safety considerations if performed in a therapy context	Patients who perform the task standing may need supervision related to balance and/or endurance.
			Patients with limited sensation in digits need to be aware of the sharpness of pins as they go through fabric into the clasps.
Identify the primary therapeutic aspect of the task; adapt task demands to align with therapy goals	Sensorimotor	Range of motion	Uniform decorations are positioned so that the patient has to reach for them repeatedly
		Strength, motor control	Patient may wear weight cuffs during task performance.
			The uniform can be hung at eye level or higher to work against gravity.
		Postural control, endurance	If postural control is problematic, activity can be done in a seated position with uniform on the table.
			To work on endurance, uniform can be placed further away from the patient.
		Coordination, dexterity	The activity involves multiple small items that can be increased or decreased to change the size of items or the number of repetitions.
	Vision-perceptual	Visual scanning	Rather than separating all decorations, items can be placed in one pile requiring patient to locate specific decorations working on figure-ground skills.
		Visual perception, extrapersonal space	
			Require exact placement of decorations according to regulations to work on position in space skills.
			Decorations can be scattered across table to work on visual scanning skills.
	Cognition	Attention, memory	Patient is challenged to work in an increasingly noisy, distracting environment.
			Therapist creates interruptions to determine whether patient is able to return to task efficiently.
			Decorations are placed on the uniform in a specific sequence to work on memory.

	Executive functioning, problem solving, awareness	Patient is given general instructions (assemble uniform according to regulations). Ribbons to be placed on a ribbon rack according to order of importance.
	Emotional-relational	Mood, engagement, interactions with others	Patient performs task in parallel with others or in cooperation with others.
Modify task demands to calibrate difficulty level	Objects used	Number of decorations to place on uniform. Location of uniform decorations (within reach, within visual field, within clinic space). Patient can use clasps to increase physical demands or assemble without clasps.
	Space demands	Stimulus arousal properties of the environment. Options to sit versus stand while working.
	Social demands	Working alone versus working with others.
	Contextual demands	Incorporate meaning by having the uniform inspected by another member of the military.
	Sequencing and timing	Establish specific time parameters by which patient must assemble the uniform. Allow patient to assemble decorations without regard to sequence to make task easier or provide instructions on specific sequence of assembly to increase cognitive demands.

Table 20-1   **Prerequisite Biomechanical Capacities, Abilities, Skills Necessary for Placing Decoration on the Uniform**

Motions	ROM (°), Distances	Primary Muscles	Gravity Assists, Resists, No Effect	Minimal Strength Required	Type of Contraction
Shoulder flexion	0–90	Anterior deltoid, coracobrachialis, pectoralis major	Resists	4– to 4	Concentric
Elbow extension	90–0	Triceps	Assists	3+ to 4–	Eccentric
Shoulder extension	90–0	Anterior deltoid, coracobrachialis, pectoralis major	Assists	3+ to 4–	Eccentric
Elbow flexion	0–90	Biceps, brachialis	Resists	4– to 4	Concentric
Cylindrical grasp		Finger flexors, finger extensors, interossei	No effect	4– to 4	Isometric
Wrist extension	0–45	Extensor carpi radialis brevis and longus	Resists	4– to 4	Concentric
Wrist Flexion	45–0	Flexor carpi ulnaris and radialis	Assists	4– to 4	Concentric
Wrist stabilize		All wrist muscles	No effect	4– to 4	Isometric
3 Jaw Chuck Pinch		Flexor digitorum superficialis and Flexor digitorum profundus of index and middle finger; interossei; opponens; Flexor pollicus brevis and Flexor pollicus longus, abductor pollicis brevis and adductor pollicis	No effect	4– to 4	Isometric
Trunk flexion	0–30	Back extensors	Assists	3+ to 4–	Eccentric
Trunk extension	30–0	Back extensors	Resists	4– to 4	Concentric

technique called contract relax (CR) and agonist contraction (O'Hora et al., 2011; Sharman, Cresswell, & Riek, 2006) (see Web Chapter C). CR involves a maximal isometric contraction of the tight muscle, usually performed at the point of limitation. The muscle is contracted maximally for 3–10 seconds against resistance provided by the therapist and then relaxed. During the relaxation phase, the therapist moves the part in the direction opposite to the contraction and holds it. For example, if there is a contracture of the elbow flexors, the elbow is extended to its limit. The patient is instructed to contract the flexors isometrically and maximally and then relax, at which point the therapist smoothly extends the elbow into a greater range. The CR technique is repeated until as many increments of gain as possible are achieved.

Therapists have typically used a variety of stretching techniques, including those described here. Based on a review of studies spanning 20 years, Hall and Brody (2005) concluded that no one technique has been demonstrated to have greater benefit over any other.

Passive Stretching. Passive stretching is often done by an occupational therapist as a preparatory method for increasing ROM so patients are able to engage in purposeful activity. Techniques for passive stretching may include manual stretch and the use of orthotic devices, such as splints or casts, to provide controlled passive stretching (see Chapter 16). The procedures for manual stretching by the therapist are outlined in Procedures for Practice 20-2. Safety Note 20-1 lists precautions.

Procedures for Practice 20-2

Manual Stretching Methods

- Provide a relaxing environment for the patient.
- Describe manual stretching, noting that it involves tolerable pain.
- Use motions identical to motions used in ROM evaluation (see Chapter 7).
- Stabilize the bone proximal and distal to the joint that is to be moved to avoid any compensatory movement.
- Move the bone smoothly, slowly, and gently to the point of maximal stretch (mild discomfort indicated verbally or facially by the patient).
- Make sure the movement is in the line of pull of the muscle.
- Encourage the patient to assist in moving the limb if possible.
- Hold the limb at the point of maximal stretch for 15–60 seconds (Thompson, Gordon, & Pescatello, 2010).
- Relief of discomfort should immediately follow the release of stretch.
- If the patient complains of residual pain, future stretches should be performed more slowly and with less force.

Safety Note 20-1

Safety Precautions Related to Passive Stretching

- Inflammation weakens the structure of collagen tissues. Therefore, inflamed tissues must be stretched cautiously with slow, gentle motions (Kisner & Colby, 2007).
- Sensory loss prevents the patient from monitoring pain; thus, the therapist must pay particular attention to the tension of the tissues being stretched.
- Overstretching must be avoided because it may increase pain and inflammation and cause internal bleeding and subsequent scar formation. It may also lead to heterotopic ossification.
- Resistance can be provided by weights either held in the patient's hand or strapped around the moving part. Resistance can also be provided by tools and materials of the activity. The greater the resistance that is provided, the more aggressive the stretch will be, so the therapist must take care that the stretch is slow and gentle.

There are many ways patients can perform stretching of soft tissue contractures themselves. Patients can be given a home program on specific joint stretches, or they can participate in activities such as Pilates, yoga, or the ROM dance, which includes some passive stretching and can be integrated into their daily occupations. Occupational therapists can help a patient modify these activities to provide the necessary active and passive stretches to meet the ROM needs. Therapists must remember that with any method to increase rather than maintain ROM, the patient's limb must move to the point of maximal stretch.

Strengthening

Muscle strengthening is the process of working against resistance to increase the maximum force-producing capacity of muscle or muscle groups. Strengthening is warranted if a limitation in a patient's strength prevents participation in occupation or may lead to a deformity. Weakness can be deforming if the muscles on one side of a joint are significantly weaker than their antagonists, resulting in a muscle imbalance. If the weakness prohibits a person from maintaining a functional position or moving through a regular AROM, this may lead to a contracture deformity (Tafti, Cramer, & Gupta, 2010).

It is important to realize that strengthening is a very specific and individualized process affected by age, a person's medical condition, activity level, and training or therapeutic goals (Chodzko-Zajko et al., 2009; Hall & Brody, 2005). If a patient needs to return to a specific activity or type of work, the strengthening program needs to be designed in a way that will replicate the functional

demands of the activity in relation to the type and speed of contraction, the muscles involved, and the intensity of the task. If the patient just needs general strengthening, then variation is the key because the body adapts quickly to resistive training, so there needs to be some change in the process for continual progress to occur (Ratamess et al., 2009; Thompson, Gordon, & Pescatello, 2010).

Intervention Methods: Occupations and Exercise

Strengthening interventions are defined as any intervention that involves an attempt at repetitive, effortful, muscle contraction and may include biofeedback, electrical stimulation, muscle reeducation, and progressive resistance exercise (Ada, Dorsch, & Canning, 2006). Occupations or functional activity may also be used to increase strength. Therapists find that various occupations provide sufficient opportunities for muscle strengthening and are more effective at maintaining the patient's interest and motivation than exercise alone. At other times, therapists may develop an exercise program specifically targeted to strengthen certain muscles needed for occupation using other modalities. The specific targeting of groups of muscles for the sole purpose of reintegrating an injured worker to the work site is known as "work hardening." Through the measured use of work hardening and work reintegration, the injured worker, client, or patient can be allowed to slowly build up sufficient strength, gross motor coordination, and balance in a simulated setting to allow safe transition into the work site (Marois & Durand, 2009). Strengthening may be used as a warm-up to occupation, or occupation may be introduced to enhance carryover of the strength gained by exercise. Carefully prescribed therapeutic occupations can strengthen muscles in situations closely approximating their intended uses.

For some individuals, an exercise program may be a valued occupation in and of itself. In these cases, exercise can be used as a therapeutic occupation designed to address the individual nature of the performance, the meaning of exercise for that person, and the context in which that person typically exercises. In this instance, the occupational therapist may use the therapeutic occupation of exercise to remediate any performance component. For example, in the military the push-up is a common everyday activity with purpose and meaning to the soldier. Using the push-up not only increases strength but also touches on the role of a soldier in relation to discipline, physical fitness, and esprit de corp (see Fig. 20-10).

Grading Muscle Strength Parameters. Similar to stretching, there are many factors that influence the effectiveness of strengthening interventions. For strength to increase and muscle hypertrophy to occur, there must be a gradual increase of stress placed on the muscles (Ratamess et al., 2009). Parameters that may be manipulated to increase stress to muscle include exercise intensity, volume, the amount of rest between exercises, the type and velocity of contraction, and the frequency of exercise.

In order to increase the intensity of strengthening exercises, the amount of resistance imposed on the contracting muscle or muscle groups during each repetition is increased. For example, a patient recovering from a hand injury will progress from the use of soft Theraputty™, to medium, and then to firm as a way to increase intensity and improve grip. The starting point for resistance is based on a therapist's judgment or on the data ascertained through manual muscle testing or testing with standardized equipment. Another method to calculate the appropriate starting load for strength training is to determine a repetition maximum (RM). DeLorme (1945) and DeLorme and Watkins (1948) developed a progressive resistive exercise program based on the use of an RM defined as the greatest amount of weight a muscle can move through available ROM just one time. Once the RM is established, then the intensity of training can be set up based on a percentage of this maximum. Patients at the beginning of training or rehabilitation should use a lower percentage (40%–60% of 1 RM) versus those who have progressed or are well trained, where 80% of 1 RM is recommended (Ratamess et al., 2009).

Training volume refers to the number of repetitions and sets performed during a training session multiplied by the resistance (Kisner & Colby, 2007). An occupational therapist alters the training volume by changing the number of repetitions of an activity, changing the number of sets required of that one activity, or changing the number of activities done during a treatment session. The volume of strength training is also linked to the goal for treatment. If the goal is muscle strengthening, then it is recommended that fewer repetitions are done with increased resistance; if the goal is muscle endurance, then more repetitions are required with less resistance (McNair & Rice, 2010).

A rest period between exercises affects the muscle's response to strength training and is related to the intensity and volume of activity. If a patient is being asked to perform activity that requires a high degree of intensity such as lifting heavy

Figure 20-10 An Army soldier is demonstrating upper body strength and the strength of his triceps by performing the push-up during a physical fitness test.

boxes or if the activity demands that a box be lifted multiple times to complete a task, then the amount of rest between lifts or between tasks needs to be lengthened. If the activity involves low intensity or fewer repetitions to complete, then the rest period can be shortened. The recommendation is that for activities that call for high loads or repetitions or if the patient is very young, elderly, or easily prone to fatigue, the rest period between activity should be 3–4 minutes, and for low intensity or low repetition activity, it should be 1–2 minutes (Kisner & Colby, 2007; Ratamess et al., 2009).

The type and velocity of muscle contraction during a strengthening program is established by the demands of the task and the physical abilities of the patient. Most strengthening programs involve dynamic muscle contraction with concentric or eccentric muscle action, but isometric exercise is also a vital part of rehabilitation (review Definition 20-1). During dynamic concentric muscle contraction, the velocity of the muscle action can be manipulated to simulate the demands of functional activity that call for fast movement (sports) or slow movement (painting). The velocity of muscle contraction in training should eventually match the velocity of muscle contraction that is required in the patient's occupational routine (Ratamess et al., 2009). With dynamic eccentric muscle contraction, it is easier to control a load, meaning that it takes less effort to lower a weight than to lift a weight. This is why, when dealing with a patient who is very weak, it is better to start with active eccentric exercise (i.e., having the patient lower the weakened limb while resisting gravity) rather than lifting the limb (Kisner & Colby, 2007). Isometric strengthening is used when joint movement is not available or contraindicated, but strengthening is still warranted, such as after repair of soft tissue or to minimize atrophy during immobilization (see Fig. 20-11). Even though there is no joint movement, an isometric contraction can still produce a forceful contraction. *Safety Message: For this reason, when the patient has hypertension or cardiovascular problems, isometric contraction should be avoided because contraction of either large or small muscles increases blood pressure and heart rate* (Hall & Brody, 2005; Kisner & Colby, 2007) (see Chapter 42). Procedures for Practice 20-3 has guidelines for setting up a therapeutic exercise or occupation program. Although these guidelines are for exercise programs, the principles can be used in designing a routine of occupations to be used for strengthening.

The recommended frequency of strengthening exercises or the number of exercise sessions in a week depends on a number of variables including the patient, the patient's goals, the level of patient adherence to the home program, and the ability of the patient to come to therapy for supervised rehabilitation. The frequency of strengthening is also tied into the amount of rest that is needed for muscle or muscle groups to recover. It is recommended that people who are starting a strengthening program should exercise 2–3 days a week, which can then increase to 3–5 days a week as the strength progresses (Ratamess et al., 2009).

Figure 20-11 As the patient contracts her wrist extensors in an effort to raise her wrist, the therapist is resisting the movement, resulting in an isometric contraction.

For an example of grading the variables for strength during a comprehensive strengthening program, see the patient Case Example. In this example, Ms. C., who has poor musculature but needs upper extremity strengthening to accomplish her daily tasks, can begin by washing her face side-lying in bed (reduce the effect of gravity) until she can complete the task upright. Ms. C.'s occupational therapist can set up the task to be accomplished in bed while assisting Ms. C. in bringing her hand to her face so that she washes with her muscles in a gravity-eliminated plane. Ms. C. may next attempt to wash her face sitting upright in a chair in the bathroom. The therapist may bring Ms. C.'s hand to her face and then ask the patient to resist against gravity in an eccentric contraction. The next step in the progression involves having Ms. C. move the extremity against the resistance of gravity with a concentric contraction. The therapist can further increase the intensity by adding various weighted tools, such as a light puff, a washcloth, or a bar of soap. As Ms. C. gradually progresses in strength, the therapist can continue to increase the intensity and volume of strengthening by adding more resistive occupations, such as dressing, making a bed, washing a car, gardening, or playing basketball. With any of these activities, resistance can be graded by adding a load to the extremity

Procedures for Practice 20-3

Guidelines for a Strengthening Program

Type of Exercise	Definition	Muscle Grades	Procedures
Isometric	Exercise in which a weak muscle is isometrically contracted to its maximal force 10 times with rest periods between each contraction	Trace (0) The force of contraction is not sufficient to move the part.	Provide a stimulating environment. Explain procedures. Instruct the patient to contract the weak muscle ("hold"). External resistance applied by the therapist may help the patient isolate the contraction to the weak muscle or muscle group. Patient holds contraction at maximum effort as long as possible while breathing normally. Repeat 10 times with a rest between each contraction. Increase duration of maximal contraction as patient improves. ***Safety Message: Maximal isometric contraction is contraindicated for patients with cardiac disease.***
Dynamic assistive (active assistive ROM)	Exercise in which a weak muscle is concentrically or eccentrically contracted through as much ROM as patient can achieve; therapist and/or external device provides assistance to complete motion	Poor minus (2−) Fair minus (3−) The muscle can move only through partial available range in either a gravity-eliminated or against-gravity plane.	Provide a stimulating environment. Explain procedures. For a 2− muscle, position limb to move in a gravity-eliminated plane. For a 3− muscle, position the limb to move against gravity. Patient moves weak muscle through as much range as possible. Therapist provides external force to complete motion. Although this seems similar to PROM, it differs because the patient actively contracts the weak muscle.
Dynamic active (active ROM)	Patient contracts muscle to move part through full ROM.	Poor (2) Fair (3) Muscle can move through full available range in either gravity-eliminated or against-gravity plane.	Provide a stimulating environment. Explain procedures. For a 2 muscle, position the limb to move in a gravity-eliminated plane. For a 3 muscle, position the limb to move against gravity. Patient moves weak muscle through full available ROM. Patient repeats motion for three sets of 10 repetitions with rest break between sets.
Dynamic active resistive (active resistive ROM)	Patient contracts muscle to move part through full available ROM against resistance.	Poor plus (2+) Fair (3) Fair plus (3+) Good (4) Good plus (4+)	Provide a stimulating environment. Explain procedures. For a 2+ or 3 muscle, position limb to move in a gravity-eliminated plane. For a 3+ or above muscle, position limb to move against gravity. Therapist determines appropriate amount of resistance depending on the strengthening protocol chosen. If a 1RM has been established, then a percentage of that maximum can be used starting at 40%–60% and progressing to 80% as strength increases. Patient moves weak muscle through full available ROM against resistance.[a] The patient will do three or four sets of 10 with varying resistance and rest breaks between sets.

[a]Resistance can be provided by weights either held in the patient's hand or strapped around the moving part. Resistance can also be provided by tools and materials of activity.

(i.e., tools such as washcloth, gardening utensils, or different size and weight of the ball) or by changing the plane of movement (i.e., gravity eliminated to against gravity, to above-the-shoulder work). The frequency of the sessions started at three times a day for 4–6 weeks, but Ms. C., who is starting off very weak, may not be able to finish washing her face in bed during a session. The therapist can manipulate the rest breaks during the activity or divide up the task into subtasks, allowing Ms. C. to pace herself throughout the entire task. This technique can also be used to help a deconditioned client perform household chores or any of the other activities without tiring excessively. As Ms. C. develops enough strength to complete activities, she then works to improve endurance to participate in the activities for a longer period of time.

Increasing Endurance

Exercise programs designed to increase muscle endurance rather than muscle strength require different techniques. The following describes the underlying principles and guidelines for those modifications.

Factors That Influence Muscle Endurance

Muscle endurance refers to the ability of a muscle to maintain performance over a sustained period of time (McNair & Rice, 2010). During light resistive activities, motor units within the muscles are recruited and activated asynchronously, meaning that while some motor units are working and then fatiguing, other motor units are being recruited to make up for the recovering units (Contessa, Adam, & De Luca, 2009). This allows for prolonged activity or muscle contraction. With activities that call for maximum muscle contraction, such as lifting heavy loads, more motor units must contract simultaneously without the opportunity to recover, resulting in quicker fatigue. Other factors that influence muscle endurance include the predominant type of fiber that is contracting during the activity (type I slow twitch fibers fatigue slower than type II fast twitch fibers), the energy and oxygen storage within the muscle and external factors such as room temperature, altitude, and amount of allowed recovery time during an activity (Kisner & Colby, 2007).

Intervention Methods

Grading Occupations to Increase Endurance. The key elements of endurance training are low-intensity muscle contractions, a large number of repetitions, and a prolonged time period of training to the point of muscle overload (Kisner & Colby, 2007). The American College of Sports Medicine advocates for light to moderate loads (40%–60% of 1 RM) for high repetitions (>15) using short rest periods (<90 seconds) for endurance training (Ratamess et al., 2009). Roy et al. (2011) developed a protocol for evaluating shoulder endurance where subjects performed two isotonic exercises of internal and external rotation at 50% of peak torque for

60 continuous repetitions on two separate days and found that the muscle fatigue was reproducible over time. Muscle endurance can be improved through weight training, but occupational therapists prefer to use purposeful activity to provide the same benefits. Occupational therapists provide the patients with interest-sustaining occupations that can be graded along the dimension of time or repetition. For example, for patients who are interested in computer games or sports that can be replicated on a Wii™, the therapist may increase the number of games they play or the length of time they play to get to muscle fatigue. Occupational therapists can also work with patients to schedule their everyday routines so that they gradually increase the amount of time they engage in occupations throughout the day and/or gradually increase the duration of engagement in one particular occupation. For example, increasing the time working in the garden or the amount of muscular effort put forth through repetition (picking tomatoes versus pulling weeds) is an effective way to increase muscular endurance (Fig. 20-12).

Evidence Table 20-1 shows the best evidence regarding strengthening, stretching, and endurance training. Programming for cardiovascular endurance specifically with patients who have cardiopulmonary problems is discussed in Chapter 42.

Figure 20-12 Muscular endurance can be increased by adding to the time spent on a task or adding to the resistance of the activity. In gardening, picking tomatoes could advance to weeding the garden.

Evidence Table 20-1	Best Evidence for Occupational Therapy Practice Regarding Strengthening, Stretching, and Endurance Training						
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Stretching to increase joint range of motion (ROM)	Experimental groups received a 6-week stretching program compared to a control group that did not.	Forty-three participants (controls and those with osteoarthritis [OA]) were randomly assigned to groups (experimental group with OA, $n = 14$; control group with OA, $n = 10$; experimental group without OA, $n = 8$; control group without OA, $n = 11$).	Experimental groups performed three 60-second stretches to all muscle groups of the leg, 5 days a week for 6 weeks with two of the days being supervised. The control group did not stretch.	Randomized controlled study Level: 1C1b	Yes. All stretching groups (OA and without OA) improved range	Statistically significant differences in posttest knee extension ROM between experimental and control groups: $p < 0.05$; effect size: $r = 0.30$ (medium effect)	Reid & McNair (2011)
Effectiveness of exercise on reducing impairment and increasing activity in people with upper limb fractures	Studies included compared various dimensions of upper extremity therapy exercise programs.	Thirteen trials involving 781 participants with an upper limb fracture were identified.	Exercise therapy programs differed in timing, intensity, frequency, duration, and exercises performed.	Systematic review with a single meta-analysis	Preliminary but inconclusive evidence to support the role of exercise regimens in reducing impairments and improving upper limb function following upper limb fractures (likely because of cointerventions used in most studies)	One meta-analysis (involving two studies) did not demonstrate effects of exercise on grip strength after distal radius fracture.	Bruder et al. (2011)
Effectiveness and safety of dynamic exercise for patients with rheumatoid arthritis (RA)	Short- and long-term, land-based exercise programs to increase muscle strength	Three hundred seventy-nine participants with RA; mean age = 52 years and disease duration between 5 and 14 years	Land-based aerobic capacity training and strength training: at least twice per week for >20 minutes, lasting at least 12 weeks for short-term programs and 24 weeks for long-term programs (muscle strengthening starting at 30%–50% of repetition maximum [RM] performed under supervision)	Systematic review and meta-analysis of four studies	Yes. There is a positive effect of combined aerobic and strength training on muscle strength after 12 weeks; nonsignificant but trending toward positive effect on muscle strength at 24 weeks.	Data pooled from two studies resulted in a significant, medium positive effect on muscle strength (standard mean difference of 0.47) immediately after the 12 weeks compared to the control groups.	Hurkmans et al. (2009)

| Evidence Table 20-1 | Best Evidence for Occupational Therapy Practice Regarding Strengthening, Stretching, and Endurance Training (*continued*) |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Effect of progressive resistance exercise program	Experimental group received progressive resistive exercise training (PRET), and a control group received a standardized therapeutic exercise protocol (TP).	Fifty-two head and neck cancer survivors were randomly assigned to two groups (experimental PRET group *n* = 27; control TP group *n* = 25)	Twelve weeks of supervised sessions meeting two times a week consisting of two sets of 10–15 repetitions of five to eight exercises progressing from 25% to 75% of 1RM strength	Randomized controlled study Level: 1C1a	Progressive resistance training provided superior upper extremity strengthening, endurance and pain reduction than traditional strengthening program consisting of ROM, stretching, postural, and general strengthening exercises.	Shoulder pain and disability $p = 0.001$ (when adjusted for baseline value, age, sex, cancer stage, pain medication use), affected shoulder strength (unadjusted) $p = 0.003$ ($r = 0.45$); upper extremity endurance (unadjusted) $p = 0.017$ ($r = 0.33$).	McNeely et al. (2008)
Effectiveness of strength training after stroke	Strengthening interventions that involved repetitive, effortful muscle contractions (including biofeedback, electrical stimulation, muscle reeducation, progressive resistance exercise, and mental practice)	Twenty-one studies met inclusion criteria with a total of 768 participants categorized as acute (<6 months) or chronic stroke and into weak and very weak categories.	Ranged from 2- to 12-week programs, 3–6 days per week and 30–90 minutes a day	Systematic review with meta-analysis of 15 studies	Yes. Strengthening interventions provided a small positive effect of strength across all stroke participants.	Posttest improvements in strength (0.33 standardized mean difference; 95% confidence interval 0.13 to 0.54, $p = 0.001$). Strengthening interventions had very little effect on spasticity ($p = 0.69$).	Ada, Dorsch, & Canning (2006)

case example

Ms. C.'s Experience of Guillain-Barré

Occupational Therapy Assessment Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Ms. C. is a 40-year-old woman who was the executive administrator of a large computer company. She lives at home with her partner and her high school–aged son from a previous marriage. Her partner is a lawyer in a small law firm that requires at least 10–12-hour work days. Ms. C. is a high-powered, motivated woman who not only enjoyed but was energized by the various people with whom she interacted with at her job and the diverse assignments she supervised. When Ms. C. returned home from work, she often used household occupations as a means of changing from her high-energy level to a more relaxed state. Ms. C. shared household tasks equally with her partner and also her son. Relationships are essential in her life.

Ms. C. began to complain of tingling in her legs about 3 weeks ago. This progressed to her trunk and then to weakness in her legs and arms about 2 weeks ago. She was admitted to the hospital at that point and was then diagnosed with Guillain-Barré syndrome. She was in intensive care for about 10 days and has now been admitted to the rehab unit. At this point, she is extremely weak and has poor endurance. She is unable to lift her arms against gravity and has been up in a reclining wheelchair for about 30 minutes before she needs to go back to bed. Following an occupational therapy evaluation that included this history, the following problems were identified by Ms. C. and the therapist: (1) loss of independence in all occupations including all self-care activities and use of the phone and computer; (2) weakness throughout her arms, trunk, and legs, with manual muscle testing scores of 2–3, but very limited endurance, so that she is able to do only three or four repetitions of a motion before she is fatigued; (3) depression and anxiety because of an unpredictable future; and (4) inability to communicate with her employees, employer, and her son, which is causing considerable anxiety.

	Appreciate the context	"I think if Ms. C. reestablished some of her more important activities, such as being able to communicate with work, she would feel that she was making progress. In addition, with her endurance and strength both so low, repetition of any movements would help to increase them both."
	Develop intervention hypotheses	
	Select an intervention approach	"Ms. C. would benefit from remediation to increase strength and endurance in her extremities, which would allow her to regain independence in her occupations. However, I also think she would benefit from compensation through the use of adapted equipment to help her resume some important activities."
		"Ms. C. is really having difficulty being separated from work. I think that if she could communicate with her workplace, she would feel that she was back in some control. In addition, it is difficult for her to see her son because he can only come after school, and at that point, she is usually exhausted. If she could have some other means to communicate with both work and her son, she might begin to see that she is making progress. I will need to see if she is willing to use adaptive equipment as a bridge to independence; some patients do not tolerate 'gadgets,' so I will have to check that out."

Recommendations

The occupational therapist recommended three brief treatment sessions each day for 4–6 weeks. Ms. C. and the therapist together established the following long-term treatment goals: (1) Ms. C. will carry out her hygiene, self-care, dressing, and showering independently, which would prepare her for being at home during the day; (2) Ms. C. will prepare a light meal for lunch, which will also ready her for discharge; (3) Ms. C. will learn skills and develop strategies to be able to work from home when she is discharged, for at least a few hours a day; (4) Ms. C. will be independent in a home exercise program for strengthening and endurance; and (5) Ms. C. will resume an active role as the mother of her son.

	Consider what will occur in therapy, how often, and for how long	"I think that Ms. C. is so overwhelmed with what has happened that it is difficult for her to fully participate in goal-setting. It is such a change from her previous life of being in charge of everything. I think that we will need to start with things that are very important to her and that she can succeed at. Because work and her son are so important, I think that, if we used an overhead sling, she might be able to operate both a speakerphone and e-mail, and that would allow her to be involved. My one concern is that she might overdo it, so we will have to talk about that."
		"I will need to maintain her passive range of motion (PROM), particularly in those antigravity positions that she cannot move into. Daily PROM exercises will be necessary until she gains enough strength to move herself. In addition, care will need to be taken to ensure that she is not developing imbalances of muscle strength around joints that would lead to contractures."
		"Once she has had some success, we can begin to do other activities such as strengthening activities and self-care."

Summary of Short-Term Goals and Progress

1. *Ms. C. will start assisting with hygiene and grooming activities and then advance to independence in daily self-care.*

    Ms. C. was fitted with overhead slings, so that she could move her arms without lifting them against gravity. With that equipment, Ms. C. was able to wash her face and brush her teeth and was able to drive a power wheelchair, which greatly improved her independence.

2. *Ms. C. will access a speakerphone and e-mail to make working from home possible.*

    With the overhead slings, she was able to operate both a speakerphone and her laptop computer in her room. She was able to work for about 25 minutes before she fatigued.

3. *Ms. C. will feed herself and get food in and out of the refrigerator.*

    Ms. C. was able to feed herself with a set up using the overhead slings and progressed to feeding herself without equipment. Using the power wheelchair, she was able to get items out of the refrigerator.

4. *Ms. C. will develop ways to communicate with her son more frequently.*

    She was able to access her e-mail account and sent an e-mail to her son. She also was able to call him on his cell phone over the noon hour, and he was really excited to talk to her when she was alert and awake.

5. *Ms. C. will begin an upper extremity strengthening and endurance program.*

As she gained endurance, she was able to begin doing resistive exercises to some muscles, as well as assume some responsibility for stretching. She will have to be independent in some parts of the program when she goes home.

The therapist and Ms. C. discussed that it was important that she not overdo it, and she seemed to understand that. Her endurance for activity increased considerably over the first week, as she had the opportunity to do things that were important to her on her own schedule.

Assess the patient's comprehension	"Ms. C. seems to understand that any activities she does with her arms will help with strengthening and endurance and is motivated to do more. Now that she can access her e-mail and use the phone and feed herself, she is beginning to think about what she needs to do to be home alone for periods of time after discharge."
Compare actual to expected performance	
Know the person	"Ms. C. is accepting of the use of adaptive equipment as a bridge to independence, so that opens up a lot of opportunities. She is doing better than I expected, and she is tolerating all the activity well."
Appreciate the context	
	"We will continue to advance her to more complex activities, such as meal preparation, and more work-related tasks, such as handling files, organizing a work station, etc."
	"I need to check with her partner and her son to see how things are going at home. If the partner is working 10–12 hours a day, and her son is home alone, we may need to come up with a new plan."

Next Steps

We are also going to need to assess the accessibility of her home, because she will probably be using her wheelchair most of the time at home, particularly when she is alone.

At some point in the next several weeks, we will remove the overhead slings, progress her to a manual wheelchair, and then begin doing more activities in standing, as she can tolerate. This may be frustrating for her because occupations she is currently doing will become more difficult, so I will have to be careful of that.

We will need to plan out a typical day and make sure that Ms. C. can do all the things she will need to do at home.

Anticipate present and future patient concerns	"Ms. C. is making very good progress and will be able to leave the hospital in several more weeks. Because her partner works and they do not have any family nearby, Ms. C. will need to be home alone for periods of time after discharge. I'm not sure Ms. C. is anticipating how isolating that can be. Although she will probably be walking short distances at that time, she will likely spend most of her time in her wheelchair. I will need to be sure that she has an emergency plan, can operate a cell phone that she has with her, and has anticipated as much as possible what things she needs to be able to do. Home care may be a very feasible option for Ms. C. for a while, and then she can consider outpatient therapy when she is no longer homebound. Transportation to and from rehab will be a challenge. She will also need to check with her doctor about when he might allow her to drive."
Decide whether the patient should continue or discontinue therapy and/ or return in the future	

Clinical Reasoning in Occupational Therapy Practice

Effects of Endurance and Strength on Performing Occupations

Range of motion (ROM), strength, and endurance are needed to perform activities of daily living. How does the decline in ROM, strength, and endurance impact the patient's ability to perform house-cleaning chores? How can energy conservation be used to allow Ms. C. to engage in regular household chores? How can activity modification techniques be used to allow Ms. C. to more efficiently complete her household chores?

Clinical Reasoning in Occupational Therapy Practice

Deconstructing Activity in Order to Use Occupation-as-Means

Assembling a uniform is a common military task. What fine motor manipulation skills and bimanual dexterity are needed to accomplish this task? How does this activity directly address upper extremity positioning, active range of motion, endurance, and eye–hand coordination? How is the assembly and preparation of the army uniform considered a core occupation-based function?

Summary Review Questions

1. What are the physiological aspects of muscle contraction?
2. Give an example of a third-class lever system in the body. What is the force arm (effort force)? What is the resistance arm (resistance force)?
3. Explain turning a wrench in terms of torque.
4. Analyze the forces, stability, and motions required to put a can of soup on the shelf at nose height.
5. How should passive stretching treatment be modified if the patient acknowledges residual pain after treatment?
6. What parameters can be manipulated to alter stress on the muscle to increase strength?
7. What are the necessary characteristics of exercise or occupation required to increase muscle endurance?
8. Plan a therapeutic occupation program to strengthen a patient who has generalized poor (grade = 2) upper extremity musculature. Revise the program to accommodate changes in the patient's musculature from poor (grade = 2) to fair (grade = 3).
9. Differentiate between a therapeutic occupation program designed to strengthen muscles and one designed to increase muscle endurance.
10. Following replacement of the proximal interphalangeal (PIP) joint of the ring finger, the patient's finger and hand are edematous. What treatment choices does the occupational therapist have?

Glossary

Ankylosis—Pathological stiffening of a joint caused by fibrotic changes in the bones and/or tissues surrounding the joints.

Connective tissues—Tissues made up mostly of collagen that make up a joint structure such as bones, bursae, capsules, cartilage, discs, fat pads, labra, ligaments, and tendons.

Cross-bridge—The bonding of actin and myosin myofilaments within a myofibril that creates muscle contraction.

Guillain-Barré syndrome—An inflammatory disorder in which the body's immune system attacks the peripheral nervous system, resulting in weakness and numbness in the arms, legs, trunk, and face. Most patients make substantial improvements, but about one-third of patients still have some residual weakness 3 years after onset.

Heterotopic ossification—The process in which bone tissue forms outside the skeleton in an abnormal site, such as muscle or soft tissue.

Hypertonicity—Increased rigidity, tension, and spasticity of muscles commonly associated with high muscle tone, exaggerated reflexes, lack of selective control, and fatigability.

Kinematics—Study of the displacement or motion of a segment without regard to the forces that cause the movement.

Kinetics—Study of forces, including static forces that balance or stabilize and dynamic forces that mobilize.

Moment arm—The perpendicular distance between a muscle's point of pull and the center of the joint (axis of rotation).

Muscle hypertrophy—An increase in the size of muscle cells through mechanical, metabolic, and hormonal processes.

Rotary motion—Movement of a segment around a fixed axis also known as angular displacement.

Torque—Product of force × perpendicular distance between the force and the axis of rotation.

Translatory motion—Movement of a segment in a straight line also known as linear displacement.

Optimizing Motor Planning and Performance in Clients with Neurological Disorders

Joyce Shapero Sabari, Nettie Capasso, and Rachel Feld-Glazman

Learning Objectives

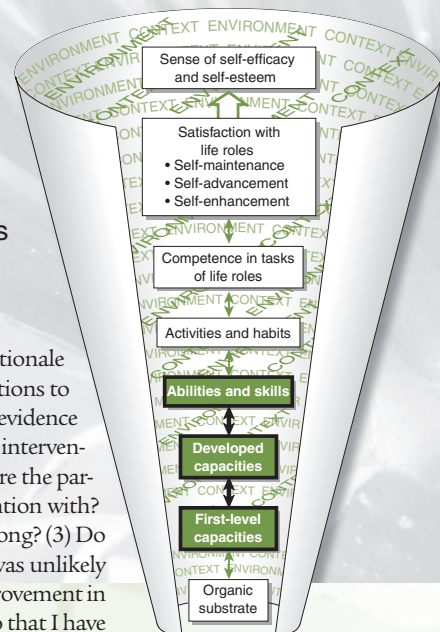
After studying this chapter, the reader will be able to do the following:

1. Identify how major theoretical paradigms influence task-based interventions to improve motor performance and motor planning in survivors of stroke and traumatic brain injury.[1]

2. Identify the multiple factors that contribute to optimal motor performance, and describe how occupational therapy interventions are designed to help patients improve each of these.

3. Describe how occupational therapists help patients with neuromotor impairments improve balance, functional mobility, functional arm and hand use, and motor planning.

4. Determine appropriate interventions and task challenges for patients at each of the Functional Upper Extremity Levels (FUEL).

[1]NOTE. Because there are so many research studies that support both the rationale for and the effectiveness of the interventions described in this chapter, the citations to that research are interwoven within the chapter instead of being put into an evidence table as in other chapters. The reader who is contemplating using one of the interventions is advised to access the original research and consider the following: (1) Are the participants in the research study similar to the person I want to use this intervention with? (2) How was the intervention administered and at what intensity and for how long? (3) Do the results indicate statistical significance, which indicates that the outcome was unlikely caused by chance? Does the size of the effect make it worth using? Was the improvement in outcome measure clinically significant? (4) Was this study conducted validly so that I have confidence that the change in the dependent variable (outcome measure) was caused by the independent variable (treatment), or does it seem that some other factor that was not controlled by the researchers could have produced the change in the outcome measure?


D ifficulty with motor performance is a critical concern for many survivors of acquired brain damage (stroke and traumatic brain injury). Occupational therapists provide intervention to assist these people in (1) optimizing their motor function and (2) integrating their improved motor skills into enhanced performance of functional activities for greater independence and engagement in their daily lives.

This chapter will

- introduce the constellation of motor impairments that are typically associated with acquired brain injury
- review the major theoretical paradigms that historically have guided neurorehabilitation interventions that are designed to improve motor performance for survivors of brain injury and stroke
- describe the multiple factors that contribute to optimal motor performance
- provide a framework for occupational therapy (OT) interventions that are geared toward improving motor performance related to
  - sitting and standing balance
  - functional mobility
  - functional arm and hand use
  - motor planning (praxis)

MOTOR CHARACTERISTICS OF CENTRAL NERVOUS SYSTEM DYSFUNCTION

Human movement is dependent on complex interactions among multiple systems, with key contributions from integrated motor centers within the brain. Damage to neural cells impacts motor, sensory, and cognitive function, and there is typically a direct relationship between anatomical pathology and functional loss. The constellation of movement problems associated with brain injury is often referred to as upper motor neuron dysfunction. This term is differentiated from lower motor neuron dysfunction, which describes the weakness and flaccidity that is associated with peripheral nerve damage.

Primary motor impairments are those deficits that are directly attributable to the brain lesion. Primary motor impairments can be further classified as positive or negative. Negative impairments include paralysis (hemiplegia or hemiparesis), sensory loss, fatigue, decreased movement speed, and difficulty organizing available movement into functional motor sequences. Spasticity (hypertonicity) and the presence of abnormal reflex activity are the hallmarks of positive impairments associated with stroke. Ataxia and intention tremor are positive impairments that are associated with cerebellar pathology. Resting tremor is a positive impairment associated with basal ganglia dysfunction such as Parkinson's disease.

Secondary motor impairments are preventable deficits that develop over time in response to immobility, inactivity, or asymmetries in postural alignment. Limitations in joint range of motion (ROM), diminished flexibility between body segments, pain, and edema are common secondary impairments in stroke survivors.

Rehabilitation specialists may also consider another category of features associated with upper motor neuron dysfunction. Adaptive features (Carr & Shepherd, 2003) are disorders of movement that develop in response to a person's attempts to move within the constraints of limited mobility, specific weakness, or hypertonicity in specific muscles. It has long been observed that many people with hemiparesis move their limbs in characteristic patterns that typically are awkward and inefficient. Throughout the history of neurorehabilitation, these abnormal patterns, often called synergies, have been interpreted in different ways. In this chapter, we will refer to these abnormal movement constellations as maladaptive strategies.

An additional dichotomy for conceptualizing movement dysfunction in brain injury survivors is to differentiate between deficits in motor *execution*, associated with specific impairments and deficits in motor *control*, which are associated with deficits in higher order processes, such as motor planning and motor learning (Raghavan, 2007). No one would argue that motor execution is an essential prerequisite to functional movement. However, it has become increasingly clear that the ability to activate specific muscle contractions, alone, is not sufficient for functional balance, mobility, or purposeful use of the arm and hand.

Finally, the amount of use in daily activities is a critical variable for describing limb motor performance in those stroke survivors who have moderate levels of function in both motor execution and motor control. Later in this chapter, we will explore the phenomenon of learned nonuse and present compelling research findings for the efficacy of maximizing continuous, long-term recovery of motor function by helping stroke survivors to incorporate use of the paretic limb when performing routine, daily tasks.

HISTORY OF THEORETICAL PARADIGMS ASSOCIATED WITH REHABILITATION INTERVENTIONS TO IMPROVE MOTOR PERFORMANCE IN CLIENTS WITH CENTRAL NERVOUS SYSTEM DYSFUNCTION

Interventions to improve motor performance in clients with central nervous system (CNS) dysfunction are heavily influenced by underlying conceptual frameworks about movement, learning, motor control, and brain plasticity. A series of paradigm shifts in the past hundred years has led to significant fluctuations in approaches to evaluating and treating patients.

Stroke and post-stroke disability have been documented medical conditions since the time of Hippocrates. However, it was not until the 20th century that society

recognized the possibility that rehabilitation interventions could improve functional capacity in stroke survivors (Pound, Bury, & Ebrahim, 1997). The earliest rehabilitation efforts recognized limb motor impairments only and took a two-pronged approach. Primarily, rehabilitation focused on ways to compensate for hemiplegia through training patients to walk with a cane and to perform activities of daily living (ADL) using the unaffected arm and hand. In addition, passive stretch was implemented in an attempt to reverse limitations in passive ROM.

Brunnstrom's Movement Therapy

In 1951, Dr. Thomas Twitchell, a neurologist, published a seminal paper in which he described the longitudinal progression of motor recovery in 121 patients. Twitchell observed that, early in recovery, these people tended to demonstrate stereotypical movement patterns. In addition, he observed that they tended to progress in their motor recovery through a consistent series of stages. Twitchell did not hypothesize why some patients recovered further than others and did not present any recommendations for therapeutic interventions that might influence motor recovery.

Signe Brunnstrom, a physical therapist, combined Twitchell's findings with her own clinical observations to develop a treatment approach that was designed to facilitate the progression through the stages of recovery that Twitchell had reported. Brunnstrom's major contributions were

- her detailed description of reflexes and associated reactions exhibited by patients with post-stroke hemiplegia
- the concept of flexor and extensor synergy patterns in the paretic arm and leg
- a postulated sequence of treatment, designed to move patients through seven stages of recovery for the arm and hand

Please see online Chapter B about Brunnstrom's Movement Therapy approach for more information about these concepts and techniques.

Many of Brunnstrom's contributions remain influential today. The associated reactions and reflexes she described are still recognized as characteristic features of motor behavior in stroke survivors with limited recovery. A major difference is that Brunnstrom advised therapists to use techniques to elicit these pathological responses in an effort to stimulate movement. Today, however, rehabilitation professionals seek to *prevent* eliciting these responses. The current understanding is that reflexive movements are *not* precursors to active, functional motor performance.

Many members of the rehabilitation community continue to consider the upper limb synergies as hallmarks of motor performance in stroke survivors. In fact, the Fugl-Meyer Motor Assessment (FMA) (Fugl-Meyer et al., 1975), sometimes called the Brunnstrom-Fugl-Meyer Motor Function Assessment, is a widely used adaptation of Brunnstrom's Hemiplegia Classification and Progress Record. This assessment, often considered to be the "gold standard" for evaluating movement ability, is used by researchers as well as clinicians, even when Brunnstrom's approach to therapy is not used. For details about the FMA, see Chapter 8. Even though there is no research support for the premise that stroke survivors pass through the predictable stages of motor recovery that Brunnstrom described, these seven stages are still used today to facilitate communication between rehabilitation professionals. Therefore, it is valuable for occupational therapists to be familiar with these stages and comfortable in grossly categorizing a patient's general arm function as "stage I," "stage II," etc. (see Definition 21-1).

Currently, rehabilitation professionals disagree on whether to consider the limb synergies as primary sequelae of the neurological damage (as Brunnstrom and Twitchell postulated) or examples of maladaptive strategies that patients develop when they attempt to move, in spite of underlying mechanical obstacles, such as immobility at the pelvis or scapula. This may be an important distinction. Those who view the flexor and extensor synergies of the upper limb as maladaptive strategies organize therapeutic

Definition 21-1

Brunnstrom Stages of Recovery for the Affected Arm

Stage I	Flaccidity: no voluntary movement, muscle tone, or reflexive responses
Stage II	Synergies can be elicited reflexively; spasticity is developing
Stage III	Beginning voluntary movement but only in synergy; spasticity may be significant
Stage IV	Spasticity begins to decrease; ability to voluntarily perform movements that deviate slightly from synergy patterns
Stage V	Increased control of isolated voluntary movements, independent of synergy patterns
Stage VI	Isolated motor control; spasticity is minimal
Stage VII	Normal speed and coordination of motor function

interventions to prevent or remove specified "obstacles to movement" that may lead the person to develop inefficient motor strategies. Those who view the synergies as unavoidable motor deficits that precede full recovery of motor function are not concerned when patients move in these stereotypical patterns of movement. There is *no* controversy, however, about the efficacy of following a therapeutic sequence in which the therapist guides the patient in moving through the six postulated stages of recovery. This paradigm for structuring motor therapy is *not* supported by current understanding of neural plasticity and recovery of motor function after stroke.

Rood and Proprioceptive Neuromuscular Facilitation Approaches

The Rood and proprioceptive neuromuscular facilitation (PNF) approaches, advanced during the mid-20th century, shared Brunnstrom's reliance on the predominant paradigms for understanding motor performance at the time. Reflecting the view that motor development and motor recovery from stroke followed a hierarchical sequence, these approaches advocated that patients "recapitulate" the movement sequence exhibited by typically developing infants during the first year of life. Hence, therapy techniques included exercises that required the person to first learn how to maintain stability and then to move, in the prone position on elbows, quadruped positions, and kneeling positions. Subsequent understanding of motor recovery in adults with acquired brain injuries has negated the value of using a developmental model. In fact, today, the emphasis is on providing movement practice to patients in natural contexts. Therefore, motor activities are performed in supine, sitting, or standing postures. Decisions about which posture is most effective at a given session with a particular patient are based on mechanical factors (such as the influence of gravity) and the patient's functional goals (such as the desire to kneel during housecleaning or gardening activities) rather than on developmental considerations.

Another hierarchical concept, also influenced by knowledge of infant development, was that stroke survivors recovered motor function in a proximal to distal sequence. Hence, therapeutic interventions always began at the pelvic and shoulder girdles. When working to improve upper limb motor function, proximal control over scapular and glenohumeral motions was considered to be a prerequisite for implementing treatment that focused on forearm and hand function. Today, it is understood that survivors of stroke or TBI may demonstrate distal voluntary movements (e.g., some capacity to flex the thumb joints) before they have achieved a particular level of proximal control of scapular and glenohumeral motions (Beebe & Lang, 2008, 2009). In addition, research about reach and grasp has revealed that, during functional performance, the neural plan begins with attention to the object that is going to be lifted or moved. Neural signals to proximal muscle groups are based on orienting the shoulder, elbow, and forearm so that the hand is in the optimal position for interacting with the goal object (Paulignan et al., 1997). Therefore, current motor intervention for patients recovering from stroke or brain injury does *not* follow a proximal to distal sequence. Instead, each patient's constellation of motor abilities guides the therapist in setting treatment goals. At the same time, however, therapists must be mindful of the kinesiological interactions between proximal and distal limb segments. Proximal alignment and stability at the scapula, trunk, and pelvis affect functional use of the arm and hand. For the purpose of minimizing mechanical constraints to pain-free movement, several interventions (described later in this chapter) focus on improving proximal function.

Like Brunnstrom's model, both the Rood and PNF approaches advocated the use of specific sensory stimuli for facilitation or inhibition of motor "firing" within selected muscles. Stimuli that facilitate the spinal level myotatic reflex, like quick stretch, or vibration over a muscle belly, were used to stimulate the stretch reflex and thus elicit a momentary increase of muscle fiber contraction. The physiological principle of reciprocal inhibition (that stimulation to a muscle will simultaneously elicit inhibitory neural signals to its antagonist) was used to relax spastic muscles. For example, a quick stretch to the triceps would elicit a momentary increase of neural signals to elicit contraction of muscle fibers in the elbow extensor muscle and also elicit a momentary decrease of neural "firing" to the muscle fibers of the biceps. The observed result was a temporary decrease in hypertonicity in the biceps and greater ease in passively or actively moving the elbow into extension. Generalized inhibitory stimuli included slow, rhythmic vestibular input (as in slow rolling) and various types of relaxing somatosensory stimuli.

Although these techniques are no longer used in neurorehabilitation as initially prescribed by the Rood and PNF approaches, there are certainly modern correlates to these ideas. Functional electrical stimulation (FES) has replaced the facilitation techniques. Medical interventions such as botulinum toxin injections and GABAergic medications (Denham, 2008; Ivanhoe et al., 2006) and generalized relaxation strategies, as applied through yoga poses, controlled breathing, guided imagery, and meditation, have replaced the reflex-based inhibitory techniques advanced by the Rood and PNF approaches. A major contribution by the PNF approach is the use of diagonal patterns of limb movement (see figures C-5 through C-8 in online Chapter C), which are consistent with well-supported kinematic and kinetic linkages (Surburg, 1997). Before PNF, rehabilitation professionals tended to view movement as occurring only through the three cardinal planes (sagittal, coronal, and transverse). Passive movement through diagonal patterns ensures safe and efficient stretch to all muscles, at all

joints of the upper limb. Active and resisted movements through diagonal patterns provide exercise to groups of muscles in the limbs and trunk that are recruited synergistically by the CNS. PNF diagonals and ancillary techniques continue to be used effectively in orthopedic rehabilitation and athletic training. Their effectiveness as an intervention to improve motor function after brain injury has never been supported by research. Most likely, this is related to the fact that PNF interventions are directed toward improving motor execution, without providing task-related practice to improve motor control. Even so, occupational therapists apply a core concept of PNF, which is that functional movements comprise integrated interaction between multiple joints and muscles through an infinite number of diagonal planes. Please see online Chapter C about the Rood and PNF approaches for more information about these concepts and techniques.

Neurodevelopmental Therapy (The Bobath Approach)

Berta Bobath, a physical therapist, and her husband, Karel Bobath, a psychiatrist and neurophysiologist, began advancing a different set of ideas for enhancing motor recovery in children and adults as early as the 1940s. Their first major publication about stroke rehabilitation (Bobath, 1970) was, in several ways, a direct challenge to primary tenets espoused by Brunnstrom. Where Brunnstrom's approach capitalized on spasticity and hyperactive reflexes as *opportunities* to elicit early movement, the Bobaths viewed hypertonicity as an *obstacle* to a person's ability to move freely. In addition, they recognized that once a person begins to move his paretic limbs in abnormal patterns, it is extremely difficult to break away from these obligatory patterns for flexible movement sequences that meet the contextual demands of activity performance.

Finally, the Bobath approach conceptualized the underlying cause of limb synergies quite differently than Twitchell and Brunnstrom. Instead of viewing the synergies as primary impairments that are directly associated with cerebral damage, they conceptualized these abnormal movement patterns as secondary maladaptive strategies. Carr and Shepherd (2003) later coined the term "adaptive features" to describe disorders of movement that develop in response to a person's attempt to move within the constraints of limited mobility, specific weakness, or hypertonicity in specific muscles. For example, Figures 21-1A and 21-1B illustrate the marked difference in scapular mobility in two people. Notice the extent to which the scapula protracts and upwardly rotates when the young man on the left flexes his shoulder. As demonstrated by the photo on the right, many stroke survivors experience limited scapula mobility (also described as impaired dissociation between the scapula and the thorax). This is a secondary impairment,
Figure 21-1 Influence of scapulohumeral kinematics on arm and trunk movement. **A.** Notice the degree of scapular protraction and upward rotation as this healthy young man reaches forward. **B.** A man with right hemiparesis is attempting to reach forward, but his scapula remains fixed in retraction and fails to upwardly rotate. Note that he attempts to compensate for his difficulty raising the arm by laterally flexing his trunk to the opposite side. (Used with permission from Davies, P. M. [2000]. *Steps to follow: The comprehensive treatment of patients with hemiplegia* [2nd ed., p. 68]. Berlin: Springer-Verlag.)

usually caused by loss of muscle length in the middle trapezius muscle. As the man in the photo tries to raise his arm into flexion, his lack of scapulohumeral rhythm interferes with efficient kinematics. To achieve the movement, he uses what motor capacities are available to him. He laterally flexes his trunk, elevates his scapula, abducts his arm away from the body, and ultimately, to achieve greater active range of motion (AROM), externally rotates at the glenohumeral joint. Compare this photo to Figure A-1 in online Chapter A, which illustrates a flexor synergy pattern.

Neurodevelopmental therapy (NDT) introduced the concept that therapy could "prevent" the development of abnormal limb synergy patterns by removing mechanical obstacles to movement. NDT training, which continues today, prepares therapists to have keen observational skills and to employ kinesiological concepts when determining motor interventions. In particular, NDT provides specific guidelines for observing a patient's postural alignment, predicting how misalignment might impact the kinematics of limb movement, and improving the patient's postural symmetry and balance.

The Bobaths were the first to articulate that motor performance problems in stroke survivors are due to factors beyond the activation of individual muscles. They stressed that many stroke survivors have "lost the feeling of normal movement" (Bobath, 1970). In today's lexicon, this concept of "normal movement" is described as motor programs or flexible attractor states (to be discussed later in this chapter). In addition, they recognized that postural alignment and postural control provide a critical foundation for functional movement.

Thanks to the foresight of Berta and Karel Bobath, the NDT approach has continued to evolve over time, in response to newer ideas about motor control and relearning. Numerous textbooks by the Bobaths and others who have studied with them provide helpful guidelines for structuring motor interventions with stroke survivors (Davies, 2000; Howle, 2002; Ryerson & Levit, 1997). However, outcome studies have not supported the efficacy of the total package of NDT intervention, as compared with other approaches to improving motor control in stroke survivors (Kollen et al., 2009). In addition, some have suggested that NDT therapists put too much emphasis on monitoring the kinematics of movement and using hands-on techniques in an attempt to prevent the person from developing "abnormal movement patterns." Because of this, NDT interventions may fail to provide patients with sufficient opportunities to actually practice using their emerging motor skills (French et al., 2010).

Influences from Neuroscience Evidence about Brain Plasticity

There has been an explosion of evidence in the past 30 years that confirms the human brain's capacity to reorganize after injury has occurred. The American Occupational Therapy Association (AOTA) Practice Guidelines for Adults with Stroke present an extensive review of research findings that support the importance of activity-based environmental challenges and repetitive practice opportunities in facilitating this neural reorganization (Sabari, 2008). Combined with advances in medical treatment of acute cerebrovascular accident (Wardlaw et al., 2003) and stroke rehabilitation (Stroke Unit Trialists' Collaboration, 2007), emerging concepts related to neuroplasticity have contributed to a heightened sense of optimism that stroke survivors have the potential to recover motor function (Gauthier et al., 2008).

Depending on the extent of neuropathology, all stroke survivors have varying potential for spontaneous recovery and reorganization of neural mechanisms. Studies of humans and other mammals have provided significant evidence that recovery of function after brain lesions is associated with recruitment of brain regions not typically activated for a specific function (Butefish, 2004; Murphy & Corbett, 2009). These studies consistently find that brain plasticity is a dynamic process that is influenced by the individual's active efforts to meet environmental and task demands (Hoffman et al., 2008). This finding has contributed significantly to changing views about neurorehabilitation. The philosophy, long held within the OT profession, that engagement in specially designed therapeutic activities can improve motor function is now supported by the scientific community. In addition, neurorehabilitation goals have been reframed from a focus on motor execution to an emphasis on helping patients improve motor control and, with regard to paretic limbs, amount of use. Several streams of research, in a variety of disciplines, have added support to incorporate these ideas into rehabilitation interventions to improve motor performance in survivors of stroke and brain injury.

Evolution from Impairment-Focused Interventions to Interventions Designed to Help Patients Develop Effective Movement Strategies

Although kinesiology has long been a core subject of study in OT and physical therapy curricula, it was not until the 1970s and 1980s that rehabilitation professionals began to seriously consider how principles from the academic disciplines of movement science and motor learning could be applicable to therapeutic interventions. Many of these principles related to stages of learning, types of feedback, and therapeutic use of practice are described in Chapter 13, "Learning." We recommend that you review this chapter, with particular emphasis on Definition 13-2 (implicit learning and explicit learning) and Procedures for Practice 13-2 (Therapeutic Use of Context, Feedback, and Practice to Promote Transfer and Generalization).

At the same time, a major paradigm shift was occurring in neuroscience. Previously, neural control of movement was explained by tracking the descent of neural signals through corticospinal pathways, delineating the direct influences from brainstem nuclei on motor neurons in the spinal cord, and describing communication between alpha motoneurons and muscle fibers (the "final common pathway"). In essence, motor performance was viewed as the collection of neural stimuli to individual muscles. Furthermore, regions of the CNS were viewed as relatively static structures, with assigned functions that did not change in response to experience or injury.

A proliferation of neuroscience research provides significant evidence that neural control of movement can best be conceptualized as a fluid, dynamic system. Through repetitive but varied practice, people develop motor programs that govern the production of generalized categories of movement. These motor programs are then adapted to suit particular features of task performance. Therefore, a unique pattern of activity with core foundational characteristics emerges whenever the motor program is executed. For example, a tennis player develops an underlying motor program that structures her posture and sequence of muscle recruitment for producing a forehand swing. This set of kinesiological relationships forms a core foundation, but the athlete alters the force characteristics, timing, and spatial details each time she returns the ball. The tennis player chooses these alterations (or variant characteristics of the motor program) based on the speed, force, and direction of the tennis ball, as well as the player's intentions regarding how to return the ball to her opponent.

The confluence between empirical findings in movement science and neuroscience research has led to increasing overlap between these two fields of study. These findings have had significant influence on rehabilitation interventions to improve motor performance in survivors of stroke and TBI. Schmidt and Lee (2011) provide useful background information about core concepts and research evidence related to human motor control and motor learning. Shumway-Cook and Woollacott (2012) provide more specific applications to OT and physical therapy practice. Winstein and Knecht (1990), Carr and Shepherd (1998, 2003), and Mathiowetz and Bass-Haugen (1994) developed practical guidelines for therapeutic intervention based on dynamic systems, ecological systems, and motor program theories.

Influences from Dynamical Systems, Ecological Systems, and Motor Program Theory

Dynamical systems theory, also known as nonlinear dynamics, provides a mathematical paradigm for conceptualizing phenomena that are subject to unpredictable changes over time (Hirsch, Smale, & Devaney, 2004). True dynamical systems theorists are mathematicians and

philosophers, but in the 1980s scholars in the movement and neural sciences began to apply these ideas to explanations of motor learning, skill development, and recovery of motor function after brain injury (Schmidt & Lee, 2011).

Ecological systems theory began as an exploration of how multiple factors interact to influence child development (Bronfenbrenner, 1979). Several OT scholars have synthesized these concepts into broad-based models for OT intervention (Dunn, Brown, & McGuigan, 1994; Law et al., 1996).

Dynamical systems and ecological systems theories have significantly impacted our current understanding of how people develop motor skill and recover motor function after brain injury. The following principles guide the way rehabilitation professionals conceptualize our role in helping patients reach their maximum functional potential.

- **Dynamic systems are self-organizing.** When a system is in a state of equilibrium, all influences are in perfect balance, and the system perpetuates itself without any need for change. As occupational therapists, we are most interested in understanding systems in states of *disequilibrium*. The human CNS can be conceptualized as a dynamic system. The hypothetical "system" that plans and organizes movement can also be conceptualized as a dynamic system. Dynamic systems continuously seek to "solve problems" that are presented by internal or external challenges. Furthermore, dynamic systems have the capacity to self-organize for the purpose of meeting these challenges. For illustration purposes, when learning to water ski, a person develops a strategy that will enable him or her to rise from a crouched position to standing, and then maintain his or her balance—all while wearing skis, on the surface of a lake, and being pulled by a motor boat that will vary its speed and direction. Similarly, when recovering from brain injury, a person relearns motor strategies for skills as basic as maintaining sitting balance, rising to a standing position, and coordinating arm and hand movements to reach and grasp objects. In dynamic systems theory (DST), external challenges are described as "perturbations." Without perturbations, a system will have no reason to use its self-organizing capabilities. Just as a person learns to water ski by "solving the problems" that are presented when participating in this sport, a person recovering from brain injury needs task-based challenges to begin the active process of "figuring out" how to move, using his or her current motor capabilities.
- **Influences on dynamic systems are heterarchical rather than hierarchical.** By that we mean that responsibilities for motor control are distributed among a number of structures within and external to the CNS. Spinal level structures are not completely dependent on higher centers for direct movement commands. Instead, the role of hemispheric structures is to tune and prepare the motor system to respond most efficiently to changing

environmental and task demands. Within the person, but external to the nervous system, factors such as muscle strength, ROM, and peripheral pain also contribute significantly to the choices that are made when selecting the best solution to a motor challenge. Finally, features in the environment and specific factors related to the task provide additional heterarchical influences that determine how the "motor system" will decide to adapt in order to meet a particular goal. (Refer to Chapter 12 for specific examples of how occupational therapists adapt tasks for the purpose of changing motor demands.)

- **The most efficient solutions in a dynamic system are those which present the fewest** degrees of freedom.
- **Dynamic systems inherently seek the most efficient solutions in their attempts to self-organize.** Bernstein's (1967) "degrees of freedom problem" has been supported in the literature that guides current neuromotor interventions. As you may recall from studying statistics or kinesiology, degrees of freedom in any system refer to the number of components (variables) that are free to vary. If we consider the number of degrees of freedom involved in controlling the muscles of the arm when picking up and drinking from a cup of coffee, it becomes clear that the system could not possibly be controlled via separate commands to individual muscles. Bernstein proposed that people reduce the degrees of freedom by creating linkages among muscular activities at various joints. Various terms have been used to describe these linkages: coordinative structures, function generators, and, most recently, motor programs and attractor states (Schmidt & Lee, 2011; Shumway-Cook & Woollacott, 2012).

Motor Programs and Attractor States. Two distinct concepts, advanced by different sets of theorists, provide conceptually similar descriptions of the mechanisms that are used to limit degrees of freedom during motor performance. A motor program is a memory-based schema that controls coordinated movement. Generalized motor programs (GMPs) are "prestructured sets of central commands" that govern a particular class of actions (Schmidt & Lee, 2011). They consist of both invariant and variant components. The invariant components comprise the core elements of the GMP. The variant components are flexible; they change dynamically in response to continuous changes in environmental and task parameters. For example, when a person develops a GMP for water skiing, the invariant dimensions are the muscle interactions required to maintain an appropriate posture. Variant dimensions include flexible shifts in alignment and muscle activation to meet the dynamic demands of the speed, direction, and wake created by the motorboat.

An attractor, as conceptualized in dynamic patterns theory, is a preferred pattern within a motor control system that leads to a consistent pattern of performance (Shumway-Cook & Woollacott, 2012). A preferred movement pattern
Figure 21-2   Various attractor states. **A.** No attractor state. **B.** Shallow well; stable and flexible attractor state. **C.** Deep well; stable and inflexible attractor state.

can be illustrated by how a marble moves on different surfaces (see Fig. 21-2) (Thelen, 1989). When people first attempt to learn a new motor skill, they have not yet developed an attractor state and thus do not exhibit any underlying pattern (see Fig. 21-2A). Every time they attempt to perform a task, they do it in a different way. Performance is irregular and unpredictable, and the person is not effective or efficient in achieving the goal. Think of the novice water skier who tries a different strategy every time, but at the end of the session has never succeeded in reaching a standing position. Early after stroke or head injury, people find themselves unsure of how to coordinate movement within the new constraints of their motor impairments. They are in a situation of having no attractor states for achieving functional motor performance. When people are inflexible in the way they perform a motor skill, they are demonstrating stable wells (see Fig. 21-2C). Consider a person who has learned to water ski but has been afraid to try to cross the wake or to allow the driver to vary the speed or acceleration of the boat. This person will develop a stable well, allowing her to show competence only when the task variables are unchanged. When motor learning occurs without opportunities to vary the task parameters, the person is at risk for developing stable wells. Stable wells are like "bad habits." They seem to serve a short-term purpose, but over time it becomes apparent that they are not useful in the real world where environmental and task affordances are continuously changing. The upper limb synergy patterns described by Twitchell and Brunnstrom can be conceptualized as attractor states with stable wells.

The goal in neuromotor rehabilitation is to assist patients to develop shallow wells, or flexible motor programs, for performing motor sequences that serve as the foundation for many types of functional movement. Variability in practice is a key component to helping people develop flexible attractor states. Using the terminology of dynamical systems theory, the therapist manipulates control parameters in therapeutic tasks to provide task-based challenges that will "drive" the individual to develop the most effective and versatile attractor states (see Procedures for Practice 21-1).

Procedures for Practice 21-1

Applying Principles from Dynamical Systems, Ecological Systems, and Motor Program Theory to Occupational Therapy Practice

- Reduce kinesiological constraints to movement performance such as limited range of motion, excessive effects of gravity, etc.
- Present task-based challenges designed to provide graded practice in using available capacities to achieve functional goals.
- Manipulate affordances/regulatory conditions within therapeutic tasks (and the environmental context) to provide varied and graded opportunities to practice incorporating effective motor programs into performance of functional tasks.
- Provide opportunities for practice and active experimentation with varied strategies in a variety of contexts to develop flexibility and skill in motor performance.

Constraints and Affordances

Motor performance is the result of a series of choices (often at the unconscious level). These choices are influenced by internal and external factors that shape the way we move. Constraints are factors that limit the choices that are available. Limitations caused by secondary impairments after stroke and brain injury impose constraints on movement choices. Although these are certainly negative constraints that therapists seek to prevent or reduce, there may also be external constraints to movement that are integral to a task. In the case of learning to water ski, having one's feet in the skis and one's hands on the tow rope imposes constraints that influence the ultimate strategy a person will use to rise to and maintain an upright posture. Affordances are factors that invite particular choices (Wu et al., 1998). An object's shape, size, perceived weight, location, and purpose all influence the constellation of movements that will be most efficient for using the object. For example, when a person sees a coffee mug, he or she immediately perceives its affordance as something to be picked up by the handle and brought to the mouth for drinking a hot beverage. The term, regulatory condition is used to describe task-related features that influence movement (Gentile, 2000). The term "control parameter" is used to describe any variable that, when changed, can cause a change in motor behavior. External control parameters, such as regulatory conditions or object affordances, influence a person's plan of action for executing a particular task. Internal control parameters, such as body alignment, muscle length, and muscle strength, also influence one's

motor tactics. Maladaptive movement strategies can be conceptualized as inefficient deep well attractor states that develop as a person attempts to move within the context of internal negative control parameters (see Fig. 21-2).

Learned Nonuse and Constraint-Induced Movement Therapy

Although the constraint-induced movement therapy (CIMT) approach is applicable to only a small population of stroke survivors who demonstrate high levels of motor ability, its underlying tenets and its methods of evaluation and intervention mark a significant paradigm shift in neurorehabilitation to improve movement performance. Edward Taub, a psychologist with little interest in the kinesiological details of human movement, developed the foundations for CIMT after making critical observations during animal lesion research.

Background and Research Findings

In studying the effects of deafferentation to the forelimbs of experimental monkeys through dorsal rhizotomy, Taub (1976) observed that the monkeys behaved as if these limbs were paralyzed, even though the animals were capable of performing voluntary movements with the affected extremities. He coined the term "learned nonuse" to describe the phenomenon in which the monkeys developed a learned behavior of relying exclusively on a single forelimb when they were faced with initial difficulty moving the contralateral limb. Taub postulated that learned nonuse developed in response to the coupling of negative reinforcers when the monkeys unsuccessfully tried to use the affected forelimb and positive reinforcers when they successfully used compensatory behavior patterns to perform tasks unilaterally with the unimpaired forelimb. Even when the animals experienced neurological recovery, they continued this behavior of relying exclusively on the unimpaired forearm for functional performance. To provide experimental evidence for his theory of learned nonuse, Taub restrained the unimpaired forelimbs of monkeys who had undergone lesion surgery. As predicted, when the restraining devices were removed after several weeks, the animals were able to use the deafferented limb and demonstrated smooth, functional motor performance.

Taub (1976) hypothesized that, in some stroke survivors, the failure to recover motor function in the affected arm and hand was due to learned nonuse rather than to specific difficulties in generating movement. To test this hypothesis, Taub and colleagues established minimal criteria for participation in constraint-based research. Although these criteria have changed slightly over time, they have always required participants to demonstrate the capacity to generate significant movements of the hand (see Definition 21-2).

Definition 21-2

Inclusion Criteria for Participating in Constraint-Induced Movement Therapy Clinical Trials

- Paretic hand
  - ≥10° active wrist extension
  - ≥10° active thumb abduction or extension
  - ≥10° extension in at least two additional digits
  - ability to repeat these movements three times in 1 minute
- Adequate balance while wearing a restraint and transferring to and from the toilet independently
- Able to stand from a sitting position without relying on assistance from the unaffected hand
- Ability to stand for at least 2 minutes with or without upper extremity (UE) support
- Score of ≥24 on Mini-Mental State Examination
- Stamina and motivation required to participate in a 2-week program, including
  - constraint of the less impaired UE for 90% of waking hours (7 days per week)
  - 6 hours of intensive therapy per day (5 days per week)
  - at-home practice

From Wolf, S., Winstein, C. J., Miller, J. P., Taub, E., Uswatte, G., Morris, D., Giuliani, C., Light, K. E., Nichols-Larsen, D., & EXCITE Investigators. (2006). Effect of constraint-induced movement therapy on upper extremity function 3 to 9 months after stroke: The EXCITE randomized clinical trial. *Journal of the American Medical Association, 296,* 2095–2104.

In the past 30 years, Taub has collaborated with colleagues from a variety of disciplines to develop interventions that are designed to improve functional use of the arm and hand in this population. The first clinical application was the program of "forced use." In this protocol, which closely mirrors Taub's earlier work with laboratory monkeys, participants constrained their unaffected upper limb for 90% of waking hours over a 2-week period. This constraint alone, without supervised practice, resulted in clinically significant changes among individuals who had survived stroke or head injury more than 1 year prior to participation in the forced use protocol (Wolf, 1989). In the following decade, Taub and colleagues added the component of supervised practice sessions, using the technique of shaping to gradually refine task demands and coined the term constraint-induced movement therapy to describe the combined intervention of intensive practice and constraint of the unaffected upper limb. Over time, the method of constraint has shifted from restraining the entire unaffected upper limb in a sling to less restrictive hand mitts that serve as constant reminders not to use the unaffected limb. Furthermore, although it is beyond the scope of this

chapter, CIMT has been applied to other populations, most notably children with hemiparesis caused by cerebral palsy and other developmental disabilities (Hoare et al., 2007).

In the current CIMT intervention protocol, participants wear a hand mitt for 90% of their waking hours over a 2-week period, including two weekends, for a total of 14 days. On each weekday, these individuals participate in shaping and standard task training of the paretic limb for up to 6 hours per day (Wolf et al., 2006). Results from multiple studies have provided consistent evidence that, with the intended population, CIMT is effective in improving function related to motor execution, motor control, and amount of use (Shi et al., 2011; Sirtori et al., 2009). In addition, several studies have used neuroimaging techniques to provide evidence of changes in neural organization following CIMT (Liepert, 2006; Lin et al., 2010b; Murayama et al., 2011).

Of all the considerable evidence in support of CIMT, the Extremity Constraint-Induced Therapy Evaluation (EXCITE) trial is particularly noteworthy. This prospective, single-blind, randomized, cross-over, multisite clinical trial is the largest systematic outcomes study in the history of stroke rehabilitation (see Research Notes 21-1, 21-2, and 21-3). In addition to the three seminal articles reporting results from the EXCITE trial, the researchers have contributed multiple publications that delineate the study design (Morris et al., 2009; Winstein et al., 2003) and reflect on implications of findings to future research and clinical practice (Park et al., 2008; Wolf, 2007; Wolf et al., 2007). A long-term case report of one EXCITE trial participant with assessments 4 and 5 years following CIMT intervention (Rowe, Blanton, & Wolf, 2009) revealed that this individual continued to maintain the gains reported in the aggregate studies described in the Research Notes.

Modified Constraint-Induced Movement Therapy Protocols

In spite of the overwhelming research support for CIMT, two concerns limit its application: (1) issues related to clinical feasibility and (2) the small percentage of stroke survivors who can participate in the standard CIMT protocol. Therefore, several adaptations to CIMT have been proposed and evaluated. The goal is to find a level of modification that will decrease costs and improve accessibility to more stroke survivors while maintaining highly beneficial outcomes.

The high intensity of practice sessions and the significant demand of wearing a restrictive mitt for 90% of waking hours are the two critical concerns related to CIMT's clinical feasibility. Beyond staffing considerations, patient fatigue and overall preference indicate the need for shorter periods of practice, spaced over a longer time period than 2 weeks (Page et al., 2001). Regarding the constraint component of CIMT, several researchers have found that patients have difficulty complying with an intense mitt-wearing

Research Note 21-1

Abstract

The participants were 222 individuals who had sustained a first stroke (predominantly ischemic strokes) within the previous 3–9 months. They were assigned to receive either a 2-week constraint-induced movement therapy (CIMT) program ($n = 106$; wearing a restraining mitt on the less affected hand while engaging in repetitive task practice and behavioral shaping with the hemiplegic hand) or usual and customary care ($n = 116$; ranging from no treatment after concluding formal rehabilitation to pharmacological or physiotherapeutic interventions). For group assignment, patients were stratified by gender, prestroke dominant side, side of stroke, and level of paretic function. For participants in the CIMT group, several behavioral techniques were used to enhance mitt use outside of the training sessions. These methods included behavioral contracts for participants and their caregivers, a sensor-based mitt compliance device, and formal, daily schedules. The Wolf Motor Function Test (WMFT) and Motor Activity Log (MAL) were the main outcome measures. Of all the participants, 98 completed treatment and testing in the experimental group, and 105 completed treatment and testing in the control group. Data were collected on five occasions: baseline, posttreatment, and at 4-, 8-, and 12-month follow-up. Data analysis of results revealed that "the CIMT group showed significantly larger improvements immediately after treatment than the control group in quality and speed of paretic arm movement (WMFT Functional Ability and Performance Time) and in the quality and amount of paretic arm use in daily life (MAL). . . . The advantages for the CIMT group on all primary outcomes persisted at the 12-month follow-up" (p. 2102).

Implications for Practice

Direct implications: For stroke survivors who meet inclusion criteria, a 2-week program of intensive task-related training, combined with restraint to the unaffected arm during 90% of waking hours, has immediate and lasting effects (up to 12 months after participation) on motor performance and spontaneous, functional use of the paretic arm.

Indirect implications:

- Intensive practice using the paretic arm and hand in functional tasks has the potential to improve motor performance and spontaneous use.
- Behavioral methods that ensure accountability in complying with practice schedules within and outside of treatment may have the potential to improve patients' compliance and thus contribute to improvements in motor performance and spontaneous use of the paretic upper limb.

Research Note 21-2

Abstract

Of the 98 participants who completed treatment in the experimental group of the EXCITE Trial (described in Research Note 21-1), 70 completed additional follow-up testing at 16 months and 24 months after intervention. Follow-up tests included Wolf Motor Function Test (WMFT), Motor Activity Log (MAL), and several subtests on the Stroke Impact Scale (SIS). The findings "extend previous results by showing that the improvements in function at 12 months after a 2-week Constraint-Induced Movement Therapy (CIMT) intervention are retained or improve further" (p. 38). Statistically significant improvements at 24 months (when compared to scores at the 12-month follow-up) were on strength-related scores on WMFT, and several domains of the SIS (a self-report measure used extensively in stroke research). The SIS domains showing significant, continued improvement were strength, activities of daily living (ADL) and instrumental activities of daily living (IADL), social participation, and overall assessment of physical ability.

Implications for Practice

Direct implications: Participation in a 2-week CIMT program has long-lasting impact on motor, ADL, and social function. This finding is critical because other longitudinal follow-up studies of stroke survivors after participation in rehabilitation programs have failed to show that short-term improvements are retained over time.

Indirect implications: The findings suggest that a change in the pattern with which stroke survivors use their paretic limb may be instrumental in fostering ongoing practice in using this limb during daily activities. This ongoing practice can lead to ongoing improvements in performance, an overall sense of optimism about potential for future gains in motor function, and continuous improvements in satisfaction related to physical, ADL, IADL, and social participation.

Wolf, S. L., Thompson, P. A., Winstein, C. J., Miller, J. P., Blanton, S. R., Nichols-Larsen, D. S., Morros, D. M., Uswatte, G., Taub, E., Light, K. E., & Sawaki, L. (2010). The EXCITE Stroke Trial: Comparing early and delayed constraint-induced movement therapy. *Stroke, 41,* 2309–2315.

Abstract

The EXCITE Trial followed a cross-over design. One year after the study, the participants who were randomized to the control group were given the opportunity to receive contraint-induced movement therapy (CIMT) intervention. The same procedures reported in Research Notes 21-1 and 21-2 for intervention and data collection were followed. Of the initial 116 members of the control group, 86 participated in this delayed CIMT intervention, 78 completed the intervention and were tested immediately posttreatment, and 61 were retested after 24 months. The results were similar to results previously reported for the original experimental group (called the "early CIMT" group in this report). Even when CIMT was initiated an additional year after the original period of 3–9 months after stroke, delayed CIMT participants showed statistically significant improvements on Wolf Motor Function Test (WMFT) and Motor Activity Log (MAL) scores. However, they did not exhibit the statistically significant improvements on Stroke Impact Scale (SIS) scores that are reported in Research Note 21-2. When comparing data from both the early and delayed participants, researchers found that, although both groups showed significant improvements, the earlier CIMT group showed greater improvement than the delayed CIMT group in WMFT performance time and the MAL, as well as in the SIS hand and activity domains.

Implications for Practice

- "CIMT can be delivered to eligible patients 3 to 9 months or 15 to 21 months after stroke. Both patient groups achieved approximately the same level of significant arm motor function 24 months after enrollment" (p. 2309).
- It may be more effective to provide CIMT earlier, rather than later, after a person has sustained a stroke. It is not clear whether this is due to factors related to neural plasticity or to the possibility that members of the delayed CIMT group may have already solidified their expectations related to motor, activities of daily living (ADL), and social function.

schedule, particularly if they are living alone (Flinn et al., 2005). Levine and Page (2004) proposed the first alternative to CIMT that meets the practical realities of reimbursement and professional staffing, as well as patient fatigue and desire to participate in work and leisure activities. Today, there are several variations of modified (or distributed) constraint-induced movement therapy (mCIMT). Typically, constraint is limited to 5 hours per day, 5 days per week for a duration of 10 weeks. Practice sessions range from 30 minutes to 3 hours, 3 days per week. Group sessions are cost-effective, and the camaraderie they promote is beneficial to the rehabilitation process (Brogårdh & Sjölund, 2006; Flinn et al., 2005). Sessions can also be modified with regard to therapist supervision. A case report (Ploughman et al., 2008) and a cohort study (Hosomi et al., 2011) have reported that dividing practice sessions into a smaller percentage of time with direct supervision and a larger percentage of time devoted to self-training yields similar outcomes to the standard CIMT protocol. Results from a number of randomized controlled trials have confirmed that outcomes of mCIMT interventions are similar to those of standard CIMT (Lin et al., 2010b; Page et al., 2008; Shi et al., 2011).

Kinematic Analyses of Constraint-Induced Movement Therapy Outcomes

The definitive EXCITE trial studies of CIMT focused on outcomes related to task performance, as measured by the Wolf Motor Function Test (WMFT) and changes in self-perceived amount and quality of movement, as measured by the Motor Activity Log (MAL). Other researchers have used motion analysis to investigate the effect of CIMT and mCIMT protocols on the kinematic aspects of movement. These studies seek to determine whether CIMT improves the *way* people use their paretic upper limb in addition to improving success in task completion. Several studies have found that, in addition to improved scores on standardized evaluations, CIMT participants also improve the following kinematic aspects of movement in the paretic upper limb:

- Ability to initiate movement more quickly and perform tasks with straighter and smoother reaching trajectories (Wu et al., 2007a)
- Improved movement speed and coordination between shoulder and elbow motions (Caimmi et al., 2008)
- Temporal and spatial improvements in the efficiency of movements and better evidence of preplanned motor control (Wu et al., 2007b)
- Improved movement time, average velocity, and stability of the reach trajectory, as well as increased shoulder flexion during reach (Massie et al., 2009).

However, it has also become apparent that, even with other improvements, CIMT participants may continue to rely on common compensatory movement patterns, such as

- excessive anterior trunk displacement with reach
- poor dissociation between the thorax, shoulder, and elbow
- maladaptive shoulder abduction during attempts at forward reach (Massie et al., 2009).

Previous researchers, investigating potential limitations to other forms of task-related training, have identified compensatory trunk movements as a contributing factor to inefficient arm and hand control in stroke survivors. Excessive trunk rotation and anterior displacement seem to be most problematic in stroke survivors with more severe upper limb impairments (Cirstea, Ptito, & Levin, 2003), who may not qualify to participate in standard CIMT protocols. Reminiscent of NDT procedures that were designed to prevent stroke survivors from using maladaptive compensatory strategies, there is a trend to provide passive trunk restraint to patients while they engage in task-based practice sessions. Trunk restraint is typically provided by using a shoulder belt attached to a chair back, similar to the seat belt in a car (but without the "give").

A few studies have investigated the short-term effects of trunk restraint combined with either task-related training (see Definition 21-3) or mCIMT (Michaelsen, Dannenbaum, & Levin, 2006; Woodbury et al., 2009; Wu et al., 2012). These studies have found some promising outcomes. In particular, the trunk restraint groups showed greater gains in shoulder flexion and elbow extension during forward reach, as well as less compensatory trunk movement and improved grasp control, when tested immediately after participation in a 2-week protocol. It is important to note that no studies have yet assessed retention of these improvements over time. Additionally, there has not been any assessment of whether trunk restraint may have negative effects on the integration between pelvic, trunk, and upper limb kinematics during functional reach that naturally requires movement at each of these body segments.

Effect of Constraint-Induced Movement Therapy Research on Paradigms for Conceptualizing Stroke Rehabilitation

Clearly, not all stroke survivors are candidates for CIMT interventions. However, several concepts and findings related to CIMT can be applied to OT intervention for *all* individuals with hemiparesis caused by stroke or brain injury.

Empirical Support for Applying Dynamic Systems Theory to Neuromotor Rehabilitation. One way to view the concepts and findings of CIMT is in relation to DST. A central tenet to DST is that all systems are capable of reorganization, but this reorganization occurs only in response to some external perturbation (or challenge). Rehabilitation therapists provide external challenge through structuring constraints and affordances during task-related practice. The constraint of not being able to rely on one's unaffected arm and hand, combined with specific affordances of activities presented during shaping sessions, provides a double dose of perturbations that challenge the motor system to reorganize itself. Furthermore, practice sessions are structured to provide the person with opportunities to "figure out" how to meet task-based challenges. This is a major paradigm shift from previous therapies that relied on exercise-based repetitions of specific movements.

Empirical Support for Motor Learning Theories Related to Practice. The success of CIMT can be attributed primarily to the wide opportunities this intervention provides for varied, intense, practice—in which the motivation to move begins with attention to objects in the environment that a person wishes to move, grasp, or manipulate. The constraint is a vehicle for ensuring that the person will participate in practicing with the paretic upper limb. Shaping sessions are similar to traditional activity-based OT: the therapist grades activity demands and creatively designs tasks and competitive games in which the patient is motivated to use her arm and hand again and again, faster and faster, further and further, and using increasingly complex patterns of proximal and distal control. A two-group, randomized study found similar improvements in stroke survivors who participated in a CIMT program and others who participated in a bilateral task-based program of equal intensity (Hayner, Gibson, & Giles, 2010). This finding, coupled with a failure to find significant differences in WMFT scores between the two groups, suggests that the nature and intensity of the practice are the key variables to CIMT's success. The challenge to occupational therapists is to find creative ways to provide this type of motor practice to patients with stroke and brain injury who are not candidates for CIMT.

A New Outcome Variable: Amount of Use. Taub introduced the notion that recovery is integrally tied to amount of use. Although there is no empirical support, to date, to confirm this relationship between amount of use and changes in motor skill, this is an intriguing hypothesis. Consistent with motor learning and dynamical systems theory, Taub highlighted that stroke survivors improve their functional movement skills when they are faced with tasks and environmental challenges to harness their available capacities. When people change their activity patterns to incorporate the paretic arm and hand, they are providing their own opportunities for practice—not only during therapy sessions but also during functional tasks performed throughout the day. Before CIMT, few interventions led to generalization of motor capacities, and they were rarely sustained over time. Changes in pattern of use lead to infinite opportunities to practice. The outstanding long-term results of the EXCITE trial studies indicate (but do not prove) that a positive cycle takes effect (see Fig. 21-3). Improved performance leads to enhanced confidence in functional success. When the person experiences pride in using the limb throughout the day, he uses it even more, and, with this further increase in practice, improves even further—developing enhanced strength and dexterity over time.
Figure 21-3 Paradigm to promote long-term, continuous improvement in motor control.

Procedures for Practice 21-2

Key Principles from Constraint-Induced Movement Therapy That Can Be Applied to Occupational Therapy for All Stroke Survivors

- Prevent learned nonuse by teaching patients how to capitalize on emerging abilities to execute specific movements.
- Design/adapt activities that the person can perform with existing capabilities.
- Teach the person how to design/adapt activities for functional use of available abilities within natural contexts.

Support for the Concepts of Patient Accountability and Motivation. It is hard, frustrating work to practice using a paretic upper limb. Coupled with the fact that humans can quickly learn to perform many daily tasks with one hand only, it is not surprising that stroke survivors experience the phenomenon of "learned nonuse." The literature in motor learning consistently finds that, when learning a new skill, it is most difficult to practice during early stages, when performance is difficult and clumsy. Think about how you may have hated to practice a musical instrument when taking lessons as a child. Once a person attains a critical level of skill, further practice becomes enjoyable, and it no longer seems arduous to perfect one's skill even further (Schmidt & Lee, 2011). At the early stages of learning, internal motivation may not be forceful enough to compel the person to stick with a practice routine. Therefore, accountability to others may be critical. Several factors in the CIMT protocol enhance accountability. Patients and caregivers sign behavioral contracts before participating in the program. Patients are supervised for 6 hours per day during task-related training. To ensure compliance in wearing the mitt outside of training sessions, a sensor is embedded in each constraint mitt. The person knows that, if she fails to wear the mitt appropriately, she may be asked to terminate the CIMT program. Although these approaches may not be appropriate in clinical OT practice, we can use other behavioral strategies that increase patient accountability to practice using their emerging abilities. One tactic is to provide patients with structured homework logs and check sheets that they share with the therapist at the beginning of each session. Another strategy is to challenge patients to determine their own task goals and to share their achievements with the therapist. Most people have a competitive spirit. It is easier to practice a repetitive task when the goal is to complete a designated set of repetitions in an arbitrary amount of time. It is fun to see if you can "break your previous record."

Tasks, which might otherwise seem meaningless, become motivating if the person knows he will be recording his performance time or racing against the clock (see Procedures for Practice 21-2).

Unanswered Questions. The success of CIMT, albeit with a small subset of stroke survivors, raises two additional questions that remain unanswered for clinicians who are providing neuromotor rehabilitation.

How Important Are Kinematics during Early Learning? Perhaps because Taub is a psychologist rather than a movement scientist or rehabilitation professional, he has never articulated any interest in the kinematics of movement. Abnormal movement synergies and maladaptive movement patterns are simply not considered in Taub's theories about learned nonuse and CIMT. Intervention focuses on preventing learned nonuse and providing extensive opportunities to practice using the hemiparetic limb. Although shaping (or activity grading) is used during therapy sessions, there is no mention of kinematic analysis or any physical manipulation or guidance. Research is needed to determine the best balance between encouraging patients to move and restraining them from moving inefficiently.

Does It Matter if Task Practice Is Unilateral or Bilateral? Because the unaffected upper limb is constrained, task practice in CIMT is inherently unilateral. In reality, however, most functional task performance is bilateral—typically, with one upper limb playing a dominant role in manipulating an object while the other arm assists in stabilizing the same object or another related item. For example, a person may use his or her left hand to stabilize a piece of paper while writing on the paper with his or her right hand. When opening a water bottle, one hand may grasp the cylindrical shaft of the bottle while the other hand turns the cap. To pour water into a glass, one hand

manipulates the pitcher while the assisting hand holds the glass in place. To place a pair of trousers on a closet hanger, the assisting hand will grasp the hanger while the manipulating hand drapes the garment neatly onto the hanger. Finally, while using the right hand to load dishes from a kitchen sink into the dishwasher, a person may rest her left hand on the counter—to provide overall stability while she shifts her body weight. Hayner, Gibson, and Giles (2010) compared bilateral training with CIMT, while controlling for amount of practice, and found similar results from both protocols. One potential value is that patients who do not meet the motor criteria to participate in a CIMT protocol may be candidates for a bilateral training program.

Bilateral arm training (BAT) is a therapeutic technique in which patients perform repetitive identical movements with both arms simultaneously. Some examples are

- using bilateral robotics devices, such as BATRAC (Hesse et al., 2005; Whitall et al., 2011)
- pushing/pulling with both arms (as in opening and closing a drawer with two handles or two identical drawers
- wiping a table, using both arms symmetrically
- moving two identical grocery objects from countertop to shelf with both hands (Stoykov, Lewis, & Corcos, 2009)

A comparison of unilateral versus bilateral training groups, matched for amount of practice, revealed that although both groups showed statistically significant improvements on the Motor Status Scale and measures of muscle strength, the bilateral group improved significantly more on a measure of proximal arm function (Stoykov, Lewis, & Corcos, 2009). A randomized controlled study comparing BAT to standard rehabilitation found moderate and statistically significant effects on reaching kinematics and FMA scores, but no differences between groups on ADL function, as measured by the FIM™ (Functional Independence Measure), or amount of use, as measured by the MAL (Lin et al., 2010a). Two randomized controlled studies comparing BAT to mCIMT and a control group (Lin et al., 2009; Wu et al., 2011) found that participants in the BAT group showed significantly better performance than the other groups on factors related to proximal upper limb function. However, the mCIMT group performed significantly better on the MAL and several domains of the Stroke Impact Scale. In summary, when comparing BAT to CIMT, the advantages are the following:

- More stroke survivors can participate in this type of therapy.
- It has therapeutic influence on improving proximal arm control.
- It can be used as a cost-effective enhancement to standard therapy.

A major drawback is that BAT does not impact the extent to which participants incorporate the paretic limb into spontaneous daily activity. Thus, it is difficult to predict meaningful long-term changes in practice and, ultimately, functional use of the paretic upper limb.

Robotics and Virtual Technology

Although the specifics of using robotics and other technologies for neurorehabilitation are discussed in Chapter 18, it is appropriate here to discuss how robotics-related research has contributed to conceptual paradigms about therapeutic interventions designed to promote recovery (especially of proximal arm function). In addition to the clinical advantages of robot-assisted therapy (Lo et al., 2010), robotics technology offers research opportunities to carefully control and study several variables that are difficult to operationalize when therapy is provided by human therapists. Findings from robotics research have lent support to several principles related to the nature of motor relearning and effective therapeutic practice (Hogan et al., 2006; Krebs, Volpe, & Hogan, 2009):

- Intensity of practice is a key factor to recovery of function, but it may not be more important than other factors.
- For improvements to occur, patients must be actively engaged and attempting to move for a functional purpose. Repetitive, passive movement does not improve motor control. Robotics are most effective when they are designed to provide dynamic assistance and challenges based on the robot's continuous monitoring of current performance.
- It is more effective to focus therapy on kinematic challenges rather than on muscle strengthening.
- Neural plasticity is activity dependent.
- The most relevant improvements in motor skill result from implicit rather than explicit learning.
- Treatment that continuously challenges and assists the patient to perform task-driven movements is more effective than exercise to individual muscles.

In addition, robotics researchers have explored the long-standing controversy about limb synergies and recovery. One study (Dipietro et al., 2007) found that, in patients whose arm motor function improved after robotics training, videographic movement analysis revealed that they had modified their existing maladaptive synergy patterns, rather than learning a completely new adaptive strategy. This finding may provide support for interventions that encourage patients to move, regardless of the initial kinematics of the movement.

MULTIPLE FACTORS CONTRIBUTE TO OPTIMAL MOTOR PERFORMANCE

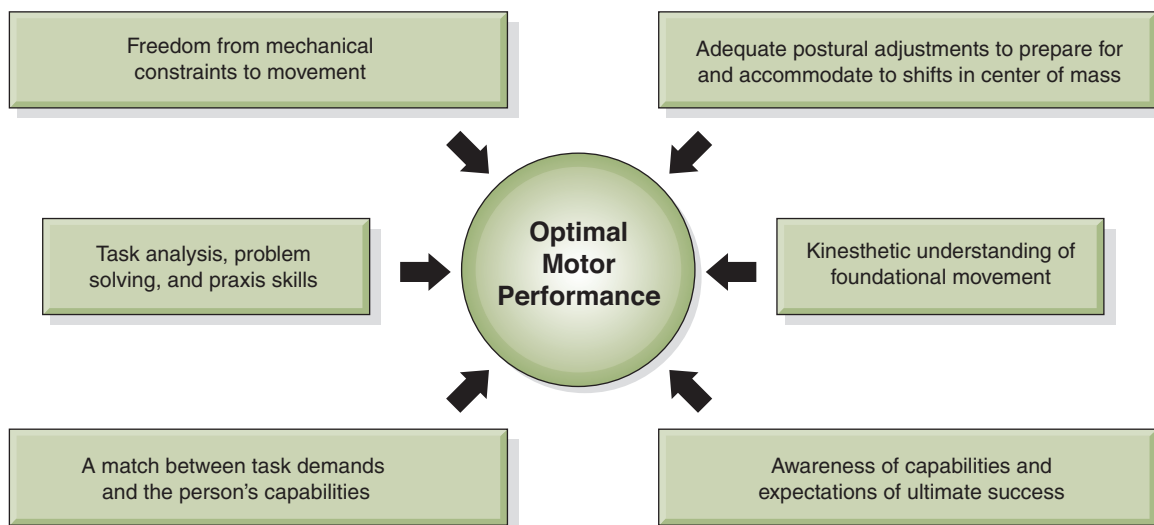
Figure 21-4 illustrates that several sets of factors are required for a person to move in a functional way. The interaction among these variables determines the degree


Figure 21-4 Multiple factors contribute to optimal motor performance.

to which an individual can be successful in performing daily tasks. Occupational therapists need to evaluate and intervene in all of these areas to help our patients meet their full potential.

Mechanical Requirements for Movement Execution

The most elemental requirements for motor performance are freedom from mechanical constraints. Thus, joint mobility, fluid dissociation between body segments, optimal postural alignment, the absence of limiting factors such as edema and pain, and the capacity to generate specific movements are essential to a person's capacity to develop functional motor control.

Joint Mobility

Joint mobility, the capacity for limbs to be moved passively around a joint fulcrum, is necessary for active movement and functional performance. Deficits in passive ROM are preventable, secondary, impairments associated with immobility. Histologically, soft tissues do not maintain their underlying distensibility (capacity to be stretched to maximum length) unless they are routinely lengthened by antagonist muscles or an external force. Figure 21-5
Figure 21-5 Cycle of immobility and soft tissue shortening.

illustrates the importance of interventions that are designed to prevent pathological "shortening" of muscles, tendons, and ultimately joint capsule tissue. In survivors of stroke or TBI, spasticity may be a factor that contributes to loss of joint mobility.

Dissociation

Dissociation between body segments refers to the underlying potential for adjacent body segments to move independently of one another. When applicable to the task or movement desired, every segment within our bodies must have the capacity to move freely, without undue restraint from loss of length of multijoint or single-joint muscles. For example, in a healthy musculoskeletal system, the scapula moves freely within the thorax for a variety of passive and active motions within all planes of movement. The thorax is free to move independently of the lumbar spine and pelvis. The pelvis moves freely in all planes, with relation to the lumbar spine. Therapeutic interventions to prevent and improve impairments in dissociation between body segments are presented in the interventions section of this chapter.

Optimal Postural Alignment

Optimal postural adjustment allows a person to efficiently maintain balance against the force of gravity, to freely dissociate adjacent body segments, and to move the arms and legs on a stable foundation at the body core. In our popular culture, there are many exercise programs whose essential goals are to improve postural alignment for efficient, pain-free movement and core muscle strength. Dancers, athletes, and other individuals who wish to reduce biomechanical stress can choose from well-established interventions like Pilates (Kloubec, 2010), the Alexander technique

(Jain, Janssen, & DeCelle, 2004), and the Feldenkrais method (Schlinger, 2006). Each of these interventions provides educational programs to train practitioners. Occupational therapists who have additional training in one or more of these exercise approaches bring an additional level of skill to their professional practice.

OT students have previously learned, in anatomy and kinesiology courses, that the pelvis serves as a cornerstone to alignment of the trunk and limbs. In the sagittal plane, a resting posture of excessive anterior tilt will accentuate lumbar lordosis (with abnormal shortening of extensors and abnormal distension—and weakness—of abdominals). A resting posture of excessive posterior tilt will decrease the normal lordotic curve of the lumbar spine (with abnormal shortening of the abdominals and latissimus dorsi and excessive lengthening of the lumbar extensors). In terms of function, this will limit the person's capacity to flex the hips, which is crucial when moving from stand to sit and when reaching forward while sitting. This posture will also accentuate the kyphotic curve of the thoracic spine, which can impact respiratory capacity and mechanics at the scapula and humerus. In the frontal plane, a resting posture of lateral tilt will accentuate lateral trunk flexion away from the weight-bearing side and lead to asymmetries in posture throughout the scapulae and upper limbs, as well as throughout the lower limbs.

When assessed in sitting, stroke survivors with impairments in postural alignment often exhibit excessive posterior pelvic tilt and excessive lateral pelvic tilt—either toward or away from the paretic side. Based on influences from the NDT approach, many clinicians refer to abnormalities in lateral pelvic tilt as problems in weight bearing. A person with excessive left lateral pelvic tilt demonstrates an abnormal pattern of weight bearing, with most of the body weight supported on the left ischium.

When assessed in standing, stroke survivors with impairments in postural alignment may vary in pelvic posture from the sagittal view but almost always exhibit asymmetries with a greater degree of weight bearing (and pelvic lateral tilt) toward the unaffected side. Typical abnormalities in scapular alignment will be discussed later in this chapter. Because postural alignment impacts all other mechanical factors that influence movement, occupational therapists and physical therapists typically assess postural alignment before administering other motor-related evaluations.

Freedom from Other Secondary Impairments

Problems with postural alignment, dissociation between body segments, and joint mobility are all preventable secondary impairments in stroke survivors. Distal edema, localized pain, and complex pain syndromes are examples of other secondary impairments that will also impede a person's capacity to use his or her available motor ability

in a functional way. Evaluation and treatment of these factors are described in Chapter 33.

The Capacity to Generate Muscle Contraction

The capacity to generate muscle contraction determines whether an individual will be able to produce specific movements. There is no debate that this capacity, long viewed as the ultimate goal in neuromotor rehabilitation, is critical to motor performance. In fact, FMA scores within the first month after stroke is a key predictor of ultimate recovery (Kwakkel et al., 2003). However, in the absence of other factors affecting motor control, motor execution alone is not sufficient for ensuring that a person will be able to move functionally or to continue the process of motor recovery. Techniques to improve patients' capacity to generate muscle contraction are described in the interventions section of this chapter.

Kinesthetic Understanding of Foundational Movement Strategies

When the neuromuscular system is functioning optimally, a person can rely on automatic kinematic and kinetic linkages to serve as a foundation for functional movements. Often, patients who are recovering from brain injury have lost the automatic kinesiological linkages associated with efficient movement (Shumway-Cook & Woollacott, 2012). This may be a result of limited mobility of body segments, weakness of specific muscular components, or loss of the motor program that links muscles or joints during a given movement sequence.

Normally, when a seated person wants to reach forward to grasp an object, the CNS calls forth a movement pattern that includes anterior pelvic tilt, hip flexion, scapular abduction, and upward rotation, as well as glenohumeral flexion and external rotation. Additionally, wrist extensors contract to establish optimal mechanical efficiency for the finger flexors. Many persons with hemiplegia cannot rely on automatic generation of these complex muscle linkages, and each attempt at movement presents the challenge of coordinating an unmanageable number of degrees of freedom.

Motor skill learning is dependent on the consolidation of motor memory that guides muscle recruitment (Krakauer & Shadmehr, 2006). Research in motor learning consistently confirms that people develop the strongest motor memories when the following criteria are met:

- The learner has significant opportunities to practice (Schmidt & Lee, 2011).
- The practice occurs in a natural setting, where constraints and affordances within a task context allow the person to actively experiment to determine the most effective strategy (Ma & Trombly, 2004).

- The learner participates in variable rather than repetitive or blocked practice schedules (Davids et al., 2003; Kantak et al., 2010).
- The learner develops an intrinsic feedback system (i.e., he or she "feels" when he or she is performing most efficiently), which lessens his or her reliance on external feedback.

Occupational therapists draw on sound knowledge of kinesiology to determine when a patient is demonstrating inefficient movement strategies. After intervening to reduce mechanical obstacles, the therapist structures therapeutic tasks so that the patient gains practice in implementing a selected motor strategy in a variety of contexts. For example, the therapeutic goal may be to develop the linkage between anterior pelvic tilt, hip flexion, and symmetrical trunk extension as a foundational motor program for forward reach in sitting, as well as standing up from a seated position. The session may begin with the therapist moving the patient's pelvis so that the person understands the kinematic model of action. The therapist may then ask the patient to sit on a therapy ball, which is rocked forward and backward using anterior and posterior pelvic movement. After this, the seemingly unrelated task of reaching for objects from the seated position will emphasize that the patient anteriorly tilt the pelvis by directing attention to "keep your back straight" and "bring your nose over your toes." Following this, the patient will practice standing up and sitting down on a variety of surfaces with an emphasis on the same lumbopelvic interactions previously practiced in different contexts. Finally, the patient may practice this same sequence but while holding a variety of objects. The size and shape of the object may require either unilateral or bilateral grasp, as well as varying configurations of the arms in relation to the body. Research findings from studies with healthy participants (Giuffrida, Shea & Fairbrother, 2002) and men with traumatic brain injury (Giuffrida et al., 2009) provide support for using this approach for learning the invariant structure of a GMP.

Lots and lots of practice is a key variable in determining whether any person will be successful in developing a new foundational movement strategy. Unfortunately, researchers have found that stroke and TBI patients in typical rehabilitation settings tend to get far fewer practice opportunities than laboratory animals in studies of neural plasticity (Kimberley et al., 2010). When opportunities for practice repetitions were increased to recommended levels, patients demonstrated statistically and clinically significant improvements in motor control, with few complaints of pain or fatigue (Birkenmeier, Prager, & Lang, 2010).

Postural Adjustments

Every time a person moves, his or her body's center of mass (COM) changes its relationship to the base of support (BOS). Postural control mechanisms enable us to maintain balance by ensuring that our body's COM remains within the BOS. Effective balance requires adequate function in sensory and motor systems. Sensory processing of visual, vestibular, tactile, and proprioceptive information allows a person to maintain continuous and dynamic awareness about the body's COM and alignment between body segments. Muscle contractions
Figure 21-6   Patient practicing sit to stand with the added challenge of a glass of water in his hand. **A.** Patient is in posterior pelvic tilt. **B.** Patient shifts to anterior pelvic tilt and hip flexion in preparation to stand. **C.** Patient bears weight through both legs as he rises from the seating surface. **D.** Patient completes the sequence of moving from sit to stand.

of appropriate amplitude and timing allow for predictive and ongoing force production to match the changing influence of gravity during motor performance. Sufficient joint mobility and muscle length allow the necessary movements to be generated through their full ROM (Hall et al., 2010).

During daily activities, a person's COM can be displaced in three ways: (1) by an external force applied to the body, as occurs during contact sports; (2) by external movement of the support surface, as occurs when we sit or stand in a moving vehicle; and (3) during performance of activities requiring self-initiated movement of the head, limbs, or trunk (Carr & Shepherd, 2003). Typically, balance challenges arising from self-initiated movement are more important to daily function than are balance challenges arising from external perturbations. Postural adjustments are both task and context specific. Studies have shown that muscle activation patterns for balance control vary according to (1) the position of the person, (2) the task being performed, (3) the context in which the activity occurs, and (4) the person's perception of which body part is in contact with the more stable BOS (Dean, Shepherd, & Adams, 1999a, 1999b). Furthermore, during self-initiated movement, postural adjustments are *anticipatory* (Hall et al., 2010). Simultaneous with the motor plan to reach or even turn one's head in a particular direction, tectospinal and vestibulospinal signals are transmitted to produce tonal changes in muscles that will be necessary to counteract excessive displacement in the body's COM (Bear, Connors, & Paradiso, 2007).

Figure 21-7 shows a healthy woman using effective postural adjustments when she shifts her body weight to the right side. Notice that her trunk laterally flexes to the left. If this automatic anticipatory postural adjustment did not occur, the woman's COM would fall to the right of her BOS (her pelvis), and she would be in danger of losing her balance. Of course, trunk lateral flexion to the left cannot occur without lateral elongation of the trunk on the opposite side. As her body weight shifts further and further, she implements additional postural adjustments to keep her COM over her BOS. These adjustments include abduction of her left arm and leg. This is one illustration of significant integration between muscles of the limbs and trunk.

Postural set is a constellation of postural adjustments that precede the performance of a specified motor activity (Layne & Spooner, 1992). If you were to stand up right now, you would "posturally set" yourself by positioning both feet on the floor in an appropriate BOS. You would establish ≤90° angles at your hips and knees, and you would free your lumbar spine by anteriorly tilting your pelvis. When standing, people automatically change the configuration of their BOS in anticipation of the direction toward which they expect to shift their body weight.

Figure 21-7 Efficient postural adjustments during self-initiated weight shift in sitting. Notice that, with weight shift to the right, the woman laterally flexes her trunk to the left and abducts her left arm and leg. These postural adjustments ensure that, even as her center of mass (COM) shifts significantly, her COM will remain safely over her base of support (BOS). Notice also that her head remains erect and her trunk is elongated on the right.

For example, if they plan to move forward, as in bowling or throwing, they will establish an anterior-posterior BOS. If they plan to shift to the left or right, as in a tennis swing, they will establish a medial-lateral BOS. In addition, when they plan to move a limb, they intuitively shift their body weight to provide the most efficient postural set. In the case of the lower limb, during gait, you shift your body weight in the opposite direction to "unweight" that side. Clearly, you cannot swing your right leg forward unless you have shifted your body weight onto the left leg.

Individuals with impairments in postural adjustments will be fearful of falling when sitting or standing without support, and, even more so, when attempting to move their limbs. They are likely to develop adaptive

strategies that may seem effective in the short run but that have long-term maladaptive influence on balance and other motor function (Carr & Shepherd, 2003). When people feel unable to maintain their balance in posturally threatening situations, one such strategy is to constrain movement at selected body parts and thus decrease the number of motor elements, or degrees of freedom, the CNS must control. Individuals with postural adjustment deficits as a result of CNS dysfunction may feel insecure about their ability to maintain balance, even in routine sitting or standing positions. The strategy of fixating one's pelvis on the lumbar spine or the scapula on the thorax has short-term benefits for enhancing the person's sense of postural security. A negative consequence is that these patterns lead to soft tissue shortening and difficulty dissociating the scapula and pelvis from adjacent proximal structures. This lack of sufficient mobility at the limb girdles subsequently limits the normal kinematics of upper and lower extremity movement. Figure 21-5 illustrates how immobility and muscle shortening interact in a self-perpetuating cycle.

The strategies of shifting weight away from a paretic leg, unnecessarily widening the BOS, or using one's hands excessively for support present further obstacles to using and improving available muscle strength and sensory processing skills. In addition, these strategies contribute to additional problems in gait and in using the upper limbs to their maximum potential. Conversely, with improvements in balance, a person has greater potential to dissociate adjacent body segments and to use his or her available motor capacity for moving the upper limb.

Match between Task Demands and the Person's Capabilities

In studies of motor control using kinematic analysis, skilled performers consistently exhibit more efficient strategies than novice performers (Schmidt & Lee, 2011). Even among individuals with healthy neuromuscular systems, when the task demands exceed one's capabilities, people demonstrate a variety of maladaptive motor behaviors. Some examples are using a postural set that is ineffective in supporting the movement sequences associated with the task, assuming a stiff posture in an ineffective attempt to reduce degrees of freedom, and recruiting muscles that are not required for performance.

People with CNS dysfunction face additional problems that make their motor success even more dependent on a good match between their current capabilities and a task's demands. Muscle spasticity is highly influenced by physical, cognitive, and emotional stress. In the face of an overly strenuous or otherwise challenging task, a patient is likely to experience an increase in hypertonicity and, possibly, pathological influences of primitive reflexes. Frustration and anxiety impede anyone's performance

during motor tasks. These factors are even more critical for people whose bodies are responding in unpredictable ways.

Chapter 12 provides critical information about the process occupational therapists use to select, grade, analyze, and adapt activities. We recommend that you review material in this chapter about the use of occupation-as-means. Pay particular attention to Procedures for Practice 12-5. Occupational therapists combine skills in activity adaptation and knowledge of kinesiology with their evaluation findings to develop individualized therapeutic tasks that are within the person's capability while providing just the right amount of challenge for meaningful practice that will lead to improvements in motor skill.

Awareness of Capabilities and Expectations of Ultimate Success

Early after a stroke or closed head injury, many survivors exhibit motor deficits that reflect widespread physiological impairment in the affected cerebral hemisphere. In addition to cell death in those neurons directly affected by the brain injury, indirect damage includes changes in cerebral blood flow, cerebral metabolism, edema, and cascading degeneration along neural pathways. This transient inhibition of neurons in a wide penumbra surrounding the site of infarct or hemorrhage is often referred to as diaschisis (Seitz et al., 1999). As diaschisis resolves over time, neural activities return to the temporarily suppressed regions, and the stroke survivor experiences return of function. Diaschisis is a probable explanation for the shift to spontaneous innervation of some flaccid muscles so often seen in the early weeks after a stroke.

One likely explanation for learned nonuse is that, when this recovery begins, the individual does not know how to detect the reemergence of movement capacity because he or she has already learned how to perform most activities unilaterally with the unaffected upper limb. Another explanation is that the person notices some isolated abilities to perform specific movements, but it is extremely difficult to use these movements for integrated functional performance. As a result, the person continues to rely exclusively on the unaffected upper limb and loses the opportunity to practice using his or her newly emerging capacities in the affected arm and hand.

Learned nonuse begins a negative spiral of events. Without active use, the paretic limbs are more vulnerable to developing secondary impairments associated with immobility, such as limited ROM and edema. Furthermore, practice opportunities with the affected limbs, which are essential to neural reorganization following brain injury, are lost if the person does not attempt to use the paretic arm or leg during functional activities. The theory of learned nonuse may explain why upper limb

recovery often lags behind recovery of function in the paretic lower limb. Whereas each attempt to stand or walk requires bilateral activity in the legs, many upper limb activities may be accomplished by using the unaffected side exclusively.

Task Analysis, Problem Solving, and Praxis Skills

In any situation that requires motor action, we automatically "size up" the task and environmental parameters before creating the motor plan that will guide the action. In addition to preplanning postural adjustments (previously discussed in this chapter), we rely on complex interactions between the visual (striate), parietal, premotor, and primary motor cortices to match our arm and hand motions to the task requirements. Praxis, or motor planning, is the ability to

- quickly analyze the motor requirements of a task
- determine the best solution to the motor "problems" that are inherent to the task

These abilities seem to be dependent on two networks, described below, with primary functions in the dominant, left hemisphere.

Neural Networks

As described by leading theorists (Jeannerod et al., 1995), the process begins in the visual cortex and continues through two parallel networks: the ventral stream and the dorsal stream. Connections within the ventral stream, between the striate cortex and specific premotor areas, enable us to accurately determine the purpose of an object. Connections within the dorsal stream, between the striate cortex and various regions within the parietal lobe, enable us to accurately determine which physical properties of the object goal are essential to formulating the specifics of a motor plan. These parameters include information about the object's size, shape, weight, texture, and location. To use a term introduced earlier in this chapter, the essential first step in motor planning is to accurately interpret the affordances of task objects for the purpose of determining the most efficient movement strategy.

Feedforward Control

It is essential to remember that this intricate analysis of task requirements occurs *before* a person makes contact with the task objects. Control of reach and grasp is anticipatory, just as is control of postural adjustments during task performance (Frey et al., 2011). Feedforward control is much like the strategic planning process used to manage organizations. Based on previous experience and accurate interpretation of current trends, the business manager

sets forth a plan of action. Corrections, based on feedback, are necessary only when errors occur. In the case of reach and grasp, visual and somatosensory information, combined with previous experience and learning, contribute to preprogramming a general plan for the motor action. In addition to postural adjustments, this general plan includes all the variables for

- determining and presetting the hand position—for pointing, swiping, pushing, or grasping the object
- positioning the shoulder, elbow, forearm, and wrist so that the hand will be oriented in precisely the right direction at precisely the right time so that, when the hand makes contact with the target object, it is in the best position to interact with the object.

Treatment for patients with apraxia, the inability to effectively use the process described above, will be presented in the interventions section of this chapter. However, *any* individual who has experienced significant loss in motor function will need opportunities to "figure out" strategies for using the affected arm and hand in a variety of task-based situations.

FRAMEWORK FOR OCCUPATIONAL THERAPY INTERVENTIONS GEARED TOWARD IMPROVING MOTOR PERFORMANCE

The framework for OT interventions to improve motor performance in clients who are recovering from brain injury is informed by a series of general principles and a core understanding of the factors (illustrated in Fig. 21-4) that contribute to optimal motor performance.

General Principles for Occupational Therapy Interventions to Improve Motor Performance

Take a moment to review the Glossary and "Fundamentals of the Teaching–Learning Process" sections in Chapter 13. We will be applying many of these concepts in our presentation of general principles related to task-based interventions, viewing the therapist as a coach, and well-established tenets of effective practice for motor learning.

Task-Based Interventions

It is a core, historical assumption of OT practice that engagement in specially designed therapeutic activities can improve motor function. As illustrated in this chapter and throughout this entire textbook, recent literature in neuroscience, movement science, and rehabilitation provides consistent support for the efficacy of task-oriented practice in promoting motor skill development and neural plasticity in humans with movement impairments caused by CNS dysfunction. Some of the

many different terms used to describe the use of activities as a therapeutic intervention to improve motor control are repetitive task training/practice (French et al., 2010), task-related training (Carr & Shepherd, 1982, 1998, 2003, 2010), activity-based therapy (Dromerick, Lum, & Hidler, 2006), task-specific training (Hubbard et al., 2009), and goal-directed training (Mastos et al., 2007).

Consistent with dynamical systems theory and ecological theory, task-based intervention capitalizes on the interrelationship between the task, environment, and the person in shaping human movement and promoting the development of new motor skills.

Definition 21-3 describes the core elements of tasks as therapeutic interventions to improve motor performance. In addition, when designing task-based intervention, the therapist appreciates the natural interdependence between balance, gross mobility, and functional limb movement. Therefore, even though we have divided our discussion of intervention into these three categories, the treatment program will strive to integrate all three types of motor demands into therapeutic tasks.

Unlike compensatory training, generalization of learning is the goal of task-based neuromotor intervention. Even though the patient practices specific tasks, the therapeutic purpose is *not* focused on fostering independence in those particular tasks. Rather, the therapeutic goal is that the patient will develop an underlying strategy (or motor program) for performing an infinite variety of tasks that require foundational skills in balance, gross mobility, and/or functional movement of a paretic limb.

Definition 21-3

Task-Based/Task-Related/Activity-Based, Goal-Directed Training

Definition of Task-Based, Goal-Directed Training and Criteria for a Therapeutic Task

"Client-selected goals are used to provide opportunities for problem solving and to indirectly drive the movements required to meet the task demands" (Mastos et al., 2007, p. 47).

Criteria for a therapeutic task:

- The task uses natural objects whose affordances are clear to the client.
- The task inherently allows for repetitive actions that vary with natural changes in the task demands.
- The task is well matched to the client's current motor abilities and therapeutic goals.
- The client fully understands parameters related to his or her own position and the placement of task-related objects.

Therapist as Coach

The patient–therapist relationship in task-related training is an active, collaborative mentorship with regard to motor performance. Just as an athletic coach is well versed in the motor strategies that are critical to success in a particular sport, therapists bring an expertise about functional movement for performance of daily tasks. Therapists must have extensive knowledge about the kinetic and kinematic features of movement, both as performed by individuals with intact neuromuscular systems and as frequently observed in people demonstrating specific motor dysfunction, such as hemiparesis or ataxia. Therapists apply this knowledge when assessing performance, setting goals, structuring practice sessions, and providing feedback and instruction. The therapist's critical goals as coach are (1) to encourage performance of the most important mechanical features within a given category of motor tasks and (2) to discourage behavioral adaptations that have limited effectiveness (Carr & Shepherd, 2003).

As coaches, therapists structure practice sessions in order to

- direct the patient's attention to features of the task that are most salient for learning
- provide appropriate instructions
- develop each patient's ability to actively analyze his or her own performance (Carr & Shepherd, 2003).

Focusing Attention. An early step in the process of learning a motor skill is to identify the key components of the action. In other words, early learning of a motor skill requires explicit instruction to establish key parameters that will be critical for successful performance. At this stage, demonstration and instructions, which focus on one or two salient points, are important in directing the patient's efforts. Learning proceeds most smoothly when the patient has a clear idea of the motor goal and which strategies are appropriate or inappropriate for reaching that goal. Carr and Shepherd (2003) recommend that therapists routinely ask patients to describe or demonstrate, with another body segment if necessary, the specific movements required to achieve a task. This allows therapists to understand what patients think they are being asked to do. Instructions can then be modified to ensure that both patient and therapist are actually working toward the same goal.

Once an individual has internalized this "model" of an action, the next goal is to develop skill and efficiency in coordinating actions to perform the action in a smooth, efficient manner. This implicit learning is dependent on continued task practice, with increasing demands on speed, strength, and coordination. At this stage, it may be detrimental to focus a patient's attention on the details of performance (Fasoli et al., 2002). Instead, the therapist structures control parameters within the task objects to shape the intended kinematics of a movement sequence.

Instructions and Feedback. Instruction is important when the therapist's goal is to promote explicit learning. With oral instruction, words should be kept to a minimum. The therapist identifies the most important aspect of the movement and presents directions in terms of an object goal. Visual demonstration can be provided through the therapist's own performance of the task, with a focus on one or two components that are most essential to the motor strategy. Pictures and photographs are particularly helpful in clarifying procedures for "homework practice" to be completed outside of therapy sessions. Physical "handling" can also be valuable at times to convey information about postural alignment or a desired movement trajectory. This manual interaction by the therapist can help to clarify the model of action by passively guiding the patient through the path of movement or by physically constraining inappropriate components. For example, during attempts at task-related forward reach, the therapist may provide passive movement to the scapula, with simultaneous cues over the acromium for the patient to limit elevation of the entire shoulder girdle. When a patient attempts to sit down, the therapist's manual guidance behind the shoulders reinforces the concept that the individual must move the upper body forward to achieve the necessary hip and knee flexion for smooth controlled descent.

Feedback, or information about a response, can be intrinsic or extrinsic, concurrent or terminal, and can provide knowledge of performance (KP) or knowledge of results (KR). Intrinsic feedback is a result of an individual's own proprioceptive, tactile, vestibular, visual, and auditory sensory systems. Often after a stroke, somatosensory function is impaired, which limits the effectiveness of intrinsic feedback about motor performance. Extrinsic feedback from a therapist or feedback technology can provide useful supplementary information to facilitate early awareness and learning. However, the goal is for patients to return to providing their own intrinsic feedback so they can continually perfect their motor performance. Therefore, in therapy sessions, extrinsic feedback is gradually decreased, and patients are encouraged to use their own internal sensations to guide their movement.

Concurrent feedback is provided during task performance. It includes intrinsic somatosensory feedback and ongoing verbal or manual guidance by a therapist. Terminal, or summary, feedback is given after task completion. There are no published studies that compare the effectiveness of concurrent and terminal feedback, but research has established that excessive external concurrent feedback is distracting to the learner and may prevent the patient from learning to rely on his or her own internal, concurrent feedback (Schmidt & Lee, 2011).

KP feedback is information about the processes used during task performance, such as the way a person moves the pelvis or scapula. Individuals with intact proprioceptive systems receive concurrent, intrinsic KP feedback as they move. Survivors of stroke or brain injury, however, may no longer have access to this continuous supply of information. Therapists provide extrinsic KP feedback when they call a patient's attention to specific aspects of his or her postural alignment or key features of a movement trajectory. Research findings about the value of extrinsic KP feedback in stroke rehabilitation are mixed. The results of some studies indicate that a focus on internal performance factors may be counterproductive to learning (Fasoli et al., 2002). On the other hand, a randomized controlled trial of 28 chronic stroke survivors found that KP feedback was more effective than KR feedback in improving the kinematics of arm movement (Cirstea & Levin, 2007).

KR feedback is feedback about the outcome of an action. Results of laboratory research with healthy subjects indicates that frequent, accurate, immediate KR tends to promote improved performance during early learning but results in poorer retention and generalization of the learning (Schmidt & Lee, 2011). Therefore, when using technologies that provide consistent and immediate KR feedback, such as robotics, or electromyograph-triggered neuromuscular stimulation (EMG-TMS), therapists are advised to gradually "wean" patients from depending on this extrinsic feedback and help patients develop their own intrinsic feedback mechanisms.

Helping Patients Develop Skills in Analyzing Their Own Performance. Because the goal is to help patients learn to monitor their movement through intrinsic feedback, from the beginning, they must be active participants in analyzing their own performance. This practice allows therapists to see how well each person understands the salient features of the current therapeutic task. Furthermore, this process of self-analysis encourages individuals to develop insight about their own motor abilities, develop problem-solving skills, and understand the goals of the treatment program.

The Nature of Practice

Practice is a critical component to motor skill learning. Chapter 13 presents findings from several studies about practice conditions that are relevant to OT intervention. The following principles about practice are particularly important when designing therapy to improve motor skill in persons recovering from stroke or brain injury:

- Random (or variable) practice schedules lead to better generalization of learning than blocked practice schedules. Therefore, therapists structure practice tasks that require mild variations in movement patterns during successive repetitions.
- People learn what they practice. Therefore, patients must clearly understand instructions about the key kinematic components of general movement strategies they will be practicing during and outside of therapy sessions.

- Greater amounts of practice are important to skill learning and generalization. Because therapy sessions do not provide sufficient opportunities for patients to practice developing new motor skills, therapists help patients develop routines for practicing new skills on their own or with family members. It is human nature to practice more when we know that someone will hold us accountable. Therefore, patients should be responsible for keeping "homework logs" and reporting their progress to the therapist at the beginning of each session.
- Practice of specific movements leads only to improvements in motor execution but not in functional performance. Therefore, the goal of therapeutic practice is that patients learn general strategies for solving motor problems.

Self-care and leisure activities provide logical opportunities for task-based practice. Too often, occupational therapists prescribe universal methods for ADL that contradict our goals for optimum motor performance. Unless balance and limb function are routinely challenged during daily activity performance, there are no environmental challenges to stimulate brain plasticity. Unless patients have opportunities for routine practice of motor skills required for balance, mobility, and functional use of their affected limbs, time spent during therapy sessions will have little effect. *Therefore, the occupational therapist must design safe, individualized methods for each patient that continually include that person's emerging capacities into daily self-care and leisure performance.*

Interventions are Informed by the Multiple Factors that Contribute to Optimal Motor Performance

Earlier in this chapter, we presented multiple factors that contribute to optimal motor performance. These are summarized in Figure 21-4. Occupational therapists consider the effect of each of these factors on a person's ability to maintain balance during task performance, to perform gross functional movements, and to use the arm and hand. Overall, the sequence of intervention is as follows:

- Analyze a person's motor performance to determine key limiting factors that are amenable to change through therapeutic intervention.
- Prevent or reduce these key limiting factors through direct intervention and client education.
- Design activities for use as therapeutic challenges that promote development of effective movement strategies.
- Adapt the physical environment to promote maximal function.
- Assist clients in developing strategies for approaching and mastering the motor challenges of new activities they may wish to perform in the future.

Intervention to Improve Postural Alignment and Balance

Neuromotor intervention typically begins with assessment and treatment to improve alignment and balance in sitting and standing. There are two major reasons for this:

1. Some patients will never develop functional arm and hand use on the paretic side, but they can still be independent if they can develop adequate balance and gross mobility.
2. A person's abilities in gross functional mobility and use of a paretic arm and hand are highly influenced by his or her foundational balance. In other words, sitting and standing balance serve as a critical foundation for the development of other functional motor skills.

Intervention to Improve Sitting Balance

To assist patients in improving sitting balance, the occupational therapist ensures that each person achieves optimal alignment for seated task performance, develops a kinesthetic understanding of alignment and postural adjustments, and has ample opportunity for implicit learning through task-based challenges that require the person to actively shift his or her COM.

Optimal Alignment for Seated Task Performance. Earlier in this chapter, we described positions of optimal alignment in sitting, as well as common problems exhibited by patients with neuromotor impairments. One critical step in a balance intervention is to help the person develop kinesthetic awareness of efficient alignment between body segments. First, however, the therapist determines which mechanical constraints are influencing a person's posture. This assessment takes place on a surface where the trunk is unsupported, such as sitting over the side of the patient's bed or on a therapy mat (short sitting). If the person demonstrates soft tissue stiffness, leading to difficulty dissociating the thorax and the lumbar spine, the scapula and the thorax, or the lumbar spine and pelvis, then the therapist provides passive stretch before asking for active engagement in balance activities.

If, however, the "cause" for limited dissociation between body segments can be attributed to the person's postural insecurity, then the intervention will focus on providing additional external support—usually through physical "handling" by the therapist.

Gillen (2011) provides an excellent description of the "seated position of readiness for function." The pelvis is in neutral to anterior tilt, with equal weight bearing on both ischial tuberosities. The trunk is extended and in a midline orientation. Shoulders are symmetrical

and positioned anterior to the hips. Hips and knees are flexed and neutrally rotated. Both feet are flat on the floor, and each foot is ready to accept body weight as the trunk moves forward.

Developing Kinesthetic Awareness. To help patients develop kinesthetic awareness of the model for optimal sitting alignment, we precede each therapeutic task with a request to the person to assume this "position of function." If the patient assumes a position in which specific elements are less than optimal, the therapist, as coach, points out these errors in alignment and challenges the person to actively correct his or her posture. Patients must also develop kinesthetic awareness of postural adjustments that accompany active shifts in their COM during activity performance. To achieve this, they must have opportunities to participate in graded, task-based challenges.

Introducing Task-Based Challenges that Involve Active Shifts in Center of Mass. Balance is the process of maintaining one's COM over the BOS. Postural adjustments involve strategic changes in alignment that will minimize changes in COM when we shift body weight in a variety of planes and directions. During functional performance, task demands may require us to move

- forward and backward (sagittal plane)
- to the left and to the right (coronal plane)
- by rotating our trunk to the left or right (transverse plane)
- in any combination of the three cardinal planes listed above (e.g., forward motion to the left) and in any combination of the cardinal planes plus the upward or downward direction

Each direction of weight shift is accompanied by its own associated postural adjustments. For example, when shifting weight forward while sitting, the hips flex, the pelvis anteriorly tilts, and the trunk extends at the lumbar, thoracic, and cervical spine. (see Fig. 21-6). Conversely, when shifting weight backward, the pelvis posteriorly tilts and the trunk flexes. When shifting weight to the right side (as illustrated in Fig. 21-7), the pelvis tilts to the right, and the left side of the pelvis lifts off of the sitting surface. The right hip externally rotates and the left hip internally rotates. The trunk laterally flexes to the right and, concomitantly, extends on the left. This lateral flexion (or concavity) may be described as "trunk shortening on the left" and the accompanying lateral extension (convexity) as "trunk lengthening on the right" (Bobath, 1990; Davies, 2000).

Research evidence shows that stroke survivors develop sitting balance in the context of task performance (Dean, Channon, & Hall, 2007; Dean & Shepherd, 1997; Shumway-Cook & Woollacott, 2012). The therapist structures activities that require the patient to shift weight in a variety of directions. These include the following:

- Looking in a variety of directions (e.g., up at the ceiling, behind oneself).
- Reaching for and moving objects that are strategically positioned (e.g., in front, to the left, and lower than the arm position in a typical seated posture to a variety of other predetermined locations). The upper limb diagonal patterns described in the PNF approach provide therapists with a helpful model for structuring activities that provide postural challenges through an infinite combination of planes and directions of movement.
- Simulated and natural performance of self-care activities, such as dressing, bathing, and grooming, with graded changes in placement of goal objects and degree of postural support.

Early in the process, the therapist may provide tactile/proprioceptive cues that provide the "model of the action" of the motor program for each associated postural adjustment. Figure 21-8 illustrates a therapist providing somatosensory cues for a patient to "shorten" his trunk on the contralateral side and "elongate" his trunk on the ipsilateral side during lateral weight shift (Davies, 2000).

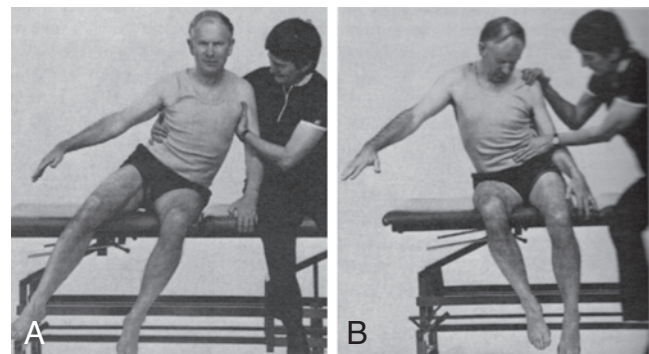
Strengthening of postural muscles occurs within the context of self-initiated shifts in body COM. For example, tasks involving posterior weight shift provide strengthening "exercise" to the rectus abdominis. Tasks involving trunk movement through multiple planes provide strengthening exercise to virtually every abdominal and extensor muscle of the thoracic and lumbar spine (Gillen, 2011).


Figure 21-8 Therapist providing cues about appropriate postural adjustments during weight shift in sitting. **A.** The patient is shifting weight to his left (paretic) side as the therapist promotes trunk elongation/lateral extension on the left and lateral flexion on the right. Note that the patient appropriately abducts his unaffected right arm and leg as an automatic postural adjustment to maintain his center of mass (COM) over his base of support. Note also that the therapist is positioning his left arm to allow for some weight bearing onto his left hand as the patient shifts his weight to the left. **B.** The patient is shifting weight to his right side as the therapist promotes trunk lateral flexion on his left (paretic). (Used with permission from Davies, P. M. [2000]. *Steps to follow: The comprehensive treatment of patients with hemiplegia* [2nd ed., p. 168]. Berlin: Springer-Verlag.)

Standing Balance

There are key similarities and differences between standing balance and sitting balance.

The Goal Is to Maintain the Body's Center of Mass over Its Base of Support as We Shift Body Weight in a Variety of Directions. A key difference between standing and sitting is that, when standing, one's feet are the BOS. Although, this creates an inherently smaller foundation than the pelvis and thighs (in sitting), we have the capacity to rearrange our foot position to suit the balance demands of a particular activity. As discussed earlier in this chapter, we make quick, anticipatory judgments about how the COM will shift during task performance. If we plan to move our body weight forward or backward, we increase the anterior-posterior BOS by positioning one foot in front of the other. If we plan to move our body weight to either side, we increase the medial-lateral BOS by positioning our feet side by side. If we plan to move our body weight in a diagonal direction, we have an infinite number of options for arranging the BOS.

Another significant difference is that, in standing, the COM is further displaced superiorly from the BOS. In addition to increasing the complexity of balance adjustments in standing, this factor contributes to postural sway, the continuous displacement and correction of the COM within the BOS. In actuality, there is no such thing as static standing balance, because when standing, a person constantly "sways" over the BOS. When the postural set is anterior-posterior, we sway in a lateral-medial direction. When the postural set is medial-lateral, we sway in an anterior-posterior direction. Of course, the smaller the BOS, the greater the ongoing postural sway will be.

Optimal Alignment Contributes Significantly to Efficient Balance. Functional standing balance requires the ability to shift weight from one leg onto the other. In patients with hemiparesis caused by stroke or brain injury, an early goal is to establish bilateral weight bearing on both the left and right legs. Patients need to learn how to recognize when they are, in fact, supporting weight over their paretic leg. Key factors in postural alignment during bilateral weight bearing will be symmetrical posture at the pelvis, hips, trunk, shoulders, and head.

The next goal is for the patient to be able to shift weight onto the paretic leg—so the other leg will be free to move. However, it is not sufficient to merely be able to support body weight through the affected leg. In addition, the person must be able to quickly "unweight" that leg in order to swing it forward for functional gait. One common maladaptive strategy after stroke or brain injury is to assume a weight-bearing posture that makes the leg into a "rigid pillar" (Davies, 2000). The hallmark of this posture

is hyperextension (locking) at the knee often accompanied by pelvic retraction and ankle plantar flexion.

Optimal alignment of a weight-bearing leg is characterized by

- at least 90° of ankle dorsiflexion—so the foot is flat on an even surface
- relaxed, active extension at the knee (with no locking)
- active hip extension
- neutral position of the pelvis

In addition, if weight is shifted onto the left leg

- the pelvis will be laterally tilted to the left
- the trunk should be laterally flexed to the right and elongated on the left

Sensory Awareness Is Critical to Effective Balance Adjustments. In addition to the kinesthetic awareness of postural alignment discussed earlier with regard to sitting balance, considerable research has established that a triad of sensory systems is necessary for adequate standing balance. Complex and dynamic interrelationships between somatosensory, vestibular, and visual processing ensure that we will be able to maintain standing balance in a variety of sensory conditions. For example, when walking in a dark environment, people rely more on kinesthetic cues from muscles and joints, tactile cues from the floor surface on our feet, and vestibular cues (Shumway-Cook & Woollacott, 2012). In stroke survivors, somatosensory cues from the paretic leg and arm may be disrupted. Therapeutic goals are to (1) enhance somatosensory awareness by introducing many opportunities to experience weight bearing on the affected leg (Davies, 2000) and/or (2) to promote enhanced vestibular functioning by providing task-based challenges in which vision and somatosensory cues are reduced (Bayouk, Boucher, & Leroux, 2006).

Postural Adjustments and Strength in Key Postural Muscles Are Developed through Task-Based Challenges. Extensive research supports the use of task-related training to develop muscle strength and postural adjustments needed for standing balance and gait (see, for example, Grabiner et al., 2012 and Sullivan et al., 2007). Lower limb muscles are exercised as the patient supports and shifts body weight during task performance (Carr & Shepherd, 2003). Initially, the focus may be similar to the therapeutic strategy described earlier to improve sitting balance. The therapist designs tasks that require reach, grasp, and placement of objects while the patient is standing. Later, when the goal is to provide opportunities to use the paretic limb exclusively for body weight support, the therapist selects tasks that inherently require active movement of the other leg, such as stepping forward, stepping onto a bathroom scale, or knocking down objects (such as toy bowling pins) with the unaffected foot. Choreographed

dance routines that involve kicking or swinging one leg at a time also provide varied, repetitive, activity-based practice in bearing weight and then taking weight off of the paretic lower limb. As the patient gains balance control, task objects are strategically positioned so that the patient is required to actively move from place to place to complete the task. Dynamic tasks, such as ball or balloon toss games or virtual reality games, present additional challenges to standing balance (see Fig. 11-5). Familiar homemaking tasks, such as loading/unloading a dishwasher, picking up clothes from the floor, and placing them in a laundry basket are natural therapeutic activities to improve standing balance. Dolechek and Schkade (1999) found that this type of intervention was more effective in improving dynamic standing endurance than an exercise-based program that did not include meaningful tasks. In a motion analysis study, Lin et al. (2007) found that the presence of a task object in a standing reaching task contributed to factors that decrease postural sway in standing.

Functional Mobility

Functional mobility training includes task-specific interventions that enable patients to move efficiently in bed, to rise from supine to a sitting position, to move about within the sitting position through "scooting," to stand up and sit down, and to perform daily activities while standing and walking. Other authors have presented detailed analyses of the kinematics and kinetics of functional mobility tasks, as well as instructive photographs to guide therapists in assisting patients in their initial learning (Davies, 2000; Kane & Buckley, 2011). Like balance, efficient functional mobility inherently requires optimal postural alignment and dissociation between body segments. Like balance interventions, task training in functional mobility tasks provides the opportunity to strengthen core muscles and improve postural adjustments. During the rehabilitation process, therapeutic interventions to improve functional mobility and balance are rarely separated.

Moving in Bed

In the acute phase of recovery after a stroke or brain injury, patients find themselves in a body with unfamiliar sensations and an inability to control many movements. Early goals for the patient include learning to access the nurse call buzzer and learning to assist caregivers in adjusting the position in bed.

In crook lying, a person is supine with both legs flexed at the hips and knees and both feet flat on the supporting surface. From this starting position, bridging is the act of pushing weight through one's feet and lifting the buttocks off of the bed or mat. Bridging is an important component to moving vertically in bed. In addition, the task of bridging gives patients the opportunity to discover what it means to move the pelvis in isolation of the lumbar spine and to experiment with alternating between anterior and posterior pelvic tilt. This learning serves as a precursor to developing a model for optimal alignment in sitting and standing.

Rolling in bed, toward either the affected or unaffected side, requires dissociations between adjacent body segments: the scapula and thorax, the thorax and the lumbar spine, and the lumbar spine and pelvis. When rolling toward the unaffected side, the patient learns to capitalize on any available motor control in the paretic arm. He or she can also use the unaffected arm to assist, as needed.

Multiple studies have examined the kinematics of sitting up from supine, and the ultimate finding is that people choose from a variety of effective strategies (Carr & Shepherd, 2003). All the strategies involve some level of weight bearing and "push off" over one arm. When patients show potential to use the paretic arm for this function, therapists structure the activity to incorporate this challenge into the task training. To promote the best retention and generalization, training should be varied. Opportunities to practice short sitting can be alternated with opportunities to practice rising from supine to long sitting (knees extended, with feet remaining on the supporting surface). The task is easier when the ultimate short sitting position provides support to the feet (i.e., feet on the floor when sitting on a chair or chair-height therapy mat) but should also be practiced on higher surfaces when the feet will be unsupported. Finally, practice is also required to move from sitting to supine. Task demands shift to requiring concentric and eccentric contractions from different groups of muscles when the goal is to slowly lower oneself onto the bed.

Moving in the Seated Position

In our earlier discussion of interventions to improve balance, we presented concepts and strategies for helping patients improve their ability to perform activities in the seated position. One key concept is that the trunk elongates on the side toward which weight is shifted and shortens on the other side. This is an equilibrium adjustment that keeps the body's COM over the BOS. Often, we shift our weight so far laterally that the opposite ischium completely rises off of the supporting surface. This is necessary when we wish to smooth our clothing or, more importantly, when we readjust our seated BOS.

In "scooting," a seated person repositions his or her buttocks—forward, backward, or to the side. He or she achieves this by shifting all of his or her body weight over the left ischium in order to freely move the right ischium in the desired direction. This is followed by a reverse shift of

body weight to the right ischium in order to move the left ischium in the desired direction. This process is repeated until the person has repositioned his or her BOS—either at the front edge of the seating surface in preparation for standing or back into the chair as the final step in sitting down. Scooting is a valuable motor skill. In addition to its importance in safely standing up and sitting down, practice in scooting provides patients with opportunities to experiment with producing pelvic movements that are independent of movement at the lumbar spine. At the same time, patients develop a motor program for the postural adjustments that accompany extreme shifts in COM. Finally, through scooting, patients implicitly learn that active movement can only be achieved when a body segment is "unweighted." This is an important precursor to functional balance in sitting and standing. Scooting practice can be incorporated creatively into games and activities on a therapy mat. The therapist places a goal object in various places on the mat, and the patient is challenged to scoot so that his or her buttocks make contact with the object. This intervention provides infinite opportunities to vary the direction of each weight shift and simultaneously affords varied challenges to balance in both the short and long sitting positions.

Standing Up and Sitting Down

Rising to a standing position, and its counterpart, sitting down safely and efficiently, are critical to performance of daily tasks. Although each must be trained separately, the components of "sit to stand" and "stand to sit" are similar enough that the abbreviation "STS" is often used to refer to both. Successful performance of STS requires the integration of

- adequate mobility at the pelvis and hips
- kinesthetic awareness of postural alignment
- automatic postural adjustments during weight shift
- sufficient strength in muscles of the lower limbs and trunk
- a motor program that guides the action.

Direct training in STS is an important component of any stroke rehabilitation program. Research shows that this intervention is effective in improving actual performance (Canning et al., 2003; Janssen et al., 2010). In addition, a systematic STS training program contributes significantly to improvements in dynamic balance, postural alignment in standing, and strength in extensor muscles of the paretic limb (Tung et al., 2010).

It is important to note that STS training is *different* from stand-pivot transfer training. The stand-pivot transfer is a compensatory approach for assisting a person into and out of a wheelchair. For individuals who have the motor potential to stand and walk, learning how to stand up and sit down has greater functional implications

and is more natural to learn than stand-pivot transfer techniques.

Successful performance of sit to stand relies on effective postural set. The body must be symmetrically aligned, with a BOS that is ready to accept weight through both legs, and the body's COM must lie directly within the BOS. Sit-to-stand training, then, is inherently related to activities (described previously) that require the person to maintain balanced sitting while shifting weight forward and in a variety of other directions. Practice moving one's buttocks in the seated position will enable a person to perform the first step of sit to stand, which is to scoot to the edge of the support surface.

A key goal for patients with hemiparesis is to perform STS with symmetrical posture through the neck, trunk, and lower limbs. This is critical because future progress related to standing balance and walking is dependent on appropriate alignment, ability to shift body weight onto and off of the paretic leg, and efficient balance adjustments. Research comparing individuals with hemiparesis after a stroke to healthy individuals has confirmed that, in addition to presenting greater asymmetry in weight bearing, stroke survivors fail to perceive that they are asymmetrically aligned (Briere et al., 2010). Therefore, it is important to provide patients with opportunities to analyze their own performance. Before standing, the therapist asks, "Are you sitting straight? Is your weight evenly distributed over both hips?" Some individuals respond well to viewing their own performance on videotape and critiquing elements that the therapist delineates for them. After this self-analysis, the person tries again, with greater awareness about specific components that will improve the efficiency and safety of future performance.

A number of biomechanical studies (reviewed in Shumway-Cook and Woollacott [2012] and in Kane and Buckley [2011]) have described the kinematics and kinetics of STS. See Procedures for Practice 21-3 for the general sequence of sit to stand and stand to sit. Many healthy older people use a strategy of pushing down with their arms to assist in standing up and sitting down. Although this strategy may be useful as a compensatory technique to reduce force requirements at the hip, knee, and ankle, there are two major drawbacks for patients recovering from stroke or brain injury:

- Extending the arm at the elbow and shoulder girdle provides a "model of action" that contradicts the essential motor strategy of moving the entire upper body in an anterior direction. In the early phase of rising to stand, reaching backward with one's arm makes it more difficult to anteriorly tilt the pelvis and flex the hips and knees. These same movements are necessary during the later stage of controlling one's descent into the chair when sitting down. Therefore, reaching backward with one's arm may contribute to an inefficient

Procedures for Practice 21-3

Procedures for Improving Performance of Sit to Stand and Stand to Sit (STS)

Sit to Stand: The Sequence

1. Scoot forward on the seated surface and establish a position of "readiness to stand" (hip, knee, and ankle <90°, pelvis neutral in all planes, trunk extended and symmetrical).
2. Bring center of mass (COM) over base of support (BOS) by anteriorly tilting pelvis and flexing hips, while keeping the trunk and neck extended and symmetrical. This also establishes momentum that will assist with step 3. Mnemonic for patients: "Nose over toes."
3. Transfer momentum from the upper body and raise buttocks off the seated surface onto both legs.
4. Rise to the upright position by extending (but not locking) the hips and knees.
5. Adjust standing posture to meet environmental/task demands.

Stand to Sit: The Sequence

1. Position body directly in front of the seating surface ("feel" the seat behind both legs).

2. "Fold" body onto the chair (anterior pelvic tilt, hip and knee flexion, ankle dorsiflexion, while keeping trunk and neck extended and symmetrical). Eccentrically contract leg extensors to control the downward pull of gravity.
3. After upper thighs are resting on the seating surface, "scoot" to assume a position of "readiness for function" in seated activities.

Possible Environmental Modifications

- Raise seat to decrease lower limb force requirements (while still providing a stable surface for the feet).
- Grade seat to lower heights as strength in leg extensors improves.
- Use chair without arms if patient shows too much reliance on using hands for push-off.
- Select chair that allows for placing the feet back (knee and ankle <90°).

---

tendency to extend at the hips and "plop" onto the sitting surface.

- A patient with upper limb paresis will use only the unaffected arm as a support. This will, inherently, create an asymmetrical posture. As we have discussed previously, an asymmetrical posture during STS will change the mechanics of the movement sequence and prevent the opportunity to regain any kinesthetic awareness and motor performance in the paretic leg.

Although sitting down from standing has several similarities to standing up, it is a different activity that must be practiced as well. No momentum to reduce force requirements is present, so additional muscle strength (particularly in knee extensors) is needed just before the body mass is lowered onto the seat. Carr and Shepherd (2003) recommend that, when learning STS, patients should be instructed to stop the movement midway and reverse their directions for a few degrees. This will help them develop control over changing from concentric to eccentric muscle activity.

Functional Ambulation

Walking, a critical component of daily task engagement, is a reasonable expectation for many individuals with CNS dysfunction. Occupational therapists work with patients who wish to improve their performance in kitchen and bathroom activities, and in leisure or work pursuits.

In each of these contexts, the occupational therapist must help patients reach their optimal walking potential.

The Gait Cycle. Research on individuals with no neuromuscular or musculoskeletal impairments has revealed remarkable consistency among people in the kinematic aspects of gait. Patterns of muscle use, however, vary widely. The kinetics of gait vary between subjects and within a single subject, depending on walking speed and fatigue. Furthermore, a natural redundancy in the motor system for walking allows for compensation by stronger muscles when specific muscles are weak.

Walking forward in a uniform direction is achieved through repetitive performance of sequential gait cycles. Each cycle begins when the heel of one foot makes contact with the ground. As that leg supports the body weight, it rocks forward until its only ground contact is at the toes. Simultaneously, the other leg swings forward until its heel makes contact with the ground. Double support is the brief period when both feet are on the ground. Immediately after double support, the first leg swings forward while the second leg supports the body weight. One gait cycle is completed when the heel of the first foot touches the ground once again. For purposes of description, the gait cycle for each leg is divided into a stance phase, which comprises approximately 60% of the gait cycle, and a swing phase. Definition 21-4 shows the subdivision of these phases of the gait cycle, and Figure 21-9 provides an illustration.

Phases of the Gait Cycle, Using the Right Leg as a Reference

Stance phase—The right foot is on the ground, supporting body weight (60% of one gait cycle).

- Heel contact
- Foot flat
- Midstance
- Heel off
- Toe off

Swing phase–The right foot is in the air and is advancing forward toward its next contact with the ground.

- Early swing
- Midswing
- Late swing

From Neumann, D. A. (2010). *Kinesiology of the musculoskeletal system: Foundations for rehabilitation* (2nd ed.). St. Louis: Mosby, Elsevier.

Physical therapists provide evaluation and intervention to prevent and reduce gait deviations that are commonly seen in patients with hemiparesis. A variety of ankle–foot orthoses (AFOs) may be prescribed to compensate for weakness in ankle dorsiflexors and foot evertor muscles. Neuroprosthetic devices (e.g., Ness L-300®, marketed by Bioness, Inc.) provide electrical stimulation to the tibialis anterior during gait to ensure appropriate heel strike and foot clearance during the swing phase. Research has found that the use of neuroprosthetic devices during gait has significant short-term and long-term influence on gait performance (Ring et al., 2009) as well as social participation (Laufer, Hausdorff, & Ring, 2009). Gains continue to be enhanced over time, and improvements in balance and gait velocity are apparent even when participants are no longer using the device (Laufer et al., 2009).

Occupational Therapy Contributions to Preventing and Reducing Gait Deviations. In collaboration with our physical therapy colleagues, occupational therapists contribute to the process of maximizing efficient gait patterns. Using activity-based interventions described in previous sections of this chapter about postural alignment and balance, we

- promote active ankle dorsiflexion in a closed kinematic chain through activities in sitting and standing that require the tibia to move forward over a weight-bearing foot
- promote stability mechanisms in pelvic muscles through activities in sitting and standing that require weight shift in a variety of directions
- promote appropriate postural adjustments during weight shift in standing
Figure 21-9 Subdivisions of the gait cycle, illustrating the stance and swing phases and periods of single-limb and double-limb support. (Used with permission from Neumann, D. A. [2010]. *Kinesiology of the musculoskeletal system: Foundations for rehabilitation.* St. Louis: Mosby, Elsevier.)

- promote a balance between stability and mobility at the pelvis, hip, knee, and ankle through standing activities that require the person to reciprocally shift body weight onto and off of the paretic leg.

Functional Ambulation. Occupational therapists contribute to maximizing walking skill during interventions that require the simultaneous performance of walking with tasks involving use of the upper limbs. This integration is inherent in naturalistic activities within home, work, and leisure environments. Think of all the things we do while walking! We *push* shopping carts and strollers. We *carry* objects, with one or both hands, positioned close to or far away from the body. We *reach* for objects at a variety of heights, while cleaning our homes or shopping. For those individuals who rely on the use of a cane, the challenge includes being able to negotiate the intermittent need to stand without any external support while using one or both upper limbs. Therapists determine interventions for functional ambulation based on our clients' identification of their daily tasks, as well as creative integration of our knowledge of activity requirements with each client's current level of motor function.

Functional Use of the Arm and Hand

Recovery of arm and hand function after stroke or brain injury is a complex and varied process. Many patients struggle to regain the capacity to generate basic contraction of muscles in the upper limb. Others are constrained by inefficient, stereotypical movement patterns that make it virtually impossible to use the arm and hand for functional task performance. Many stroke survivors remain unaware of their actual capacity to move their arm and hand. Finally, some individuals demonstrate potential to perform reach and grasp activities, but their movements are slow and clumsy and they do not get the practice they need to improve their performance because they rarely use the affected upper limb when participating in daily tasks.

Every patient has a different constellation of abilities, interests, and functional goals. Even so, intervention to improve upper limb function is always integrated with therapy to enhance postural alignment, balance, and functional mobility. In this section, we will present intervention strategies to

- prevent/reduce mechanical constraints to functional use of the arm and hand
- promote the capacity to generate contractions of specific muscles in a paralyzed arm
- prevent learned nonuse
- provide opportunities for patients to practice using their available function by matching task demands to the person's current capabilities

- develop effective motor programs for reach and grasp
- help patients develop task-analysis and problem-solving skills so they can continue to use their arm and hand in a variety of new situations, after they have completed their participation in OT rehabilitation.

Interventions to Prevent/Reduce Mechanical Constraints to Upper Limb Function

Four factors may impose mechanical constraints to upper limb function: problems with pelvic and trunk alignment and mobility, spasticity, problems with scapular alignment, and scapular immobility.

Pelvic/Trunk Alignment and Mobility. A study of 59 healthy adults showed that performance on the Jebsen Taylor Hand Function Test is significantly affected by trunk posture (Gillen et al., 2007). Specifically, speed for completing selected tasks was significantly slower when participants assumed positions of thoracic flexion (kyphotic posture) and lumbar lateral flexion (accompanied by asymmetrical pelvic alignment). This is because changes in pelvic, lumbar, and thoracic alignment have a direct effect on the resting posture of the scapulae. In turn, the relative position of the scapula within the thorax affects its stability, mobility, and the orientation of scapulohumeral muscles (Davies, 1990). Therefore, it is important for stroke and brain injury survivors to develop a core understanding of optimal postural alignment and to assume an efficient postural set before attempting to perform challenging tasks with the paretic upper limb. For activities in sitting, there are several ways to structure the environment to foster optimal proximal alignment. One example is to seat the patient on a solid support surface at a height that allows the feet to be positioned securely on the floor. Other examples (listed in Resources 21-1) are the Nada chair, the Dyna disc, and therapy wedges, which are available in a variety of shapes and sizes. Figure 21-10 illustrates the effect of pelvic position on a person's ability to perform active shoulder flexion.

Spasticity. Spasticity, a common primary motor impairment associated with brain injury, is a state of heightened tone in selected muscles. Because spastic muscles are highly resistant to quick, passive stretch, spasticity creates a significant obstacle to joint mobility, dissociation between adjacent segments, and production of active movement by antagonist muscles. Spasticity typically affects superficial, multijoint muscles in a distinct pattern for the paretic upper and lower limb. Upper limb spasticity is commonly associated with hypertonicity in

- middle trapezius and rhomboid muscles (scapula retractors)
- pectoralis major (glenohumeral adductor and internal rotator)

Figure 21-10 Impact of pelvic position on shoulder range of motion. **A.** The patient's pelvis is in a position of posterior tilt, which limits range of motion in shoulder flexion. **B.** With assistance from Dyna disc (see Resources 21-1), the patient aligns his pelvis into a position of anterior tilt, which enables him to increase range of motion in shoulder flexion.

provided in the form of slow, prolonged stretch to spastic muscles. Therapists use slow prolonged stretch to

- temporarily reduce tension in spastic muscles to make it easier for the person to move
- reduce muscle stiffness to prevent long-term limitations in ROM.

A recent systematic review reports that slow, prolonged stretch has a small immediate effect but no short-term or long-term effects on joint mobility (Katalinic, Harvey, & Herbert, 2011). However, two reports of preventive positioning protocols for the shoulder have generated more positive findings. Ada et al. (2005) found that positioning the shoulder in maximum external rotation reduced limitations in ROM for external rotation in acute stroke survivors. deJong, Nieuwboer, and Aufdemkampe (2006) found that limitations in shoulder abduction were minimized through the use of a similar positioning protocol.

Slow, prolonged stretch can be provided by the therapist or caregiver, by the patient, or through static positioning. When applying slow stretch, the patient must assume a posture in which the pelvis, trunk, and scapula are optimally aligned. Our experience is that slow prolonged stretch is most effective when provided simultaneously over multiple joints: protraction at the scapula, external rotation (and, if possible, abduction) at the glenohumeral joint, extension at the elbow and wrist, and supination at the forearm. Patients can learn to hold this posture immediately before beginning therapeutic activities and when

- biceps brachii (elbow flexor)
- pronator teres (forearm pronator)
- flexor digitorum superficialis and profundus (wrist and finger flexors).

A number of pharmacological interventions are available to reduce spasticity. Occupational therapists must be familiar with side effects of all medications each patient is currently taking and alert the physician if a patient is exhibiting unusual levels of drowsiness or fatigue.

Because the myotatic stretch reflex is velocity dependent, spastic muscles are only hyperresponsive to quick, rather than slow, sustained stretch (Bear, Connors, & Paradiso, 2007). Therefore, intervention to prevent muscle "overshortening" and subsequent joint contractures can be

resting or watching television. Engagement in yoga may also be effective in reducing abnormal muscle tension and maintaining pain-free joint mobility (Garrett, Immink, & Hillier, 2011).

Many patients with spasticity report that they experience an increase in muscle tension when they engage in activities that elicit high degrees of physical, emotional, or cognitive stress. They can learn to control this excessive tone by implementing their own slow, prolonged stretch to the spastic muscles at these times. Generalized relaxation strategies, such as deep breathing, mental imagery, and meditation may also be effective.

Scapular and Glenohumeral Alignment. In persons with healthy musculoskeletal systems, the scapula sits in the thorax in a resting position of 5° upward rotation and 30° anterior to the frontal plane (Neumann, 2010). This resting position, which allows for optimal kinematics between the scapula, the thorax, and the humerus, is often disrupted in patients with hemiplegia. The most common problems of scapula alignment, with their associated misalignments in trunk and pelvic posture, are

- depression and downward rotation (associated with asymmetrical weight bearing on the unaffected side, and trunk lateral flexion toward the affected side)
- elevation (associated with asymmetrical weight bearing on the unaffected side, accompanied by trunk lateral flexion toward the unaffected side)
- excessive protraction (associated with thoracic kyphosis)
- excessive retraction (associated with pelvic retraction and excessive shortening of muscle fibers in the middle trapezius).

Because each person may demonstrate differences in postural alignment, the therapist uses careful observational assessment to determine problems and goals.

Changes in resting alignment of the scapula are directly related to abnormal resting alignment of the humeral head at the glenohumeral joint and an alteration in the line of pull for rotator cuff muscles (Neumann, 2010). Several orthopedic impairments are associated with misalignment of the scapula and glenohumeral joint but are beyond the scope of this chapter. These include shoulder subluxation, complex regional pain syndrome (CRPS; previously called shoulder–hand syndrome), rotator cuff injury, and adhesive capsulitis (see Chapter 36).

When problems with scapular alignment are related to inefficient alignment of the pelvis and trunk, the therapist uses techniques, presented earlier in this chapter, to promote the patient's kinesthetic understanding of optimal postural set. Often, problems persist even when the patient is sitting or standing with good alignment at more proximal body segments. This indicates losses in length (distensibility) or spasticity in selected muscles. Slow, passive stretch in the directions of scapula protraction and upward rotation are critical to promoting an optimal resting position for the scapula and humeral head. The therapist provides this manual stretch before asking a patient to assume an erect aligned posture for task engagement. Therapists also teach patients how to provide appropriate stretch to themselves, in the context of enhancing scapular mobility.

Scapular Mobility. Efficient, pain-free shoulder motions are dependent on integrated movement between the clavicle, scapula, and humerus. In particular, during upward motions of the shoulder (abduction, flexion, and scaption), the scapula must upwardly rotate (Bourne et al., 2007). During forward reach, the scapula must also protract (abduct away from the vertebral column). Figure 21-1A shows how much the scapula moves in a healthy adult. Figure 21-1B shows the extent to which scapular mobility may be impaired in stroke survivors and illustrates compensatory movements this individual uses to try to achieve some arm motion, in spite of an immobile scapula. A recent motion analysis study compared scapular and humeral movement patterns between people with stroke and a group of matched healthy controls (Hardwick & Lang, 2011). The researchers found significant decreases in scapular upward rotation and glenohumeral lateral rotation in the stroke group. These findings confirm long-held assumptions, based on clinical observation, about the kinematics of shoulder movement in persons with hemiparesis.

To prevent the development of secondary orthopedic disorders and to promote a foundation for future upper limb function, therapy begins by helping patients understand how the scapula must move during passive and active shoulder motions. One early lesson takes place with the patient seated (in appropriate postural set) and his or her unaffected arm flexed forward to 90°. The person experiments to see how far he or she is able to protract his or her unaffected shoulder girdle to "make his or her arm long," and the therapist helps him or her appreciate that this change in arm length is due to movement at the scapula. Following this explicit instruction, the person learns to passively protract his or her paretic arm by holding the forearm with his or her other hand (with as much rotation as is comfortably possible at the glenohumeral joint). This can be done while lying supine (both shoulders flexed to 90° and reaching "toward the ceiling," rolling from supine to side lying (toward the unaffected side, reaching "across the mat") or sitting (reaching down and forward, or forward on a table that is slightly lower than seated height). The therapist may passively assist to ensure appropriate alignment.

In the absence of full scapular mobility, serious injury can occur as a result of active or passive shoulder motion beyond 90° (Kumar et al., 1990). It is important to adhere to all points listed in Safety Note 21-1 when implementing therapeutic programs for individuals with hemiparesis.

Safety Note 21-1

To Prevent Injury and Secondary Orthopedic Impairments at the Shoulder in Patients with Limited Scapular Mobility:

- Avoid passive humeral flexion or abduction without appropriate concomitant scapular motion.
- When providing passive range of motion (ROM), *always* provide manual mobilization to ensure appropriate scapular movement.
- Avoid any passive movement of the arm by individuals who are unfamiliar with scapula-humeral interactions.
- When teaching patients to perform self-ROM, focus on scapular rather than glenohumeral motion and limit glenohumeral motion to 90°.
- Do *not* use overhead pulleys as exercise.

Promoting Early Movement in the Arm and Hand

Functional use of the upper limb is dependent on an underlying ability to execute movement. For patients who are unable to generate any muscle contraction in the arm or hand, there are several options to facilitate this level of motor recovery. We will introduce several of these techniques and present information about research findings that support their efficacy: electrical stimulation, EMG-TMS, mental imagery, priming, mirror therapy, BAT, and Kinesio tape.

Functional Electrical Stimulation (FES) to Selected Muscles. We have previously discussed neuroprosthetic devices using electrical stimulation to activate contraction of ankle dorsiflexors at appropriate times during the gait cycle. The NESS H200® hand rehabilitation system from Bioness is a medical device that uses low-level electrical stimulation to activate various muscle groups in the hand and forearm, allowing patients to open and close their hand while wearing the device. Using this type of system provides patients with the opportunity to practice a variety of reach and grasp tasks that would otherwise be impossible for them to achieve. In the process, patients are able to actively use their available function at other joints in a meaningful way. In addition, it is postulated that the challenge to open and close the hand, with assistance from electrical stimulation, contributes to a process of neuroplasticity, in which intact cortical regions take on responsibility for controlling hand function (Popović, Sinkaer, & Popović, 2009). A pilot study comparing stroke survivors who used a FES device with other stroke survivors who participated in task-specific upper extremity (UE) rehabilitation found statistically significant better speed of performance on the task-based Box and Block Test and higher scores on a modified FMA.

Electromyograph-Triggered Neuromuscular Stimulation. EMG-TMS combines electrical stimulation with elements of biofeedback, in which a monitoring device provides information about an automatic bodily function. Systems such as Neuromove and Biomove monitor electromyograph (EMG) signals from target muscles and provide electrical stimulation that enables the person to produce a visible movement.

Neuromuscular stimulation is provided only when EMG signals are above a designated threshold, which is set by the therapist. Thus, the system "rewards" a person's muscular efforts with the momentary capacity to produce functional movement. In addition, the person is provided an opportunity to practice performing functional tasks that would not be possible without the presence of electrical stimulation to target muscles. There is significant evidence for the efficacy of these devices (Ivanhoe et al., 2006), and the active component to triggering the stimulation may account for better effectiveness, as compared to FES (de Kroon et al., 2005). The understanding is that these modalities must be used in conjunction with, or as immediate predecessors to, task-based interventions if the goal is to improve motor skill (Page & Levine, 2006; Page et al., 2009).

Mental Practice. "All other things being equal, more learning will occur if there are more practice trials" (Schmidt & Lee, 2011, p. 347). Mental practice is a strategy, often used by healthy individuals, to increase practice time, even when it is unfeasible to physically engage in the actual task. Thus, teachers rehearse delivering a lecture without actually talking. Athletes envision how they will perform a basketball jump shot or putt a golf ball. Neuroscience studies have recorded similar brain activity in healthy people when comparing their actual performance of a task and their mental rehearsal of the same task (Michelon, Vettel, & Zacks, 2006). A systematic review (Nilsen, Gillen, & Gordon, 2010) of multiple studies concluded that mental practice in moving one's paretic limb can be a helpful adjunct to other therapeutic interventions.

Therapists provide patients with structured directions for mental practice outside of therapy sessions. Audiotapes can consist of relaxation imagery and instructions to imagine performing particular tasks or movements with the affected arm and hand. Other protocols may involve the use of pictures, photographs, or written instructions. Patients adhere to a predetermined amount of time each day (usually 20–30 minutes) for independent mental practice, designed by the occupational therapist to capitalize on the person's level of function.

Mirror Therapy. Mirror therapy may be viewed as one example of mental practice. It is designed to help stroke

Figure 21-11 Mirror therapy.

survivors improve their ability to generate specific muscle contractions in their affected upper or lower limbs. In the case of training for motor execution in the forearm and hand, the person is seated at a table, with a mirror facing the unaffected side (see Fig. 21-11). The person places her paretic hand on the other side of the mirror, so that it is nearby, yet obstructed from view. The person's goal is to perform simultaneous, identical, bilateral movements, using both hands. Because of the mirror placement, she sees the reflection of her unaffected hand as if it were her paretic hand.

Case studies (Stevens & Stoykov, 2004) and two randomized controlled trials (Dohle et al., 2009; Yavuzer et al., 2008) provide support for mirror therapy as an adjunct to other rehabilitation interventions. The mechanisms are still hypothetical with regard to how mirror therapy helps stroke survivors relearn to generate specific movements. Aside from viewing this as a form of mental practice, another explanation is that this approach provides the person with effective visual feedback that compensates for potentially erroneous or absent proprioceptive feedback from the paretic hand. Another explanation lies in the emerging science related to "mirror neurons" (Ramachandran & Altschuler, 2009).

Mirror boxes can be constructed at a therapy site or purchased from commercial distributors. Because people can engage in mirror therapy independently, this is a cost-effective adjunct to direct therapeutic interventions. The therapist typically instructs a patient to practice using the mirror box for 20-minute sessions above and beyond OT sessions.

Priming. In the context of neurorehabilitation, priming is the use of an intervention for the specific purpose of pre-exciting the brain so that it will be easier for the person to generate a subsequent motor response and to enhance the benefits of motor practice (Stinear et al., 2008). Most clinical interventions and research related to priming are administered by neurologists and involve the application of neurophysiological techniques, such as transcranial magnetic stimulation or continuous theta burst stimulation to selected regions in the affected motor cortex (Kim et al., 2006). Simultaneous bilateral training is one priming technique that can be administered by occupational therapists.

Simultaneous Bilateral Training/Bilateral Arm Training Neurophysiologically, optimal motor function is dependent on a balance of excitability between the left and right primary motor areas (M1) in both cortical hemiheres. Through intercallosal pathways, neural networks from each hemisphere exert inhibitory influences on the contralateral hemisphere to maintain this balance. Neuroscientists have established that, after stroke, there is an imbalance between M1 in the two hemispheres, with excessive inhibition to neurons in the affected motor cortex. Therefore, one goal is to increase excitability of neural networks within the affected motor cortex, whose purpose is to generate inhibitory signals to the contralateral hemisphere. There is evidence that, through the use of exercise technology that provides active-passive bilateral therapy, changes are seen in the balance between M1 excitability, as well as behavioral improvements in motor function in the paretic arm (Stinear et al., 2008).

Earlier in this chapter, we presented the methods and results of two clinical studies that used BAT in a task-oriented context (Lin et al., 2010a; Stoykov, Lewis, & Corcos, 2009). In addition to the potential neurophysiological benefits of BAT, performance of simultaneous bilateral movements may be of value from a motor learning perspective. When coupling the two arms as one single unit, it is possible that a single GMP can be effective in organizing performance in both arms simultaneously (Schmidt & Lee, 2011).

Kinesio Tape. Our final example of an intervention that is designed to prepare patients for therapeutic practice is not supported by research evidence. However, many therapists report that skilled use of Kinesio tape seems to make a difference in how patients respond to other interventions.

Kinesio tape is an elastic therapeutic tape. Its degree of elasticity is variable and dependent on the skilled procedure with which a practitioner applies the tape. In neurorehabilitation, Kinesio tape is most typically applied to either relax a muscle or to facilitate muscle contraction (Jaraczewska & Long, 2006). When the tape is applied with the stretch in a distal to proximal direction ("insertion to origin application"), the tape exerts an effect that seems similar to slow, sustained muscle stretch in relaxing a tight muscle. When applied with the stretch in a proximal to distal direction ("origin to insertion application"), the tape

exerts an effect that seems to assist muscle contraction. Once applied, Kinesio tape can stay in place for 3–4 days and is not affected by swimming or bathing. In the case study of Mrs. M., the occupational therapist applied Kinesio tape to the woman's wrist and finger extensor muscles to help facilitate extension when she released her grasp on objects. Although this woman progressed significantly during her course of therapy, we cannot make any inferences about the influence of Kinesio tape on the improvements she exhibited.

Preventing Learned Nonuse

Although there is no direct research evidence to support interventions that prevent learned nonuse, the concept is compatible with findings from studies of CIMT, as well as the literature that supports the value of task-based practice in promoting functional recovery after stroke. During the acute and rehabilitation stages after stroke, prevention of learned nonuse is a primary goal in OT intervention (Sabari, 2008). Therapists use every opportunity to teach stroke survivors to be aware of, and to use, their paretic limbs to the limits of current, available motor function. Using the paretic leg and arm to support body weight, called "weight bearing" in some literature (Howle, 2002), is usually the first tangible way a stroke survivor can learn to rely on his hemiparetic limbs and to reincorporate them into his overall body schema. Activities requiring the person to shift body weight in a variety of directions may also play a role in preventing learned nonuse by challenging the stroke survivor to be aware of, and use, muscles on the paretic side. To prevent learned nonuse in the paretic arm, therapists continually assess motor potential in specific muscles, using external support or special positioning to detect emerging changes. In addition, occupational therapists teach clients to understand movement linkages and to check actively for changes in their ability to recruit specific muscles. Therapy sessions become opportunities for stroke survivors to share their discoveries with their therapists. In turn, occupational therapists structure activities that enable clients to practice emerging movement capacities.

Two programs at the Rusk Institute of Rehabilitation Medicine at NYU Langone Medical Center in New York City illustrate how occupational therapists help patients maximize their awareness of capabilities and provide them with structured opportunities to successfully incorporate their paretic upper limb into performance of daily tasks. In the Use My Arm Program, therapists adapt common daily tasks according to each patient's current functional level and use homework assignment logs and behavioral contracts to ensure that patients will follow through on recommendations for practice outside of therapy sessions (Procedures for Practice 21-4). The Breakfast Group, a task-based program for four to six patients, is held Monday through Friday at 8 am in the occupational therapy clinic (Capasso, Gorman, & Blick, 2010). One therapist supervises two to three patients as they eat breakfast, using the paretic UE to the extent possible, based on the Functional Upper Extremity Levels (FUEL) described later in this chapter.

Developing Effective Motor Programs for Reach and Grasp

Humans use our upper limbs in a variety of ways. Sometimes, we use an arm and hand in a closed kinematic chain, in which proximal limb segments move over the distal components, which are stable on a supporting surface (Neumann, 2010). Two examples are (1) when rising

Procedures for Practice 21-4

Welcome to the *Use My Arm Program*

- Research shows that practice using your weaker arm as much as possible after a stroke may:
  - lead to beneficial changes in the brain
  - help your recovery
  - enable you to use your arm during daily activities
- There are many ways to practice even if you are unable to move your arm and hand or have very little movement.
- Your occupational therapist will help you to practice using your arm and hand *in the best way you can right now*.
- We are giving you a photograph showing you how you can practice using your arm and hand when you are eating. We are also giving you photographs of some practice exercises we would like you do each evening for 30 minutes.

- We are giving you a check-off log, and asking you to complete the log every evening that you practice.
- It is important that you do the practice. Remember, this is a homework program, and this is your arm and hand. Like athletes that train for competition, you are now TRAINING your arm to work again. So please *do your exercises daily!*
- Part of your homework, every night, is to figure out one new way you can use your arm. Do your best to implement your idea, and report your success to your occupational therapist at your next therapy session.

Note: This is the cover sheet to materials provided to participants in *Use My Arm Program* at Rusk Institute of Rehabilitation Medicine at NYU Langone Medical Center. The packet of materials is individualized to match the capability level of each patient. As patients progress, the occupational therapist provides new photographs with directions for practicing the recommended activities.

from supine to sitting, we bear weight, first on the forearm (with the elbow flexed) and then on the hand, with the wrist extended, and (2) when supporting some body weight over a hand placed on the kitchen counter when emptying a dishwasher.

More often, the hand moves freely in space, or on a support surface, in an open kinematic chain (Neumann, 2010). We point to a target (as on a touch-screen at a bank ATM). We depress a button with a single finger (as on a telephone). We employ independent movements of our digits to depress a series of keys (as on a keyboard). We grasp objects of varying sizes, shapes, weights, and textures. We carry these objects and release them at an appropriate time and place. We maintain a grasp while using an object as a tool. We manipulate objects in our hands.

Foundational Elements to All Reach and Grasp. Although there are many variations inherent in the multiple ways of using our arms and hands, the following foundational elements are important to all reach and grasp (Duff, Shumway-Cook, & Woollacott, 2012; Neumann, 2010; Shumway-Cook & Woollacott, 2012) and influence OT interventions:

- Reaching movements are coordinated with movements of the eye and head.
- Shoulder, elbow, and forearm motions orient the hand in space to match the task demand. For example, if you reach to grasp a telephone with your right hand, with the purpose of bringing the phone to your mouth and ear, you laterally rotate the humerus and supinate the forearm so that your hand will grasp the phone from the right side.
- Active scapular movement is necessary for efficient reach. This includes protraction during forward reach and upward rotation during abduction and flexion at the glenohumeral joint.
- When reaching against the force of gravity, complex interactions between muscles of the thorax, scapula, and humerus are necessary to provide shoulder girdle stability.
- Active wrist extension is necessary to achieve an efficient length-tension ratio for the multijoint, extrinsic finger flexors.
- Early in the transport phase, a person assumes the grasp (or pointing) pattern, in anticipation of producing grasp that is best suited to the affordances of the target object.
- A variety of specific power grips and precision grasps have been identified in children and adults (and are described in the cited references). Specific kinematic and kinetic features of these grasp patterns contribute to the efficiency of task performance.

OT intervention to assist patients in relearning the elements of reach and grasp with the paretic arm and hand is highly individualized and is based on each patient's current capabilities. We use a combination of explicit learning (one example related to scapula motion during forward reach was described earlier), designing tasks to elicit specific components of functional reach and grasp, matching challenges to each person's current level of function, and providing opportunities for implicit learning through practice with a variety of tasks.

Matching Task Demands to the Person's Capabilities

One of the greatest challenges for occupational therapists is to design tasks that are well suited to a patient's motor and cognitive capabilities. This is especially important in the early weeks after the person has sustained a stroke or brain injury, when motor recovery has been limited. The FUEL categorizes motor capability from the perspective of how an individual is able to use his or her paretic arm in functional performance. These levels inherently guide the therapist in structuring therapeutic tasks for the patient to practice during and outside of therapy sessions. See Definition 21-5, Procedures for Practice 21-5, Figure 21-12, and Clinical Reasoning Box 21-1 for specific information about applying these levels of function to OT intervention to improve arm and hand use in individuals who are recovering motor skill in a paretic upper limb after stroke or brain injury.

When implementing these task-based treatment suggestions, the occupational therapist must consider several additional factors:

- People work harder and move more efficiently when there is a task goal.
- After progressing to a higher functional level, patients should continue to practice activities that are currently easier for them. People are more likely to practice when they feel capable of achieving task demands. Opportunities to practice previously learned skills make it possible for the patient to introduce his or her own challenges, related to speed, duration, or number of repetitions.
- Whatever the task, the person should be in an optimal position of postural alignment.
- When providing tasks for the person to practice outside of therapy sessions, always consider the person's safety. Structure the task to prevent falls, and follow the points in Safety Note 21-1 to prevent injury to the paretic shoulder.
- Ensure that the setup of activity objects and targets is appropriate for the person's current ability to stabilize the shoulder girdle when moving against gravity. Note that when the demands of gravity exceed a person's current muscular potential, the person will use stereotypical movement patterns. We suggest two major ways to control the effects of gravity:
  - Structure early activities with support from a surface. The person can either slide the arm along the surface (as in dusting a table, or in moving a

Definition 21-5

Functional Upper Extremity Levels

Level	Definition
Nonfunctional	• Involved upper extremity (UE) is not incorporated into daily activities. • Decreased awareness of involved UE. • No active range of motion (AROM) present.
Dependent Stabilizer	• Involved UE is incorporated into activities as a stabilizer but is placed by the less involved UE or by a caregiver. • Some AROM may be present (scapular, gravity eliminated); however, patient is unable to initiate placement. • Increasing awareness of involved UE during functional tasks.
Independent Stabilizer	• Some AROM is present in involved UE and able to position independently (without use of other UE) in activities. • Used primarily as a weight to stabilize. • No active hand use.
Gross Assist	• Involved arm and hand are used actively to assist in accomplishing simple functional activities. • Involved UE may still be influenced by synergistic movements or have extreme weakness. • Gross grasp may have developed but no functional release. • Fine motor coordination is not functional.
Semifunctional Assist	• Involved arm and hand are used in activities that require active motor control for pushing, pulling, stabilizing. • Gross grasp and release have developed, and some individual finger movements may be developing; however, measurements for grasp, pinch, and coordination are below norms. • Hand is able to assist with fastenings.
Functional Assist	• Involved arm and hand have full AROM. • Able to use involved UE for all activities and fine motor tasks, but it remains the assistive UE with mild awkwardness and weakness.
Fully Functional	• Involved UE has returned to complete function. • Able to use as dominant UE if premorbidly dominant. • Strength, grasp, pinch, and coordination measurements are all within normal limits.

Note: This framework is used at NYU Langone Medical Center–Rusk Institute of Rehabilitation Medicine to categorize levels of function for use of the involved arm and hand following a neurological injury. After identifying the functional UE level, the occupational therapist also notes whether the person uses the involved UE spontaneously during tasks. If the person requires verbal, visual, or tactile cues to incorporate the UE, the occupational therapist notes if the patient needs minimal, moderate, or maximal cueing.

furniture slider, Beazy Board, or Saebo-glide) or use the arm to push an object, while using the object as a support against the effect of gravity (as in tipping a bar stool or pushing a bolster or a stool on wheels) (see Fig. 21-13).

■ When necessary for optimal performance, place items below shoulder height so that the person will be reaching into gravity.

• Consider how the interplay between task variables will affect overall task difficulty. Task variables include factors affecting
  ■ reach (height, direction, distance of the target objects for grasp and release)
  ■ specificity of the target (large versus small)
  ■ grasp (size, shape, and texture of target objects, type of grasp pattern required)

Procedures for Practice 21-5

Examples of Task-Based Practice Matched to Each of the Functional Upper Extremity Levels

Nonfunctional/Dependent Stabilizer

- Putting lotion on affected upper extremity (UE)
- Stabilize meal menu with affected UE to fill it out
- Stabilize a plate with affected UE while eating

Independent Stabilizer

- *Any activities from previous functional level*
- Washing table (with therapist's assistance)
- Stabilize bowl with the affected UE while stirring
- Push objects (such as bean bags) off a low surface (bench, wedge)

Gross Assist

- *Any activities from previous functional levels*
- Open screw-top containers (hold with affected UE and open with unaffected UE)

- Open milk container
- Squeeze toothpaste out of tube with affected UE

Semifunctional Assist

- *Any activities from previous functional levels*
- Wring out a washcloth
- Crumble paper
- Use built-up utensils to eat and cut food

Functional Assist

- *Any activities from previous functional levels*
- Typing
- Place coins into slot
- Hand writing

Note: Because patients differ in their specific movement capabilities within each of the functional levels, the therapist individualizes the program for each person.
Figure 21-12 Examples of each of the levels of upper extremity (UE) function described in Functional Upper Extremity Levels (FUEL). **A.** Left nonfunctional. **B.** Left stabilizer (dependent or independent is based on whether the person can actively put the limb in the stabilizing position). **C.** Left gross assist. **D.** Right semifunctional assist. **E.** Right functional assist.

⍰ Clinical Reasoning in Occupational Therapy Practice

Adapting an Activity to Meet Different Levels of Functional Upper Extremity Use

In Figure 21-12, we have provided examples of how a person would use his or her paretic upper extremity (UE) during mealtime activities at each of the Functional Upper Extremity Levels (FUEL). The FUEL levels are described in Definitions Box 21-5. Provide your own examples for the activity of brushing teeth and for the activity of playing cards.

- release (into a small versus large container),
- speed requirements
- postural demands (sitting versus standing, changes in the BOS)
- cognitive demands.
- Never increase the difficulty level of multiple variables at once. When adding challenge to one element of upper limb performance, consider decreasing the complexity of other variables. The goal is for patients to experience success and to become aware of their progress, so they will be motivated to practice even more and to use the affected arm and hand during daily activities.

Developing Task Analysis and Problem-Solving Skills

An ultimate goal in neurorehabilitation is for individuals to learn the strategy of analyzing activities in reference to their own functional strengths and impairments. During the OT process, therapists share their strategies for activity analysis and challenge patients to develop their own skills in this area. Midway through the treatment process, therapists present new tasks and require individuals to analyze each task's inherent performance requirements. In addition, occupational therapists encourage individuals to develop their own alternative strategies for task performance. The therapist's major role at this stage is to provide feedback about the safety and efficacy of the person's ideas. Before treatment is terminated, stroke survivors should develop skill in activity analysis so that they have the confidence and capability to attempt an infinite variety of new tasks and roles.

Intervention to Improve Motor Planning in Patients with Limb Apraxia

Limb apraxia, associated primarily with left hemispheric pathology, refers to difficulties in planning and executing limb movement sequences that cannot be explained
Figure 21-13 Treatment activities for patients with minimal upper extremity movement. **A.** Person pushing a bar stool tipped on two legs forward and backward. This activity reduces the impact of gravity and helps to promote initiation of shoulder and elbow flexion/extension. **B.** The same concept is used with a PVC pipe frame. This can be performed unilaterally or bilaterally.

by weakness, lack of coordination, sensory loss, comprehension deficits, memory, or motivation. Individuals with apraxia demonstrate difficulty using both the paretic and nonparetic arms. They may also have difficulty organizing gross movements during bed mobility or STS activities. If the affected (usually right) limbs are completely paralyzed, people with apraxia have difficulty using the left arm and leg during daily activities and find it exceptionally difficult to learn how to perform compensatory one-handed strategies for self-care tasks. The two types of limb apraxia are best understood by referring back to this chapter's previous discussion of the neurological processes that underlie task analysis, problem solving, and praxis skills. The capacity to plan a motor action is dependent on several neural networks, primarily in the left, dominant hemisphere, which oversee

- processing of visual information in the striate cortex
- effective communication between the striate and premotor cortex via the ventral stream to accurately determine the purposes of goal objects in order to formulate the overall plan for using these objects to achieve a functional goal
- effective communication between the striate cortex and several parietal regions via the dorsal stream to accurately determine how movements can be organized most efficiently to meet the physical/spatial properties of the object goal.

Two Types of Limb Apraxia: Ideational and Ideomotor Apraxia. Ideational apraxia (IA) is an impairment in which the individual has difficulty relating everyday objects and tools to their common usage and/or makes significant errors in sequencing multistep tasks that are performed on a daily basis. IA, in isolation of severe global aphasia and/or dementia, is rare in stroke survivors. However, Gillen (2009) and Arnadottir (2011) provide several examples of behaviors that are seen in some brain injury survivors. These behaviors may include

- using a toothbrush to comb one's hair or smearing toothpaste over the face
- using a spoon to try to "spear" a piece of food, as one would typically use a fork
- stirring coffee with one's finger
- putting trousers on before underwear and then attempting to put the underwear over the trousers

Ideomotor apraxia (IMA), which has been definitively linked to impairment in the dorsal stream (Murtha, Sainburg, & Haaland, 2010), is an inability to match the motor action to specific factors within a task such as distance of objects from the body or weight and configuration of objects. An individual with IMA has a clear understanding of the purpose of objects, but his movements are clumsy and awkward. For example, when reaching to

pick up a sandwich (with an upper limb that otherwise exhibits normal movement execution), the person will approach the sandwich with an awkward orientation or an inappropriate grasp pattern. Not surprisingly, people with IMA improve their motor performance when they are performing familiar tasks and interacting with objects that have very clear affordances. Perhaps, in these situations, they are relying on information from the ventral stream to assist them in planning their motor strategy. Standardized assessments of IMA require the person to perform movements without the cues provided by task-related objects. For example, the person may be asked to "pretend" to comb his hair, without using an actual comb. In addition, the person may be asked to perform an abstract gesture, such as waving goodbye or making the "peace sign." During rehabilitation therapy sessions, commands to "raise your arm" or "turn your body" in an exercise context, without the benefit of contextual task cues, are particularly difficult for people with IMA.

Common Additional Problems Are Frequently Associated with Ideational Apraxia and Ideomotor Apraxia

Limb apraxia is rarely exhibited as an isolated deficit after stroke or brain injury (van Heugten et al., 2000). Rather, most patients present with several other impairments that present significant challenges during rehabilitation. Most commonly, patients exhibit various forms of aphasia. Ironically, the accurate use of physical gestures would be helpful as a compensatory strategy for individuals who are unable to speak. A deficit in gesture production is particularly frustrating. Therefore improving gesture use is a valuable functional goal for patients who exhibit both limb apraxia and impairments in expressive language.

Depending on the pathology, patients with IA and IMA can exhibit all the other problems associated with brain injury, including paresis, sensory loss, spasticity, visual field loss, impaired alignment, balance problems, and learned nonuse of the paretic upper limb. One important factor distinguishes people with limb apraxia from other stroke survivors who exhibit learned nonuse. Individuals with learned nonuse but intact praxis skills can still use their unaffected upper limb to perform one-handed activities. Individuals with IMA and learned nonuse are left with very few choices for functional performance of daily tasks.

Some patients with IMA have additional challenges of memory impairment and other neuropsychological deficits. Depression and poor frustration tolerance present further obstacles to function. Although there are reports in the literature of patients with apraxia who are unaware of the motor planning deficit, most individuals with IMA are acutely aware of and distressed by their difficulty performing motor tasks. Finally, some individuals demonstrate behaviors that are associated with both IMA and IA.

Evidence-Based Occupational Therapy Intervention for Patients with Ideational and Ideomotor Apraxia

To date, there are no interventions that claim to change underlying apraxia. However, three compensatory interventions have generated strong research evidence for their effectiveness in helping people resume productive task performance.

Gesture Training. Smania et al. (2000) developed a standardized protocol that teaches patients to produce transitive and intransitive gestures. Transitive gestures require an ability to understand the relationship between motor actions and task objects. Therefore, training begins by presenting the patient with a series of actual common objects and asking the person to demonstrate how he or she would use each object. When a person makes an error, the therapist corrects him or her and the person tries again. After correctly showing how he or she would use 20 common objects, the person moves on to the next phase of transitive gesture training. In phase B, the therapist presents a series of pictures, each illustrating a different, common transitive gesture (such as a person using a spoon to eat). After viewing each picture, the patient is asked to produce a pantomime of that action. In phase C, the person views a series of pictures showing an object alone and then pantomimes how he or she would use that object. When the individual is able to correctly respond to 17 out of 20 items in each phase of transitive gesture training, he or she moves on to the next level: intransitive symbolic gesture training. Resources 21-2 lists sources for picture cards.

Intransitive gesture training prepares people to perform actions without the cues associated with task objects. In the sequential steps of the intransitive symbolic gesture training program, the patient is challenged to perform pantomime actions in response to a series of pictures that show information about the action, with decreasing levels of contextual cues. These gestures are considered to be symbolic because they are related to actual actions. For example, the person might view a man pretending to eat a sandwich and attempt to pantomime the action.

During intransitive nonsymbolic gesture training, the patient imitates meaningless, intransitive gestures performed by the examiner. If the person cannot perform a particular gesture, the examiner assists him or her through verbal cueing, passive positioning, or passively moving the person through the complete action of producing the gesture.

Results of two randomized controlled trials established that the standardized protocol for gesture training led to generalization of learning. Participants in the treatment group showed statistically significant improvements on standardized apraxia tests that included gestures that were not included in the training protocol (Smania et al., 2000). Control group participants did not show any significant change in performance. Most importantly for occupational therapists, participants in the treatment group also showed

statistically significant improvements on a questionnaire that asked caregivers to report the burden of care during performance of ADL (Smania et al., 2006).

Task-Specific Training with Errorless Support. In repeated practice of a desired ADL task, occupational therapists provide patients with the opportunity for "errorless support/learning" through cueing and assistance throughout task performance. Errorless support enables a person to complete a task when otherwise the individual's motor planning problems would prevent such achievement. Errorless learning is important in patients with apraxia, because high levels of frustration are emotionally upsetting and hinder the person's motivation to engage in continued practice. Goldenberg and Hagmann (1998) proposed that the highest level of therapist assistance is through passive "hand over hand" cueing, where the occupational therapist physically guides the person through the motor sequence. In the next degree of support, the therapist performs the action simultaneously with the patient while sitting next to him or her. As the patient progresses in learning the action steps to the task, the therapist demonstrates the action, and the patient copies the action immediately afterward. In this model, training continues until the patient achieves independent performance of the specific task.

In addition, the therapist directs the patient's attention to the details of the task and to critical features of task-associated actions. Goldenberg and Hagmann (1998) and Goldenberg, Daumuller, and Hagmann (2001) found this method to be successful in training patients with limb apraxia to perform both self-care and instrumental activities of daily living (IADL). Consistent with theories of motor learning, "direct training," in which the patient actively performed the entire activity, was effective in improving performance. However, "exploration training," which focuses on teaching about the roles of objects in a task, had no effect on performance when it was not combined with active opportunities for patients to actually perform the task. The researchers found that patients did not generalize their learning to activities they had not practiced in this manner. Evidence of retention, on long-term follow-up (6–30 months after therapy ended) was mixed. Those patients who continued to practice an activity at home, within their daily routine, preserved their ability to complete the task independently, without planning errors. Those who had stopped practicing lost their ability to perform.

Compensatory Strategy Training. A series of studies has established compensatory strategy training as the gold standard intervention for patients with limb apraxia (Donkervoort et al., 2001; Geusgens et al., 2007; van Heugten et al., 1998). This approach (summarized in Procedures for Practice 21-6 and Research Note 21-4) shares many similarities with task-specific errorless learning. However, in addition to repetitive practice, patients develop strategies that they can later generalize to compensate for limb apraxia during a variety of current and future tasks. In this approach, the occupational therapist determines how the client's deficit is impeding one of three stages required in motor planning of selected functional tasks: initiation, execution, or ongoing control. Following this, the occupational therapist teaches the client a compensatory strategy, such as verbalizing the sequence during activity performance or viewing pictures that illustrate the steps required for task execution. The therapeutic goal is to improve functioning in spite of impairment in motor planning (van Heugten et al., 1998). Evidence from both a single group pre-post design (van Heugten et al., 1998) and a randomized controlled trial (Donkervoort et al., 2001) indicates that this intervention produces statistically significant improvements in ADL function as measured by the Barthel Index. A subsequent pretest–posttest study with 29 patients provided support for the long-term and generalized effects of this compensatory strategy intervention. For stroke survivors with apraxia who were tested in their own homes after 8 weeks of training and again 7 weeks after training ended, the statistically significant improvements in ADL function made during training were maintained on retesting. In addition, patients were able to generalize their learned strategies to other tasks at home that they had never practiced during the intervention (Geusgens et al., 2007). Although apraxia is associated with other cognitive impairments, such as language comprehension, cognitive orientation, and short-term memory, this intervention to develop compensatory strategies is not influenced by cognitive comorbidities (van Heugten et al., 2000).

General Guidelines for Occupational Therapy Interventions to Improve Performance in Patients with Limb Apraxia. A few key factors differentiate OT treatment for patients with IA and IMA from other neuromotor interventions described in this chapter:

- Blocked practice is used to a greater extent than variable practice. Efficient ADL performance is the primary goal. To that end, OT sessions focus on helping the individual achieve mastery of one task at a time. Patients must have an active role in selecting therapeutic tasks. In essence, proficiency in these tasks is an end goal of intervention.
- Whenever possible, practice sessions are best held in the actual environment for task performance. Although the hope is that patients will generalize their achievements in ADL performance from a rehabilitation setting to their own home after discharge, it is important to match the context so that task performance "makes sense" to the person. For example, bathing and dressing tasks should be practiced during the routine of getting out of bed and ready for the day. Leisure tasks should be practiced with tools and materials provided by the family from the person's own home. Of course, home-based interventions would be important as well.
- Errorless learning is stressed. The therapist provides enough assistance for the person to complete the task every time. With each successive trial, the therapist fades the type of cueing and assistance provided until the individual can perform the task independently. Because many patients with limb apraxia have concomitant problems understanding language, the therapist may need to limit verbal or written directions.

In summary, however, evidence-based occupational therapy intervention for patients with limb apraxia is consistent with OT to improve other aspects of motor performance in people who are survivors of stroke or brain injury. After careful consideration of task parameters, underlying impairments and each person's activity goals, the occupational therapist structures therapy sessions to provide patients with practice, guidance, and support. As in all intervention to improve motor function in people with CNS pathology, the patient is an active participant who develops his or her own strategies through the process of engaging in challenging yet attainable therapeutic tasks.

Procedures for Practice 21-6

Phases of the Motor Planning Process during Task Performance and Intervention Strategies at Each Phase

Compensatory Strategy Approach for Improving Activities of Daily Living Performance in Patients with Limb Apraxia

- The therapist observes the patient perform a selected task.
- The therapist determines the phase of task performance at which motor planning errors occur.
- The therapist implements training or assistance, targeted at the phase where errors occur.

- The therapist provides "errorless learning" (a term used to convey that the therapist's intervention enables the patient to successfully complete the task on all trials).
- The therapist selects methods (summarized on the table below) that are appropriate to the person's needs and abilities.
- The patient practices the same task many times, as the therapist gradually reduces assistance and cues.
- Training on a particular task is completed when the patient demonstrates that he can perform the task without any assistance or cueing from the therapist.

Phase	Functions	Therapist Training and Assistance
Initiation and orientation	- Determine a general plan of action - Select appropriate objects to use in the task - Determine the sequence of steps for performing the task	- Practice selecting the correct tool (from an array of three or four choices) - Provide explicit verbal, written, or pictorial directions that describe the goal, the purpose of task objects, and steps of the task - Alert the patient to the relevant objects—by placement, pointing to appropriate objects, gestures - Simplify the activity if it is too complex (select an appropriate number of task objects and performance steps)
Execution	Perform the task in an efficient manner	- Provide explicit directions (e.g., "try reaching this way") through gesture, demonstration, or physical assistance - Show pictures of each step in the activity sequence - Sit next to, rather than across from the person, when providing demonstration - Physical assistance may entail prepositioning the limbs, guiding the limbs, and performing steps the patient cannot yet achieve
Control and correction	- Assess how effective performance has been - Make necessary corrections	- Provide extrinsic feedback (KR, KP) - Cue the person to consciously use his senses to evaluate the result (Can you taste the toothpaste on your teeth? Can you feel the comb on your scalp? Do you see a fork, knife, spoon, and plate at each table setting?) - Ask the patient to assess his or her own performance

KP, knowledge of performance; KR, knowledge of results.

Research Note 21-4

Abstract

This study evaluated transfer effects of cognitive strategy training for stroke patients with apraxia. During 8 weeks, 29 patients with apraxia received cognitive strategy training to teach them how to perform activities of daily living (ADL). ADL functioning was assessed at the rehabilitation centre at baseline and after 8 weeks of training. Assessment also took place at the patients' homes at 8 weeks and 5 months after the start of the training. Assessment included observation of both trained and nontrained tasks. Patients were equally independent in trained tasks and nontrained tasks at the rehabilitation centre as well as at home, indicating transfer of training of effects which were stable over time.

This is a follow-up study to previous reports of a strategy training approach to teach patients with limb apraxia to compensate for their deficit in automatically developing motor plans for performing daily activities (Donkervoort et al., 2001; van Heugten et al., 1998, 2000). Using the Assessment of Motor and Praxis Skills (AMPS), each of 29 apraxic patients selected six ADL tasks from a list containing 14 tasks of similar difficulty. This selection process ensured that the individuals had a choice in determining which activities would constitute the practice sessions and which activities would be tested at a later date to determine whether improvements in motor planning generalized (transferred) to tasks that had not been practiced during therapy sessions. Over the 8-week intervention, patients practiced applying a compensatory strategy approach to performing four of the selected tasks. During therapy sessions, the therapist assisted the patient with three phases of performing each task: (1) initiation and orientation, (2) execution, and (3) control and correction. Patients were all survivors of left hemisphere stroke, and many of them exhibited other cognitive and motor deficits in addition to the limb apraxia. Standard assessments of ADL, apraxia, and motor function were administered on three occasions: before training, immediately after the 8-week training while patients still resided at the rehabilitation facility, and at home 20 weeks after the start of training. In addition to the standardized Barthel Index, assessment was of the four tasks that each patient practiced during training and the two additional tasks that the patient never practiced during training but selected as meaningful tasks prior to beginning the training. Participants showed statistically significant improvements on scores for both trained and untrained tasks at both 8-week testing and 20-week testing at home. Participants also showed statistically significant improvements on the apraxia test and the Barthel Index of ADL function after 8 weeks of training. No significant changes were found on the functional motor test.

Several findings indicate that participants developed, retained, and generalized a compensatory strategy that enabled them to perform a variety of old and new tasks—both in the rehabilitation center and in their own homes, 3 months after discharge. No significant differences were found between trained tasks and nontrained tasks, either at home or at the rehabilitation center. No significant differences were found between function at the rehabilitation center and at home. No significant differences were found between performance immediately after training and at 20-week follow-up.

Implications for Practice

- Practice performing familiar tasks, with structured and graded cueing by an occupational therapist can help people develop strategies for planning their performance of daily activities, in spite of limb apraxia associated with left hemisphere dysfunction.
- Therapists can assist patients in developing motor planning strategies by focusing on the planning requirements during three phases of action performance: initiation and orientation, execution, and control and correction.
- Patients are able to generalize the use of this compensatory strategy to tasks they have not practiced directly and in new environments, including the home setting.
- This approach is effective with patients who demonstrate significant motor and cognitive deficits in addition to limb apraxia.

case example
Mrs. M.: A Woman with Right Hemiparesis

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Mrs. M. is an 85-year-old woman who had a left middle cerebral artery stroke following a carotid endarterectomy. She was admitted to an acute inpatient rehabilitation hospital 5 days post stroke. Prior to admission, she lived alone in a building with an elevator. She was independent with all activities of daily living (ADL)/instrumental activities of daily living (IADL), functional mobility, and transfers. Mrs. M. was very active prior to admission and performed community ambulation without an assistive device. Mrs. M. is a widow and has three grown children (the closest child lives 45 minutes away from Mrs. M.'s home). One daughter offered to have Mrs. M. live in her home after discharge from the rehabilitation hospital. There are five steps to enter her daughter's home, and a first floor setup for bedroom and bathroom is possible.

During her occupational therapy assessment, the following problems were identified:

1. Hemiparesis of her right (dominant) arm. Mrs. M.'s upper extremity Fugl-Meyer Motor Assessment score was 15/66. She had active shoulder flexion to approximately half range but used compensatory shoulder and trunk movements. She had three-quarters of full range of motion (ROM) of elbow flexion and extension, but the movement was uncoordinated and effortful. Mrs. M. was able to flex her fingers into a weak gross grasp but was unable to extend her fingers (Functional Upper Extremity Levels [FUEL]–gross assist; see Definition 21-5). Her postural alignment was good but with minor thoracic kyphosis noted. Mrs. M. did not have glenohumeral subluxation, edema, or limitations in passive ROM. Testing revealed a subtle impairment in light touch sensation compared with left side (she required increased time to detect the stimuli).
2. She needed assistance to perform ADL (FIM™ scores: feeding and grooming with setup assistance; upper body dressing and toilet transfers with moderate assist; and toileting, bathing, and lower body dressing with maximal assist).
3. She exhibited mild non-fluent aphasia.
4. She had decreased standing tolerance and standing balance. Mrs. M. was able to perform bed mobility with minimal assist from sit to supine and minimal assist for transfers. She was able to maintain sitting balance with extensive weight shifts. She was able to stand without assistance but could not maintain unsupported standing balance when shifting weight. With upper extremity support, she was able to maintain standing balance with supervision. She was able to walk with no device for 50 feet with minimal to moderate assistance depending on her fatigue level. She used a wheelchair for mobility in the rehabilitation hospital because of decreased balance and endurance.

Mrs. M. demonstrated good insight into her deficits and her need to ask for assistance from nursing staff for ADL.

Appreciate the context

"At this time, it is too early to predict what functional improvements Mrs. M. will exhibit in gross mobility, arm function, and ability to stand and walk. Regarding arm function, it is promising that, 5 days after she sustained her stroke, she is able to actively execute some movements in the shoulder, forearm, and hand."

"Mrs. M. would like to return to her prior level of independence including cooking, laundry, shopping, knitting, and handwriting. She expresses frustration that the stroke impacted her right dominant hand and her speech."

Develop intervention hypotheses

"Mrs. M. expressed that her greatest frustration is related to the paresis of her right arm and hand. She seems very motivated to work on her arm movement because she already has gained back some functional movement. She sees this as one of her major obstacles to gaining back her independence with ADL and IADL. Integrating the hemiparetic arm into functional activities has been shown to be effective. Using repetition and clinical modalities should help to prevent learned nonuse and maximize the movement that she has available."

Consider the evidence

"Task-related training is an effective strategy for improving arm and hand function in stroke survivors."

"Bioness® is an orthotic device that provides neuromuscular electrical stimulation to the finger flexors and extensors. A randomized controlled trial supports the effectiveness of an interactive training program using Bioness® during patients' practice of grasping, moving, placing, and releasing objects, which resulted in better functional recovery of the upper extremity in ischemic stroke survivors than task-related exercise training alone (Alon, Levitt, & McCarthy, 2007)."

"There is no research support for the effectiveness of Kinesio tape in stroke recovery, but clinical experience at this site has been positive. Bilateral arm training with auditory cueing has been shown to improve hemiparetic arm function (Stoykov, Lewis, & Corcos, 2009)."

Select an intervention approach

"I will use a combined approach of restoration and compensation to increase Mrs. M.'s level of independence and functional use of her right arm and hand. To help her arm get better, I want her to attempt and to practice functional activities using the available movement and modalities (neuromuscular electrical stimulation and Kinesio tape). I do not want her to just rely on her left arm because this could lead to learned nonuse."

| | Reflect on competence | "I have attended continuing education courses on using neuromuscular electrical stimulation and Kinesio tape and have had numerous patients with a similar clinical presentation. I have also reviewed the research studies that have been done with these approaches. I have developed a good rapport with Mrs. M., which will be helpful during our therapy sessions." |

Recommendations

Mrs. M. will receive occupational therapy 6 days per week. She would benefit from an hour of individual occupational therapy and can also participate in a 30–60-minute group session focused on practicing using her right arm during meals and other functional activities. Mrs. M. would benefit from staying in the acute rehabilitation setting for 3 weeks with the goal of a discharge to her daughter's house.

Mrs. M. and therapist collaborated to develop the following long-term goals:

1. Mrs. M. will perform toilet transfers with supervision using a raised toilet seat.
2. Mrs. M. will perform feeding with setup assistance using built-up utensils with her right hand.
3. Mrs. M. will perform toileting with minimal assist for clothing management.
4. Mrs. M. will increase standing tolerance to 15 minutes in preparation for grooming at the sink while standing.

	Consider the patient's appraisal of performance	"Mrs. M. is extremely motivated to use her right arm and hand. She reports being fiercely independent prior to the stroke and is willing to attempt any activity that is presented to her during therapy. She does not want to be a burden to her children."
	Consider what will occur in therapy, how often, and for how long	"I will have to constantly ask Mrs. M. how she is feeling during therapy and determine whether she needs rest breaks. With the combination of her motivation and her difficulty speaking because of the aphasia, it is easy to forget to give her rest breaks."
	Ascertain the patient's endorsement of plan	"Mrs. M. was actively involved in selecting goals that were meaningful to her."

Summary of Short-Term Goals and Progress

1. Mrs. M. will incorporate her right hand/arm into grooming and feeding activities 70% of the time.

   Functional activities: Mrs. M. was encouraged to incorporate her right arm into every activity, even if she had limited movement. She could use the weight of her arm and the limited grasp that she had to stabilize items such as her toothbrush while squeezing the toothpaste with her left hand. She was able to place her arm independently on table top surfaces because she had sufficient proximal movement.

   Modalities: Electrical stimulation with the Bioness® unit was used to help strengthen movement in her hand and assist with motor planning. The purposeful activities of reaching for grooming items with the Bioness® assisting with her grasp also strengthened the proximal movement in her arm (Fig. 21-14A). The occupational therapist applied Kinesio tape to her wrist and finger extensors to help facilitate extension during her release of objects (see Fig. 21-14B).

   Repetition: Grasp and release of items were practiced with a variety of items and in various environments including sitting and standing. Mrs. M. practiced moving colored balls from one bin to the other using her right hand while standing (see Fig. 21-14C). She had more difficulty with release than grasp. Mrs. M. required verbal cues to avoid compensatory movements and to ensure that she was focused on the quality of the movement. Mrs. M. responded well to verbal cues. A cognitive and linguistic component was added to the activity by having Mrs. M. move balls in a specific color sequence. On occasion, she dropped the balls and appeared frustrated. She benefited from a seated rest break at these times.

| | Assess the patient's comprehension | "Mrs. M. has aphasia. She seems to have more difficulty getting her words out than understanding what has been said. I need to consult with the speech therapist to ensure she really understands what I am saying when I give her directions. She may have more difficulty understanding or remembering what I have said than I initially expected." |
| | Compare actual to expected performance | "Mrs. M. gained back motor recovery in her arm faster than I expected or that I have seen consistently in the past. I think this is due to her persistence and practice. She also demonstrated good carryover of the movements practiced both within and between therapy sessions." |

Figure 21-14 Interventions with Mrs. M. **A.** Mrs. M. using the Bioness® for grasp and release of containers. **B.** Mrs. M. reaching for spices while standing (right hand has Kinesio tape to facilitate finger and wrist extension). **C.** Mrs. M. reaching for balls to practice grasp and release while standing.

Mrs. M. participated in bilateral arm training with an auditory cue. Mrs. M. had to touch the edge of the table with both her hands at the same time as the metronome made a sound. The speed of the metronome was adjusted to match Mrs. M.'s speed of reaching the table with her right hand. She was encouraged to perform 30 repetitions and then take a rest break. This activity was completed during the group session because she only required assistance setting up the metronome and practicing the task a few times before she was able to perform the task without the therapist's continuous assistance.

2. Mrs. M. will perform upper body dressing activities with minimal assist for fasteners.

Preparatory activities: Mrs. M. had tightness/shortening in her pectoralis minor and latissimus dorsi, which resulted in poor dissociation between the scapula and thorax. She benefited from scapular mobilization stretches in side lying as a preparatory activity. To help strengthen her arm, she performed closed chain strengthening activities in sitting and standing as well as open chain reaching activities.

Dressing: Mrs. M. performed the task while short sitting. She learned to dress the right arm first because the shirt could be moved to accommodate the movement she had in the right arm. Mrs. M. was encouraged to use the movement in her right shoulder and elbow to push her arm through the sleeve. She was unable to fasten the buttons on her shirt, so she was encouraged to either ask for assistance or wear shirts that did not have fasteners and were looser so they were easier to don/doff.

3. Mrs. M. will perform toilet transfer with minimal assist using a raised toilet seat.

Mrs. M. required moderate assistance to stand from a standard toilet seat due to impaired standing balance and fear of falling. Mrs. M. practiced sitting and standing from a variety of surfaces. Initially, she was resistant to the idea of having to use a raised toilet seat due to impaired standing balance and fear of falling. Mrs. M. practiced getting up from a regular height toilet and realized that she needed more assistance than when she used a raised toilet seat. Mrs. M. felt more confident performing the transfer with a grab bar on her left side so that she could hold on as well as using the raised toilet seat.

Next Steps

Mrs. M. achieved her short-term and long-term goals on discharge from inpatient rehabilitation after 3 weeks. She was able to use her right dominant hand as a FUEL semifunctional assist when grasping and releasing objects, i.e., item retrieval, pulling up pants, and feeding. Mrs. M.'s Fugl Meyer Motor Assessment score improved to 39/66. She was able to negotiate to the bathroom without a device and transfer on and off a raised toilet seat with supervision. Mrs. M.'s balance had improved, but her endurance was still limited, and she required additional assistance when she became fatigued.

Mrs. M. was provided with a home exercise programs that included pictures and descriptions of the activities she had practiced during therapy. She was encouraged to follow a daily schedule to ensure the home exercises were performed consistently upon discharge.

Mrs. M.'s daughter came in for caregiver training focused on ADL performance, safe transfers, and the home exercise program. A grab bar and raised toilet seat were ordered for her daughter's home.

The occupational therapist provided Mrs. M. with her contact information in case she had any questions once she left the hospital.

Mrs. M. is scheduled to receive home care services at her daughter's house for a few weeks. Following this, she is planning to participate in occupational therapy as an outpatient. Goals are to further improve standing balance/endurance, functional use of her right arm, and independence in daily activities.

Objectives	Examples of Therapist's Internal Dialogue
Anticipate present and future patient concerns	"Mrs. M. made great progress in her 3 weeks of acute rehabilitation. I think that Mrs. M. will continue to make an impressive recovery based on her motor return and her strong determination to get better."
Decide whether he or she should continue or discontinue therapy and/or return in the future	"She would benefit from occupational therapy at her daughter's home to address the barriers she encounters there. Once she has adjusted to managing life outside of the hospital environment, she would benefit from outpatient occupational therapy. Mrs. M.'s goal of returning to living independently in her own apartment is still an appropriate continued long-term rehabilitation goal."

case example
Mr. S.: A Man with Left Hemiplegia

Clinical Reasoning Process

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mr. S. is a 61-year-old right-handed male admitted to an acute inpatient rehabilitation facility approximately 3 weeks after experiencing a right middle cerebral artery infarct. He has resulting dense left hemiplegia. Mr. S. is a semiretired Broadway actor who lives with his supportive wife in a New York City elevator apartment with three steps to enter. She is a retired teacher. Mr. S. was independent in activities of daily living (ADL) and instrumental activities of daily living (IADL) prior to the stroke. His short-term primary goal at this time is to return home at the most independent level as possible. Mr. S. would eventually like to return to the stage as an actor.	Appreciate the context	"I believe Mr. S.'s left hemiparesis is a significant factor that is impacting his ability to function independently at home and at work. I am assessing the environmental context to which he will be returning and the social supports he will have there. Mr. S.'s primary goal at this time is to return home as independently as possible. He would like to return to his job as an actor in the more distant future." "It is still too early to predict the extent of Mr. S.'s motor recovery. I will do all that I can to prevent the development of secondary impairments that could limit his ability to function to his full potential."

Mr. S.'s Initial Clinical Assessment

In sitting, Mr. S. presented with a posterior pelvic tilt, right pelvic obliquity (right anterior superior iliac spine lower than the left), and left lateral trunk flexion. His left scapula was depressed, adducted, and downwardly rotated. There was a one-finger-breadth inferior subluxation of the humerus and evident supraspinatus and infraspinatus muscle atrophy. Passive range of motion was full. The more involved left upper extremity (UE) was generally hypotonic throughout except for minimal hypertonicity noted in the humeral internal rotators and adductors and elbow flexors. Right UE movement and sensation were within functional limits. Mr. S. did not report any pain.

Mr. S. did not exhibit any spontaneous UE movement against gravity; however, he was able to initiate scapular elevation in the gravity-eliminated plane. While seated with the weight of his arm displaced by the therapist, Mr. S. was also able to initiate shoulder flexion and elbow extension.

Functional use the left UE: Upon admission, Mr. S. was able to incorporate his left UE as a Functional Upper Extremity Levels (FUEL)-dependent stabilizer (see Definition 21-5) (i.e., he had enough awareness of his left UE and was able to use his less involved right UE to place his left UE on the table during functional activities such as meals) with minimal cueing from the therapist. Mr. S. was also able to use his right UE to place the left UE into the hole of the shirt sleeve and had enough movement to put the left UE down into the sleeve into the direction of gravity (i.e., sleeve placed in the direction of the floor) with moderate cueing from the therapist. He lacked the available movement at this time to move the UE against gravity during functional tasks without the support and guidance of his right UE.

Functional mobility: Mr. S. could sit unsupported, but lost his balance when attempting to turn his head or trunk. He required moderate assistance to move from supine to sitting on the edge of the bed. However, he compensated mostly with the right side of his body and made few attempts to incorporate the left side of his body (even though Mr. S. had minimal volitional movement of his left lower extremity [LE]). Mr. S. required maximal assistance to transition from sit to stand and needed maximal facilitation of his pelvis and left LE to maintain a standing position for about 30 seconds.

Sensory testing revealed impaired light touch and proprioception throughout the left UE.

Cognition/perception: Mr. S. was alert and oriented to time and place (A & 0 × 2) (he required cueing for the date). He also demonstrated moderate impulsivity and judgment (i.e., attempting to get out of bed without assistance) and had impaired insight into his deficits (i.e., stating that he does not need assistance to move from the bed to the wheelchair). Mr. S. also demonstrated moderate impairments in overall attention (able to attend to tasks for 3–5 minutes in a quiet environment) and a left spatial neglect.

Functional status: Mr. S. required minimal assistance for eating and grooming, maximal assistance for upper body dressing, and total assistance for lower body dressing, toileting, and bathing. He required maximal to total assistance for functional transfers from the bed to the wheelchair.

Develop intervention hypotheses	"I hypothesize that a combination of UE remediation interventions and compensatory strategies where necessary will facilitate Mr. S.'s return home and possible eventual return to work."
	"I also hypothesize that, to prevent future secondary impairments, it will be important for Mr. S. to improve his postural alignment in sitting. In particular, he will need to relearn how to move his pelvis into the positions of neutral and anterior tilt, and he will need to develop the ability to maintain a symmetrical trunk posture."
	"I hypothesize that improvements in sitting posture, sitting balance, and the ability to move from sit to stand and stand to sit will be important to Mr. S.'s ability to meet his ADL and functional mobility goals."
Consider the evidence	"I know that individuals with right-sided brain lesions may be impulsive and show a lack of awareness of their deficits. I also know that 'learned nonuse' is a common occurrence after stroke (Taub et al., 2006)."
	"I know that functional electrical stimulation (FES) to the supraspinatus in particular is effective in reducing shoulder subluxation."
	"I know that functional sitting balance is dependent on underlying mobility in the trunk, pelvis, and scapula."
	"I know that functional movement of the upper limb is dependent on full mobility of the scapula (for scapula-humeral rhythm), full mobility of the pelvic girdle, and the capacity to maintain sitting balance when he shifts his body weight during functional transfers."
	"Additionally, I know that I need to be particularly proactive and retrain and maintain the length of certain muscle groups, that is, humeral external rotators, which I know are currently underactive and likely to be overshadowed by the stronger and more numerous internal rotators (i.e., latissimus dorsi, pectoralis major), which are already showing some signs of hypertonicity."
	"In considering possible interventions for facilitating UE movement, I know that mental practice, mirror therapy, and FES have been shown to improve motor recovery." (Teasell et al., 2012)
Reflect on competence	"I have several ideas for how to potentially restore some UE movement. I need more information about Mr. S.'s home environment and whether his wife will need assistance in caring for Mr. S. at home."

Recommendations

Clients at the rehabilitation facility where Mr. S. is a patient receive 1 hour of 1:1 individual occupational therapy (OT) session daily, 6 days per week. The typical length of stay is approximately 17 days. Determination of the length of stay is an ongoing interdisciplinary decision (i.e., physician, occupational therapist, physical therapist, speech-language pathologist, neuropsychologist and social worker meet weekly to determine length of stay. Insurance coverage must also be considered). Additionally, Mr. S. will participate in a 1-hour morning breakfast/UE retraining group 5 days a week for extra practice, incorporating his left UE into the functional task of eating and other functional activities.

At this stage of rehabilitation, occupational therapy will focus on tasks related to Mr. S.'s ability to perform ADL. Assessment of Mr. S.'s home environment and caregiver availability and competence will be completed later. Closer to discharge from this facility, occupational therapy will collaborate with the interdisciplinary team to determine whether Mr. S. should be discharged to his home (where he will receive home therapy) or to a subacute facility. Closer to discharge, occupational therapy will address caregiver training and ordering of appropriate durable medical equipment (i.e., commode, shower chair).

Critical factors impacting Mr. S.'s ADL performance are a significant lack of available movement in his left upper and lower extremities, impaired awareness of deficits, impaired overall attention, and left spatial neglect.

Summary of Short-Term Goals and Progress

1. Mr. S. will improve pelvic, trunk, and scapula alignment and control.

   Early treatment with Mr. S. focused on manual interventions such as soft tissue stretching to address pelvic, trunk, and scapula alignment. In particular, the therapist needed to improve the following problems in postural alignment: posterior pelvic tilt, right pelvic obliquity, left trunk lateral flexion, scapular adduction, downward rotation, and depression.

   FES was used to stimulate critical scapula muscles affecting scapula-humeral alignment. These included infraspinatus (for external rotation), anterior and posterior deltoids, and serratus anterior. FES was used in the context of functional tasks involving UE weight bearing and guided reaching. Bioness® was initiated (sometimes in combination with FES at the scapula and shoulder muscles) to the left hand finger extensors and flexors to give additional distal sensory input. The therapist helped unweight and guide Mr. S.'s left UE during reaching activities while the Bioness® facilitated finger flexion and extension. Mr. S. was able to grasp and release large objects.

   Mr. S. also participated in motor retraining activities illustrated in Fig. 21-13, with the occupational therapist using FES and EMG (electromyographic)- triggered FES to assist his emerging control over his triceps and anterior deltoid muscles.

   Mr. S. was also initially given a 10–15-minute mirror therapy program to do in his room in the evenings when he was not in therapy. Mr. S.'s wife agreed to help oversee this and to encourage Mr. S. when he needed it. Mr. S. was given a mirror box, and he and his wife were instructed on how to set up the adjustable-height tray table in his room. Mr. S. was told to place his left UE into the box and to move his right UE in front of the mirror. Mr. S. was told to imagine that both hands were moving together. Mr. S.'s wife was instrumental in ensuring that Mr. S. completed this "homework" on a consistent basis most evenings.

Consider the patient's appraisal of performance

"I think Mr. S. is motivated to improve his movement and function. However, he overestimates his abilities and shows impaired awareness of his deficits. Additionally, the stroke occurred recently, so precisely how much function Mr. S. will regain is still an unknown."

Consider what will occur in therapy, how often, and for how long

"Mr. S. will be seen for OT daily for at least 1 hour for the duration of approximately 3 weeks in acute inpatient rehabilitation. From there, I expect him to either be discharged home (where he will receive home therapy) or transfer to a subacute facility where he will receive daily therapy but on a less intensive basis. If Mr. S. is discharged home, however, I anticipate that he will need a significant amount of assistance. I will need to determine whether his wife is able to provide this level of care. Even if she is able to, she may need some respite in the form of hired assistance. Mr. S. is unlikely to receive a significant amount of home care through his insurance plan. In the future, it is likely that Mr. S. will require outpatient therapy. The recovery of his function and movement will be a process that will occur over time."

"Mr. S. seems to have an appreciation of the factors that are limiting him from participating in his daily life as he did before the stroke. I anticipate he will participate in OT to the maximum extent possible."

Assess the patient's comprehension

Understand what he is doing

Know the person

"Mr. S. was distractible and had decreased attention to the left side of his body. He also had difficulty planning movements (mostly on the left side of his body). Mr. S. was motivated, however, and improved in time with repetition."

"Because Mr. S. was often distractible, I found that he performed better in a quiet environment with limited distractions. Mr. S. did improve over time, however, and I gradually incorporated more stimulation into treatment sessions (i.e., treating in a noisier therapy clinic). Fortunately, Mr. S.'s wife was very involved, and she oversaw the homework I assigned him to do in his room in the evenings. This gave him more valuable chances for practice than he would have had without her."

"Because Mr. S. had impaired awareness of his left UE, he did not incorporate his left UE into tasks. I was concerned that Mr. S.'s left UE, particularly his shoulder, would get injured (i.e., if the arm fell off his lap and he failed to notice it) so I educated Mr. S.'s wife as well as the nursing staff concerning positioning and care of the left UE because he had limited ability to carry over techniques by himself."

"Mr. S.'s recovery was slower than I would have wanted but similar to what I expected given his impaired awareness, distractibility, and left neglect. However, Mr. S. is a hard worker, and I anticipate he will continue to make clinical and functional gains over a longer period of time."

2. Mr. S. will improve his awareness and attention to the left side of his body and environment during functional activities.

   The occupational therapist arranged for Mr. S.'s bed to be placed so that he was required to turn to the left to see his wife and others as they entered the room. The occupational therapist also instructed Mrs. S. to interact with her husband so that he would be repeatedly required to attend to his left side. During all therapy tasks, the occupational therapist encouraged Mr. S. to scan the environment from left to right. For example, during grooming activities, Mr. S. was required to find his comb and toothbrush which were positioned on the left side of the sink.

   Interventions for goals 3 and 4 also facilitated the achievement of this goal. At discharge, Mr. S was consistently scanning the environment and appropriately noticing objects within his left visual field.

3. Mr. S. will manage his left UE during positioning and functional mobility tasks at least 50% of the time.

   When he was admitted to this rehabilitation facility, Mr. S. had little available movement of his left UE and required moderate cueing to manage it during functional mobility tasks, such as during functional transfers and bed mobility and while sitting in the wheelchair (i.e., placing his left UE on the half lap tray). Mr. S. demonstrated a lack of awareness of his left UE and LE.

   Initially, the occupational therapist worked with Mr. S. to manage his UE when seated in the wheelchair (i.e., use his right UE to place his left UE on the half lap tray) and to prevent the left UE from falling off his lap while seated. The goal during the first week was for Mr. S. to do these activities with minimal prompting.

   The occupational therapist also worked on Mr. S.'s transitional movements during functional mobility (i.e., scooting, squat pivot transfers, bed mobility, bed positioning, and sit-to-stand transitions). Mr. S. tended to forget about his left UE, and it was frequently in a place where it could get injured (i.e., falling off the edge of the half lap tray of his wheelchair). Compounding this issue was the fact that Mr. S. had impaired sensation in his left UE and did not know where it was. The occupational therapist repeatedly reminded Mr. S. to use his vision to see where his left UE was.

   Mr. S.'s wife and the nursing staff were also given written information with photographs depicting proper positioning of Mr. S.'s left UE (and LE) in the wheelchair and in bed. It also included how the UE should be handled during functional mobility and transitional tasks.

4. Mr. S. will independently incorporate his left UE 50% of the time as a dependent stabilizer into functional tasks such as eating, grooming, and dressing.

   Because Mr. S. had very limited available movement and impaired awareness of his left UE, he required considerable cueing to incorporate it into functional tasks such as eating, grooming, and dressing. The occupational therapist educated Mr. S. and his wife regarding the importance of trying to incorporate the UE even though it was difficult and even though he could not use his UE the way he did prior to the stroke.

"Because Mr. S. was an actor, I created an analogy to link the concept of neuroplasticity to acting and rehearsal in particular. I discussed how practice helped Mr. S. remember his 'lines' in a play. I reminded him that when he was initially studying for a role, he may not know the sequence of his lines or what he is supposed to say. However, over time and with a lot of rehearsal, this improves to the point where he is able to perform his lines in front of a Broadway audience. I asked how Mr. S. would feel if he did not have time to rehearse or had to step into a role at the last minute. He conceded that he would feel unprepared and would not be able to perform as well. Then I compared this to the role of practice in regaining function at this time."

Mr. S. participated daily in the breakfast group in the occupational therapy clinic. This group focused on ways for Mr. S. to consistently incorporate his left UE into eating at a dependent stabilizer level. During eating, Mr. S. was encouraged to place his UE on the table at all times while eating and to use it to stabilize containers as he used his right UE to open lids. He also needed to use his right UE for utensil management and bringing food to his mouth because he did not have enough movement in his left UE to do this presently. Mr. S. required moderate cueing to incorporate his left UE in this way.

Mr. S. and his wife were also given written educational materials and photos for how he could carry over these techniques in his room. Fortunately, Mr. S.'s wife was present with him for lunch and dinner, so she was able to ensure the table was set to the correct height and that Mr. S. was using his left UE as a dependent stabilizer consistently.

Still, Mr. S. had a difficult time with this concept and seemed to view the use of his left UE as an "all or nothing phenomenon," that is, if he couldn't use it the way he did before the stroke then it was "no use trying." The occupational therapist explained that there are different ways the UEs can be used and that there can be improvement with practice.

case example
Mr. J.: A Man with Right Hemiparesis and Ideomotor Apraxia

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information	Appreciate the context	"Although it is difficult to tell from Mr. J., I believe his primary goal is to return home and to function as independently as possible. His wife and children agree with this plan. However, they are open to the possibility that Mr. J. may need to go to a subacute rehabilitation facility after discharge from this facility."
• Mr. J. is a 76-year-old right-handed male who sustained a left cerebrovascular accident approximately 2 weeks ago. He is now admitted to acute rehabilitation for a 3-week length of stay.		
• Mr. J.'s primary deficits are aphasia (patient is nonverbal) and ideomotor apraxia (IMA).		"It is still too early to predict the extent of Mr. J.'s recovery. I will do all I can to promote his recovery and train and educate his family about IMA and how to help Mr. J. perform to his potential."
• Mr. J. is a retired college professor who resides in a private home with two steps to enter. He was independent in activities of daily living (ADL) and instrumental activities of daily living (IADL) prior to admission and was very active in his community, travel, and sports. His wife and three children are very supportive.		
• Postural alignment is WNL (within normal limits).		"I know that Mr. J.'s aphasia and IMA are very frustrating for him and for his family."
• Upper limb use: Mr. J. shows capacity to perform significant movement with his right upper extremity (RUE). However, he has great difficulty initiating and executing movements and tends to rely on his left upper extremity (LUE). However, movements with the LUE are far more awkward than would be expected, even for a nondominant arm. For instance, when Mr. J. was squeezing toothpaste onto a toothbrush with his left hand, he held the tube in an awkward fashion and had a hard time getting the paste onto the toothbrush.		"I will need to provide all treatment in a highly functional context and use a minimum of language-based commands during therapy sessions."
• Gross mobility: Bed mobility and sit to stand (STS) are extremely inefficient, awkward, and unsafe. To an observer, it appears that Mr. J. is "using the wrong parts of his body at the wrong times."		

• Communication/cognition: Mr. J.'s yes/no responses are unreliable either by head nod/shake or by pointing to letters or the words yes/no on a page. Gesturing is extremely difficult. He can accurately follow one-step commands about half the time during functional contextual tasks.	Develop intervention hypotheses	"A compensatory strategy training approach using errorless support techniques will help Mr. J. compensate for his IMA during performance of daily tasks. Mr. J. and his family are highly motivated to help him meet his maximum potential."
	Consider the evidence	"Level I evidence exists for the efficacy of a compensatory strategy training approach to improve ADL function in people with IMA. Constraint-induced movement therapy (CIMT) research supports the value of preventing learned nonuse of a paretic upper limb, whenever possible."
	Select an intervention approach	"I have decided to use a compensatory strategy training approach using errorless support techniques. We will also work toward prevention of learned nonuse of RUE."
	Reflect on competence	"I have worked with other patients with IMA. I will be attuned to Mr. J.'s responses to my cueing strategies so that I can find the best approach to facilitate his performance."

Recommendations Mr. J. will participate in 1-hour occupational therapy sessions daily for 6 days per week. In addition, he will participate in a 1-hour breakfast/UE retraining program five mornings per week. The occupational therapist will focus on teaching Mr. J. strategies for planning gross movements (STS for stand transfers, bed mobility), using his paretic RUE, and performing tasks requiring both arms/hands while sitting and standing. In addition, the occupational therapist will implement compensatory strategy training to assist him in compensating for his IMA during functional tasks.	Consider the patient's appraisal of performance Consider what will occur in therapy, how often, and for how long	"I think Mr. J. is motivated to improve his function and movement. He tries really hard to do what I ask of him. However, I also think he is appropriately frustrated. It is difficult to explain to him the reasons why we are doing certain things because of his aphasia." "Mr. J.'s length of stay at this acute rehabilitation facility will be about 3 weeks."

Summary of Short Term Goals and Progress
 	
1. Mr. J. will be able to perform functional mobility tasks (i.e., supine to sit, sit to supine, and STS) with minimal prompting.
  • Task-specific training focused on STS, and later, sit to supine and supine to sit—using errorless support (teaching him to posturally set himself, using manual assistance to pelvic and trunk movements, and decreasing to tactile cues).
  • Physical therapy and nursing staff collaborated, using similar strategies during physical therapy sessions and activities on the nursing unit.
  • After 2 weeks, Mr. J. was able to perform STS, supine to sit, and sit to supine with minimal cueing.
 	
2. Mr. J. will perform purposeful, bilateral activities—using his RUEs and LUEs.
  • Treatment initially focused on simple bilateral UE activities.
  • At times, the occupational therapist used a metronome to incorporate a timing aspect to the movements.
  • Once he was able to perform a simple, single-plane bilateral activity, treatment progressed to circular and diagonal movements. Initial interventions aimed at Mr. J. moving both UE in the same direction but progressed to him moving them in opposite directions during the first few weeks of therapy.
  • Treatment to develop foundational motor control of the right scapula enabled Mr. J. to begin to use his RUE for functional assist to his LUE during daily activities.
	Assess the patient's comprehension	"At the beginning of treatment, Mr. J. was awkward and unsafe in performing gross mobility activities."
		
		"At the beginning of treatment, Mr. J. failed to incorporate his RUE into tasks despite the presence of a considerable amount of available movement. Further, when he did try to use it, the movements were awkward, clumsy, and inefficient, and Mr. J. spilled food frequently onto his lap."
		
		"A large part of the occupational therapy treatment was educating Mr. J.'s wife and family so that they could cue him appropriately when he was not in therapy and improve his function."
		
		"Simple, uniplanar, bilateral UE activities were designed to give Mr. J. a chance to see that he was capable of moving both UEs in a coordinated way."

3. Mr. J. will use his RUE to stabilize containers 75% of the time during meals (while bringing food to his mouth with his LUE) by 1 week.
   - In the breakfast group, the occupational therapist initially demonstrated how Mr. J. could stabilize a milk container with his RUE while opening it with his left. The occupational therapist used demonstration and hand-over-hand guidance to approximate the appropriate "shape" and pressure with his RUE to get the container open with his left hand. As Mr. J. improved, she decreased this cueing.
   - The occupational therapist gave Mr. J. adapted devices to assist him in eating successfully. These included a nonskid mat to prevent the plate and containers from sliding on the table while Mr. J. was attempting to open containers or eat. The occupational therapist also provided Mr. J. with a mug with a lid so he could drink without spilling.
   - The occupational therapist educated Mr. J.'s wife and the nursing staff on how Mr. J. could carry over these techniques during times outside of therapy (i.e., when he was served lunch and dinner in his room). Mr. J.'s wife was able to follow this hierarchy of cueing, that is, the use of demonstration if Mr. J. got stuck and hand-over-hand guidance when absolutely necessary.
   - After 1.5 weeks, Mr. J. was incorporating his RUE to stabilize containers about 50% of the time.
   - Mr. J. progressed to bringing food to his mouth with his RUE when there were "easier" to eat or finger foods on his tray (i.e., bananas, toast). The occupational therapist progressed to this as soon as possible because Mr. J. was right handed, and it was more natural to eat with his RUE if he could.

4. Mr. J. will use his RUE to help with clothing management during toileting with minimal cuing.
   - The occupational therapist used hand-over-hand and cueing strategies to help Mr. J. use his right arm when managing his clothing during toileting (i.e., pushing pants down and pulling them up). Mr. J. had a lot of difficulty pushing/pulling and grasping/releasing at the appropriate times. The cues were gradually decreased as Mr. J. improved. Mr. J. met this goal in about 2 weeks.

5. Mr. J. will stand symmetrically during toileting.
   - Occupational therapy improved Mr. J.'s ability to shift his weight onto his right LE during occupational therapy clinic activities.
   - Once Mr. J. was incorporating his RUE more and once he was more secure in shifting his weight during similar dynamic tasks, the occupational therapist began to encourage Mr. J. shift his weight to his right LE during the toileting activity.

At this time, Mr. J. requires setup for eating and grooming and minimal assistance for upper body dressing and toilet transfers. He requires moderate assistance for lower body dressing and toileting. These are improvements, but Mr. J. and his family would like him to be more independent.

Understand what he is doing

"Mr. J. took pride and pleasure in seeing that he could drink from a cup without spilling."

Appreciate the context

"Mr. J.'s independence in toileting was a significant goal for the patient and his family."

"Despite the fact that Mr. J. was incorporating his RUE more during functional activities such as eating and bed mobility, there was little carryover to other activities."

"Mr. J.'s recovery was about the pace that I expected considering the extent and nature of his deficits."

"I anticipate that Mr. J.'s recovery will extend into outpatient therapy and beyond. I am encouraged by Mr. J.'s motivation and the dedication of his wife and family."

Next Steps

- The goals for the next week at this facility are to continue to work on increasing Mr. J.'s independence in ADL, continue training and educating Mr. J.'s family, and ordering durable medical equipment for Mr. J.'s bathroom activities.
- Mr. J. will receive about 2–3 hours per day Monday through Friday of home health assistance through Medicare. Mr. J.'s family plans to hire help for an additional 4 hours a day (7 days a week) to assist and offer some respite to Mr. J.'s wife. She will be with him at nighttime where the plan will be for him to use a bedside commode with the assistance of his wife if needed.
- Outpatient occupational therapy services will be arranged, closer to his home, to provide ongoing opportunity to improve function in motor planning and motor control, as well as return to social and community activities.

Anticipate present and future patient concerns	"Mr. J. has another week remaining at this inpatient rehabilitation facility. After discharge, his family would like to take him home."
Decide whether he or she should continue or discontinue therapy and/or return in the future	"I believe that home-based occupational therapy services will be essential in helping Mr. J. and his family make the transition to living at home and in training him to perform activities within his home environment."

Summary Review Questions

1. How do motor deficits associated with upper motor neuron dysfunction differ from those associated with lower motor neuron dysfunction?
2. What contributions from the Brunnstrom, Rood, NDT, and PNF approaches are still relevant in neurorehabilitation today?
3. Occupational therapists use task-based intervention to improve motor performance in people who are recovering from stroke and brain injury. In what ways is this intervention consistent with neuroscience evidence and current theories about motor learning and motor control?
4. Why is variable practice more effective than repetitive practice for developing flexible motor strategies?
5. How and why do occupational therapists use object affordances when designing treatment for persons who are recovering motor function after stroke or brain injury?
6. Identify interventions described in this chapter that have been influenced by findings in CIMT research.
7. Some researchers and clinicians believe that it is best practice to prevent patients from developing abnormal synergy patterns in their paretic upper limb. Others believe that this is merely a phase of recovery. Present arguments in support of each of these views.
8. Explain this statement: Postural alignment and motor execution are *necessary but not sufficient* for functional movement.
9. Why is it important to help patients develop balance skills in preparation for improving upper limb function?
10. In what ways are OT interventions to improve motor planning and performance in patients with IMA similar to and different from interventions with other neuromotor goals?

Glossary

Affordances—Specific characteristics of objects or environments that influence the way an individual will perform an action.

Attractor state—Preferred pattern of organization within a system.

Control parameter—Variable that, when changed, will influence changes in a system's pattern of organization.

Degrees of freedom—Number of elements that are free to vary within a system and hence must be controlled.

Explicit learning—Acquisition of information through verbal, written, pictorial, visual, or tactile/proprioceptive instructions.

Functional upper extremity levels (FUEL)—A hierarchical classification of arm and hand function that guides the choice of therapeutic tasks and challenges for patients with neuromotor disorders.

Ideational apraxia (IA)—Inability to plan movement caused by difficulty in judging the overall purpose and/or sequence of task performance.

Ideomotor apraxia (IMA)—Inability to plan movement caused by difficulty matching motor actions to physical qualities of the task objects.

Implicit learning—Skill development through active practice.

Kinematics—Description of movement in terms of direction, speed, and position of body segments.

Kinetics—Description of movement in terms of forces required.

Postural adjustments—Automatic, anticipatory, and ongoing muscle activation that enables individuals to maintain balance against gravity; optimal alignment between body parts; and optimal orientation of the head, trunk, and limbs in relation to the environment.

Practice—Opportunity to develop skill through engagement in tasks that require problem solving and implementation of effective motor strategies.

Regulatory condition—Control parameters within the task or environment.

Scaption—Movement at the glenohumeral joint within a plane that lies between the sagittal and coronal planes.

Shaping—Psychological term used to describe training that provides incremental challenges to the learner.

Skill—Goal-directed patterns of movement that efficiently address the spatiotemporal demands of a task.

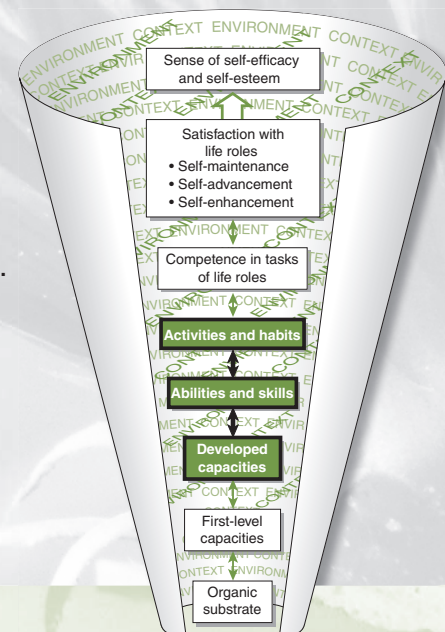
Optimizing Motor Behavior Using the Bobath Approach

Kathryn Levit

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Identify the major problems that result from stroke according to Bobath and Bobath.
2. Describe the major principles underlying the Neuro-Developmental Treatment (NDT)/Bobath approach to stroke rehabilitation.
3. Discuss the role of muscle tone and postural control in the production of normal movement, and describe how problems in these areas contribute to impaired occupational functioning.
4. Integrate NDT/Bobath concepts and techniques with the Occupational Functioning Model.
5. Develop an occupational therapy treatment plan for a patient with acute stroke using NDT/Bobath principles and techniques.


Berta and Karel Bobath, a physiotherapist and a neurologist, respectively, developed the Neuro-Developmental Treatment (NDT) approach to reduce impairments of sensorimotor control of children with cerebral palsy and adults with stroke. They founded a center in London and traveled, teaching their method to physical and occupational therapists. As a result, the Bobath approach is widely used in the United Kingdom (Raine, 2006; Tyson & Selley, 2007) and other European countries as well as the United States. Of 107 therapists in Kansas and Missouri responding to a questionnaire, 93% of the physical therapists and 85% of the occupational therapists reported using either the Bobath or Brunnstrom approaches (Natarajan et al., 2008).

Bobath practitioners elicit and reestablish movement patterns through therapist-controlled sensorimotor experiences within the context of task accomplishment (Levin & Panturin, 2011). The therapist inhibits synergistic movements and abnormal tone and facilitates normal movement through handling techniques (Teasell et al., 2008). The therapist assists and/or guides normal movement patterns to accomplish functional tasks until no guidance is necessary (Tyson & Selley, 2007).

The Bobath approach has been researched more than any of the other neurophysiologically based approaches. The online chapter mentions some of the studies. Since that was written, several other studies have been reported. One study compared the Bobath approach to the Motor Relearning Programme (MRP) of Carr and Shepherd (2003) and found that the task-oriented exercises of the MRP resulted in significantly better quality of movement in acute rehabilitation of patients with stroke (Langhammer & Stanghelle, 2011). Another study found the two approaches equally effective for improving movement ability and functional independence (Van Vliet, Lincoln, & Foxall, 2005). A systematic review of randomized, controlled trials designed to evaluate the effectiveness of the Bobath concept in stroke rehabilitation (16 studies involving 813 patients) concluded that the Bobath concept is not superior to other approaches (Kollen et al., 2009). However, the Bobath approach was found superior to an orthopedic approach of strengthening weak muscles using passive through resistive movement for improving functional mobility (Wang et al., 2005).

Bobath instructors continue to publish (Gjelsvik, 2007) and offer courses in this method, which continues to develop as therapists' understanding of movement science broadens (Raine, 2006). Worldwide course locations and schedules are available from the NDT Association, which is listed in the Resources Box of the online chapter.

This chapter is available online at http://thepoint.lww.com/Radomski7e.

Optimizing Motor Behavior Using the Brunnstrom Movement Therapy Approach

Catherine A. Trombly Latham

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. State the assumptions that underlie the Brunnstrom Movement Therapy approach.
2. List the six stages of recovery for the upper extremity and for the hand.
3. State the treatment principles of this approach.
4. Describe the treatment procedures to facilitate movement control in the trunk and upper extremity of patients with hemiparesis following stroke using this approach.
5. Suggest functional activities suitable to encourage practice of movement behavior at various stages of recovery.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate
Using the literature of the time and through reflective practice, Signe Brunnstrom, a physical therapist, devised a program of therapy aimed at recovering movement and therefore function in the paretic trunks, arms, and legs of people who had suffered stroke (Brunnstrom, 1970; Sawner & LaVigne, 1992). The program was designed for patients at any level of recovery, from flaccid to synergistic movement to beginning voluntary movement. To move the patient in the flaccid stage of recovery from preserved organic substrate to first-level capacities (reflexive movement), Brunnstrom used sensory stimulation. Once reflexive movement was evoked, she advocated attention to movement (willed movement to gain control over synergistic movement patterns) and functional, repetitive use of the movement in everyday activities to move the patient to developed capacities (voluntary movement). Ms. Brunnstrom practiced at a time when demonstration of the method and its effects by her or other skilled therapists was enough evidence for other therapists to adopt the method. There has been no formal research on the effectiveness of this approach, and therefore it lacks an evidence base.

From observation of patients recovering from stroke and prior work of Twitchell (1951), Brunnstrom developed what has come to be known as the Brunnstrom Stages of Recovery, still commonly in use and verified to be valid (Naghdi et al., 2010). That classification system was further refined and quantified by Fugl-Meyer et al.

(1975) into what is now called the Fugl-Meyer Motor Assessment (FMA), a widely used tool in research as well as clinical evaluation. It has been found to be a valid and reliable assessment tool (Duncan, Propst, & Nelson, 1983; Gladstone, Danells, & Black, 2002). There is an example of it in the online chapter.

This chapter is available online at http://thepoint.lww.com/Radomski7e.

Kathy Longenecker Rust

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Use knowledge of controlled sensory input to reduce first-order motor impairments and prepare patients with orthopedic and central nervous system conditions for successful participation in occupational performance.
2. Delineate treatment strategies for improving mobility and stability.
3. Analyze the diagonal components of functional activities, and use this knowledge to incorporate optimal movement patterns and positions in treatment.
4. Perform the proprioceptive neuromuscular facilitation (PNF) diagonal patterns of the head, neck, trunk, and upper extremities.

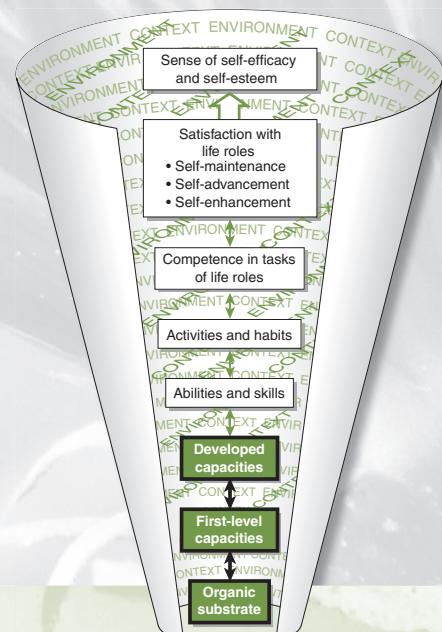
First-level capacities

Organic substrate


Therapists find pieces of each of the two approaches described in this chapter useful in remediating first-level motor capacities when muscular activity has been lost because of injury or disease of the central nervous system, although neither approach has been validly researched *in toto*. Both approaches used Sherrington's (1910, 1947) findings on reflex neurophysiology.

Margaret Rood, both a physical therapist and an occupational therapist, developed and taught her procedures of controlled sensory stimulation and ontogenetic postures and movement patterns for children with cerebral palsy and later adults with a variety of neurological impairments (Rood, 1956). The Rood approach was later further explicated by Stockmeyer (1967). No study examines both aspects of her approach, but a few studies have examined the sensory stimulation aspect, which has been found to be effective in activating muscular response when there appears to be none, although, without specific training, the elicited response does not carry over to functional movement (Carey, 1990; Feys et al., 1998; Kawahira et al., 2010).

Margaret Knott, a physical therapist, and Dr. Herman Kabat, a clinical neurophysiologist, developed the philosophy and practices of proprioceptive neuromuscular facilitation (PNF) in the 1940s (Adler, Beckers, & Buck, 2008; International PNF Association [IPNFA], 2011). Kabat, Knott, and later Voss identified spiral and diagonal patterns of movement as being basic to functional movement. They looked for a balance of agonists and antagonists and facilitated the inclusion of all the muscles involved in a movement through sensory stimulation (resistance) to movement (Voss, 1967; Voss, Ionta, & Myers, 1985). Resistance to movement was believed to cause not only recruitment of muscles in the limb being worked on but also cross-education, that is, activation of the comparable muscle(s) on the opposite side of the body, a notion that has received some research support (Arai et al., 2001). As part of the approach, Knott and Voss developed several techniques to achieve particular goals. One of those techniques, contract-relax, is used frequently by physical therapists and athletic trainers who find it useful in limbering up athletes or patients with orthopedic problems. The effectiveness of this procedure is generally acknowledged (Sharman, Cresswell, & Riek, 2006), although the proposed underlying mechanisms have not been supported (Azevedo et al., 2011; Mitchell et al., 2009).

The PNF approach was initially used in the treatment of persons with multiple sclerosis or poliomyelitis and later applied to patients with neurological and musculoskeletal impairments (Adler, Beckers, & Buck, 2008; IPNFA, 2011). Therapists underwent 3–6 months of advanced training in order to practice PNF. PNF courses are still offered throughout the world by the International PNF Association (Adler, Beckers, & Buck, 2008: IPNFA, 2011).

Both approaches focused the treatment of neuromuscular impairments on remediation of the impaired underlying neuromuscular substrate at a time when treatment was otherwise focused on adaptation. Successful demonstrations by the developers and skilled practitioners of these approaches provide the only testament to their effectiveness.

Optimizing Sensory Abilities and Capacities

Catherine Trombly Latham and Karen Bentzel

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Select appropriate sensory treatment for a patient.
2. Explain the rationale for sensory reeducation and desensitization.
3. Demonstrate a variety of sensory reeducation and desensitization strategies for patients following peripheral nerve injury or repair.
4. Name several mechanisms of damage to areas of skin that result in diminished protective sensation and describe related compensatory strategies to prevent injury.
5. Demonstrate a variety of passive sensory training and active sensory training strategies for patients with sensory impairment following stroke.

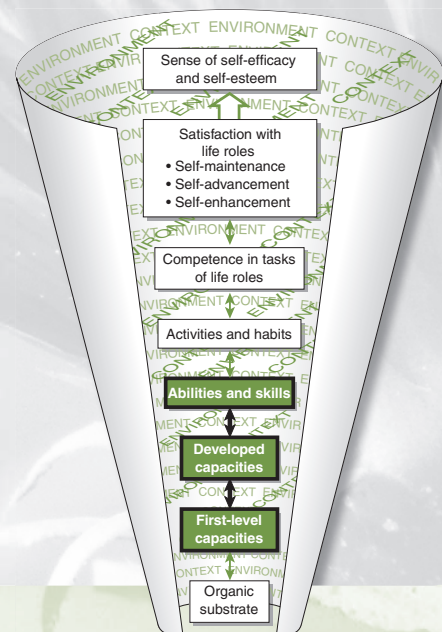
Developed capacities

First-level capacities

Organic substrate


The extent and number of difficulties resulting from loss of tactile and proprioceptive information are difficult to comprehend. The story of Ian Waterman (Cole, 1991), who lost all tactile and proprioceptive sensations from the neck down as a result of a rare neurological illness, can help us understand the disability. When Waterman tried to explain to others what was wrong with him, he found that they could not begin to realize the severe difficulties he faced as a result of his sensory loss. His family and friends failed to find the connection between his sensory loss and his inability to move and complete activities of daily living. Even those in the medical community did not comprehend the extent of his difficulties. Cole provides a detailed account of Waterman's struggle to compensate for his lost sensation in the book *Pride and a Daily Marathon*.

Touch is a developed capacity that supports abilities and skills such as grasping and releasing objects (Duff & Estilow, 2010). These abilities and skills are necessary for competence in self-maintenance, self-enhancement, and self-advancement. Handling and manipulating objects enhances learning and helps human beings appreciate the world. Touch is also a means of communication and a source of pleasure (Lundborg & Rosén, 2007; Rosén & Lundborg, 2010).

Without sensation in the hand, there is a greater risk of injury to the hand and decreased ability to manipulate small objects. There is also a tendency not to use the hand in functional activities, which adds to the phenomenon of learned nonuse, loss of function that results from not using the hand (Carr & Shepherd, 2010; Lundborg & Rosén, 2007; Oud et al., 2007). Because of the role of tactile sensation in learning, exploring, and communicating and because loss of hand sensation is particularly disabling, occupational therapists should provide treatment or education in compensatory strategies for patients with lost or diminished sensation.

CHOOSING AN INTERVENTION STRATEGY

The choice of interventions for sensation is based on the diagnosis, prognosis, and evaluation findings. Diminished or lost protective sensation, the inability to feel pain in response to stimuli that are potentially damaging, suggests a need for teaching the patient and/or caregiver compensatory strategies to prevent injury. Findings of discomfort associated with touch (hypersensitivity) suggest a need for desensitization. Passive sensory training is provided for patients who have lost sensation but are expected to regain some sensory ability. Sensory reeducation (active sensory training) is provided for patients who have some sensation and potential for better sensation or better interpretation of sensory information. Most of the sensory interventions described in this chapter are learning experiences for the patient. Strategies of learning (see Chapter 13) should be applied including practice within the natural context of activities.

COMPENSATION FOR IMPAIRED OR ABSENT PROTECTIVE SENSATION

Protective sensations are sensations of pain and temperature extremes that signal the threat of tissue damage. When the brain receives this message, the normal response is to move the body part away from the source of the stimulus. Without this message, tissue damage can quickly occur. The goal of treatment for the patient with diminished or absent protective sensation is to avoid injury. Treatment consists of teaching the patient and/or the caregiver precautions necessary to prevent injury to any body part with compromised protective sensations. The loss of sensation could be due to diagnoses such as stroke, head injury, spinal cord injury, peripheral nerve injury, or nerve reconstruction.

Rationale for Compensation

In a classic 1969 article in the *American Journal of Occupational Therapy*, Helen Wood described the role of the occupational therapist in preventing injury and deformity in hands that lacked sensitivity. She stated that when hands are used in activities without protective sensory feedback, there is a high frequency of burns, cuts, lacerations, and bruises. Damage or injury to an insensitive limb is the result of external forces that are normally avoided by people who are able to feel pain, which acts as a warning mechanism. Sensations of pain warn us when we are gripping an item too tightly or sitting in one position for too long. Therefore, pain has been considered the most valuable sensation that humans have (Brand, 1979).

Brand (1979) described five mechanisms of damage to insensitive limbs: continuous low pressure, concentrated high pressure, excessive heat or cold, repetitive mechanical stress, and pressure on infected tissue (Definition 22-1). Prevention principles evolve from an understanding of these mechanisms of damage.

Compensation Techniques

Brand et al. (1999) recommend the following content for patient education sessions, based on the five mechanisms of damage to insensitive skin. Skin areas over bony prominences are particularly prone to pressure ulcers because the cutaneous tissue is trapped between the unyielding bone and the external pressure. Frequent position changes are necessary for patients with decreased or absent protective sensation to avoid damage caused by **continuous low pressure**. Cushions for seating and shoe insoles help to distribute forces over larger areas.

Definition 22-1

Mechanisms of Damage Secondary to Loss of Protective Sensation

- Continuous low pressure: With sustained pressure as light as 1 pound per square inch, capillary flow is blocked; this can cause tissue necrosis, leading to pressure sores (decubitus ulcers).
- Concentrated high pressure: Sudden high force that is accidental and/or a high force applied over a very small area, so that the force is inadequately distributed. This may result in tearing of skin and/or soft tissue or tissue necrosis as a result of insufficient blood supply.
- Excessive heat or cold: Temperature extremes that lead to burn or frostbite injuries.
- Repetitive mechanical stress: Repetitive motions or shearing of skin against clothing or objects that causes inflammation of the tendons or skin. Blistering of skin can also occur.
- Pressure on infected tissue: Continued use and pressure on infected tissue can hinder or prevent the natural healing process.

Adapted from Brand, P. (1979). Management of the insensitive limb. *Physical Therapy, 59,* 8–12.

Instruct patients to avoid **concentrated high pressure** by careful handling of sharp tools and by using enlarged handles on suitcases, drawers, tools, and keys. Patients may need to become consciously aware to use only as much force as necessary to grasp objects. Excessive pressure can also result from splint straps that are too narrow and splints that are too tight; therefore, therapists must carefully construct splints to prevent injury.

Teach patients to increase their awareness of potential sources of **extreme heat or cold** and to protect themselves from contact with them. Insulated coffee mugs are recommended. Oven mitts or quality pot holders are necessary for cooking. Utensils with wooden or plastic handles are better than metal ones. Patients using wheelchairs should insulate exposed hot water pipes under sinks. In cold weather, gloves or mittens are necessary protection for insensate hands.

Instruct patients to avoid **repetitive motions and excessive friction** between skin and objects. Decrease repetitions by working for shorter periods, resting, using a variety of tools, or alternating hands or type of grip. Methods to reduce friction include wearing well-fitting gloves and using enlarged or padded handles on tools.

Educate patients who have lost protective sensation regarding special care for blisters, cuts, and bruises necessary to avoid infection. If infection occurs, in conjunction with treatment for the infection, the **infected part** should

be completely rested to keep it **free from pressure** and overuse, allowing healing to occur.

Additional techniques of compensating for absent sensation incorporate reliance on other senses. For example, vision may be used to prevent contact with sharp objects. Using a body part with intact sensation to test water temperature before immersion of any body part without sensation is recommended. Auditory cues may also help to prevent injury. For instance, a person with paraplegia might hear the rubbing of the wheelchair caster against the foot if it slips from its proper position on the leg rest.

Finally, patients should be instructed in good skin care. Applying lotion or oil daily enhances skin hydration. Well-hydrated skin is more elastic and pliant and less prone to injury. Skin needs to be visually inspected daily. A warm or reddened area indicates a possible site of tissue breakdown, which will lead to a decubitus ulcer, and extreme care must be taken to relieve pressure totally from this area until the color returns to normal. *Safety Message: If the time for the skin to recover its normal color exceeds 20 minutes, it is absolutely essential to discover the cause of the skin irritation and correct it. Modification of position, schedule, procedure, equipment, or orthotics is necessary.* If the patient cannot inspect and care for the skin properly, instruct a care provider to perform these tasks every day.

Effectiveness of Compensatory Techniques

A review of the literature reveals no research studies that confirm the effectiveness of instructing patients to avoid injury. These compensatory techniques have face validity in that they evolved out of evidence that patients lacking protective sensation had incurred injuries, many of which could have been prevented. Anecdotal evidence of effectiveness includes Wood's (1969) description of a patient who had a series of hand injuries prior to occupational therapy and none following instruction and fitting of gloves to be worn in his electronics repair work.

Widespread acceptance of compensatory techniques is further evidence of reliance on their assumed effectiveness. The American Diabetes Association (2004) recommends sensory testing of the feet of all people with diabetes so that foot ulcers and amputations can be prevented in those with sensory loss. Techniques of testing and education for patients with diabetes appear in the nursing and physical therapy literature (e.g., Thompson, Medley, & Motts, 2002).

DESENSITIZATION

Desensitization is chosen when the sensory evaluation reveals an area of hypersensitivity, in which ordinary stimuli produce exaggerated or unpleasant sensations (Pillet, Didierjean-Pillet, & Holcombe, 2010). The term

hypersensitivity includes allodynia, which is the perception of pain as a result of a nonpainful stimulus, and hyperesthesia, which is a heightened sensitivity to tactile stimuli. Desensitization is an intervention designed to decrease the discomfort associated with touch in the hypersensitive area. A program of desensitization generally includes repetitive stimulation of the hypersensitive skin with items that provide a variety of sensory experiences, such as textures ranging from soft to coarse.

Rationale for Desensitization

Hypersensitivity is observed in some but not all patients following nerve trauma, soft tissue injuries, burns, and amputation. Patients with hypersensitivity tend to avoid using the affected part in functional activities and typically hold the affected part protectively (Hardy, Moran, & Merritt, 1982). Hypersensitivity can lead to disability through nonuse of the involved body part (Robinson & McPhee, 1986).

Desensitization is based on the idea that progressive stimulation will allow progressive tolerance. The origin of the concept of desensitization is unknown. Civil War veterans with amputations were known to tap silver spoons on their residual limbs to improve their tolerance of artificial limbs, which, in those days, were constructed from wood (Hardy et al., 1982). Desensitization can be considered relearning to interpret sensory stimuli as nonnoxious (Dellon, 2000; Jerosch-Herold, 2011), and therefore learning principles and methods apply, including structured practice within the context of functional activities.

Desensitization Techniques

Initially, a patient may have to compensate for hypersensitivity by wearing a splint or padding over the affected area but is gradually weaned from the protective device as improvement occurs. In the treatment program, the patient develops progressive tolerance to a hierarchy of sensory stimuli. Several different hierarchies of desensitization materials exist. The hierarchy described by Hardy, Moran, and Merritt (1982) includes five levels:

- Level 1. Tuning fork, paraffin, massage
- Level 2. Battery-operated vibrator (Fig. 22-1), deep massage, touch pressure with pencil eraser
- Level 3. Electric vibrator, texture identification
- Level 4. Electric vibrator, object identification
- Level 5. Work and daily activities

Desensitization begins outside the area of hypersensitivity and progresses toward the area of greatest sensitivity. Constant contact of the stimulus is preferable to intermittent contact, which may be harmful (Walsh, 2010). Patients advance to the next level after they demonstrate tolerance of the current level without signs of irritation.

Figure 22-1 The small head of this battery-powered vibrator is useful for desensitization of specific areas of the hand. (Photo courtesy of North Coast Medical, Inc., Gilroy, CA.)

McCabe (2011) suggests use of mirror visual feedback (MVF) in conjunction with a desensitization program. In MVF, the mirror is positioned at the patient's midsagittal plane so that the affected arm is hidden from view behind the mirror and the reflected image of the unaffected limb is in the perceived position of the affected one, thereby giving the impression of the patient having two "normal" limbs. The patient observes the unaffected limb in the mirror as it is touched with various textures. The touch is perceived to be applied to the affected limb and found tolerable. Then the mirror is removed, and the affected limb is actually touched. This procedure has anecdotal clinical support but no research support (McCabe, 2011).

Table 22-1 shows the Downey Hand Center hierarchy of textures and vibration (Barber, 1990/2010; Yerxa et al., 1983). Commercial dowel and immersion textures (Resource 22-1) are similar to this hierarchy. Patients arrange the dowel textures and immersion textures (Fig. 22-2) according to their own perception, in the order of least to most irritating. They select the dowel texture, immersion texture, and vibration level that are uncomfortable but tolerable for 10 minutes three or four times daily. Advancing to the next level of treatment depends on tolerance of lower levels. Documentation should include the patient's initial hierarchy and progress for each of the three modalities (dowel texture, immersion texture, and vibration level).

Other interventions thought to decrease hypersensitivity include weight-bearing pressure, twice daily massage of a surgical scar less than 6 months old with steroid-containing cream, transcutaneous nerve stimulation (TENS), fluidotherapy, and home shower-massager (Dellon, 2000). Use of the affected body part in leisure, work, and daily occupations is believed to facilitate desensitization; the activities must be tailored to the patient's interests and occupations to promote compliance.

Table 22-1 Hierarchy of Texture and Vibration Used in Desensitization

Level	Dowel Textures	Immersion Textures	Vibration
1	Moleskin	Cotton	83 cps near area
2	Felt	Terry cloth pieces	83 cps near area, 23 cps intermittent
3	QuickStick[a]	Dry rice	83 cps near area, 23 cps intermittent
4	Velvet	Popcorn	83 cps intermittent, 23 cps intermittent
5	Semirough cloth	Pinto beans	83 cps intermittent, 23 cps continuous
6	Velcro loop	Macaroni	83 cps continuous, 53 cps intermittent
7	Hard foam	Plastic wire insulation pieces	100 cps intermittent, 53 cps intermittent
8	Burlap	Small BBs, buckshot	100 cps intermittent, 53 cps continuous
9	Rug back	Large BBs, buckshot	100 cps continuous, 53 cps continuous
10	Velcro hook	Plastic squares	No problem with vibration

St. Louis: Mosby. Archived online in T. M. Skirven, A. L. Osterman, J. M. Fedorczyk, & P. C. Amadio (Eds.). (2010). *Rehabilitation of the hand and upper extremity* (6th ed.). Philadelphia: Mosby, Inc./Elsevier.

Effectiveness of Desensitization

Evidence of the effectiveness of desensitization techniques in therapy is limited to a small number of studies. Barber (1990/2010) completed a chart review with descriptive statistics and reported the effectiveness of a graded program. Additional evidence of the success of desensitization includes a narrative single-case study (Robinson & McPhee, 1986) and a small-sample, nonrandomized trial (Hardy, Moran, & Merritt, 1982).

Despite the lack of evidence, desensitization techniques are generally accepted as effective in clinical practice. Experts in the field of hand therapy describe patient improvement and promote use of desensitization techniques (Dellon, 2000; Porretto-Loehrke & Soika, 2010; Walsh, 2010). In a large study of hand therapy practice, all of the therapists surveyed used desensitization techniques on at least some of their patients, and more than half of the therapists elected to use the techniques for 26%–50%

of their patient caseload (Muenzen et al., 2002). Failure of desensitization is believed to be a result of early abandonment of the program, inadequate time spent with each modality, or inappropriate stimulus choice (Walsh, 2010).

SENSORY TRAINING

Because of the newer research evidence concerning brain reorganization in response to lack of stimuli, to repetitive stimuli, and to problem solving, sensory training currently consists of two approaches: passive sensory training and active sensory training. Sensory training may be passive, for those with and without any sensation, or active, for those with beginning return of sensation.

Ninety-nine percent of hand therapists in the United States (Muenzen et al., 2002) and 90% of 70 therapists in 10 European-member countries (Jerosch-Herold, 2011) surveys reported using classical and newer sensory reeducation techniques. Sensory reeducation is an appropriate and commonly used treatment for patients with a variety of peripheral nerve injuries, including nerve lacerations and neural compressions and injuries resulting in replantation, toe-to-thumb grafting, and skin grafting (Dellon, 2000). Sensory reeducation is also used for patients who have diminished or distorted sensation secondary to cerebral vascular accident.

The goals of sensory training are to maintain or restore the cortical hand representation and to regain the use of sensation of the hand (Lundborg & Rosén, 2007; Rosén & Lundborg, 2010). Therefore, treatment must address both the brain and the peripheral nerve. Passive sensory training involves use of repetitive stimulation of the denervated part to maintain the cortical representation of that part. Passive sensory training requires no attention on the part of the patient but improves sensation through long-term highly repetitive stimulation of the patient's skin.

Active sensory training, or sensory reeducation, combines techniques of attention, learning, repeated practice, and use of alternative senses such as vision or hearing to help the patient learn to reinterpret sensation (Dellon, 2000; Jerosch-Herold, 2011; Rosén & Lundborg, 2007, 2010). Dellon (2000), a hand surgeon, related his experience in the 1970s with nerve-injured patients who could feel fingertip stroking, pinprick, and pressure but could not correctly identify a nickel and a quarter using only touch sensation. These patients could feel a difference between the coins, but they could not identify them because the coins did not feel the same as before the injury. Dellon concluded that the sensibility was recovered but that there was a mismatch of the new sensory profile with past profiles in the association cortex. Within a few minutes, he could train patients to tell the difference between the two coins. With the patient's vision shielded, he placed a nickel in the hand, said what it was, and explained that it did not feel the way a nickel used to feel but that what the patient was feeling should thereafter be called a nickel. After repeating the process with a quarter, the patient could correctly identify both coins. The sensation had been reeducated. Dellon (2000) described sensory retraining strategies based on learning principles. His recommendations included this advice: tailor training and training materials to the interest and ability of the patient, grade the activity so that the patient can meet the expectations for improved performance, and be sure that the patient attends to the stimuli and information provided and perceives them as important and relevant.

Rationale for Sensory Reeducation after Peripheral Nerve Injury or Repair

Cortical hand representation has been found to change immediately as a result of peripheral nerve injuries (Lundborg & Rosén, 2007; Merzenich & Jenkins, 1993). After nerve repair, the corresponding area of the somatosensory cortex reorganizes (Dellon, 2000; Merzenich & Jenkins, 1993). In children, this reorganization is sufficient for return of normal sensory interpretation without sensory retraining. In adults, the neural reorganization requires sensory reeducation (Dellon, 2000; Rosén & Lundborg, 2010; Rosén et al., 1994).

The return of sensation following hand injury is an extremely complex process. Recovery is not just a process of altering the cortical representation; it also depends on reinnervation. Following nerve laceration and surgical repair, some sensory fibers, given sufficient time, regenerate. Peripheral nerve regenerates at a rate of 1 mm per day or 1 inch per month (Dellon, 2000). No surgical repair technique can ensure recovery of tactile discrimination after nerve damage in adults (Lundborg & Rosén, 2007). Sensory return is limited by malalignment of axonal sheaths that allows misdirection of regrowing fibers, meaning that fibers do not usually regrow to innervate the same sensory receptors that they innervated before the injury (Callahan, 1995/2010; Rosén & Lundborg, 2010). Return of sensation is further limited by scar tissue that blocks sensory fiber regrowth and atrophy of sensory receptors prior to reinnervation.

As a result of scar tissue, atrophy of sensory receptors, and the misdirection of fibers, there is an inevitable change in the profile of neural impulses reaching the sensory cortex. A previously well-known stimulus initiates a different set of neural impulses from that elicited by the same stimulus before the injury. When this altered profile reaches the sensory cortex, the patient cannot match it with patterns previously encountered and remembered (Callahan, 1995/2010; Dellon, 2000) and hence cannot identify or recognize the stimulus. According to Rosén and Lundborg (2010), "The hand speaks a new distorted language to the brain" (p. 637). The purpose of active sensory reeducation in patients with peripheral injuries is to help them learn to recognize the new sensory patterns from the hand and associate the new sensation to current movements or tactile experiences (Lundborg & Rosén, 2007).

Sensory Reeducation Techniques after Peripheral Nerve Injury or Repair

In the past, sensory reeducation after peripheral nerve injury or repair was delayed until adequate axonal regeneration and reinnervation of the hand had occurred (Lundborg & Rosén, 2007). However, a newer approach, based on current knowledge of brain plasticity, is to begin phase 1 of sensory reeducation immediately after nerve repair to preserve the cortical representation of the denervated part (Lundborg & Rosén, 2007; Rosén & Lundborg, 2010) and has been found effective in improving tactile gnosis (Rosén & Lundborg, 2007). Phase 2 of sensory reeducation begins when the patient first can appreciate deep, moving touch. At first, in phase 2 of reeducation, the patient concentrates on learning to match the sensory perception of stimuli with the visual or auditory perception. The alternative sense, vision or hearing, is used to train the new sensation and thereby improve tactile discrimination (Lundborg & Rosén, 2007). After time, when reinnervation allows for perception of light nonmoving touch with good touch localization, the focus of intervention changes to more functional tasks, such as object identification through touch (Fig. 22-3) (Dellon, 2000).

Phase 1 Techniques

Phase 1 is the period following nerve injury or repair and before the start of reinnervation. During phase 1, the formerly innervated part is without sensation, and cortical representation is undergoing rapid remodeling. Treatment techniques used in phase 1 have the goal of maintaining the cortical hand representation (Lundborg & Rosen, 2007).

Alternative Sensation Techniques. The somatosensory cortex is activated by visual observation of touch (visuotactile interaction) or by listening to the sounds of
Figure 22-3 Late-phase sensory reeducation after peripheral nerve injury includes identification of various objects by touch.

touching (e.g., a hand touching various textures) (audiotactile interaction) (Lundborg & Rosén, 2007; Rosén & Lundborg, 2007). Visuotactile techniques include direct observation of the part being touched by the therapist and use of a mirror.

One Form of Visuotactile Interaction Therapy: Mirror Therapy or Mirror Visual Feedback Therapy. Mirror therapy was first proposed as a means to relieve amputee phantom limb pain in the 1990s. Therapists have increasingly tried it to treat a range of other chronic pain conditions and as a means to reeducate sensorimotor abilities and capacities in persons with peripheral and central nerve injury (McCabe, 2011). Mirror visual feedback therapy is thought to work by improving sensory perception of the affected limb via false but congruent visual feedback of the unaffected limb, thereby restoring the normal sensory feedback–motor intention linkage (McCabe, 2011). A mirror is placed in front of the patient so that the sensory-deprived hand is hidden behind the mirror and the healthy hand is visible in the mirror and appears as if it were the affected hand. Touching the healthy hand gives the illusion of touching the affected hand. Using a different protocol, Moseley and Wiech (2009) reported that looking towards the reflected hand while the sensory stimulation was applied to the affected hand, hidden behind the mirror, improved two-point discrimination in the affected limb of patients with complex regional pain syndrome and that improvement lasted at least until the 2-day follow-up reevaluation.

Audiotactile Interaction Therapy. Audiotactile interaction techniques can range from simple (listening and identifying sounds of the healthy hand touching various textures) to complex (Sensor Glove System mechanism with microphones and ear phones that allows the patient to listen intently to what the hand feels) (Rosén & Lundborg, 2007).

Deficient Sensation Techniques: Selective Cutaneous Anesthesia. Deafferentation of a specific cortical area, such as that serving the shoulder and elbow, allows expansion of adjacent cortical representation areas, such as the hand (Björkman, Rosén, & Lundborg, 2004; Lundborg & Rosén, 2007). Therefore, cutaneous deafferentation of the forearm of the affected hand should result in expansion of the adjacent hand representation (Rosén, Björkman, & Lundborg, 2006). Cutaneous deafferentation of the forearm is accomplished using a topical anesthetic cream (2.5% lidocaine and 2.5% prilocaine) applied for 1 hour twice a week for 2 weeks in conjunction with classical sensory retraining (Lundborg & Rosén, 2007; Rosén, Björkman, & Lundborg, 2006). This procedure was found to be significantly effective in two small samples of persons with ulnar or median nerve repair in improving perception of touch/pressure, tactile gnosis, and two-point

discrimination as compared with the control/placebo groups (Hassan-Zadeh et al., 2009; Rosén, Björkman, & Lundborg, 2006).

Phase 2 Techniques

Phase 2, active sensory reeducation, begins with the start of reinnervation of the hand. Sensory reeducation protocols differ among facilities, even those treating patients with similar diagnoses. A summary of the protocol Dellon (2000) presented from the Raymond M. Curtis Hand Center of Union Memorial Hospital, which is based on his earlier work, is given in Procedures for Practice 22-1. Others describe similar procedures. They begin each moving and constant touch sequence with eyes closed, followed by eyes open, and concluding with eyes closed. They recommend using a smaller and lighter stimulus as the patient improves, with a goal of localization of a touch that is near the light-touch threshold. Touch localization continues throughout the sensory reeducation process, and more tasks are added to the training program. Discrimination of similar and different textures using sandpaper, fabrics, and edges of coins are introduced early. Patients practice identification of shape or letter blocks and graphesthesia, which is the ability to identify a letter or number drawn on the skin. In the later stages of training, patients feel for objects from containers filled with sand or rice and identify them by feel before looking at them for feedback. They progress to practicing identification of common objects. A variety of activities, including games or puzzles, are more engaging and therefore may be more beneficial than simply practicing with various objects. Finally, patients practice daily living activities, especially those in which the hand is out of the line of vision.

Procedures for Practice 22-1

Phase 2 Sensory Reeducation

Sensory Reeducation Principles

- Choose a quiet environment that will maximize concentration.
- Sessions in the clinic should be brief, approximately 5–15 minutes, two or three times a week.
- Because in-clinic training is brief, homework practice sessions are important. Three or four 5-minute sessions per day are recommended.
- Instruct the patient and/or family in techniques to be used during practice.
- Monitor patient's home program and progress during therapy sessions.
- Allow frequent rest breaks during which the patient can open his eyes. This reduces feelings of disorientation and anxiety.

Prerequisites for Early-Phase 2 Sensory Reeducation

- Patient must be able to perceive 30 cycles per second vibration and moving touch in the area.
- Patient must be motivated and able to follow through with the program.

Techniques for Early-Phase 2 Sensory Reeducation

- Use the eraser end of a pencil.
- Apply moving strokes to the area.
- Use enough pressure for the patient to perceive the stimulus but not so much that it causes pain.
- Ask the patient to observe what is happening first and then to close the eyes and concentrate on what is being felt.

- Instruct the patient to put into words (silently) what is being felt.
- Instruct the patient to observe the stimulus again to confirm the sensory experience with the perception.
- When perception of constant touch returns to the area, use a similar process for constant touch stimuli.
- Test the patient by requiring localization of moving and constant touch without seeing the stimulus.

Prerequisites for Late-Phase 2 Sensory Reeducation

- Patient must be able to perceive constant and moving touch at the fingertips.
- Patient must demonstrate good localization of touch.

Techniques for Late-Phase 2 Sensory Reeducation

- Use a collection of common objects that differ in size and shape.
- Instruct the patient to grasp and manipulate each item with eyes open, then with eyes closed, and then with eyes open for reinforcement.
- The patient should concentrate on the tactile perception.
- Grade the practice by starting with large familiar objects with great differences in size, shape, and texture. Further grade practice by introducing objects of similar sizes but different textures and then small objects that vary in size and shape but are similar in texture.
- Test the patient by counting the number of objects correctly identified or the time required to correctly identify each object without vision.

Adapted from Dellon, A. L. (2000). *Somatosensory testing and rehabilitation*. Baltimore: The Institute for Peripheral Nerve Surgery.

Nakada and Uchida (1997) described a five-stage sensory reeducation program that was useful for a patient with very limited sensation in her left hand as a result of peripheral neuropathy secondary to leprosy (Hansen's disease). She also had total impairment of vision, so that sensory feedback was critical to occupational performance. Following reeducation, the patient regained hand function for activities of daily living such as drying dishes, putting on socks, and holding dentures while brushing them. The reeducation program included the following five stages:

- Stage 1. Object recognition using feature detection strategies. Objects that varied greatly in shape, material, and weight were used. The patient was encouraged to handle each object, pay attention to the object, and identify the characteristics of the object.
- Stage 2. Prehension of various objects with refinement of prehension patterns. In this stage, grasping objects that varied in size and shape was emphasized. The patient needed to maximize the contact between the object and the hand to develop the ability of the hand to closely contour to objects, which is seen in normal grasp.
- Stage 3. Control of prehension force while holding objects. Feedback regarding excessive force that was used to maintain grasp was provided through the use of a strain gauge and therapy putty.
- Stage 4. Maintenance of prehension force during transport of objects. While holding an object, the patient moved the shoulder, elbow, and wrist into varying positions of flexion and extension.
- Stage 5. Object manipulation. The patient practiced grasp and release of objects and moved objects in the hand into various positions.

Appropriate grading of sensory reeducation activities is important to optimize patient motivation and progress. Choose activities that provide a challenge but allow for success. During stimulus localization tasks, progress from firm pressure to lighter pressure. When working with objects, progress from larger items to smaller items and from dissimilar items to more similar items. Progress from differentiation of a few objects to selecting, sequencing, or organizing many objects.

Because daily training is necessary for successful sensory reeducation, teach patients techniques appropriate for after-therapy practice. Patients can be involved in assembling their own collection of objects for use in their program. Include objects with varying size, shape, texture, weight, and temperature (Fess, 2002/2010). Development of a new set of stimulus-response associations has been shown to require thousands of trials (Lewis et al., 2009). Recovery from peripheral nerve injury can take years and is often incomplete with ongoing discomfort and poor tactile gnosis (Jerosch-Herold, 2011).

Effectiveness of Sensory Reeducation after Peripheral Nerve Injury or Repair

To evaluate the effectiveness of sensory reeducation following peripheral nerve injury, Oud et al. (2007) reviewed the 7 out of 760 identified studies that met inclusion criteria. Five of those were characterized by poor methodological quality; the methodology of the two others was adequate to high quality. They concluded that there was positive but limited evidence for the effectiveness of sensory reeducation. This review represents the best evidence in the therapy literature for the effectiveness of sensory reeducation to date. Further evidence is described in Evidence Table 22-1. Sensory reeducation effectiveness following digital replantation and revascularization has also been demonstrated in a small, randomized controlled trial (Shieh et al., 1995).

Rationale for Sensory Treatment after Cerebral Vascular Accident

Loss of sensation impairs a person's ability to explore the immediate environment and execute everyday tasks and therefore affects quality of life and personal safety (Carey, Macdonell, & Matyas, 2011; Smith et al., 2009). Sensory dysfunction following stroke involves tactile discrimination and proprioceptive senses more than pain or temperature senses (Carr & Shepherd, 2010). This loss significantly limits the use of the upper limb (Doyle et al. 2010). Functional use of the arm and hand with reduced sensation is possible, but spontaneous use is limited. Without training, there is a tendency not to use the extremity, and learned nonuse leads to further loss of sensory and motor abilities (Dannenbaum & Dykes, 1988; Sabari & Lieberman, 2008). Therapists may alter the cortical map by directing the sensory experiences of the patient. Increased cerebral blood flow and changed cerebral activation in the somatosensory cortex following proprioceptive stimulation has been demonstrated experimentally (Nelles et al., 1999).

Studies of both passive and active therapeutic interventions have shown improvements in use of the extremity. Passive sensory training is based on evidence of cortical reorganization in response to repetitive stimulation. Passive sensory training procedures involve extensive repetitive stimulation applied to the impoverished part and do not require participation by the patient. Carr and Shepherd (2010), in their review of the scientific evidence for the ability of the brain to reorganize following brain lesions, stated that reorganization seems to be related to frequency of use.

Active sensory training after cerebral vascular accident (CVA) is based on the concepts of neural plasticity and learning. Carr and Shepherd (2010) suggested that enlargement of sensory receptive areas within the cortex is a result of increased participation of the body part in activities requiring

Evidence Table 22-1	Best Evidence for Occupational Therapy Practice Regarding Sensory Reeducation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Early tactile stimulation for digital nerve injuries	In-clinic stimulation of digital sensation by pressing injured finger against rotating disc with raised and lowered segments; home program of rubbing finger over rows of raised staples on a plastic card	Forty-nine subjects with a total of 65 digital nerve injuries following surgical repair	Clinical program required 20 minutes twice weekly; home program completed daily, as much as patient desired; clinic program averaged 11 weeks in duration; home program averaged 16 weeks	Randomized controlled trial, using ordinal measures and nonparametric statistics; Level: IB2a	More participants in the experimental group recovered touch threshold measuring 0.217 g or less, and static and moving two-point discrimination of 6 mm or less.	$p = 0.097$, $r = 0.22$ for touch threshold; $p = 0.0023$, $r = 0.48$ for static two-point discrimination; and $p = 0.0144$, $r = 0.36$ for moving two-point discrimination	Cheng, 2000; Cheng et al., 2001
Temporary anesthesia in combination with sensory reeducation	Experimental: Anesthetic cream (Lidocaine-PTC) applied to the flexor aspect of the affected arm (from wrist to 15 cm of forearm) under occlusive bandage; sensory reeducation not described; Control: Placebo + sensory reeducation	Thirteen patients with median ($n = 7$) or ulnar ($n=6$) nerve repair at wrist level; age range 20–43 years; range of time since surgery 5–38 months; randomly assigned to experimental or control groups	One hour, two times per week, for 2 weeks + reeducation time	Randomized controlled trial; Level: IC2b	Yes. Perception of touch (Semmes-Weinstein monofilaments) improved significantly immediately and at 4-week follow-up in the experimental vs. control group. Two-point discrimination (Disk-Criminator) improved significantly immediately and at 4-week follow-up in the experimental vs. control group. Effects were large for all comparisons.	Differences between groups: touch perception, $p = 0.025$, $r = 0.56$ for post treatment and $p = 0.003$, $r = 0.76$ for 4-week follow-up; two-point discrimination, $p = 0.000$, $r = 0.97$ for post treatment and $p = 0.001$, $r = 0.85$ for 4-week follow-up	Hassan-Zadeh et al., 2009

Perceptual learning-based sensory discrimination to improve lost abilities of texture discrimination, limb position sense, tactile object recognition	Experimental: Graded progression of discrimination from easy to difficult; attentive exploration with vision occluded, anticipation trials, cross-modal calibration via vision, feedback on sensation and method of exploration, intermittent feedback and self-checking of accuracy, feedback on ability to identify distinctive features in novel stimuli (shape, size, weight, texture, hardness, temperature), summary feedback, and intensive training; Control: grasping of various objects and passive movements of the limb	Fifty subjects with impaired tactile discrimination, limb position sense, and/or tactile object recognition at least 6 weeks poststroke. Randomized to experimental and control groups, with attrition of 3; mean age = 61 years; 29 left and 21 right hemispheric lesions; Median time poststroke = 48.14 weeks	Trained on each sensory task in random sequence for 15–20 minutes at a time. Ten total treatment sessions of 60-minute duration, 3 times/week	Randomized controlled trial with blinding of subjects, assessors, and data analysts; Level: IA1a	Yes. Sensory retraining is effective in improving sensory discrimination in stroke survivors in the chronic phase of recovery. Thirty-six percent of subjects had a reduction of deficit of at least 50%, 24% performed in the normal range, and only 2 did not show improvement. There were no adverse effects. Improvement lasted at 6-week and 6-month follow-ups. Effects transferred to novel stimuli not trained. Sensory discrimination of the experimental group improved 19.1 points on the composite standardized somatosensory deficit index as compared with 8.0 points by the control group (t_{47} = 2.75, p = 0.004, r = 0.38).	Carey, Macdonell, & Matyas, 2011

tactile sensations. Therefore, the goal of both passive and active sensory treatment after CVA is to gain a larger cortical representation for the areas of skin from which sensory feedback is crucial to performance of daily tasks.

Sensory Therapeutic Techniques after Cerebral Vascular Accident

Cerebrovascular accident often disrupts the sensory–motor relationship of the affected side, resulting in paralysis or weakness, sensory loss or distortion, and subsequent loss of spontaneous usage and occupational performance. Therapy to recover motor behavior was discussed in the previous chapter, and therapy to recover occupational performance is discussed in the chapter on stroke (Chapter 33). Here, therapy to improve sensory awareness and discrimination of the affected limb is described.

Passive Sensory Training

Passive sensory training or tactile coactivation via electrical stimulation or repetitive mechanical stimulation is applied to the patient and does not require the patient's active attention. The following studies provide guidelines for application of these types of interventions, although no standard protocol has been established.

In a study of passive tactile coactivation to improve sensorimotor functions in healthy elderly, Kalisch, Tegenthoff, and Dinse (2008) demonstrated significant improvement in tactile acuity (two-point discrimination), haptic object recognition, and fine motor object manipulation skills as compared with a sham control group. The tactile coactivation was administered via 8-mm solenoid devices attached to each finger of the dominant hand. These devices tapped the fingertips to deliver stimuli to the dermal mechanoreceptors in the fingertip skin. The taps of approximately 100 microns for 10 milliseconds with a variable interstimulus interval of 100–300 milliseconds were delivered for 3 hours, during which the subject could move and pay attention to other activities such as watching TV or reading. The sham group participated in the same setup but did not receive tactile coactivation via the taps. Touch thresholds did not change significantly in either group. Two-point discrimination thresholds were significantly ($p \leq 0.007$) and strongly ($r = 0.52$) lowered (improved) in the coactivation group. Time to complete ($p = 0.004; r = 0.56$) haptic object recognition and number of errors ($p = 0.019; r = 0.58$) reduced significantly in the experimental group. Manipulation of fine objects improved significantly in the experimental group as compared with the sham group ($p \leq 0.001; r = 0.65$). The researchers suggest this treatment as potentially useful in improving sensorimotor functions in patients.

Smith et al. (2009) conducted a preexperimental study of the effects of tactile coactivation via electrical impulses on four persons with a Fugl-Meyer Motor Assessment upper extremity subtest score of 56–60 and loss of sensory abilities more than 6 months poststroke. The fingers of the involved hand were electrically stimulated (20-Hz single pulses of 5–50 mA current range in bursts of 1 second with a 5-second interburst interval) for 90 minutes, 4 days a week for 6 weeks. There was improvement in sensory discrimination and motor task performance in all four subjects, and the results held over the 4-week follow-up period, although no statistical analysis was reported. There were no adverse reactions.

In another, more controlled study of 36 patients in the acute stage of recovery post-CVA, the results were equivocal between two groups receiving Bobath neurodevelopmental treatment or Bobath neurodevelopmental treatment plus electrical stimulation of the wrist and finger extensors. That is, both groups improved in kinesthetic sense and proprioception, as well as hand movement (Yozbatiran et al., 2006). The results cannot be appreciated separately from ongoing recovery that occurs during the acute stage. Although the use of passive interventions makes sense on the basis of documented effects of repetitive peripheral stimulation on brain reorganization (Jenkins, Merzenich, & Ochs, 1990), the evidence to date is insufficient to recommend a particular protocol.

Active Sensory Training

Sensory reeducation after CVA is less well defined than the protocols described for peripheral injuries. Carr and Shepherd, in their book *Neurological Rehabilitation* (2010), emphasize task-specific sensory training in which learning occurs concurrently with motor learning. They advocate the use of meaningful and relevant sensory and motor experiences very early in rehabilitation. Use of the more involved hand in bimanual tasks such as opening jars and using eating utensils is advocated. They suggest that the patient be cued to attend to the goal of the task and the tactile aspects of the objects involved in the task.

Dannenbaum and Jones (1993) gave detailed goals and proposed methodology for sensory intervention following CVA. According to them, appreciation of some form of tactile stimulation and some basic motor skills are prerequisite to success in sensory reeducation. To establish that a patient with severe sensory loss can perceive some stimuli, they recommend testing and early training using 100-Hz electrical stimulation. Patients identify which finger was stimulated, first with vision and then with eyes closed. Patients with better sensation perform a similar task, first with textured moving stimuli followed by nonmoving stimuli. In addition, they suggested early incorporation of the hand into functional activities and prevention of abnormal patterns of grasp and movement. Further suggestions are to add textures to handle surfaces to increase the friction and support weak grasping ability, to enlarge or modify handles to facilitate both tactile contact and tactile feedback, and to have patients practice modulation of grip forces in response to various objects and maintenance of appropriate grip force during forearm movements.

Yekutiel and Guttman's (1993) research protocol included the following sensory reeducation activities, all completed with vision occluded:

- Identification of the number of touches
- Identification of numbers or letters drawn on the arm or hand (graphesthesia tests)
- "Find your thumb" without looking
- Discrimination of shape, weight, and texture of objects or materials placed in the hand
- Passive drawing and writing: patient identification of a letter, number, or drawing made by the therapist passively moving the patient's hand while it holds a pencil

They started and ended each session with sensory tasks the person could do.

Mirror Therapy

Mirror therapy is reported to elicit cortical activation (Dohle et al., 2009) and restore sensorimotor linkage (McCabe, 2011) in patients post-CVA. The mirror is placed so that the unaffected arm appears to be in the position of the affected arm. The patient is asked to move both limbs into a variety of gradually more difficult postures. One protocol for mirror visual feedback is outlined in Procedures for Practice 22-2.

A secondary finding in a study of mirror therapy used in combination with standard therapy to improve motor recovery in severely affected patients after initial ischemic stroke was a significant ($p = 0.009$) and strong effect ($\eta = 0.57$) on light touch, as measured by the sensory subscale of the Fugl-Meyer Motor Assessment, compared with a control condition of viewing the affected extremity (Dohle et al., 2009). In this study, the mirror was placed in the participant's midsagittal plane, presenting the mirror image of the nonaffected arm as if it were the affected one. The therapy protocol for both the experimental and control groups required execution of arm, hand, and finger postures in response to verbal instruction. Both groups were told to move the affected limb as well as possible. Neither the side nor site of the lesion were related to outcome.

These sensory treatment activities are just a few examples of a wide variety of techniques that can be used in clinical treatment for patients after CVA. Therapists working with this population use creativity, patients' interests, and theoretical understanding to develop programs of sensory intervention because no one protocol has been widely accepted or thoroughly researched.

Effectiveness of Sensory Reeducation after Cerebral Vascular Accident

Multiple interventions for upper limb sensory impairment after stroke are described in the literature, but Doyle et al. (2010) concluded from their review of 13 studies out of a pool of 662 possible studies that there is insufficient evidence to support or refute their effectiveness in improving sensory

---

Procedures for Practice 22-2

One Protocol of Mirror Visual Feedback Therapy in Sensory Reeducation

1. Remove all jewelry that could interfere with imagining the reflected limb as the affected limb.
2. Position the patient comfortably so that the mirror is easily accommodated between the upper limbs and the patient can visualize the reflected unaffected limb. The mirror should be large enough to hide the affected limb and to show the entire reflected limb while the patient performs a range of bilateral movements.
3. Ask the patient to look at the reflected limb, without movement, and to try to believe that it is his affected limb.
4. Once the patient feels engaged with the mirrored limb, have him perform slow, easy-to-achieve bilateral movements while looking at the reflected image.
5. Check behind the mirror to see that the affected arm is moving, moving synchronously, and not stopping after initial movement. For those for whom movement is impossible, they should simply look at the reflected image until they are able to progress to moving.
6. To fully believe in the illusion requires concentration; therefore, the technique should be used often, but for short periods (five or six times per day until concentration is lost, but no longer than 5 minutes). Patients are advised to practice this therapy in a quiet area, without distraction, so that concentration can be at the optimum.
7. If adverse effects are observed (e.g., dystonia, tremor, increased pain levels), therapy should be stopped immediately. Otherwise, the patient is advised to carry out the therapy as long as he perceives it to be helpful.
8. Contraindications to mirror visual feedback therapy are **motor extinction**, increased pain, exacerbation of movement disorders, and inability to believe in the illusion.

Adapted from McCabe, C. (2011). Mirror visual feedback therapy. A practical approach. *Journal of Hand Therapy, 24,* 170–179.

---

impairment. This review included only studies that used the randomized controlled trial design. Three of the 13 studies examined active sensory training, and the remainder studied passive sensory training. Schabrun and Hillier (2009) concluded from their systematic review of 14 studies that met their inclusion criteria, involving 199 subjects, that there is some evidence to support use of passive sensory training on patients poststroke, but at this time data are insufficient to determine the effectiveness of active sensory training. The best evidence of effectiveness of active sensory reeducation following CVA is the study by Carey, Macdonell, and Matyas (2011), published after the above-mentioned reviews were completed and described in Evidence Table 22-1. That carefully controlled study of 50 subjects showed significant and large improvement using a systematic program that heavily incorporated principles of learning.

case example
Mr. T.: Sensory Remediation after Median Nerve Laceration

Occupational Therapy Intervention Process	**Clinical Reasoning Process**	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Mr. T., a 25-year-old appliance repairman with a laceration of the median nerve, was reassessed approximately 6 weeks after his injury. The outpatient occupational therapy reassessment identified the following sensory problems:

- Absent and decreased protective sensation in the thumb, index and middle fingers, and radial palm
- Mislocalization of touch sensations in the radial portion of the palm
- Hypersensitivity in the area of the scar
- Decreased ability to pick up and manipulate objects
- Decreased use of the right hand in functional activities

	Objectives	Examples of Therapist's Internal Dialogue
	Appreciate the context	(See Chapter 9 for description of the assessment process and patient's background.)
	Develop intervention hypotheses	"Although a good bit of time in therapy will be spent on Mr. T.'s motor deficits, I know that good sensation is needed for hand coordination and for return to full function at work."
	Select an intervention approach	"Because Mr. T. has multiple sensory issues, he will need multiple approaches. A compensatory approach will be needed for lost protective sensation, and a remedial approach will be needed to decrease hypersensitivity and relearn touch localization and object identification."
	Reflect on competence	"As I work with Mr. T., I may need to discuss ideas with a colleague, particularly for creative sensory retraining strategies to increase the variety of activities."

Recommendations

The occupational therapist recommended outpatient occupational therapy twice a week for 6 weeks followed by reassessment, with reduction to one session per week likely at that time. Mr. T. has demonstrated quick learning of therapy instructions and will be responsible for an intensive home program. Because recovery of the ability to differentiate small objects at the fingertips will probably not occur until 10–12 months after the nerve repair, therapy would ideally continue for that length of time. In collaboration with Mr. T., the occupational therapist established the following long-term goals for sensory intervention:

- Mr. T. will correctly interpret sensory stimuli throughout the right hand, as demonstrated by correct tactile identification of objects.
- Mr. T. will demonstrate good use of the right hand in work simulation activities that rely on touch sensation.

	Objectives	Examples of Therapist's Internal Dialogue
	Consider the patient's appraisal of performance	"Mr. T. has demonstrated quick learning of therapy instructions so far. He does not seem to fully understand the connection between sensation exercises and his eventual hand function, so I may need to give him more examples of how he uses sensory feedback in his work and daily activities."
	Consider what will occur in therapy, how often, and for how long	"During therapy, I will definitely need to focus on teaching Mr. T. what he needs to do at home. Experts in the field of hand therapy suggest that the home program should be completed three to four times daily. The various aspects of the program should not require more than 10 minutes at a time to facilitate compliance. During therapy sessions, I will need to provide evaluation of progress, grading of sensory activities for the home program, and motivational strategies."
	Ascertain the patient's endorsement of plan	"Mr. T. seems eager to complete therapy tasks right now, and if he follows through with his home program, that should further indicate his agreement with the plan of care."

Summary of Short-Term Goals and Progress

1. Mr. T. will avoid injury to the right hand by demonstrating compensatory protective strategies during functional activities. The therapist instructed Mr. T. about risk of injury from sharp and hot objects and gripping forces. Mr. T. and the therapist discussed an appropriate routine for skin care and implementation of precautions in his daily routine. By the end of the second session, Mr. T. demonstrated good understanding of these techniques during home and simple work simulation activities.

2. Mr. T. will tolerate touch of all textures over and around his scar area so that hypersensitivity does not interfere with functional hand use. Mr. T. ranked the 10 dowel textures from least to most irritating. At that time, he easily tolerated the first four textures as they were rubbed by the therapist over the scar area. He disliked touch from the fifth texture and was unable to tolerate textures 6–10. The therapist provided textures for a home desensitization program, beginning with textures 5 and 6. Mr. T. used these textures three or four times a day for scar desensitization. During therapy sessions, massage and vibration were provided around and over the scar area. At the end of 3 weeks, Mr. T. tolerated all textures and no longer reported discomfort from sleeve cuffs or inadvertent touch during functional activities.

3. Mr. T. will demonstrate touch localization below 10 mm in the right palm to improve interpretation of tactile sensations during work activities. The therapist initiated a sensory reeducation program for touch localization using moving and static touch stimuli in the palm. Instructions were provided, and Mr. T. faithfully followed through with this program at home, four sessions per day. At the end of 3 weeks, localization in the palm measured 12–14 mm. The therapist initiated graphesthesia and texture discrimination activities in the palmar area. After 6 weeks of sensory reeducation, localization measured 9–10 mm, and Mr. T. could identify 50% of the letters and shapes drawn in his palm and 40% of the textures.

Next Steps

Revised Short-Term Goals (1 month):
To improve interpretation of tactile sensations during work activities, Mr. T. will demonstrate:

- 100% correct graphesthesia and texture identification in his right palm
- touch localization below 10 mm in the proximal phalanges of the right thumb, index, and middle fingers

Assess the patient's comprehension	"Mr. T. not only understands his home program but is also learning when to progress to the next dowel texture without me needing to tell him."
Understand what he is doing	
Compare actual to expected performance	"Mr. T. is progressing even faster than I expected he would in his desensitization program. His sensory reeducation is proceeding at the expected rate, consistent with the typical rate of neural regrowth."
Know the person	"Mr. T. demonstrated such good learning of techniques that, after these first 3 weeks, I could consider decreasing the frequency of therapy for his sensory deficits to once weekly. He will need to continue his home program at the same intensity of three to four sessions daily. Whether or not to decrease frequency of therapy will also depend on how his motor recovery is progressing."
Appreciate the context	
Anticipate present and future patient concerns	"Mr. T. has made exceptional progress over the past 6 weeks and is eager to return to work, which will make attendance at therapy and completion of his home exercise program more difficult."
Analyze patient's comprehension	"Mr. T. continues to need extensive home program activities to improve his sensation. He has learned his home program well and knows how to advance it."
Decide if the patient should continue or discontinue therapy and/or return in the future	"Because recovery of the ability to differentiate small objects at the fingertips will probably not occur until 10–12 months after the nerve repair, he will require ongoing sensory reeducation for at least a year or more. It would be advisable to follow up with reassessment and program revision every 2–3 months during that time period. This will also help Mr. T. to be more motivated to continue his home program throughout this long time period."

Transition of Sensory Reeducation Program from Early Phase to Late Phase

Mr. T. will begin the second phase of sensory reeducation at the fingertips approximately 6–8 months after his surgery to repair the median nerve. What reassessment findings will indicate the appropriate time for Mr. T. to begin late-phase sensory reeducation? What treatment activities and home program activities would be appropriate for Mr. T. as he begins this phase? What work simulation activities could be incorporated into his therapy program during sensory reeducation?

Facilitating the Effects of Desensitization and Sensory Reeducation through Mirror Therapy

Mr. T. read about mirror therapy in the popular press. He asked his therapist about incorporating mirror therapy into his program. The therapist has heard about the use of mirror therapy for patients with amputation and stroke, but not for improving sensory abilities and capacities. Instead of immediately agreeing or disagreeing to this request, how should the therapist proceed? How will the therapist and Mr. T. use it as part of the desensitization program? The reeducation program? What recommendations does the therapist make regarding incorporating mirror therapy into Mr. T.'s home program?

Summary Review Questions

1. What are the rationales for sensory reeducation after peripheral nerve injury or repair and CVA?
2. What are the differences and similarities between early-phase 2 and late-phase 2 sensory reeducation for patients with peripheral nerve injury or repair?
3. Describe or demonstrate intervention techniques for a patient with hypersensitivity after a fingertip amputation.
4. List five mechanisms of injury for skin areas with absent or diminished protective sensation. For each of the five mechanisms of injury, describe appropriate preventive education and/or adaptive strategies.
5. What should be done if a patient with sensory loss develops an area of skin redness?
6. Describe the procedure for mirror therapy to reeducate sensory perception.

Glossary

Active sensory training—The patient is actively involved in the reeducation process. Sensory retraining is based on learning principles.

Allodynia—Condition in which nonpainful stimuli produce painful sensations.

Decubitus ulcer—Open sore caused by pressure, friction, and moisture. These factors lead to reduced blood flow to the area and consequent tissue death. The most common sites for decubitus ulcers are over bony prominences.

Graphesthesia—The ability to identify numbers or letters traced on the skin.

Hyperesthesia—Condition in which there is increased sensitivity to somatosensory stimuli.

Hypersensitivity—Condition in which ordinary stimuli produce an exaggerated or unpleasant sensation.

Learned nonuse—Loss of capacity in an impaired extremity because of a tendency to avoid using that extremity and to use other body parts instead.

Motor extinction—Motor neglect; underutilization of one side, without defects of strength, reflexes, or sensibility (McCabe, 2011).

Passive sensory training—Stimulation applied to the patient who is not required to pay attention (Kalisch, Tegenthoff, & Dinse, 2008). Sensory training is delivered via high-repetition modalities, e.g., mechanical tapping, electrical stimulation, passive rubbing of the skin surface over highly textured materials.

Protective sensation—Painful sensation evoked by potentially damaging sensory stimuli, such as excessive temperature, pressure, or tissue stress.

Tactile gnosis—Functional tactile perception; ability to complete functional tasks through the use of sensory feedback.

Optimizing Vision and Visual Processing

Jennifer Kaldenberg

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Identify and describe specific treatments for low vision and oculomotor dysfunction.
2. Identify and describe treatment approaches for visual field defects and unilateral neglect.
3. Describe the similarities and differences between low vision diagnoses and visual deficits resulting from neurological insult.
4. Apply understanding of best intervention strategies with accompanying case examples.
INTRODUCTION

Occupational therapy practitioners working with adults often address the impact of visual impairment on occupational performance as a result of neurological insult or age-related eye disease. Occupational therapy practitioners should understand the impact of visual impairment on occupational performance and be prepared to provide clients with appropriate intervention to maximize independence and safety in desired occupations.

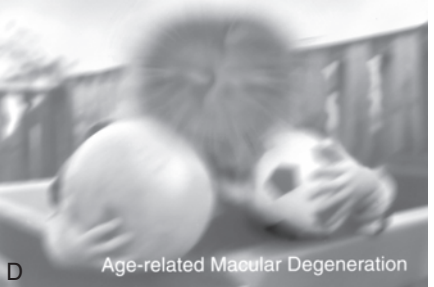
Although the literature on the identification and evaluation of visual and perceptual dysfunction is extensive, information on the effectiveness of treatment is limited. In addition, much of the research in the area of vision impairment and low vision (LV) has been carried out by ophthalmology and optometry, even though the compensatory techniques for adapting to vision impairment are carried out by a variety of practitioners including occupational therapy, ophthalmology, optometry, LV therapy, rehabilitation teachers, or orientation and mobility specialists. Unfortunately, occupational therapy practitioners, who see first hand the deleterious effects of visual and perceptual dysfunction on a person's daily living skills, have been slow to generate research that supports this type of intervention.

Warren (1993a) developed a hierarchy of visual perception (see Fig. 5-1 in Chapter 5), which emphasizes the importance of intervention for visual foundation skills including acuity, visual fields (VFs), and oculomotor function before addressing higher level perceptual skills. Therefore, rather than focus on high-level perceptual skills, this chapter discusses specific treatment options for visual foundation skills including LV, ocular motor dysfunction, and homonymous hemianopsia (also called hemianopia as termed in Chapter 5) and for the visual processing or cognitive deficit of unilateral neglect (UN).

In this chapter, occupational therapy intervention is discussed specific to two key areas: intervention to address the functional implications of LV and intervention for vision issues associated with neurologic conditions. It is important to appreciate this because clients may have comorbid conditions (e.g., client who has had a stroke may also have age-related vision problems), and occupational therapy practitioners often incorporate intervention strategies from both areas with a given client. The chapter concludes with a discussion of intervention for UN, which is a neurologically based visual processing or cognitive disorder rather than vision impairment.

VISUAL IMPAIRMENT RELATED TO LOW VISION AND AGING

Visual impairment affects 3.4 million Americans, and with our aging populations, these numbers are expected to increase (Eye Disease Prevalence Research Group, 2004). Visual impairment has been linked to falls, deficits in activities of daily living (ADL) and instrumental activities of daily living (IADL) performance, as well as increased secondary health conditions (Campbell et al., 1999; Congdon, 2004). Although many older adults equate vision loss to normal aging, some age-related visual changes occur (such as yellowing of the lens or smaller pupil size) that do not result in vision impairment. Four of the five major causes of visual impairment are directly related to the aging process: age-related macular degeneration, diabetic retinopathy, glaucoma, and cataracts (Table 23-1). Uncorrected refractive errors is the fifth leading cause of vision impairment; however, in many cases this can be addressed through education and improved access to health care (Coleman et al., 2006).

Low Vision


LV is defined as a bilateral visual impairment that cannot be corrected by corrective lenses, medication, or surgery (Freeman et al., 2007). For reimbursement purposes, a visual impairment diagnosis is based on visual acuity and VF measurement, and ranges from 20/70 visual acuity to total blindness, or a VF constriction of 20° or less, central scotoma, or homonymous or heteronomous bilateral VF defect (Colenbrander & Fletcher, 1995; Social Security Administration, 2011) (discussed further in Chapter 5; see Table 5-1).

Most occupational therapists do not specialize in vision rehabilitation but, instead, encounter LV as a complication in clients with other functional impairments and medical conditions (Weisser-Pike & Kaldenberg, 2010). Because of our education and expertise, occupational therapists are in a unique position to collaborate with LV specialists (see Definitions 5-1 in Chapter 5) by providing input on the client's functional impairment and how this may affect the selection and use of assistive devices. For example, an individual with tremors may not benefit from a handheld magnifier or may require certain positioning before using the device. Occupational therapy input is necessary for the most informed recommendations for assistive devices and the parameters for their use. Occupational therapists should have supervision and/or specialized training to recommend and train clients in the use of their prescribed LV aides.

Occupational Therapy for Low Vision

The goal of occupational therapy in working with individuals with visual impairment is to maximize the individual's use of his or her remaining vision in order to be able to complete occupations of choice. Many basic ADL tasks can be completed with minimal vision. However, individuals with LV often struggle to complete tasks that require reading such as meal preparation, financial management, and social participation. When considering intervention, occupational therapy practitioners need to consider the

Table 23-1 **Age-Related Changes in Vision**

Condition	Definition and Functional Complaint	Simulation	Medical Treatment and Occupational Therapy (OT) Interventions
Cataracts	Opacity or clouding of the crystalline lens of the eye Functional Complaint: decreased visual acuity, decreased contrast sensitivity, difficulty with night driving, and diplopia	 **Figure 23-1A** Courtesy: National Eye Institute, National Institutes of Health.	Medical: surgery OT: color and contrast enhancement, magnification, management of lighting, sensory substitution, organizational strategies
Glaucoma	Damage to the optic nerve caused by increased intraocular pressure results in decreased peripheral vision; in end stages impacts central visual acuity. Functional Complaint: difficulty with night vision, mobility impairment, in end stages deficits in central visual field (reading, facial recognition)	 **Figure 23-1B** Courtesy: National Eye Institute, National Institutes of Health.	Medical: medications, surgery OT: color and contrast enhancement, glare control, field enhancement, sensory substitution, visual skills training, organizational strategies, and in end stages magnification for central field loss, mobility training (may benefit from Orientation and Mobility [OM] referral)
Diabetic retinopathy	Affects nearly 40% of all individuals with diabetes (Kempen et al., 2004). Diabetes affects the small blood vessels in the retina, causing swelling or bleeding, which can lead to serious vision loss. Functional Complaint: Diabetes can impact all aspects of visual function. A person can develop scotomas, decreased contrast and color discrimination, decreased night vision, and fluctuations in vision.	 **Figure 23-1C** Courtesy: National Eye Institute, National Institutes of Health.	Medical: surgery, laser treatments, vitrectomy OT: color and contrast enhancement, glare control, magnification, lighting, visual skills training, sensory substitution, organizational strategies mobility training (may benefit from O&M referral)
Age-related macular degeneration	A progressive and irreversible loss of central vision caused by fibrous scarring or atrophy of the macula. Two types: wet and dry Functional Complaint: decreased visual acuity, central scotoma, decreased contrast sensitivity, difficulty with facial recognition, and reading	 **Figure 23-1D** Courtesy: National Eye Institute, National Institutes of Health.	Medical: for dry, vitamins and antioxidants, implantable miniature telescope (IMT); for wet, laser surgery OT: color and contrast enhancement, magnification, management of lighting, visual skills training, sensory substitution, and organizational strategies

goals of the client and the individual client factors, activity demands, performance skills, performance patterns, and contexts and environments that either support or inhibit participation in desired occupations. Occupational therapy intervention often includes visual skills training, environmental adaptation (lighting and contrast), magnification, compensatory techniques (sensory substitution-auditory and tactile strategies), organizational strategies, and client/family education (refer to Table 23-2).

Visual Skills Training

Individuals with peripheral or central VF defects often can learn new visual skills to maximize their awareness and functional use of their available VF. Use of scanning and/or eccentric viewing can be effective strategies for ADL and IADL tasks, work, education, play, leisure and social participation.

Visual scanning is the ability to locate a target using an organized visual search pattern (Pambakian, Currie, & Kennard, 2005). Teaching a systematic method of scanning can assist an individual in moving through their environment safely and independently. Central field impairments (such as macular degeneration with a central scotoma) have a significant impact on reading, writing and facial recognition and affect 83% of individuals with visual impairment (Colenbrander & Fletcher, 1995). A central scotoma may cause a blurring, distortion, or absence of part or all of an image. Individuals may be aware of their central scotoma or may require education to locate it. For instance, when looking in a certain direction, he or she may notice that things appear clearer, but when turning to look at the object face on, the blur or distortion returns. To use their residual vision, individuals with central field impairment must learn to move the scotoma out of the way and use their peripheral retina as central (macula) retina through eccentric viewing training (EV). Individuals can be taught to use their peripheral vision as an alternate viewing area or preferred retinal locus (PRL) to maximize the use of their remaining vision. This new PRL can be used for near and distance tasks and can be used independently or with LV aids. EV can be a very successful strategy, but it takes patience and hard work (Wright & Watson, 1995). Some individuals with central scotoma can locate their PRL independently, whereas others need training to do so. However, even if an individual is able to locate a PRL, it may not be the best viewing area. Instead, the patient may benefit from developing another area or trained retinal locus (Nilsson, Frennesson, & Nilsson, 2003; Stelmack, Massof, & Stelmack, 2004). Virtually all clients require training to develop the ability to efficiently and effectively use this new PRL (Crossland, Culham, & Rubin, 2005; Schuchard, 2005). Development of oculomotor skills, fixation stability, and the ability to refixate on an object is essential in order to return to reading and independence in all areas of occupation (Crossland, Culham, & Rubin, 2005; Fletcher, Schuchard, & Watson, 999; Markowitz, 2006;

Schuchard, 2005; Wright & Watson, 1995) (refer to Procedures for Practice 23-1).

Environmental Adaptations

Environmental adaptations are often necessary to maximize independence and safety. Managing lighting, glare and contrast for individuals with LV and neurological visual impairments is important. Increased lighting is needed for all older adults, because of age-related eye changes; those with vision loss often require even greater levels of lighting. Increased lighting has been shown to increase independence, safety, and quality of life (Brunnstrom et al., 2004; Duffy, 2002; Figueiro, 2001). Lighting should be tailored to the individual and the specific task (see Procedures for Practice 23-2).

As with the need for increased lighting, there is also an increased need for higher contrast as one ages. Improving contrast can increase safety and support safe navigation of the environment. For example, clients with poor contrast sensitivity require increased contrast and lighting and may have difficulty identifying curbs, stairs, and finding objects in low light, whereas a person with VF loss may have more difficulty in a busy, moving environment.

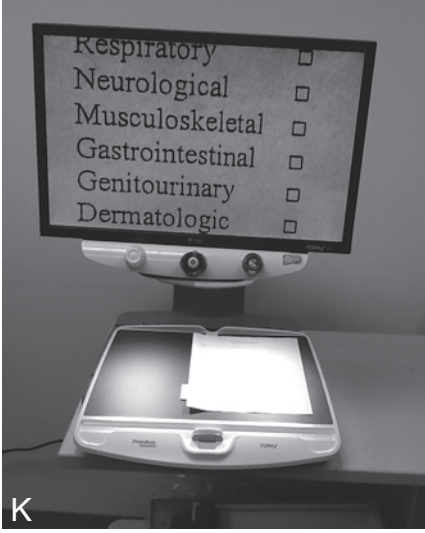
Environmental factors can be adapted to improve the person's ability to perform a task. For example, an individual experiencing difficulty with meal preparation may benefit from changing the lighting, marking the oven controls with contrasting colors, using high–color-contrast utensils, using proper positioning, and avoiding glare from windows or surfaces. All of these adaptations may assist clients in meeting their desired goals. For additional examples of environmental factors, refer to Table 23-2.

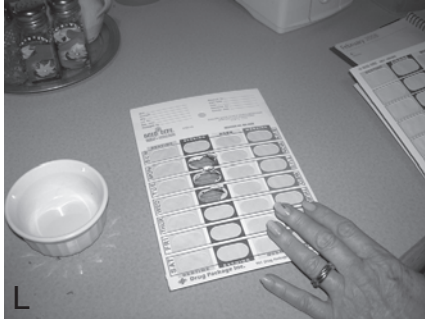
Magnification

Most older adults with LV will benefit from some form of magnification. Magnification is a fundamental means of improving vision by making an object larger and thus more visible (Nowakowski, 2000). For some, use of large-print items can be helpful to complete desired activities. There are now many commercially available large-print items, such as clocks, checks, books, newspapers, telephones, remotes, and bingo cards. (Patients may also choose to adjust computer screens for greater contrast, brightness, and magnification. For other individuals, optical devices may be required.) A variety of optical devices are available including spectacles (microscopes), stand magnifiers, hand magnifiers, telescopes, and electronic magnification. When working with optical devices for magnification, it is important to assess monocular and binocular function in order to determine eye dominance and the potential for eye rivalry. For example, if the dominant eye is no longer the better seeing eye, it may interfere with binocular function and may require occlusion (Markowitz, 2006). There are benefits and challenges to all devices, and these factors must be considered to determine best fit (refer to Table 23-2). Further,

Table 23-2 Low Vision Interventions

Intervention Approach	Methods	Description
Visual skills	Scanning	Use with peripheral or central visual field defects Simplest to learn No needed equipment Improves safety and independence
	Eccentric viewing training	Use with central visual field defects Train to use an alternate viewing area or preferred retinal locus (PRL) to maximize the use of his or her remaining vision Can be used for both distance and near tasks, such as facial recognition or reading Requires patience and hard work (Mogk & Mogk, 2003; Warren, 1996; Watson et al., 1996)
Environmental adaptation	Lighting **Figure 23-2A**	All older adults regardless of visual impairment Should be tailored to activities regularly performed Consider natural, ambient, and task lighting Even lighting transitions, avoid dark and bright Task lighting—use of a gooseneck lamp is optimal for task lighting and can be adjusted so that light is directed onto the task rather than on the person. For writing, the lamp can be positioned on the side opposite the dominant hand to avoid shadows.
	Contrast **Figure 23-2B**	Increasing contrast between objects and their backgrounds is a simple and effective way to improve visual function, such as high contrast black numbers on a silver mailbox or a black light switch cover on a white wall.
	Filters **Figure 23-2C**	Filters can be used for glare control, contrast enhancement, retinal adaptation, and eye protection. Filters absorb certain portions of the light spectrum, heat energy, and harmful light rays and can assist with light scatter. Filters can improve comfort, increase visual acuity and contrast sensitivity, and assist with light/dark adaptation. Filters come in a variety of colors, levels of light transmission, styles, and costs.

Table 23-2   **Low Vision Interventions** *(continued)*




Intervention Approach	Methods	Description
Sensory substitution	Tactile strategies **Figure 23-2D**	Cost effective, commercially available Bump dots on appliances to mark settings, i.e., 350° on the oven or one-minute button on the microwave Puff paint, safety pins, rubber band, Braille markings
	Auditory strategies **Figure 23-2E**	Commercially available audio books are a simple and accessible resource for many individuals with visual impairment; occupational therapists can register a client to receive this service. Other available talking items: "say when" device, talking scales, talking glucometers, medication reminders, and organizers
Magnification *Safety Message: Optical devices are generally prescribed by an optometrist or ophthalmologist.*	General principles	Does not necessarily make vision clearer; it enlarges the object of regard, which is then more recognizable. The stronger the magnification, the smaller the field of view and the closer the magnifier is held to the eye.
	Relative size magnification	Increasing the size of the object: large print
	Relative distance magnification	Moving closer to an object makes it relatively larger, for instance, holding a book closer to the face.
	Large print **Figure 23-2F**	Simple, commercially available Limitations in power/size Examples: books, address books, bill statements can be requested from companies, and checks and check registers can be requested from banks

Table 23-2 **Low Vision Interventions** *(continued)*

Intervention Approach	Methods	Description
	Spectacles **Figure 23-2G**	Most individuals with visual impairment would like to get a pair of glasses that improve their vision and magnify the image; however, often individuals require greater powers that result in decreased focal distances, which are not acceptable to the individual. **Range of power:** binocular +1.00 diopter (D) to +14 D; or monocular up to 64 D (A diopter is a unit of power of the lens.) **Pros:** Common, in lower powers allow for greatest field of view, portable, relatively inexpensive **Cons:** Reduced focal distance
	Stand magnifiers **Figure 23-2H**	Stand magnifiers consist of a convex lens in a housing that is held flat onto the material. Clients should wear their own eyeglasses while using the optical device unless instructed otherwise by the doctor. The stand housing sets the focal distance. Devices can come illuminated or nonilluminated. **Range of power:** 6-50D **Pros:** Common, allows for increased working distance, relatively inexpensive, does not have to be held, less grasp required **Cons:** Portability and size, less light because of housing in nonilluminated forms
	Hand magnifiers **Figure 23-2I**	Hand magnifiers consist of a convex lens with a handle. Devices can come illuminated or nonilluminated and in many styles, i.e., folding, pocket, etc. **Range of power:** 2-60 D: variety of powers similar to stand magnifiers **Pros:** Because it does not have a housing that sets the focal distance, the individual must hold the magnifier at the focal distance to have a clear magnified image. There is greater flexibility with hand magnifiers for spot reading tasks. **Cons:** Must maintain focal distance, which would be difficult for extended reading tasks
	Telescopes **Figure 23-2J**	Telescopes can come in a variety of styles—handheld or spectacle mounted, monocular or binocular, Galilean or Keplarian. In a reverse position a telescope can be used for field enhancement. **Range of power:** 2–14× **Pros:** Great for brief spotting tasks, can be modified for near tasks **Cons:** Reduced visual field, limited depth of focus

(continued)

Table 23-2 **Low Vision Interventions** *(continued)*

Intervention Approach	Methods	Description
	Electronic magnification **Figure 23-2K**	Comes in variety of formats; in general, used for long-term reading or distance spotting. Most typical form is closed-circuit television (CCTV): portable or table top versions. Portable camera-based magnifiers are also available. **Range of power:** up to 70× magnification **Pros:** Can be used for reading, writing, and leisure activities. It has its own light source and brightness controls, the contrast can be enhanced through reversing the polarity, and it allows for a wide field of view, especially in lower magnifications. It allows for greater working distance and allows the individual to comfortably read for extended periods. **Cons:** Cost, portability, requires coordination and eye–hand coordination
Organizational strategies	Effective organizational strategies **Figure 23-2L**	Avoid clutter Establish regular schedules for cleaning Create consistent locations for common items: keys, low vision devices

training in proper care and use of LV devices is also required for device acceptance and functional use (Fok et al., 2011).

Sensory Substitution

Many people who cannot use residual vision to safely complete a task use tactile or auditory strategies. Tactile strategies are cost effective and easy to incorporate into many daily activities. For instance, older adults often have difficulty distinguishing blues and blacks, thus making identification of clothing difficult. A tactile strategy, such as placing rust-proof safety pins in the label of the clothing can aid in color identification (one safety pin for black, two for blue). Tactile strategies can also facilitate safe use of appliances, such as demarcating 350° on the oven dial with a high contrast bump dot or pouring salt into the palm of the hand prior to adding it to food to avoid over seasoning.

Someone with peripheral neuropathy who cannot safely rely on tactile sensation may use auditory strategies. There are many commercially available talking products, such as audiobooks, computer screen readers, talking watches, or talking thermostats. To that end, it is important to consider the type of voice that is used, because some pitches or sounds are easier to comprehend than others. As with any condition, it is important to look at an individual's abilities and limitations, in order to determine the best interventions strategies.

Organizational Strategies

Using good organizational strategies is important for individuals with visual impairment. General considerations include

- **C**onsistency: keep walkways clear from clutter and place items in a consistent location

Procedures for Practice 23-1

Eccentric Viewing Progression

1. Educate client on the presence of the scotoma.
2. Identification of scotoma.
3. Identification of the preferred retinal locus (PRL).
4. Client learns to move in and out of scotoma, looking at an object, bring the object in and out of focus using the new PRL.
5. Begin with large, simple, static targets (identify distance or near single targets).
6. Use steady eye technique or scrolling technique; maintain a fixed gaze and physically move the object or text into the best area of vision (rather than using saccadic eye movements to scan across the page of text).
7. Progress to complex, small, dynamic targets (words, sentences, saccades).

- **O**rder items: keep address books, phone books, or money in a wallet alphabetized or sorted by denomination
- **P**air like items: put shoes, socks, or outfits together
- **E**stablish routines: such as cleaning

These strategies can decrease frustration and potential for injury for those with visual impairment. In addition, it is important when working with family and caregivers to ensure that systems of organization are maintained. For example, caregivers or those providing housekeeping assistance must be consistent about object and furniture placement after cleaning so that the client knows where things will be. If a

Procedures for Practice 23-2

Principles for Managing Lighting

- General ambient lighting is important for safe mobility.
- When addressing task lighting, it is important to consider safety as well as brightness of light. Often, a gooseneck lamp is recommended for reading and writing tasks. Note, these lamps often come with metal shades and when used with an incandescent bulb can create a lot of heat. Use of a compact fluorescent lightbulb can reduce the risk of injury.
- The closer the light is to the task, the brighter the illumination. Therefore, you can use a lower wattage bulb if you can manipulate the distance from the light.
- When increasing light, it is important to remember the negative influences of glare on performance. Glare from light sources or a reflected source can cause discomfort, as well as functional impairment. Use of filters, visors, or polarized lenses can assist in decreasing glare discomfort.

caregiver neglects to place a low-lying footrest back under the coffee table, the client with LV could trip and fall.

Client/Family Education

Education to the client and family on the ocular condition, prognosis, and functional implications of the visual impairment is essential. Review of recommendations for environmental adaptations/modifications, psychological consequences, and need for support, as well as available support and social services can ease adjustment to visual loss. Family and caregiver education can assist with carry-over of information taught, as well as assist in the individual's ability to transfer the techniques to new situations or changes as they arise.

VISUAL IMPAIRMENT AS A RESULT OF NEUROLOGICAL CONDITIONS

Many people with neurological conditions also present with vision-related difficulties. Some of the performance problems can be attributed to difficulty coordinating eye movements, such as ocular motor dysfunction, whereas others are the result of brain damage that interferes with the interpretation or processing of visual stimuli, such as VF deficits and UN. As visual deficits are identified, it is important that an optometrist or ophthalmologist be consulted or an appropriate referral is made in order to maximize the individual's rehabilitation potential.

Clients who have had a cerebrovascular accident (CVA) may experience a variety of vision-related problems. VF impairments associated with CVA or traumatic brain injury (TBI) include hemianopsia or quadrantanopsia. There is reported VF loss in 36% of those with right (R) stroke and 25% of people with left (L) stroke and visual inattention impairment in 82% of R stroke and 65% of L stroke (Wolter & Preda, 2006). The VF impairment (nasal, temporal, superior, inferior) is specific to the area of the brain that is involved. The patient may also experience diplopia caused by cranial nerve palsy or oculomotor dysfunction; sensitivity to light; VF impairments; and/or UN (Rowe et al., 2009).

Similarly, Suchoff et al. (2008) found that 39% of individuals with TBI experienced VF defects. Many service members from Operation Enduring Freedom and Operation Iraqi Freedom have survived blast injuries resulting in TBI and eye injuries. It has been estimated that up to 18% of returning troops have mild TBI, and 75% of those individuals report visual deficits (Hoge et al., 2008; Stelmack et al., 2009). Brain injury may result in acuity loss, VF defects, ocular motor dysfunction, and binocular vision dysfunction (Ciuffreda, Ludlam, & Kapoor, 2009; Stelmack et al., 2009) (refer to Table 23-3).

In addition, individuals with visual deficits occurring as a result of neurological conditions often demonstrate symptoms similar to those of individuals with more typical LV diagnoses. Photosensitivity or light sensitivity;

Table 23-3 **Visual Complications Associated with Traumatic Brain Injury**

Visual Complication	Rates	Definition	Functional Implications
Convergence insufficiency	40%–56%	Inability of the eyes to turn in enough to allow for fusion during near tasks	Reading deficits Diplopia Blurred vision
Accommodative deficits	21%–56%	Inability of the eyes to adjust focal power for distance and near tasks	Reading deficits Diplopia Blurred vision
Pursuits and saccades deficits	25%–59%	Pursuits: inability of the eyes to follow a moving target Saccades: inability to accurately and efficiently refixate from one point to another	Reading deficits Visual motor deficits Balance and vestibular deficits Blurred vision
Fixation instability	5%–13%	Inability of the eyes to maintain gaze so that the image falls on the macula	Reading deficits Visual motor deficits Blurred vision
Strabismus	11%–32%	Misalignment of the eyes	Binocular vision deficits Depth perception deficits Potential visual field deficits Eye movement deficits Double vision Balance deficits
Diplopia	19%	Double vision	Blurred vision Balance and vestibular deficits Nausea Reading deficits Visual motor deficits

difficulty with light/dark adaptation; deficits in scanning, saccades, and pursuits; difficulty tolerating complex visual environments; deficits in depth perception; and eye strain are all visual complaints associated with LV and neurological visual diagnoses (Chang, Ciuffreda, & Kapoor, 2007; Roth et al., 2009; Schrupp, Ciuffreda, & Kapoor, 2009). In terms of treatment, the occupational therapist should consider the functional complaint and develop appropriate intervention strategies. For example, when an individual with homonymous hemianopsia complains of glare discomfort, the occupational therapist should consider lighting and glare control and perhaps use filters to manage the photosensitivity.

In this section, interventions for three categories of neuro-related vision dysfunction are presented: VF deficits, ocular motor dysfunction, and UN.

Intervention for Visual Field Deficits

As part of their intervention, occupational therapy practitioners teach clients to use scanning techniques and compensatory strategies, as well as train and assist the individual in adapting to the use of prisms (Fresnel, Yoked, Peli prism, or visual awareness systems) as prescribed by optometry or ophthalmology (see Evidence Table 23-1).

Scanning

Visual scanning, the most common intervention for field loss, is the ability to use an organized visual search of the task or environment (left to right, top to bottom). If an individual has awareness of his or her impairment, visual scanning training can be done simply with no special equipment, and family can be easily instructed to facilitate carryover of

Evidence Table 23-1	Best Evidence for Vision Intervention

Intervention	Description of Intervention Tested	Participants	Dosage	Types of Best evidence and Level of Evidence	Benefit	Statistical probability and effect size of outcome	Reference
Prism (UN)	Effectiveness of prisms creating a 10° deviation to the right to ameliorate neglect symptoms	Twenty patients with stroke, mean age = 62 years, mean time post stroke = 10 months	Ten daily sessions over 2 weeks with 90 pointing tasks throughout the visual field, while wearing prismatic goggles deviating the visual field 10° toward the right	Randomized controlled trial Level: IB1a	Yes. Sustained improvements in visuospatial abilities and reading performance	Long-term effects: Behavioral Inattention Test $p < 0.00001$, $\eta = 0.81$; cancellation scores $p < 0.0001$, $\eta = 0.75$; reading accuracy $p < 0.0003$, $\eta = 0.61$	Serino et al. (2009)
Prisms (hemianopsia)	Adaptation to a 40D prism for mobility and obstacle avoidance	Forty-three patients with homonymous hemianopsia; mean age = 63 years	Patients were fitted with a 40D Fresnel prism, followed by an in office interview	One-group, pre-post design Level: IIIB2b	Yes. Improved awareness of visual field and improvements in mobility and obstacle avoidance	Seventy-four percent of patients continued to wear the prism; patients rated the prism as very helpful and reported significant benefit for mobility and obstacle avoidance: $p < 0.001$	Bowers, Keeney, & Peli (2008)
Scanning	Examined restoration of visual field, visual search/scanning strategies, and transfer of scanning skills to activities of daily living (ADL) performance, especially reading	Fourteen studies included in review	Systematic review of interventions: restoration visual field, visual search/scanning strategies, and transfer of scanning skills to ADL performance, especially reading	Level: I	Yes. Improved attention to the side of visual loss or inattention and improved reading performance	With scanning training, improvements were noted in reading time and reading errors; improved scanning up to a 30° visual search field; unclear findings with restoration therapy; recommendation for further study	Bouwmeester, Heutink, & Lucas (2006)
Patching	Patching interventions: hemifield and full-field patching	Twenty-two RCVA patients with left unilateral spatial neglect	Patching 1. Half visual field patching 2. Complete visual field patching 3. Control, no patching	Randomized controlled trial Level: IB2b	Yes. Improved awareness of left, improved scanning, and improved ADL performance	Improvements noted with half visual field patching; improved Functional Independence Measure (FIM) scores $p = 0.01$; scanning (left reference zone) $p = 0.02$ (data not available to calculate effect size)	Beis et al. (1999)

Intervention	Description of Intervention Tested	Participants	Dosage	Types of Best evidence and Level of Evidence	Benefit	Statistical probability and effect size of outcome	Reference
Visuomotor feedback training	Exercises included visual scanning, reading, and copying	Fifty-nine patients with right brain damage (RBD), 12 received training for neglect, 36 had no neglect	Visual scanning training, specific training for five 1-hour sessions per week for 8 weeks, altered cognitive stimulation three times per week for 8 weeks; all training done in conjunction with physical rehabilitation	Random assignment to intervention groups; cross-over design with repeated measures Level: IC2b	Yes. Functional and motor improvements as well as improved scanning	Improvements were noted in intervention group of motor skills and function; Rivermead mobility, $p < 0.05$, $r = 0.367$; Barthel Index, $p < 0.05$, $r = 0.373$; letter cancellation, $p < 0.01$, $r = 0.484$	Paolucci et al. (1996)
Limb activation	1. Lateralized task approach 2. Controlled sensory stimulation 3. Limb activation	Forty-seven patients with cerebrovascular accident (CVA) and visual neglect without hemianopsia	Reviewed studies related to three approaches to addressing visual neglect: 9 group studies, 22 single-subject design studies	Meta-analysis Level: I	Improved body image and visual awareness with limb activation	Unilateral neglect appears to be amenable to change by way of activation of the right hemisphere (group designs $r = 0.77$ and single subject designs $r = 0.89$); line bisection tests, cancellation tests, copying tasks, reading tests	Lin (1996)

See other important intervention studies (Fortis et al., 2010; Pisella et al., 2006; Scheiman, Gwiazda, & Li, 2011; Shiraishi et al., 2010; Ting et al., 2011).

Figure 23-3 Dynavision.

training. Training can include paper and pencil tasks; computer programs; scanning in a functional setting, such as a grocery store; and use of the Dynavision (Fig. 23-3) (Suchoff & Ciuffreda, 2004). Research supports improvement on visual perceptual tasks, reading, and academic work with this type of training but found it does not generalize to gross motor tasks (Pollock et al., 2011). The literature indicates that the effects of scanning training are contextual, that is, specific to the situation. If the goal is to improve the client's ability to read or scan at tabletop, tabletop scanning training is appropriate. However, if the therapist wants to

Table 23-4 **Training Guidelines for Visual Attention and Visual Scanning**

Train client to use scanning strategy.	Use anchoring techniques; reorganize scanning strategies (Weinberg et al., 1979).
Broaden visual field which requires that client must scan.	Use activities that the client is required to turn the head or change body positions to complete the task (e.g., scanning items on a kitchen shelf).
Reinforce visual experience with sensorimotor experiences.	Use activities in which the client is required to manipulate what is seen (e.g., reach for or touch items scanned).
Emphasize conscious attention to detail and careful inspection of objects.	Use matching tasks in which the client may be encouraged to slow down and double-check interpretation of what is seen.
Practice the skill in context to ensure carryover.	Treatment may begin in the clinic, but strategies must be practiced in a variety of real-life situations.

From Warren, M. (1993b). A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, part 2. *American Journal of Occupational Therapy*, *47*, 55–66.

improve a client's ability to scan in the community, practice in the community is needed. Warren (1993b) provided guidelines for the selection of treatment activities for clients with deficits in visual attention and visual scanning (Table 23-4). Visual scanning training, including mental imagery, pencil-paper tasks, computerized visual scanning, and functional scanning tasks, has been shown to improve attention in individuals with VF defects as well as UN (Bouwmeester, Heutink, & Lucas, 2006; Niemeier, Cifu, & Kishore, 2001).

Clients being trained to scan must learn to synthesize information in an organized manner, such as left to right or through use of anchoring (supplying a cue on the impaired side to indicate starting position). This assists the client in focusing attention back to the side of VF loss or neglect (Table 23-5). In order to develop an organized

Table 23-5 **Anchoring Technique**

Sequence of Cueing	Task Demand
1. A vertical anchoring line is used on the left side; the beginning and ending of the line are sequentially numbered.	Client uses the vertical line to find the beginning and the numbers to avoid skipping lines.
Example: 1 The law was passed to allow the 1 2 state to conduct a national FBI 2 3 criminal records check before 3 4 certifying teachers. 4	
2. A vertical anchoring line is used on the left side; only the beginning of the line is sequentially numbered.	Client uses the vertical line and numbers on the left; the number cue on the right has been eliminated.
Example: 1 Family members, followed by 2 coworkers, are the most 3 frequent targets of 4 anger.	
3. A vertical anchoring line is used on the left side.	Client uses only the vertical line to find left side.
Example: Environmental groups hope to minimize the divisiveness and avoid mistakes made in the Pacific Northwest.	
4. No cues are provided.	Client must read without any cues.
Example: The state distributes its lottery proceeds without regard to which communities generate the revenue.	

From Quintana, L. A. (1995). Remediating perceptual impairments. In C. A. Trombly (Ed.), *Occupational therapy for physical dysfunction* (4th ed., pp. 529–537). Philadelphia: Williams & Wilkins.

search, it is helpful to begin scanning training with cancellation tasks, a structured array (symbols arranged in neat, straight rows across the page), or computer-based programs (Suchoff & Ciuffreda, 2004). This array can be made increasingly more complex by instructing the patient to scan for two target letters, decreasing the spacing between letters, or decreasing the size of the letters as the client progresses (Cooke, 1992).

Compensatory Strategies

Individuals with homonymous hemianopsia or quadrantanopsia often have difficulty with reading tasks. Individuals with right VF impairment must look into their field impairment as they read across the line. They may lose their place reading along or have difficulty identifying the end of the line. They may also have errors in word identification, such as with compound words; they may read foot when the word is football. Individuals with left VF impairment may have difficulty finding the beginning of the reading materials. Use of anchoring, cueing techniques, and reorientation of the reading materials can be effective techniques for reading tasks (Pambakian, Currie, & Kennard, 2005) (see Fig. 23-4).

Prism

A prism is a type of lens that is thicker on one side than the other. Its purpose is to bend the light coming into the eye, moving the image onto the fovea. In the case of hemianopsia, prisms are often used to shift an image from the nonseeing area into the seeing area. Current prism interventions look to improve VF awareness (Gottlieb, Freeman, & William, 1992; Peli, 2000, 2001) versus shifting the VF (yoked or sector prism). Prisms may be a permanent part of the client's prescription or they may be temporary. For example, a Fresnel prism, is a flexible plastic sheet with small ridges that can be cut to shape and adhered to the client's glasses. The Fresnel prism is advantageous because it is inexpensive and temporary and can be easily applied and removed. The

disadvantages are that it may distort visual acuity and tends to cloud and increase distortion (Gianutsos & Suchoff, 2002).

Prisms appear to improve VFs through a number of mechanisms. For example, Gottlieb, Freeman, and Williams (1992) developed a button-type prism (a round, base out prism) that is placed in the peripheral field of the individual's glasses. As the individual shifts gaze, the prism shifts the image from the nonseeing area into the seeing area. This shift creates improved VF awareness and is referred to as a visual awareness system. Peli (2000) introduced another method of field expansion using Fresnel prisms. The 40D monocular prisms are initially placed in the superior VF, with the prism's base positioned toward the side of the VF defect, in the peripheral field. It is placed along the entire length of the glasses so that the prism creates peripheral diplopia, while allowing for clear central vision. This diplopia acts as a cue to look to the side of the visual impairment. Traditionally, prisms were used in the hemianopic field when the individual is in primary gaze, only creating a shift in the image when the individual switched their gaze. The Peli prism placement, created a constant peripheral diplopia, providing a field expansion of about 20°, in standard perimetry testing (Bowers, Keeney & Peli, 2008; Giorgi, Woods, & Peli, 2009). The advantages of using prisms include effects can be obtained within a short period of time, they do not require voluntary orientation of attention to the involved side, and they are noninvasive and can be used anywhere (Frassinetti et al., 2002). Occupational therapists work with vision specialists (such as optometrists) when incorporating prisms into intervention (see Fig. 23-5).

Ocular Motor Dysfunction

Ocular motility refers to the ability of the eyes to move smoothly and with coordination through full range of motion. Ocular motor dysfunction includes problems with binocular vision, accommodation, scanning, and

saccades. Problems with binocular vision typically result in diplopia or double vision, deficits in reading, and other functional tasks. Intervention for oculomotor dysfunction may include lenses, prisms, occlusion, and/or vision therapy.

Vision Therapy

Vision therapy (VT), or orthoptic training, "is an organized regime used to treat a number of neuromuscular, neurophysiological, and neurosensory conditions that interfere with visual function" (Scheiman, 2002, p. 129). VT can range from the use of an eye patch to more complex treatment involving instrumentation and computers. It is generally used to treat disorders of binocular vision, accommodation, ocular motility, strabismus, and visual information processing (Scheiman, 2002). Some of the training provided in VT such as saccades, pursuits, and ocular motility exercises are often incorporated into typical occupational therapy intervention, whereas others, such as base-in and base-out stereograms, pencil push-ups, Brock String exercises, jump-ductions, prisms, and use of lenses, are more typically carried out by optometrists or an occupational therapist under the supervision of the vision specialist (refer to Table 23-6).

Lavrich (2010) and the Convergence Insufficiency Treatment Trial Study Group (2008) found that an intensive VT program appears to be the most effective

Table 23-6	**Vision Therapy**	
Intervention	**Description**	**Deficits**
Base in and base out stereograms	Pair of images that are viewed through lenses to facilitate binocular vision (try viewing training on YouTube)	Binocular vision deficits Eye teaming and fusion
Pencil push ups	Hold a pencil out at arm's length in front of you. Focus on the tip of the pencil. Slowly bring the pencil in toward your nose. Bring it in until you are no longer able to see just one pencil tip. At that point, hold the pencil and try to refocus on the tip (hold 10 seconds). Slowly return to the starting position. (try viewing training on YouTube; convergence insufficiency exercises)	Binocular vision deficits Convergence insufficiency
Brock string exercises	Place three beads (one red, one yellow, and one green) on 4 feet of string. Hold one end of the string against the bridge of your nose. Place the red bead at about 60 cm from the nose, yellow at 40 cm, and the green at about 20 cm. Look at the green bead, what do you see? You should see one green, two yellow, and two red beads. Now, look at the red bead. You should now see one red bead and two yellow and two green beads. (try viewing training on YouTube)	Binocular vision deficits Convergence and divergence
Jump vergences	Alternating viewing from near to distance objects.	Binocular vision deficits Convergence and divergence

intervention for convergence insufficiency. However, it was unclear whether the duration or intensity of programming impacted the effectiveness. Pencil push-ups and prism glasses, especially in the presbyopic population, had the most positive outcomes.

The occupational therapy practitioners addressing and training clients with lenses, prisms, and occlusion should always be supervised by an eye care professional (Hellerstein & Fishman, 1999). The occupational therapist can (1) provide the optometrist with critical observations of the client and his or her function; (2) assist with compliance of wearing schedules of prisms, patches, and/or glasses; (3) report on improvements in function or complaints/symptoms; and (4) integrate oculomotor activities, eye exercises, saccades, and pursuits into interventions. It is important to work closely with the eye care professional to provide input as to the client's functional needs and situation and then follow through with training that is set up by the eye care professional.

Lenses and Prisms

Lenses are used to treat a variety of refractive, accommodative, and binocular disorders. In most cases, they are used as a means of compensation to allow the person to function despite any disorder (Suchoff, Ciuffreda, & Kapoor, 2001). The purpose of prisms in the treatment of oculomotor dysfunction is to bend the light entering the eye, allowing the image from each eye to converge onto the fovea, allowing for single vision. Lenses and prisms are recommended by the eye care professional, who is responsible for the strength of the lenses and prisms and any vision exercise programs recommended. The occupational therapist assists the client with follow-through of the eye care professional's recommendations and encourages compliance with the wearing schedule.

Occlusion

Occlusion should be carried out in consultation with the eye care professional. It may be either total or partial and helps minimize the impact of diplopia by forcing the patient to primarily rely on monocular vision. Total occlusion is achieved by means of a patch or opaque tape on the client's glasses (Fig. 23-6). Compliance with this method is often poor because (1) total occlusion can cause clients to feel off balance because of loss of peripheral and central vision input to the central nervous system,

Figure 23-6 Total occlusion. **A.** Pirate patch. **B.** Opaque material covering lens of glasses.

and reduced depth perception; and (2) monocularity can cause discomfort, especially when the dominant eye is occluded (Warren, 1993). The recommendation is to avoid total occlusion if at all possible (Hellerstein & Fishman, 1999) and, if necessary, to alternate occlusion between the eyes every hour (Warren, 1993).

Partial occlusion appears to have better compliance (Rucker & Tomsak, 2005). With partial occlusion, an opaque material added to the client's glasses blocks input to the central VF, leaving the peripheral field unobstructed (Fig. 23-7). Partial occlusion can result in single vision while preserving the greatest amount of peripheral field. Two types of spot patching can be used: (1) a round disk of tape is placed in the individual's line of sight; or (2) the tape is placed in the nasal portion of the individual's glasses (nasal occlusion) allowing for maximal single vision. Because diplopia in the central VF is the most bothersome, the tape is applied to the nasal portion of the

Figure 23-7 A method of partial occlusion to alleviate diplopia.

glasses of the nondominant eye (Warren, 1993). As the client focuses on a target, the tape is applied as far centrally as the client reports diplopia. As the muscles get stronger, the occluded area is decreased. When using occlusion, the client should do prescribed range-of-motion exercises to the unaffected eye to prevent contractures. Warren (1999) recommends that exercises first be done with the unaffected eye covered and then with both eyes together.

Unilateral Neglect

UN is referred to by a variety of names, including hemi-inattention, hemispatial neglect, and unilateral spatial agnosia, and is reported in approximately 23% of individuals with CVA (Marshall, 2009). It is manifested by a failure to respond or orient to stimuli presented contralateral to a brain lesion (Hillis, 2006). It is observed functionally in the client who eats the food on only half of the plate, shaves only one side of the face, and walks into objects on the side contralateral to the brain lesion. It has been suggested that there are two types of neglect: motor or output neglect (impaired initiation or execution of movement into contralateral hemispace by either limb) and sensory or input neglect (awareness of stimuli on one side of the body or one side of space) (Pierce & Buxbaum, 2002; Plummer, Morris, & Dunai, 2003). The presence of UN negatively impacts rehabilitation and functional outcomes of clients with right brain damage (RBD) (Cumming et al., 2009; DiMonaco et al., 2011; Gillen, Tennen, & McKee, 2005). As discussed in Chapter 5, UN is not related to eye function but is a processing problem associated with brain damage.

Intervention Approaches for Unilateral Neglect

Intervention for UN can be approached in a variety of ways. First, the client must be aware of the problem. If aware that they have a problem, many clients can voluntarily orient, even though they have difficulty doing so automatically (Ladavas, Carletti, & Gori, 1994). If they are unaware and unable to orient voluntarily or automatically, the only recourse is to modify and simplify the environment (Warren, 1993).

Some of the early research on the treatment of neglect was done by Weinberg et al. (1977), who developed a training program that included reading, writing, and calculation. It was expanded to include sensory awareness and spatial organization and tasks to increase complex visual perception (Weinberg et al., 1979, 1982). Unfortunately, although improvements were seen, they tended to be task specific, with little generalization to other tasks or areas of self-care. Therefore, it is important to train persons in a functional setting using objects readily available in the environment.

The results of a systematic review by Riggs et al. (2007) suggested that the most effective interventions for unilateral inattention or neglect were prisms, scanning, visuomotor feedback training, and patching intervention.

However, much of the current literature relies on paper and pencil tasks as outcome measures rather than measures of functional abilities.

Attention Training. One theory of UN is that the problem is due to an attention deficit. If this is the case, a treatment program aimed at increasing attention and general level of alertness should improve UN. Robertson et al. (1995) trained clients with RBD and UN to self-alert during activities. With 5 hours of training, they could mentally alert themselves during tasks. Improvement in UN and sustained attention lasted 1–14 days.

In another study, Robertson et al. (1998) found that providing a warning tone as a means of alerting the client that something was going to happen prior to a task increased perceptual processing and shifting of spatial attention to the left. This system was further expanded by a limb-activation device that can be attached to the affected shoulder, arm, or leg (Robertson et al., 2002) that is programmed to emit a tone if there is no movement within a set period of time (2–120 seconds). The researchers found a significant effect on motor function of the arm and leg, which persisted for 18–24 months.

Another method of self-activation is the client's use of the contralateral extremity as a cue to attend to the neglected side (e.g., to mark the left side of the page while reading or to move the extremity while walking to increase attention to that side). Robertson and North (1994) found that clients who moved their contralateral hand when walking through a doorway exhibited a decrease in neglect.

Scanning. Similar to visual scanning training for individuals with VF defects, individuals with UN may benefit from mental imagery, computerized visual scanning, and functional scanning tasks. Mental imagery can be used to self-direct environmental or task scanning in an organized manner. Niemeier (1998) and Niemeier, Cifu, and Kishore (2001) developed a visual imagery technique called the lighthouse strategy in which clients are taught to visualize themselves as a lighthouse and use the eyes to sweep the environment. This method was found to increase attention to the neglected side of space. Paolucci et al. (1996, 2001) used a training program for neglect that included scanning, copying, and description of scenes in addition to a traditional rehabilitation approach and found that there was an improvement not only on tests of neglect but also in function. On the other hand, although Bailey, Riddoch, and Crome (2002) found an improvement with scanning and cueing, no generalization to functional activity was present.

It seems that scanning tasks and cueing should be included in functional activities whenever possible to facilitate transfer to functional tasks. Scanning tasks must be practiced in a variety of settings because clients can improve on a task without a measurable decrease in VF neglect. An excellent therapeutic model to guide practice is the use of Toglia's (1991) multicontext treatment approach. An example of levels of transfer for a letter cancellation task, consisting of crossing out a specific letter on a page of four rows of random letters, can be seen in Table 23-7.

Patching. Eye patching techniques for UN include single-eye patching (see Fig. 23-6) and half-field patching

Table 23-7 Levels of Transfer for a Letter Cancellation Task

Transfer Distance	Task
Near	Client is instructed to cross out the number 5 on a worksheet comprised of rows of numbers (number cancellation task).
Intermediate	Four horizontal rows of various coins are presented. Client is instructed to place a marker over all the nickels (tabletop task).
Far	Client is presented with a spice rack and is asked to pick out all of the jars that need to be refilled (standing and reaching at kitchen cabinets).
Very far	Client is evaluated on the ability to initiate spontaneously left-to-right scanning in the context of simple, everyday life tasks (reading four lines in a large-print magazine or locating an item in the medicine cabinet or on a shelf).

Feedback	• Verbal feedback:
	  ○ In terms of the result
	  ○ To encourage the client to consciously evaluate the results (see, hear, feel, smell, taste)
	• Physical feedback as to:
	  ○ Posture of the client
	  ○ Support of the limbs
	  ○ Pointing or handing the object to the client
	• Verbal and physical feedback to assist client's knowledge of performance:
	  ○ Place a mirror in front of the client
	  ○ Video record performance and then review together

Adapted from van Heugten, C. M., Dekker, J., Deelman, B. G., van Dijk, A. J., Stehmann-Saris, J. C., & Kinebanian, A. (1998). Outcome of strategy training in stroke patients with apraxia: A phase II study. *Clinical Rehabilitation*, *12*, 294–303.

Figure 23-8 Right hemifield patching for left visual neglect.

(Fig. 23-8). For the client with neglect, either the entire eye ipsilateral to the lesion is covered, or the hemifield of both eyes is covered. For example, in the case of left UN, the right eye or right hemifields of both eyes is patched.

Patching one eye is believed to influence the central nervous system by way of the superior colliculus (Posner & Rafal, 1987), increasing eye movements to the contralateral side and decreasing neglect. Patching the ipsilateral hemifield is thought to increase activation of the involved hemisphere, resulting in increased attention to the contralateral side. Butter and Kirsch (1992) found that patching the right eye of clients with left neglect decreased the clients' left neglect score. When lateralized visual stimulation was added, the relative benefits were larger. The beneficial effects, however, were present only when the eye patch was on, and the study did not include generalization to functional tasks.

Beis et al. (1999) followed 22 clients with UN: 7 wore glasses with patches covering the right eye, 7 wore glasses with right half-field patches, and 8 controls had no patching. The patches were worn up to 12 hours a day for 3 months. The results of the clients with the right half-field glasses were significantly better from those of the controls, with the right half-field clients exhibiting an increase in total Functional Independence

Measure (FIM™) score (Uniform Data System for Medical Rehabilitation, 1997) and increased time looking to the left. Similarly, Zeloni, Farne, and Baccini (2002) looked at continuous wear of hemi blinding goggles for 1 week and found improvements that continued over the 3-week testing. Arai et al. (1997) also looked at the effects of half-field patching with 10 RBD clients. They found a decrease in neglect, improvement on pencil and paper tasks, and good functional return in one client. Harrell, Kramer-Stutts, and Zolten (1995) also reported an improvement of neglect in clients wearing goggles with half-field glasses. Riggs et al. (2007) and Jutai et al. (2003) completed an analysis of the evidence, 27 studies and 32 studies, respectively, on the effectiveness of UN interventions and found that hemifield patching showed moderate improvements on standard neglect tests.

Patching has many benefits. It may be used throughout the day during a variety of functional activities and does not rely on memory and training. Patching is simple, inexpensive, and carried out by a variety of disciplines.

Prisms. Prisms are also used in the treatment of UN, in which the image from the neglected area is shifted into the non-neglected area. Gianutsos and Suchoff (2002) recommended the use of the Fresnel prisms as a temporary or diagnostic device. Unlike the use of Fresnel prisms with individuals with VF defects, these were not as beneficial as yoked prisms ground into the client's prescription for individuals with UN. The strongest evidence shows that full-field yoked prisms are most beneficial for individuals with UN because they do not require the individual to shift gaze into the prism to elicit the VF shift (Rossetti et al., 1998). This prism does not require effort of the individual to shift focus into the prism; the image is shifted in the direction of the apex of the prism. Nys et al. (2008) and Serino et al. (2009) studied the use of prism goggles with 10° rightward deviation while engaged in pointing tasks to improve greater VF awareness. These randomized controlled trials found significant improvement in standard neglect tests at the end of the study and 1 month follow-up.

Rossetti et al. (1998) used prisms to shift the VF to the right in 16 RBD clients with left UN. Initially, the clients exhibited a shift to the left when pointing straight ahead. Following adaptation, clients were given tasks including line bisection, line cancellation, copying, drawing from memory, and reading. Clients in the experimental group exhibited an improvement in neglect, which was maintained for 2 hours. Frassinetti et al. (2002) expanded this and found that the prism adaptation was maintained for at least 5 weeks and, for some subjects, was maintained for up to 17 weeks.

Spatiomotor Cuing. It has been suggested that there are two types of neglect (Bisiach et al., 1990; Coslett et al.,

1990; Tegner & Levander, 1991), and therefore, it is reasonable to expect that each has its own form of intervention. For a client with primarily a motor or output neglect, encouragement of left-hand activation may reduce neglect to a greater extent than visual perceptual cuing. An example might be having the client move the left hand (or use whatever movement is available) while performing a scanning task, instead of using a visual anchoring technique such as supplying a visual cue on the impaired side to indicate starting position. Robertson and North (1992) found that left motor activation in left hemispace reduced neglect more than did left motor activation in right hemispace, right motor activation in left hemispace, or visual cuing. They further reported that (1) left lower extremity activation reduced neglect, (2) passive movement of the left extremity had no effect on neglect, (3) bilateral movements produced no effect, and (4) there was no effect if the movement became automatic. In a further study, Robertson and North (1994) found that simultaneous activation of right and left hands produces a phenomenon similar to extinction, such that the advantage gained by activating the left hand is lost. Only single left-hand movement produced a large reduction in neglect. This could have implications for use of bilateral activities, such as those used in the Bobath techniques. Opportunity for unilateral activation of the hemiplegic arm as well as bilateral activation should be provided (Robertson & North, 1994). Lin (1996) completed a meta-analysis looking at three approaches to UN in right CVA: lateralized task approach, controlled sensory stimulation, and limb activation and found that there was reduction in neglect symptoms with hemispheric activation.

If the client demonstrates a sensory or input neglect, he may benefit from visual cuing such as anchoring (Table 23-5) or reminders to look to the left. Training the client to use the left upper extremity as an anchor during functional activities provides both a perceptual anchor and a means of left-limb activation (Robertson, North, &

Geggie, 1992). Kalra et al. (1997) found that spatial cueing with motor or functional activity improved neglect symptoms, improved body image, and decreased length of stay.

Compensatory Techniques. Compensatory techniques can be environmental or cognitive. Adaptation of the environment includes such things as arranging the client's bed so that the involved side is toward the activity in the room and always interacting with the client on the involved side. If the client has a left visual neglect, the bed should be arranged so that the client must turn to look to the left to see people enter the room or watch television, thus allowing for constant cueing to look to the left.

Cognitive compensation includes metacognitive training (Toglia, 1991), use of video feedback (Soderback et al., 1992), and teaching clients a routine to complete a specific activity like donning a shirt while self-cueing themselves through each step. What is most important is that clients must be aware that there is a problem before they can successfully use compensatory techniques (Crosson et al., 1989; Tham, Borell, & Gustavsson, 2000). These techniques must be practiced, and eventually, if the client becomes an active problem solver, the techniques can be generalized to new situations involving visual challenges.

SUMMARY

Our population is aging, and as a result occupational therapy practitioners are often faced with addressing multiple conditions as a result of aging, disease, or injury, including vision impairment. It is important that occupational therapists have the skills and knowledge to be able to provide appropriate, evidenced-based interventions, including visual skills training, environmental adaptation (lighting & contrast), magnification, compensatory techniques (sensory substitution—talking and tactile strategies), organizational strategies, and client/family education to maximize their client's occupational performance.

case example

Mrs. F.: Occupational Therapy Intervention to Address Problems with Reading

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Client Information Mrs. F. is a 78-year-old female who was admitted for rehabilitation following a hip fracture, past medical history included osteoarthritis, hypertension, and macular degeneration. She participated in an inpatient occupational therapy (OT) assessment, and the following problems were identified: (1) decreased awareness and acceptance of her ocular condition, (2) decreased awareness of how her visual impairment will impact the rehabilitative process, (3) difficulty recognizing people's faces, (4) difficulty reading standard newsprint, and (5) difficulty comprehending reading materials.	Appreciate the context	See Chapter 5 for description of the assessment process and client's background.
	Develop intervention hypotheses	"I believe that Mrs. F.'s visual skills are limiting her ability to read and participate in the rehabilitative process. These abilities may be further limited by her depression. She is motivated to return home."
	Select an intervention approach	"I think that Mrs. F. would benefit from large print, increased contrast, and improved lighting, which, according to the research, is successful although task specific. She will probably need to learn compensatory techniques that she can apply to various functional situations." "I'm afraid that Mrs. F. is going to continue to require support and increased time for task completion and acceptance of compensatory strategies because of her probable depression and lack of acceptance of her visual impairment."
Recommendations In collaboration with Mrs. F., the occupational therapist established the following long-term goals: 1. In 2 weeks, Mrs. F. will be independent in her home exercise program with 100% accuracy. 2. In 2 weeks, Mrs. F. will be independent in activities of daily living (ADL) and instrumental activities of daily living (IADL) tasks using compensatory and visual strategies. 3. In 2 weeks, Mrs. F. will verbalize awareness of her ocular disease and its impact on occupational performance and will make an appointment for outpatient OT to continue to address visual skills, psychosocial adjustment, and functional implications of vision loss.	Consider what will occur in therapy, how often, and for how long	"I know Mrs. F.'s goal is to return home. In order to do this, she will need to address not only her hip fracture but also her vision loss. She will need to be able to accept the permanence of her visual impairment and accept recommendations to compensate. Her family or personal care attendant will be instrumental in assisting her to follow through with recommendations and compensatory techniques. Hopefully, she and her family will be accepting of recommendations for a low vision assessment and outpatient vision rehabilitation services."
Summary of Short-Term Goals and Progress 1. Mrs. F. demonstrated improved use of compensatory strategies (large print, increased contrast, and improved lighting) such that she was able to read her exercise program with 80% accuracy. 2. Mrs. F. is having difficulty with lower extremity (LE) dressing using long-handled reacher, sock aid, and shoe horn. The task was adapted by use of high-contrast tape to increase contrast between clothing, floor, and adaptive devices. With increased contrast, Mrs. F. was able to don her pants with stand-by assistance. 3. Mrs. F. was having difficulties with ADL task completion. It was decided to continue to address necessary ADL and IADL tasks for discharge home. Because Mrs. F. was unable to read her menus or home program, it was probable that she would be unable to read labels, medicine bottles, or the mail. It was determined a home evaluation would be needed prior to discharge home.	Assess the client's comprehension Understand what she is doing Compare actual to expected performance	"When she first started, Mrs. F. had difficulty because she did not accept the need for modifications. We spent some time working on visual skills, and she was able to see the benefit of the strategies. I am encouraged this has worked for her." "Mrs. F. is making progress on LE dressing with use of compensatory strategies." "I hope Mrs. F. will be accepting of a home assessment."

Next Steps

Revised short-term goals (1 week):

1. In 1 week, Mrs. F. will independently complete her home program using compensatory and visual strategies with 100% accuracy.
2. In 1 week, Mrs. F. will be independent in dressing using high-contrast adaptive devices.
3. Mrs. F. will make an appointment with outpatient OT services to continue to address visual skills, psychosocial adjustment, and functional implications of vision loss by discharge.

Anticipate present and future client concerns	"Mrs. F. has made progress on established goals. Her accuracy and use of compensatory strategies have improved but would benefit from continued outpatient treatment. She is also managing her ADL, but will require continued treatment to address IADL tasks (i.e., money management, medication management, home management)."
Decide whether the client should continue or discontinue therapy and/or return in the future	"I feel Mrs. F. is progressing and will benefit from outpatient occupational therapy one to two times per week for 6 weeks."

Clinical Reasoning in Occupational Therapy Practice

Effects of Low Vision on a Functional Task

Based on an optometrist's report for the client, Mrs. F., after her discharge from rehab, her best corrected acuity is 20/80 at distance. She was able to read standard large-print materials; however, her speed was slow. She has macular degeneration in both eyes and a history of a hip fracture following a fall. She lives alone in a single-family home with limited family support. She has recently lost her husband. She is a retired teacher, and her primary leisure pursuits are reading and cross-stitch.

You have received a referral to see Mrs. F. because of her visual impairment. The home assessment from the rehabilitation facility found a cluttered environment and decreased lighting throughout.

What modifications could be made to her environment to support engagement in occupations of choice?

Summary Review Questions

1. List three compensatory techniques for use with clients with low vision, and give two examples of each.
2. You have a client with diabetic retinopathy. What might you need to consider when deciding on treatment options?
3. You have a client with macular degeneration and mild cognitive decline whose goal is to be able to read. What potential intervention strategies may be difficult? What intervention strategies would you use?
4. You have a client with double vision. What should you do first?
5. Based on an optometrist's report, your client's best corrected acuity is 20/160. He has a cataract in the right eye and glaucoma in both eyes, for which he is receiving medication. How might his low vision affect his ability to do self-care, meal preparation, and money management?
6. Summarize the guidelines for visual scanning training.
7. How does the use of occlusion for diplopia differ from that used for unilateral neglect?
8. Your client has a left visual field defect and is struggling with reading. What would you expect to be difficult, and what compensatory strategies would you implement?
9. Your client with left unilateral neglect is having difficulty finding things in the kitchen cabinets during meal preparation. What activities might you plan for your therapy session?
10. Why is it important for occupational therapists to become involved in research?

Glossary

Anchoring—Method of providing a cue on the side contralateral to the brain damage, in the presence of unilateral neglect.

Extinction—Phenomenon of neglect that occurs when stimuli are presented in both visual fields or both sides of space at one time and only one stimulus is reported, whereas if presented to either side individually, the client reports the stimulus.

Fresnel prism—A prism that is applied to glasses to shift an image from the nonseeing area into the seeing area, typically used with individuals with hemianopsia or unilateral neglect

Low vision—A bilateral visual impairment that cannot be corrected by corrective lenses, medication, or surgery that impairs an individual's ability to complete occupations of choice.

Occlusion—Covering part or all of the visual field of the eye.

Prism—A type of lens that is thicker on one side (base) than the other (apex); the purpose is to bend the light and shift the image from the base of the prism to the apex.

Vision rehabilitation—The process of providing education and treatment to individuals with visual impairment that aims to maximize the individual's awareness of their visual impairment, optimize their adjustment, and facilitate participation in occupations of choice.

Vision therapy—An organized regimen used to treat a number of neuromuscular, neurophysiological, and neurosensory conditions that interfere with visual function carried out typically by eye care professionals or by occupational therapists with additional training and under the supervision of the prescribing eye care practitioner.

Optimizing Cognitive Performance

Mary Vining Radomski and Gordon Muir Giles

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Discuss the field of cognitive rehabilitation in general.
2. Distinguish cognitive rehabilitation approaches used by occupational therapists from those provided by other disciplines.
3. Describe theoretical approaches to occupational therapy cognitive intervention for persons with physical disabilities and/or who are aging.
4. Employ specific clinical interventions that are supported by theory and research.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

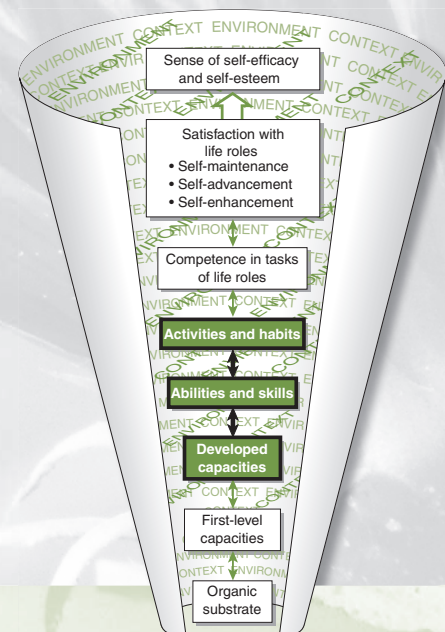
Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate


Many people who are referred for occupational therapy experience cognitive dysfunction associated with injury, illness, pain, emotional distress, and/or aging. Because a person's ability to concentrate, remember, and solve problems is central to fulfilling the valued life roles described in Chapter 1 (self-maintenance, self-advancement, and self-enhancement), cognitive dysfunction is often the primary focus of occupational therapy intervention.

The central aim of this chapter is to advance evidence-informed cognitive intervention that reflects occupational therapists' focus on occupational performance. To that end, we first highlight milestones in the history of the cognitive rehabilitation field and then describe both theory and practices associated with occupation-oriented cognitive rehabilitation.

COGNITIVE REHABILITATION

Although definitions vary, the term cognitive rehabilitation generally describes a multidisciplinary field and the application of "therapeutic interventions designed to improve cognitive functioning and participation in activities that may be affected by difficulties in one or more cognitive domains" (Brain Injury Association of America, n.d., p. 1). Many rehabilitation disciplines, including occupational therapy, speech-language pathology, special education, and neuropsychology, attempt to help patients optimize cognitive abilities, with occupational therapy and speech therapists most often providing cognitive rehabilitation services (Stringer, 2003).

Historical Perspectives

Interest in the possibility of "reeducating" persons with a damaged brain dates back to the 1800s (Finger, 1994), with the earliest efforts stemming from Broca's work that localized articulate speech to the frontal brain region (Boake, 1991; Finger, 1994). Concurrent with the development of the field of cognitive psychology, the wars of the 20th century were, in large measure, the impetus for worldwide research and interventions to improve cognition after penetrating brain injuries. Most notably, the needs of head-injured veterans injured in the 1973 Yom Kippur war led to the development of an intensive, interdisciplinary rehabilitation program in Israel that focused on patients' cognitive and behavioral disabilities (Boake, 1989). This program influenced the development of similar programs in the United States (Boake, 1989).

COGNITIVE REHABILITATION APPROACHES

There has been considerable evolution in the field of cognitive rehabilitation since the 1970s, with continued debate about the extent to which the aims of intervention should be restitution (or recovery) of lost brain functions or compensation (the development of new ways to circumvent or "get around" the problem) (Institute of Medicine [IOM], 2011). Within these two broad aims, this chapter reviews five approaches to cognitive rehabilitation: skill-task-habit training, strategy training, task-environment modification, cognitive stimulation therapy (CST), and process-specific training. Because there is no agreement regarding the labeling and composition of cognitive rehabilitation approaches, readers will likely find approaches otherwise labeled as they continue to expand their reading on this topic. Best evidence for each approach is described in Evidence Table 24-1. Evidence suggests that the first three approaches (skill-task-habit training, strategy training, and task-environment modification) can result in improved occupational performance and as such are especially important to cognitive rehabilitation as practiced by occupational therapists. The effectiveness of these three approaches is linked to the teaching-learning concepts and methods employed in therapy, some of which are described in Definition 24-1. Readers are also referred to Chapter 13 of this text.

Skill-Task-Habit Training

It is widely accepted that human beings have two systems for the control and execution of behavior: a conscious, controlled, slow, effortful, and deliberative cognitive system used when people are engaged in problem solving, and a rapid, relatively effortless, habitual, or automatic system that supports frequently performed skills, tasks, and habits (Schneider, Dumais, & Shiffrin, 1984). These two systems may be seen as paralleling the implicit and explicit memory systems described in Chapter 13. Solving novel problems constitutes a relatively small part of people's days, and most of human behavior is automatic (Muraven, Tice, & Baumeister, 1998). Automatic habits and routines enable people to perform complex skills and carry out everyday tasks with little or no mental energy, freeing people to think and react to new events in the environment (Jog et al., 1999). For example, most people employ relatively consistent procedures for daily activities such as showering, brushing teeth, crossing the street, and getting to work. These activities are engaged in effortlessly, and mental resources are deployed to review unrelated upcoming events as a function of automaticity (the ability to perform tasks with little or no contribution from the conscious mind). The automatic activities only enter conscious awareness if there is a problem that the automatic system cannot manage. In fact, many people are somewhat disturbed by this ability when they find that they have driven to school or work and have no recollection of the process of doing so because they relied almost entirely on automatic skills.

Helping patients develop new habits and routines that improve specific skills/behaviors (sometimes called specific

Evidence Table 24-1	Best Evidence for Occupational Therapy Practice Regarding Cognitive Intervention					
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Skill-habit training	Cognitive-didactic versus functional-experiential rehabilitation therapy (neurofunctional approach [NFA]) integrated into interdisciplinary acute inpatient programs with another 2–2.5 hours daily of standard occupational and physical therapy	Adult veterans or active-duty military service members (n = 360) with moderate to severe traumatic brain injury (TBI)	1.5–2.5 hours of protocol-specific intervention provided for 20–60 days as needed	Level IA2b Single-blind, multicenter randomized controlled trial	No significant difference overall between the two groups in outcome measures Post hoc exploratory analyses suggested that the younger group (<30 years) and those with less education who participated in the cognitive intervention had better work-related outcomes at 1 year follow up than the NFA group. Also, the older group (>30 years) and those with more education who participated in the NFA intervention had better independent living outcomes at 1-year follow-up than the cognitive group.	Primary outcome measures showed no between group difference for the two experimental treatments at 1-year follow-up	Vanderploeg et al. (2008)
Metacognitive strategy instruction (MSI)	Instruction in use of metastrategy such as time pressure management or goal management training Examples of control intervention included concentration training and motor skills training.	One hundred sixty-five participants in the five synthesized studies; subjects varied in injury severity (mild to severe impairment)	Intensity and duration of intervention varied across the five studies, ranging from a single 3–4-hour intervention to 2–3 hours of weekly treatment for 24 weeks.	Level I Meta-analysis involving 15 studies, 5 of which were randomized controlled trials of step-by-step MSI. The results of the 5 studies were synthesized and are reported here.	Effect sizes (ESs) from immediate activity-participation outcomes were significantly larger for MSI than the control intervention. ESs from immediate impairment outcomes after MSI and the control intervention were similar (both significantly greater than chance).	*Activity and participation outcomes:* $p < 0.05$; mean ES = 0.57	Kennedy et al. (2008)

(continued)

Evidence Table 24-1 | Best Evidence for Occupational Therapy Practice Regarding Cognitive Intervention (*continued*)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-environment modification training	Home-based family caregiver education and physical and social environmental modifications provided by an occupational therapist. Control condition: unspecified usual care	Two hundred two family caregivers (171 at posttest) living with a person with Alzheimer's disease (AD) or similar condition 66.1% (113) of the caregivers in posttest analyses were female.	Five 90-minute sessions every other week over 3 months	Level IA2a No control for therapist time and attention; unblinded evaluation	Yes. At 3-month posttest, persons with AD whose caregiver received intervention had fewer declines in instrumental activities of daily living (IADL) compared to controls. Interaction effects between sex of caregiver and intervention. Female caregivers who received intervention reported reduced upset and improved ability to manage behavior and functional dependency.	$p = 0.030$; $r = 0.21$ Reduced patient upset ($p = 0.049$); managing behaviors ($p = 0.038$); managing functional dependence of loved one ($p = 0.049$) (data not available to calculate effect sizes)	Gitlin et al. (2001)
Cognitive stimulation therapy	Intervention incorporated Reality Orientation and Reminiscence Therapy. It was composed of four phases: the senses (involving multisensory stimulation), remembering the past (reminiscence), recognizing people and objects, and general orientation (recognizing money, knowing way around) (see Spector et al. [2001] for more details).	Two hundred one people with dementia who were recruited from 23 day centers and nursing homes (intervention group 115, control group 86)	Fourteen 45-minute group sessions provided twice weekly for 7 weeks	Level IA2b Single-blind, multicenter randomized controlled trial	Yes. At follow-up, those who received intervention showed statistically significant differences in cognition and quality of life as compared to controls.	Mini-Mental Status Exam ($p = 0.044$; $r = 0.156$), Alzheimer's Disease Assessment Scale–Cognition ($p = 0.014$; $r = 0.19$) Quality of Life–Alzheimer's Disease scales ($p = 0.028$; $r = 0.171$)	Spector et al. (2003)
Process-specific training	Three intervention groups + one no treatment group: Memory training Reasoning training Speed of processing training (SOPT)	2,832 persons aged 65–94 years who were living independently with good functional and cognitive status	Intervention was provided during ten 60–75-minute sessions over a 5–6-week period in small group setting. Eleven months after the initial training, booster training was provided to a subset of subjects in each group (four sessions over 2–3 weeks)	Level IA1b Randomized, controlled, single-blind four-group design (one no-contact group)	Yes. Participants who received process-specific training demonstrated statistically significant improvements in the respective domain of training at 1 and 2 years posttest. No statistically significant changes in everyday functioning for any group at 1 or 2 years posttest; significant improvement for posttest only for SOPT group.	$p < 0.001$ for all groups in their respective domains at 1 or 2 years posttest (effect size data unavailable) $p = 0.02$ for SOPT at posttest on measure of everyday speed of processing (data not available to calculate effect sizes) Booster training had no impact on everyday functioning	Ball et al. (2002)

📖 Definition 24-1

Concepts and Methods Central to Teaching-Learning in Cognitive Rehabilitation

Errorless Learning

When errorless learning is employed during the teaching-learning process, the therapist orchestrates the training and practice process so that the patient consistently performs the desired behavior or strategy correctly. In trial-and-error learning, errors are corrected; in errorless learning, errors are prevented. The therapist provides sufficient support (i.e., cueing, environmental physical and verbal, implicit guidance) to prevent the propagation of errors; cues are faded as learning occurs. See Procedures for Practice 24-1 for more details on graded cueing.

The errorless learning method has been established as a viable intervention across populations (e.g., healthy adults, older adults, and persons with mild and major neurocognitive disorder) (Kessels & de Haan, 2003; Kessels & Olde Hensken, 2009), age groups (Kessels & de Haan, 2003), and types of material to be learned (e.g., word list learning, face-name association, procedural skills) (Kessels & de Haan, 2003; Kessels & Olde Hensken, 2009). Errorless learning is recommended as the "foundation for all information to be presented to patients with severe memory impairment" (Haskins, 2011, p. 48) in part because these individuals may not recognize when they make errors and/or get "stuck" with early response errors (Baddeley & Wilson, 1994). As a practical matter, it may be difficult to completely prevent all errors, but errors can be kept to a minimum. Giles et al.'s (1997) report of washing and dressing training are examples of errorless learning techniques applied to clinical practice, which may be used as an intervention guide. A review of the available literature suggests that the techniques are effective (Ehlhardt et al., 2008). Errorless learning is particularly important in the skill, task, and habit training approach in cognitive rehabilitation.

Spaced Retrieval

Spaced retrieval involves asking the patient to recall information for progressively longer periods of time and is used to maximize the recall of relatively limited amounts of information in people with severe memory disorder (Cermak et al., 1996;

Davis, Massman, & Doody, 2001). The technique has been used primarily with face-name recognition training because this aspect of memory impairment may be particularly disturbing to people and improvement can have positive effects on self-esteem (Davis, Massman, & Doody, 2001).

Here is an example of how spaced retrieval might be used to help a client learn the name of a friend whom he met at a day program. The memory failure is important to the client because he is embarrassed that he cannot recall his friend's name each day when they meet at the center. The therapist might show the client a photograph of the person whose name is to be learned, saying, "This is Mary. What is her name?" After a 15-second delay, the client is again asked the friend's name. If the patient correctly states the friend's name, the therapist builds in a progressively longer delay, 15 seconds and then 30 seconds, 45 seconds, 2 minutes, 5 minutes, and so on. Failure leads to going back to the beginning and starting the process again. The effectiveness of the technique has been demonstrated in people with TBI, stroke, and Alzheimer's disease (Clare et al., 2000; Davis, Massman, & Doody, 2001; Thivierge et al., 2008). These techniques are not used to retrain memory in the abstract sense but rather to facilitate memorization of specific information in which the client is trained. Spaced retrieval may be used during the acquisition phase of strategy training.

Multicontext Approach

Toglia's (2011) Dynamic Interactional Model of Cognition posits that cognition is a product of the dynamic interaction between the person (his or her capacities, self-awareness, and personal context), the activity at hand, the strategies used, and the environment in which the activity occurs. Cognitive dysfunction is viewed as a mismatch among personal (such as cognitive capacities), task, strategy, and environmental variables. This approach emphasizes the establishment of transfer criteria and practice in the context of varied activities and environments (Table 24-1). Client-specific processing strategies are selected or designed and then practiced in a variety of graded tasks and settings. The therapist guides the transfer of learning by asking the client to employ the new skill or strategy first on similar tasks and then in the context of those that are increasingly dissimilar (Toglia, 1991).

---

skill or task-specific training) (Mastos et al., 2007) is a potentially potent means of advancing occupational performance (Giles, 2011; Spikeman & van Zomeren, 2010). Skill-task-habit training addresses the disruption in long-standing habits and routines that may accompany disability, aging, and life changes (Dyck, 2002; Wallenbert & Jonsson, 2005). Previously automatic skills and tasks can require conscious control and become effortful and time

consuming. The loss of effortless predictability in an individual's own performance has a profound impact on that individual's energy level and sense of continuity, competence, and self (Charmaz, 2002).

Therapists use different methods to teach patients to use new cognitive strategies (discussed in the next sections) than those used to teach new skills-tasks-habits. Strategy training, which relies more on the conscious control

Procedures for Practice 24-1

Graded Cues

Graded or vanishing cues are used in cognitive rehabilitation to enable the patient to perform tasks with the least amount of cueing (Dougherty & Radomski, 1993). The following terms (from Sohlberg & Mateer [1989]) are useful when writing goals and documenting progress.

- A **general or nonspecific cue** alerts the patient to monitor performance. It usually takes the form of a statement such as, "You'll need to make sure you remember to do this before our next session." The therapist or family offers a general cue if the patient fails to recognize situational or environmental conditions that might otherwise prompt use of a compensatory strategy or behavior.
- A **specific cue**, which is presented if the patient does not respond to a general cue, reminds the patient he or she must act. It often takes the form of a question such as, "What do you need to do to make sure you remember to do your homework before our next session?"
- An **explicit instruction**, the most directive of the graded cues, is sometimes provided if the patient does not initiate the desired strategy or behavior upon first receiving a general cue and then a specific cue. For example, the patient may be asked to take out the planner and record the assignment to ensure follow-through before the next session.

system, is typically applied to persons with mild to moderate impairment and relatively intact self-awareness. Skill-task-habit training, which relies on procedural and errorless learning, is often used with persons with severe impairment or impaired self-awareness (Giles, 2011) and/or those who have problems with activities of daily living (ADL) or instrumental activities of daily living (IADL) (Giles, 2010). However, skill-task-habit training is not reserved for those with disabilities. This cognitive rehabilitation approach may benefit anyone interested in making a complex skill automatic (e.g., a golf swing) or adding a new health behavior (e.g., daily exercise program) (see Duhigg [2012]).

Clinical Example(s) of This Approach

Numerous case examples and single-subject research studies in the rehabilitation literature describe the use of applied behavioral analysis to establish or reestablish self-care and/or home-management routines and habit sequences for persons with cognitive impairment (Giles & Clark-Wilson, 1988; Giles et al., 1997; Giles & Shore, 1989; Schwartz, 1995; Zanetti et al., 2001). The following principles of applied behavioral analysis frame occupational therapy intervention to establish routines and habit sequences. However, therapists should be sensitive to the

fact that some patients may not be ready to establish new ways of doing things. Wallenbert and Jonsson (2005) reported that some persons with stroke were reluctant to create new habits and routines, believing that doing so could interfere with their physical recovery. Therefore, the development of new habits and routines are presented as a key method for advancing recovery from illness or injury.

- Guided by the client (and caregiver where appropriate), the therapist selects a key behavioral sequence that becomes the target of intervention (Giles, 1998; Parish & Oddy, 2007). Giles emphasized the importance of working with the client to select behaviors and prospective routines that clients regard as having clinical and personal significance.
- The therapist analyzes the physical and social context in which the routine or sequence is expected to occur to identify environmentally available cues or determine where to create new cues (Schwartz, 1995). Because routines and habit sequences are thought to be context specific, training is most effective if it occurs in the environment in which the routines will ultimately be performed (Giles, 1998).
- A task analysis is performed on the target behavioral routine or sequence (Giles, 1998; Parish & Oddy, 2007). Task analysis involves examining each step of the task as well as the setting, stimulus events, and consequences (Gelfand & Hartmann, 1984). (See further discussion of activity analysis in Chapter 12 of this book.)
- The therapist and client decide on an optimal sequence of steps and use chaining, prompting, and reinforcement each time the sequence is performed (Giles et al., 1997). Giles et al. (1997) suggested that "[routine] tasks can be thought of as complex-stimulus-response chains in which the completion of each activity acts as the stimulus for the next step in the chain" (p. 257). They also recommended the use of the whole-task method, in which each step of the chain is trained on each presentation. The therapist often creates a checklist that outlines each component of the task so that the desired sequence of steps remains invariant (Davis & Radomski, 1989) (Fig. 24-1).

For some clients, prompts and reinforcers are established. The checklist itself may be both a prompt (if placed in an obtrusive location) and a reinforcer as the patient checks each completed step. Technology may also be employed. Schwartz (1995) reported use of a daily tape-recorded message activated by an automatic timer that prompted initiation of a self-care routine. In addition, NeuroPage™, a time- and task-specific vibrating paging system, was used to facilitate establishing routines related to taking medications and using checklists (Wilson et al., 2001; Wilson et al., 2003). Family members may also be enlisted to provide prompts and reinforcement, typically social praise.

The therapist facilitates consistent repetition of the behavioral routine or sequence beyond mastery to

Table 24-1 **Components of the Multicontext Treatment Approach**

Component	Definition	Example
Consideration of personal context	Gaining understanding of the client's premorbid personality characteristics, beliefs, valued occupations, and previous lifestyle	Interviewing the client about his or her premorbid everyday routines and exploring how those routines have changed after injury or illness and using this information to inform occupational therapy assessment and intervention
Enhancing self-monitoring and self-awareness	Methods designed to enhance the client's understanding of his or her strengths and limitations that are incorporated into every treatment session	• Asking the client to anticipate and identify specific challenges or obstacles that might occur in performance of a therapy task • Instructing the client to watch the therapist perform a task during which client-relevant errors are demonstrated (such as distractibility). Asking the client to identify problems and recommend strategies
Strategy training	Small units of behavior that reflect internal or external cognitive techniques that contribute to the effectiveness of performance	• Mental repetition, visual imagery (i.e., internal processing strategies) • Memory notebooks, alarm cueing devices, use of checklists (i.e., external processing strategies)
Activity analysis	Identifying, manipulating, and/or stabilizing salient activity parameters (e.g., physical features, number of items, number of steps or choices involved in the task)	As part of her therapy, a homemaker who has difficulty attending to visual details locates the soup spoons in a drawer of unsorted spoons, forks, and knives. As she progresses, she will locate a set of soup spoons in a drawer of unsorted spoons of different sizes (teaspoons, soup spoons, serving spoons). Note how differentiating between spoons of different sizes requires greater visual attention than differentiating between spoons, forks, and knives.
Establishment of criteria for transfer	Identify series of tasks that decrease in degrees of physical and conceptual similarity to the original task	Task: Donning a pullover T-shirt in the therapy area
	Near transfer: only one or two surface characteristics changed	Donning a pullover sweater (color and texture different from T-shirt)
	Intermediate transfer: three to six surface characteristics change; tasks share some physical similarities	Donning a button-down cotton shirt in the client's room (type of clothing, color and texture, fine motor requirements, and environment changed)
	Far transfer: tasks are conceptually similar; surface characteristics are different or only one surface characteristic is similar	Donning outerwear (coat, jacket), pajamas, undershirt or camisole (different types of upper body clothing)
	Very far transfer: generalization, spontaneous application of what is learned to everyday life	Donning pants (strategy of dressing affected side first remains the same for lower body dressing)
Practice in multiple environments	Strategies are used in a variety of situations (e.g., tasks and locations) to demonstrate their applicability and use to the client	The strategy of left-to-right scanning is practiced on letter cancellation tasks and then used to locate items in a medicine cabinet or to count books on a shelf.

From Toglia, J. P. (1991). Generalization of treatment: A multi-contextual approach to cognitive perceptual impairment in the brain-injured adult. *American Journal of Occupational Therapy, 45,* 505–516; Toglia, J. P. (2011). promote overlearning (Parish & Oddy, 2007). Patients with neurological impairment typically need to perform as many practice trials to truly consolidate learning (and maximize resistance to skill loss) as it took to be able to reliably perform the skill in the first place (Driskell, Willis, & Copper, 1992). As the patient frequently and consistently performs the behavioral sequence and learning occurs, steps begin to "chunk" together so that gradually prompts can be combined and the program shortened (Giles, 2011). The therapist tracks ongoing compliance with the target behavioral sequence; monitors the patient's perceptions of ease, accuracy, and speed (evidence of increasing automaticity); and, with the patient, determines when applied behavioral analysis methods should be employed to make another important task routine.

Morning planning checklist

Directions: Check-off each step after it is completed.

	M	T	W	Th	F	Sa	Su
1) After breakfast, open planner to yesterday's page.							
2) Check off all of the tasks you completed yesterday.							
3) Draw an arrow in front of undone or incomplete tasks							
4) Re-write these tasks on today's page.							
5) Move the bookmark to today's planner page.							
6) Review your schedule.							
7) Ask your wife if there are any tasks or appointments that you should write down for today.							
8) Write down at least 3 tasks you intend to complete today.							

Wind-down routine

Directions: Check-off each step after it is completed.

	M	T	W	Th	F	Sa	Su
1) When your MotivAider vibrates at 9:00 p.m, discontinue your current activity.							
2) Make notes where you left off on your project.							
3) Put on your pajamas.							
4) Brush your teeth.							
5) Wash your face.							
6) Gather your magazines and go to your recliner.							
7) Set the MotivAider for 30 minutes and peruse your reading material.							
8) When cued by the MotivAider, retire to bed.							

Figure 24-1 Checklists like these are used to help patients reestablish routines and habit sequences.

Presumed Mechanisms

Although the exact mechanisms are not known, automaticity is believed to occur as the brain becomes increasingly efficient in processing specific stimulus encoding, storage, and retrieval sequences (Logan, 1988a, 1988b; Logan, Taylor, & Etherton, 1999). Practice progressively strengthens automaticity by virtue of additional representations in memory; thus, performance may be more automatic after 100 repetitions than after 50. Practice increases the availability of target responses, such that conscious decision making is replaced by the implementation of automatic action sequences (Kramer, Strayer, & Buckley, 1990). When a skill becomes automatic, it becomes the easiest behavior to initiate from an array of possible behaviors, reduces interference error, and is experienced by the individual as effortless. Automatization, then, is a relative phenomenon in that, although it may occur after only a few trials, it may never be complete (Logan, 1988b).

Expectations for Transfer-Generalization

Implicit memory refers to an unconscious change in behavior that results from previous experience (Eldridge, Masterman, & Knowlton, 2002) and is closely tied to the original learning situation and hence is less flexibly applied to novel contexts (Reber, Knowlton, & Squire, 1996). Habit learning is a form of implicit learning (Squire, Knowlton, & Musen, 1993) and so generalization of skills to new stimulus conditions may be problematic.

In order for generalization to occur, the stimulus conditions in which the skills are exercised have to be varied. Random practice schedules, in which many different tasks are interspersed in a practice schedule, may also facilitate transfer of skills (Giuffrida et al., 2009). (See Chapter 13 for further discussion.) For example, a client had a severe traumatic brain injury (TBI) and is working to independently and safely cross the street. In occupational therapy, she has learned a set of skills composed of finding the crosswalk, pressing the button on the stoplight, and stepping off the curb only after "walk" is displayed on the light and traffic has stopped. She receives supervision and cueing as she practices crossing a wide range of different streets. Ultimately after much repetition, she automatically classifies the stimulus characteristics of a wide range of streets that she routinely encounters and her street-crossing skill is elicited. Tasks undertaken frequently, on a daily basis or more, are likely to be self-maintaining once competency has been achieved (e.g., washing and dressing). Tasks that are engaged in less frequently will be learned more slowly and will be less stable and are more likely to be extinguished.

Alignment with Occupational Therapy Theory and Objectives

Skill-task-habit training reflects a recommended, occupation-oriented approach to cognitive rehabilitation. However, cognitive interventions have historically been preferred to functional interventions for people with neurological impairments based on the erroneous assumption that "fixing" cognition will automatically lead to improved function (Giles, 2010; Vanderploeg et al., 2008). According to this logic, treatment of occupational performance deficits would be unnecessary if cognitive functioning could be adequately remediated: cognitive rehabilitation would "automatically" result in improved functional behaviors (Giles, 2010). For this reason, the direct approach to occupational performance problems offered by skill-task-habit training has unfortunately often been undervalued by occupational therapists despite its alignment with occupational therapy theory and goals. Therapist concerns regarding having adequate patient contact time for skill-task-habit training and/or generalization may be addressed by using family members and technology as "therapy extenders."

Strategy Training

In the context of cognitive rehabilitation, compensatory cognitive strategies refer to an array of tactics that are intentionally employed in order to optimize performance despite a cognitive limitation. Cognitive strategies take many forms: using a global metacognitive strategy or rubric to organize a project to manage executive dysfunction, using a device (e.g., diary or smartphone) to keep track of information that might be otherwise forgotten, employing a task-specific strategy such as setting alarms on a cell phone as a reminder to return from morning and afternoon breaks at work, and selecting a workspace with minimal noise and visual distractions to best manage problems with attention. Although expectations for strategy transfer and generalization will vary for each patient's situation, the effectiveness of compensatory strategy training often depends on the patient's ability to transfer what is learned in the clinical setting to everyday activities. Currently, there is considerable interest in training clients in metacognitive strategies so that they can develop their own methods to overcome ADL or IADL problems rather than retrain these skills directly. Strategy training is not aimed at relearning specific tasks, but at teaching patients new ways to handle problems resulting from cognitive impairment.

Cognitive strategy training is organized around three training phases: acquisition, application, and adaptation (Haskins, 2011; Sohlberg & Mateer, 2001). Because clients must have some degree of insight into the skill deficit for which they need to compensate, intervention also typically addresses self-awareness (see Procedures for Practice 24-2).

- Acquisition—Through drill and practice exercises, clients learn the mechanics of using the compensatory tool or strategy. For example, with coaching and written

Procedures for Practice 24-2

Helping Patients Improve Self-Awareness

Occupational therapists use a variety of techniques to help patients become more aware of their cognitive strengths and weaknesses:

- Appreciate the differences between organically based unawareness and adjustment-based denial. Anticipate that sometimes, as patients become more aware of impairments, they may feel emotional distress, including depression and anxiety (Fleming & Strong, 1995).
- Recognize levels of awareness and focus intervention on helping the patient move up the awareness hierarchy (see Chapter 6). For example, therapists try to help patients who are unaware of their cognitive impairments first to develop intellectual awareness of the problem and then to progress toward emergent or anticipatory awareness (Crosson et al., 1989).
- Create opportunities for the patient to monitor and judge his or her own performance, analyze the results, and determine what to continue or do differently next time. Dougherty and Radomski (1993) recommended a graded approach to performance analysis that consisted of three levels: (1) using an answer key to self-correct; (2) answering multiple choice questions about various aspects of performance after performing the task; and (3) making

predictions about performance ahead of time, comparing actual performance to predictions, and determining how to modify performance in the future.
- Introduce therapeutic structured failure when appropriate. That is, do not interfere with the natural consequences of the cognitive impairment during selected supervised activities. For example, if the patient fails to initiate a cognitive compensatory strategy in response to general or specific cues, do not provide further instruction, but rather create an opportunity for the patient to observe what happens when the strategy is not used.
- Collaborate with family members to provide feedback. In some cases, family members should focus on maintaining harmony in the household and appropriately prefer that the therapist assume the responsibility of providing any negative feedback to the patient. In other cases, family members or coworkers are so afraid of offending or discouraging the patient that they insulate the patient from any and all challenges or avoid mentioning errors and, as a result, deprive him or her of information that might improve self-awareness.
- Respect the patient's readiness to participate in therapy. Avoid badgering the patient into improved awareness of deficits by maintaining a therapeutic partnership so that he or she will want to return for services in the future.

---

instructions from the therapist, clients rehearse setting their alarm watches or practice filing and finding information in function-specific sections of their day planners.
- Application—Clients use the compensatory strategy during clinic-based simulated work tasks. These tasks are designed to require use of the targeted strategy and may include clerical or clinic maintenance projects or crafts. With guidance from the therapist, clients also directly apply the compensatory strategy to real-life problems at home or work.
- Adaptation—Once the client has experience with the strategy in simulations and real-life tasks, the strategy may be further adapted to the client's personal preferences and the demands of additional areas of application in daily life.

As indicated earlier, patients may improve occupational performance by learning to use attention-management strategies, executive functioning strategies, memory strategies, and metacognitive strategies. (See Haskins [2011] for a detailed discussion of all of these.) An exhaustive review of all possible methods to circumvent cognitive impairments or inefficiencies is beyond the scope of this chapter. Instead, we provide an overview of two categories of cognitive strategies: memory-related strategies and metacognitive strategies.

Presumed Mechanism

Cognitive strategy training is based on the premise that given cognitive processes are no longer able to support independent functioning and that the original cognitive processes cannot be restored. Learning is hypothesized to be top-down (i.e., learning based on explicit knowledge structures that may or may not become implicit with practice) (Geusgens et al., 2007).

Memory Strategies

Occupational therapists consider the client's degree of memory impairment, his or her specific needs and preferences, past memory strategy or technology use, recovery status, expectations, and goals in planning intervention for memory-related problems. The intervention approach will be informed, in part, by whether the patient is anticipated to be a passive user or active initiator of the memory compensation strategy (Radomski et al., 2004). *Passive memory strategy users* are typically individuals with severe memory impairment whose carers set up and maintain the external memory strategy/system. In this situation, for example, the goal of therapy may be to teach the patient's wife to fill out a daily timetable or task list and the patient to perform listed tasks when prompted by an alarm

(also set by the patient's wife). (The next section describes this approach in greater detail.) *Active initiators* are aware of their problems with forgetting and would be expected to learn to recognize situations in which to use the memory strategy and then correctly perform the strategy—possibly associated with a variety of tasks and contexts.

In this section, we discuss the use of internal and external memory strategies to advance occupational performance. *Note that there is general agreement in the cognitive rehabilitation literature that direct attempts to improve memory through drill and practice of remembering are ineffective (Robertson, 1999).*

Internal Memory Strategies. Internal strategies are methods of mentally manipulating information so as to increase its likelihood of later recall. Association techniques and organizational techniques are two categories of internal memory strategies (Haskins, 2011) (see Table 24-2 for examples). These strategies received a great deal of attention in the late 1970s and early 1980s. Although some people with left-hemisphere stroke showed greater retention of material by using visual association techniques when tested in a laboratory situation (e.g., visualizing items in conjunction with absurd images [Gasparrini & Satz, 1979]), most studies failed to show transfer of the techniques to novel or everyday situations (Crovitz, 1979). Organizational techniques may involve using first letter mnemonics to form a single word or pseudo-word, which simplifies the storage and retrieval of the to-be-remembered information (Haskins, 2011). For example, the PQRST method (Preview, Question, Read, State, Test) can be used in academic contexts for recall of more complex verbal and written information (Haskins, 2011); it has been applied successfully in TBI and cerebrovascular accident (CVA) (Wilson & Moffat, 1984).

Although a recent study demonstrated positive outcomes of teaching internal memory strategies to patients with TBI who were already using external memory strategies (O'Neil-Pirozzi et al., 2010), internal memory strategies are considered effortful to learn and employ and may be best used as a complement to external strategies for memory tasks that cannot be practically managed by jotting or inputting a note (such as remembering name-face associations).

External Memory Strategies. People who are not neurologically impaired use external strategies for remembering more often than they use internal strategies (Harris, 1980). Examples of commonly used external strategies include having someone else provide a reminder to do a task, leaving objects in places so that they will be encountered when needed (e.g., placing things to take with you the next day by the front door), setting an alarm on a cell phone, smartphone, or personal digital assistant (PDA) in order to remember an appointment. Low-tech memory aids (such as notes or calendars) are the most widely used among persons with TBI (Evans et al., 2003), but this may change with the ease of use of smartphones, availability of relevant apps, and benefits of "availability at the point of need" (Gillespie, Best, & O'Neill, 2012, p. 14). Although many different types of external aids are useful to people with memory impairment, here we briefly mention checklists, timetables, memory books, day planners/organizers, and assistive technologies for cognition (ATC). Note that checklists, timetables, and memory books are often most appropriate for passive strategy users, whereas day planners and ATC are typically used by active initiators.

Checklists. A client who is memory impaired may not remember performing a task or the sequence for doing so, resulting in either a repeat of the activity or nonengagement

Table 24-2 **Examples of Internal Compensatory Strategies**

Technique	Description
Rehearsal	Patient repeats the information to be remembered out loud or to self.
Visual imagery	Patient consolidates information to be remembered by making a mental picture that includes the information (e.g., to remember the name *Barbara*, the patient pictures a barber holding the letter A).
Semantic elaboration	Patient consolidates information by making up a simple story (e.g., patient who has to remember the words *lawyer*, *game*, and *hat* develops a sentence such as "The lawyer wore a hat to the game").
First-letter mnemonics	Parenté's NAME mnemonic adds rules to observing features and drawing associations when remembering names: **N**otice the person with whom you speak. **A**sk the person to repeat his or her name. **M**ention the name in conversation. **E**xaggerate some special feature.

in the activity in the mistaken belief that it has already been performed. Being taught to mark off each instruction or activity on a checklist as it is performed may assist some clients. Some people can be taught to follow checklists as a "meta" procedure; whatever they need to learn can be designed as a checklist.

Timetables. A timetable is a simplified version of a personal calendar (diary). Most institutions have a routine that can be presented in the form of a timetable. Caregivers for people with TBI, stroke, or major neurocognitive disorder can be taught to use a timetable with regular activities throughout the day. The timetable may include wake-up time, an appropriate time to wash and dress, lunch, dinner, laundry time, and regularly scheduled individual and group therapy times. For people with major neurocognitive disorder (formerly referred to as dementia; see Definition 24-2), a timetable may provide a good means of managing repetitive questioning (Bourgeois et al., 1997). For people recovering from TBI, a timetable can be a method for gradually training self-management skills.

Memory Books. A memory book may be used at many stages of recovery from acquired brain injury (ABI) or at

certain stages of progressive neurocognitive disorders. The book—usually a loose-leaf notebook with function-specific sections—is typically composed of orientation information (e.g., a page with information about where the patient is and why) and daily log sheets, on which the patient, family, or staff write down what occurs on an hour-by-hour basis. Memory books are advantageous when new learning is very difficult. Early in recovery, the memory book is most useful in encouraging staff to interact with the client around orienting information. The client should be cued repeatedly to look up information in the memory book. As clients recover, it becomes possible for them to review the book spontaneously and make entries about ongoing events and/or progress to using a day planner/organizer.

Day Planners/Organizers and Assistive Technologies for Cognition. Individuals with mild cognitive inefficiencies (such as those with concussion/mild TBI) or neurodegenerative conditions such as multiple sclerosis (MS) and those who are recovering from moderate to severe TBI are often taught to use a day planner or ATC as a "memory prosthesis" to improve their functioning in daily life (Gentry, 2008; Gentry et al., 2008; Schmitter-Edgecombe et al., 1995). To do this successfully, clients (active initiators) are taught to recognize the type of information that is pertinent for them in real time, initiate entry of the material into the planner or device (and perform procedures for doing so), take or input notes accurately, and establish daily procedures and/or employ alarm prompts for referring to needed information in a timely fashion.

Some clients are able to manage memory problems by using day-at-a-glance organizers or day planners, which are commercially available in a variety of formats and sizes (see Fig. 24-2). As with memory books, many day planners have function-specific sections that may include a daily

Definition 24-2

Mild Neurocognitive Disorder and Major Neurocognitive Disorder

The fifth edition of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) proposes to replace the terms mild cognitive disorder and dementia (the latter is now considered pejorative or stigmatizing) with mild neurocognitive disorder and major neurocognitive disorder, respectively (American Psychiatric Association, 2012). Readers are referred to the DSM-5 manual (published in 2013) for a full discussion of symptomatology and diagnostic criteria; general descriptions of these terms are provided below.

Mild neurocognitive disorder refers to a modest cognitive decline as evidenced by testing and/or report of the patient or an informant. The individual remains independent in instrumental activities of daily living but greater effort, compensatory strategies, and/or accommodations are required.

Major neurocognitive disorder refers to a substantial cognitive decline as evidenced by testing and/or by report of patient or informant. Cognitive deficits interfere with independence in instrumental activities of daily living, and the individual requires assistance with complex tasks such as paying bills or managing medication.

Note that both types of neurocognitive disorders must be distinguished from delirium and cognitive decline from other conditions (e.g., major depression).
Figure 24-2 Use of function-specific portions of the planner page helps the patient organize notes about the day.

schedule/to-do lists; checklists pertaining to frequently performed procedures, notes about projects in-process, reference information about medical providers or family members, and contact information.

Clients may need or prefer to use some form of ATC as either a replacement for or complement to a planner/organizer. Evans et al. (2003) interviewed 101 people who reported memory problems from brain injury and their carers. External aids such as calendars and wall charts (72%) and notebooks (64%) were the most commonly used memory aids. Electronic organizers, pagers, or mobile phones were used as memory aids by only 16% of people, although this may have changed since the study was published. In another consumer survey of 80 persons with moderate to severe TBI (a median of 3.7 years postinjury), less than a third of those interviewed used PDAs, and of these, 75% of interviewees showed interest in their use (Hart, Buchhofer, & Vaccaro, 2004). Electronic memory aids and paging systems offer advantages, particularly in regard to prospective memory (Wilson et al., 2001; Wilson et al., 1997). Some examples of ATC are described below.

- Specialized pagers. NeuroPage™ uses radio paging or SMS (text messaging) technology to send reminders of things to do to people with significant memory impairment. It is operated out of the Oliver Zangwill Centre for Neuropsychological Rehabilitation (United Kingdom). The client wears an ordinary pager or mobile phone. He or she provides Neuropage™ operators with a list of required date/time-specific prompts, and then the system automatically sends out reminders for things like task initiation, taking medications, and sending birthday cards. Neuropage™ has been studied extensively and shown to improve day-to-day functioning in the postacute period after TBI (Wilson et al., 2005) and in other conditions (Wilson et al., 2001).

  Similarly, preprogrammed electronic memory aids have also been demonstrated to help outpatients with neurocognitive disorder remember to do time-specific tasks, significantly more so than use of written lists or trying to recall without any memory aid (Oriani et al., 2003).
- PDAs. Commercially-available PDAs provide time-specific alarms and reminders to help people with memory impairment complete intended tasks. Gentry reported statistically significant improvements in task performance for those with TBI and those with MS who were trained to use PDAs (Gentry, 2008; Gentry et al., 2008).
- Smartphones/mobile apps and other devices. The burgeoning of mobile technologies has expanded the array of consumer products that may help people compensate for cognitive problems. However, there is little research at present to demonstrate efficacy or effectiveness for individuals with cognitive impairment. Furthermore, smartphones tend to have smaller buttons and screens as compared with PDAs, possibly

making them more difficult to use after TBI (de Joode et al., 2010). Voice organizers, which can be set up to provide time-specific audio prompts and instructions, and smart pens, which audio record information as the user takes notes, are examples of other options that may solve client memory-related problems but for which there is no evidence at present.

Expectations for Training and Transfer-Generalization

Teaching clients to be active initiators of memory strategies should follow the three-stage progression described earlier (acquisition, application, and adaptation stages), and this may be time consuming, depending on client factors and outcome goals. For example, Schmitter-Edgecombe et al. (1995) described an 8-week protocol of 16 sessions, and Donaghy and Williams (1998) used a 9-week protocol of 27 sessions for patients with TBI to learn to use memory aids of this nature. The I-MEMS protocol (internal memory strategy instruction for persons with TBI) involved 12 group sessions of 90 minutes over 6 weeks (O'Neil-Pirozzi et al., 2010). Gentry's instructional protocol for PDA use by persons with TBI and MS required just two home-based sessions to learn to input appointments and to-dos (Gentry, 2008; Gentry et al., 2008).

The generalization of the use of internal visualization of verbal elaboration strategies with persons with significant memory impairments who are in the postacute phase of recovery has either not been evaluated or is disappointing (Harris, 1980). There is a limited literature that suggests that clients who learn to use external memory strategies are able to independently apply those same strategies to new situations (Kim et al., 2000). Additionally, clients do appear to use the newly learned material (e.g., face-name associations) in their daily lives (i.e., they generalize to the real world) (Clare et al., 2000). External strategies such as using a calendar have not been found to be effective in accelerating the return of orientation in people in the acute stage of recovery from brain injury (i.e., those in PTA) (Watanabe et al., 1998).

Alignment with Occupational Therapy Theory and Objectives

Intervention to help patients use memory strategies to improve everyday functioning is considered consistent with occupational therapy theory and objectives. Evidence suggests that persons with neurologically based cognitive impairment often do continue to use memory strategies in their daily life after intervention. Kim et al. (2000) described the experience of 12 participants exposed to the use of PDAs: 9 of the 12 found the PDA useful and 7 of these participants continued use of the PDA when followed up between 2 months and 4 years after initial exposure to the device. Based on their evidence review, the

Institute of Medicine (IOM) (2011) concluded that there are long-term benefits of teaching persons with mild TBI to use internal strategies and that individuals with moderate to severe brain injury often use external memory strategies months after treatment ends.

Metacognitive Strategies

Metacognition refers to thinking about thinking or the higher order self-awareness and monitoring of a person's own cognitive processes. It is possible to think of a hierarchy of cognitive processes with metacognition and self-awareness at the top, executive functions such as planning, organizations skills, and reasoning in an intermediate position, and basic cognitive processes (e.g., memory) at the lowest level (Stuss, 1991). Metacognitive strategy training involves teaching clients how to identify problems and develop their own methods to overcome these problems and to implement and evaluate the solutions (Polatajko & Mandich, 2004; Polatajko, Mandich, & McEwen, 2011; Toglia et al., 2010). One such approach in the occupational therapy literature is Cognitive Orientation to Daily Occupations.

Cognitive Orientation to Daily Occupations. The Cognitive Orientation to Daily Occupational Performance (CO-OP) approach teaches a global strategy (goal, plan, do, check), derived from the work of Meichenbaum (1977). This global strategy is used in a process of "guided discovery" so that clients can develop their own domain-specific strategies to solve personally relevant specific performance problems. Most of the research into the application of the CO-OP approach has centered on its use with children with developmental coordination disorder (Polatajko, Mandich, & McEwen, 2011). More recently, CO-OP has been applied to adults with TBI and stroke, and some positive results of single cases and small series have been reported (Dawson et al., 2009; McEwen et al., 2009).

The main goal of CO-OP is skill acquisition in functional everyday tasks. However, the process of therapist-guided skill acquisition is also intended to help the client learn a general approach to problem solving that he or she can apply to new performance problems and use to independently develop new domain-specific strategies (Polatajko, Mandich, & McEwen, 2011). Because a goal of CO-OP is for clients to be able to apply the global strategy beyond treatment sessions and to new issues (i.e., generalization), the process itself is a specific focus of the approach (Polatajko, Mandich, & McEwen, 2011), as illustrated next.

1. The client sets the goals that he or she wishes to work on, and then the therapist teaches the global strategy of Goal, Plan, Do, Check.
2. The client is guided in dynamic performance analysis in which he or she identifies the performance problems that interfere with goal achievement.

3. The client is further guided to identify potential strategies that may solve his or her problems. The client then implements the strategy to solve the real world functional problem and checks to see whether it worked. The implementation of the domain-specific strategy may or may not be done in the presence of the therapist, depending on the treatment context, stage of training, and other factors.

The process of guided discovery in which the client learns how to solve performance problems is central to the approach. Therefore, how the therapist interacts with the client during CO-OP is important, which the authors of the approach have distilled into key features: "One thing at a time"; "Ask, don't tell"; "Coach, don't adjust"; and "Make it obvious" (Polatajko, Mandich, & McEwen, 2011).

Expectations for Transfer-Generalization

The goal of metacognitive strategy training is for the client to independently apply newly learned strategies in novel circumstances. As such, transfer and generalization are central to this intervention approach. Metacognitive strategy training in adults with neurological impairment is a relatively new area of study for occupational therapists, and data are limited but encouraging (McEwen et al., 2010). Geusgens et al. (2007) conducted a systematic review of transfer in cognitive strategy training pertaining to information processing, problem solving/executive functioning, memory/attention, language, neglect, apraxia, and daily activities. Transfer outcomes were classified into three groups: nontrained items, standardized daily tasks, and daily life. Most studies reported at least one type of transfer; however, the methodological quality of the studies was low, and the authors concluded that further study is indicated (Geusgens et al., 2007).

Alignment with Occupational Therapy Theory and Objectives

Metacognitive strategy approaches are almost by necessity client centered and, as described here, focused on real-life problems. Practiced in this way, metacognitive strategy training is well aligned with the overarching concerns of occupational therapists. In occupational therapy practice, strategies are not taught in the abstract and are always taught within the context of an occupational performance goal. Global strategy training, rather than teaching a solution to a specific problem, attempts to equip the client to solve novel problems in the future. There are reasons to believe that metacognitive strategy training may be limited to clients with mild to moderate levels of impairment (Giles, 2010), but currently the evidence is encouraging, and further research is warranted.

Task and/or Environmental Modification Training

Patients may demonstrate improved occupational performance when caregivers are trained to make task or

environmental changes that lower the cognitive demands placed on the patient (see examples in Procedures for Practice 24-3). Caregivers are trained to use new ways of interacting with the patient; the patient is not expected to learn or change, but the **press** of the task, social dynamics, and/or environment are lessened. (See Fig. 24-3, A & B for an example of how environmental modifications may lower press.) This approach is particularly appropriate for persons with major neurocognitive disorder or severe

neurocognitive deficits from other causes (e.g., TBI, encephalitis, and anoxia).

Clinical Example of this Approach

The work of Gitlin and colleagues with individuals with dementia and their caregivers exemplify and evidence the impact of this type of approach. In an evaluation of a home-based environmental intervention, 171 caregivers

---

Procedures for Practice 24-3

Strategies to Decrease Cognitive Demands and Increase Occupational Performance

Mr. J. is a 74-year-old man with major neurocognitive disorder caused by Alzheimer's disease (AD) who lives in a suburban home with his wife of 50 years. He used to be impeccably groomed and dressed but now resists any articles of clothing perceived as unfamiliar. He was a master gardener and delighted in preparing food with ingredients from his garden. He no longer has the cognitive or physical capacities for managing the garden or preparing food independently. Mrs. J. worked with an occupational therapist to identify strategies that would enable Mr. J. to participate in activities in ways that were enjoyable to them both. Principles of lowering cognitive demand and examples are described below.

Modify the Environment

- Reduce visual and auditory clutter. *Mrs. J. set up Mr. J.'s workstation at the kitchen table before they started their task. She removed the lunch dishes, mail, and newspaper and set out only the items needed for the task at hand: first just the towel for drying the basil, then a bowl for the basil leaves and a small container for trash*.
- Provide assistive devices to optimize safety. *Mrs. J. had grab bars installed near the toilet and bath tub. Her son also installed a motion detector near the front door so that Mrs. J. could prevent Mr. J. from wandering outdoors. She had a StoveGuard installed with a 30-minute delay. The stove then automatically turns off after 30 minutes, decreasing the risk that Mr. J. will turn on and then forget to turn off a burner*.
- Use visuals to provide orientation and instructions. *Mrs. J. modified the telephone so there are pictures of family members beside their speed dial buttons. She also posted a 1-day calendar near Mr. J.'s favorite chair*.
- Organize so that the right items are easily located. *Mrs. J.'s daughter helped her remove everything from the countertop in the bathroom, leaving only a plastic basket containing Mr. J.'s toothbrush, toothpaste, and comb*.

Simplify the Task

- Break down a task into small steps. Decide what steps the client can do, what steps the clinician or caregiver will do,

and what steps might be eliminated. *Mr. and Mrs. J. prepared pesto together, using basil from their garden. Some of the steps included picking the basil from the garden; sorting, washing, and drying the basil leaves; toasting pine nuts; chopping garlic; and combining in a food processor*.
- Select tasks (or steps) for the patient that are familiar and repetitive, if possible. *With supervision, Mr. J. picked basil from the garden. Mrs. J. washed the basil leaves in the sink, and while seated at the table, Mr. J. dried the basil leaves with a towel and separated the leaves from the stems*.
- Simplify objects involved in the task. *Mrs. J. purchased duplicates of Mr. J.'s favorite sweaters and underwear so that he did not notice that he was putting on different (clean) clothes each day. She also set his clothing out each day on the bed in the order he was to put it on*.

Routinize the Day

- Establish a consistent daily schedule of activities. *Mrs. J. created a daily schedule, which she set by his calendar and newspaper. The schedule includes frequently performed activities such as meals/meal times, their afternoon walk, favorite TV show, and bedtime activities*.

Simplify Communication

- Simplify verbal instructions (one-step instructions using as few words as possible); avoid lengthy explanations. *Mrs. J. used simple instructions like "pick the basil now" and "dry off the basil now." Mrs. J. avoided making conversation when Mr. J. was involved in picking the basil because she understood that too much stimulation made the task more difficult*.
- Celebrate participation by relaxing rules and requirements. *Mrs. J. noticed that Mr. J. missed a few basil stems here and there, but she did not correct him*.

Figure 24-3 A, B. Simple changes in the kitchen lower the cognitive demands, making it easier for a person with cognitive limitations to find relevant information.

were randomized to usual care or a series of five 90-minute home visits with an occupational therapist (Gitlin et al., 2001). Caregivers received education about the impact of the environment on dementia-related behaviors, instruction related to functional concerns, and guidance to implement environmental and task simplification strategies. (See further information in Evidence Table 24-1.) More recently, Gitlin et al. (2008; 2009) developed and evaluated a tailored activity program (TAP) for those with major neurocognitive disorder and their families. TAP is an eight-session home-based occupational therapy intervention that occurred over 4 months. It involved the following: neuropsychological and functional testing; identification of the patient's preserved capabilities, habits, and interests; therapist selection and customization of activities to match patient capabilities based on testing; and training family members in how to use these activities with their loved ones. A total of 170 activities were prescribed during the study (e.g., cutting out coupons, wiping silverware, playing a matching card game, doing chair aerobics, and watching birds at a bird feeder); 81.5% were used by families (Gitlin et al., 2009). Patient-caregivers receiving TAP reported significantly fewer problem behaviors and greater activity engagement than did the

caregivers of control patients at 4 months posttest (Gitlin et al., 2008).

Presumed Mechanism

This approach is informed by the competence-environmental press framework (Lawton & Nahemow, 1973). This framework suggests that the patient's negative behaviors and/or excess disability is caused by the misalignment between the patient's declining cognitive ability and the unchanged demands of the physical and social environment. The patient's functional performance and behavioral control may be optimized as task and environmental demands are matched to the patient's capacities (Gitlin et al., 2001).

Expectations for Transfer-Generalization

Research has not been conducted on the extent to which caregivers who receive training to match cognitive demands to patients' capabilities are able to transfer or generalize this training to new problems or situations. However, it appears that the effects of this training are maintained for at least 6–12 months (Gitlin et al., 2005).

Alignment with Occupational Therapy Theory and Objectives

This approach, which emphasizes improved occupational performance, is well-aligned with occupational therapy theory and practice. In addition to education of caregivers of individuals with dementia, modification of the environment and task have also been recommended for persons with visual neglect and problems with prospective memory (Gillen, 2009). However, caregiver training protocols with these populations have not yet been formalized.

Cognitive Stimulation Therapy

In the 1970s and 1980s, general stimulation approaches to cognitive rehabilitation were applied to persons with both stroke and TBI in the acute recovery period. General stimulation was believed to facilitate the normal process of recovery from the neurological impairment by challenging the patient's deficits and/or weakened cognitive process, thereby strengthening them so that the person demonstrates gains in functional performance (Soderback & Normell, 1986a, 1986b). By the 1990s, these approaches had largely been abandoned as ineffective in regard to persons with stroke and TBI in favor of process-specific or milieu-oriented approach (Cicerone et al., 2011). During this same period, a new approach called CST emerged for people with mild and major neurocognitive impairment as a cross-pollination of reality orientation (RO) and reminiscence therapy (RT). RO is provided in a group format for 45 minutes a number of times per week or continuously (24-hour RO) and was introduced as a means to address confusion and disorientation in "geriatric" or "psycho geriatric" patients and to provide nursing staff with a positive way to interact with patients with dementia (Clare & Woods, 2004; Moniz-Cook, 2006). The approach was noted to reduce patient hopelessness; improve cognitive function and social behaviors; and provide a format for positive engagement of nursing staff with confused patients, thereby improving staff morale (Moniz-Cook, 2006). RT is usually provided at least once a week in a group context and involves the discussion of past activities, events, and experiences. Familiar music, photographs, or objects such as household items from the individuals' lives are often used as prompts. RT may also include an individual life review, in which the person is guided chronologically through life experiences, is encouraged to evaluate them, and may produce a biography (Spector et al., 2009).

Presumed Mechanism

When applied to persons with neurocognitive disorders in home or institutional settings, CST often additionally involves positive social interactions and/or deliberate attempts to improve the 24-hour stimulation in an otherwise understimulating environment. In the presence of neurocognitive impairment, a general cognitive stimulation approach presumes to address the multiple areas of cognitive decline on the premise that real-life activity requires the integration of cognitive skills rather than their use in isolation (Clare & Woods, 2004; Moniz-Cook, 2006).

Expectations for Transfer-Generalization

Woods et al. (2012) conducted a systematic review of CST including RO for people with major neurocognitive disorder. Interventions took place in various settings and were of varying duration and intensity. Data for 718 participants (407 receiving CST, 311 in control groups) were included in the meta-analyses. In the primary analysis, Woods et al. found a consistent benefit on cognitive function, and the benefit was maintained up to 3 months after treatment. In secondary analyses with smaller total sample sizes, benefits were also noted on self-reported quality of life and well-being and on staff ratings of social interaction and communication. No effects on ADL, mood (self-report or staff-rated), or behavior problems were noted. This latter finding of no impact on ADL or IADL in general stimulation approaches is the most frequent finding across studies (Woods et al., 2012).

Alignment with Occupational Therapy Theory and Objectives

Although occupational therapists have a specific focus on occupational engagement, occupational therapists also recognize the importance of other outcomes such as reducing distress in both clients and their caregivers. Therefore, the incorporation of CST programs in populations with neurocognitive disorders may be appropriate for occupational therapists.

Process-Specific Training

Process-specific training involves use of cognitive exercises to remediate or improve specific cognitive systems (Sohlberg & Mateer, 2001). Cognitive exercises, typically pencil and paper, tabletop, or computer based, are designed to stimulate the deficient cognitive capacity but may have little inherent value in and of themselves (Sohlberg & Mateer, 1989). Functional activities are typically multifaceted, require activation of many different cognitive processes, and can often be performed in many different ways. Therefore, they are not employed in process-specific training (Sohlberg & Mateer, 2001). In this section, process-specific training for attention and speed of processing are presented as examples of this approach.

Process-Specific Training: Attention

As discussed in Chapter 6, many recipients of occupational therapy services have problems with attention, including

persons who have had a stroke or TBI. Attention is thought to underlie all effortful cognitive activity (Shiffrin & Schneider, 1977); involve many dimensions such as maintaining vigilance, managing distractions, and deploying resources in complex tasks (Gray et al., 1992); and play a central role in learning (Robertson et al., 2002). Attention process training (APT) (Sohlberg & Mateer, 1987) and limb activation therapy (LAT) (Robertson, Hogg, & McMillan, 1998) are examples of process training specific to attention-related impairments.

Attention Process Training. APT was originally developed for adults with attention deficits caused by TBI. APT employs hierarchically organized tasks (pencil and paper, audio recordings, and computer) intended to challenge specific aspects of attention (sustained, selective, alternating, and divided) (Sohlberg & Mateer, 1987; Sohlberg et al., 2000). The patient performs exercises specific to his or her problematic attentional process, and the clinician or computer collects data on performance. As the patient meets criterion levels, the therapist raises the complexity or difficulty of the cognitive exercises, maintaining challenge to the original weakened process or capacity (Sohlberg & Mateer, 1989). This progression culminates with rehearsal of a naturalistic activity supported by the previously weakened cognitive capacity (Haskins, 2011; Sohlberg & Mateer, 2001).

Intensive practice of hierarchical attention tasks, such as APT, appears to have a positive impact on psychometric measures of attention (Gray et al., 1992; Sohlberg et al., 2000) and on self- and informant-reported daily performance (Sohlberg et al., 2000). The IOM (2011) and the Brain Injury Special Interest Group of the American Congress of Rehabilitation Medicine (Cicerone et al., 2011) suggest this type of intervention may be appropriate in the subacute and/or chronic phases of recovery from TBI, especially when combined with strategy training (Cicerone et al., 2000, 2005, 2011), but not appropriate during the acute phase. *Sole reliance on computer-based exercises for attention training without involvement of a therapist is not recommended (Cicerone et al., 2000, 2005, 2011).*

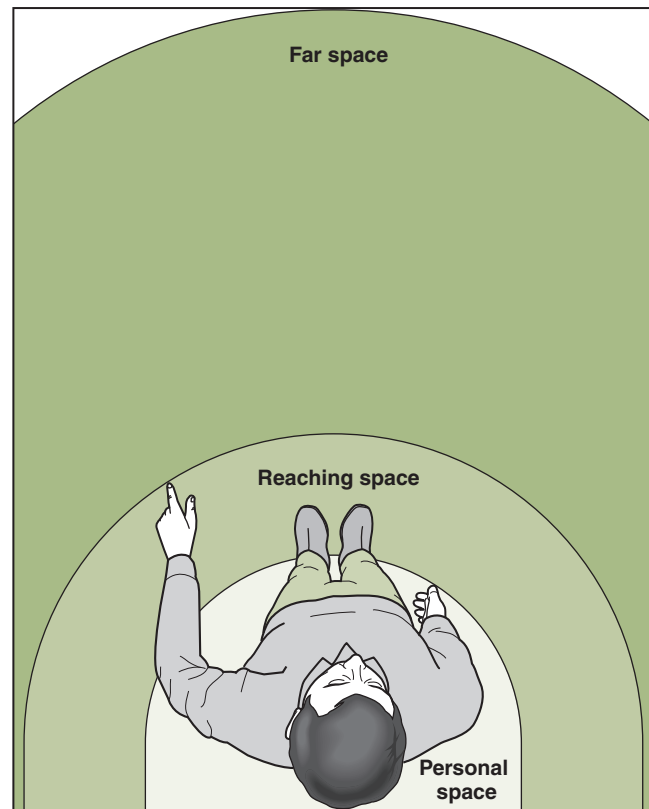
Limb Activation Therapy. As discussed in Chapters 5 and 23, unilateral neglect (UN) is "the failure to report, respond, or orient to novel or meaningful stimuli presented to the side opposite a brain lesion, when this failure cannot be attributed to either sensory or motor defects" (Maddicks, Marzillier, & Parker, 2003, p. 391). UN is a common consequence of right-hemisphere stroke and thought to be an attentional disorder that operates in three distinct areas of space (personal [body], peripersonal [reaching], and locomotor [far]) (Maddicks, Marzillier, & Parker, 2003) (see Fig. 24-4). Those who have UN appear to have poorer rehabilitation outcomes, possibly because decreased attention to the neglected hemispace interferes


Figure 24-4 Three distinct areas of space in which unilateral neglect interferes with occupational performance: personal (body), peripersonal (reaching), and locomotor (far).

with learning that is critical in rehabilitation (Robertson et al., 2002).

Robertson and North (1992) and Robertson, Hogg, and McMillan (1998) developed a process-specific intervention approach called limb activation therapy. It is based on the hypothesis that when tasks are performed using the contralesional limb in the contralesion hemispace (i.e., using the left hand or leg in the left half of space when the lesion is in the right brain), the motor circuits of the damaged hemisphere are activated, which then reduces neglect (Maddicks, Marzillier, & Parker, 2003). In LAT, the patient moves the left limb in the left hemispace when prompted by an alarm-type device at randomly occurring points during daily sessions (i.e., upon hearing a buzzer, the patient presses a switch with the left hand or foot) (Robertson & North, 1992; Robertson, Hogg, & McMillan, 1998). In some studies, LAT is incorporated into traditional occupational therapy sessions or perceptual training (Bailey, Riddoch, & Crome, 2002; Robertson et al., 1998). Most studies in this area involve multiple baseline, single subject research designs. For example, a patient who was 18 months post stroke demonstrated improvement in treatment tasks as a result of LAT added to traditional occupational therapy, with some evidence of retained gains in terms of peripersonal space but not in

personal and locomotor space (Robertson et al., 1998). In a similar study, Maddicks, Marzillier, and Parker (2003) found a treatment effect during the first phase of treatment on peripersonal and locomotor space but no long-term impact on daily life tasks. Other versions of LAT have been evaluated. Bailey, Riddoch, and Crome (2002) compared visual scanning/cueing training with a version of limb activation training in which subjects with stroke-related UN performed functional activities with the left upper extremity; patients demonstrated improvement on posttest measures with both interventions. Others have examined the impact of adding functional electrical stimulation as a means of cueing left limb movement to visual scanning training (Eskes et al., 2003), with improvements noted in visual scanning post-treatment. It is important to note that although all of the aforementioned studies demonstrated post-treatment improvements in some measures of UN, there is no clear evidence at present that results of this intervention generalize to occupational performance (Bailey, Riddoch, & Crome, 2002; Eskes et al., 2003; Maddicks, Marzillier, & Parker, 2003; Robertson, Hogg, & McMillan, 1998; Robertson et al., 2002).

Process-Specific Training: Speed of Information Processing Training

Age-related declines in speed of information processing and other cognitive capacities are considered a normal part of the aging process, but there is evidence suggesting that the cognitive abilities of older adults may be enhanced through process-specific training (Ball et al., 2002). Speed of information processing has to do with how quickly someone perceives, analyzes, and responds to sensory input. Proficiency in this cognitive capacity, as determined by a computerized measure of visual processing speed for attentional tasks called the Useful Field of View (UFOV) test (Visual Resources, Inc., Bowling Green, KY), appears to be linked with driving ability for healthy elders (Edwards et al., 2009) and individuals with TBI (Novack et al., 2006).

Speed of information processing training (SOPT) is a computerized set of cognitive exercises that involve identifying and localizing visual targets at rapid display speeds (16–500 milliseconds) that are designed to improve UFOV (O'Connor, Hudak, & Edwards, 2011). Visual stimuli in SOPT are presented in the context of a driving task. SOPT has evolved into commercial products: Road Tour and DriveSharp (see Resources 24-1).

The results of multiple, large-scale, randomized controlled studies of SOPT suggest that training may be beneficial for healthy elders. It may improve visual processing speed (as measured by the UFOV) (Ball et al., 2002; Ball, Edwards, & Ross, 2007; Wolinsky et al., 2011) and protect against driving mobility declines and incidence of at-fault motor vehicle crashes among seniors (Ball et al., 2010; Edwards et al., 2009).

Presumed Mechanism

Process-specific training is premised on the assumption that one cognitive capacity may be treated in isolation from other dimensions of cognition. It is believed to repeatedly activate and stimulate a specific cognitive system, which presumably facilitates change in cognitive capacity (Sohlberg & Mateer, 2001; Wolinsky et al., 2011). However, this assumption does not yet have empirical support. Current evidence suggests that engagement in process-specific training often improves cognitive performance on neuropsychological tests. A small but potentially important group of studies suggests that process-specific training may improve everyday performance when certain cognitive functions are targeted (most notably, speed of information processing). Even so, it may be difficult to differentiate the impact of this approach on neuroplasticity, as suggested above, from the implicit development of cognition-related skills or strategies.

Alignment with Occupational Therapy Theory and Outcomes

There are no occupational therapy cognitive models, theories, or frameworks that are directly related to process-specific training in cognitive rehabilitation. Process-specific training does not incorporate chosen occupations or occupational performance into the treatment regimen. For patients with ABI, process-specific training alone does not appear to generalize to everyday functioning, whereas SOPT for healthy elders may extend their ability to drive. Given the above, process-specific training may be appropriate in occupational therapy intervention after ABI only as an adjunct to other approaches that appear to have greater potential to impact occupational functioning.

CLINICAL REASONING IN COGNITIVE INTERVENTION

In everyday practice, occupational therapists often use multiple approaches to help patients optimize cognitive performance. For example, consider a client who is learning to use a day planner to compensate for memory impairment. Although the primary treatment approach centers on strategy training, successful outcome depends on teaching the individual's family to provide the right prompts and reinforcement (task-environment modification) and creating a daily planning routine in which the person reviews and adds notes to the planner (skill-task-habit training). Furthermore, it is possible that the learning process challenges the attentional and memory systems in such a way as to stimulate neuroanatomical and physiological changes (cognitive stimulation).

In designing a cognitive intervention plan to address a given patient's problems, clinicians must consider the

interplay between client and family factors; outcome expectations, setting, and time frame; and alignment with scope of practice, clinician competence, and interdisciplinary team.

Client and Family Factors

The occupational therapist makes decisions regarding who is the primary recipient of services—the patient, caregiver, or both. In general, care partners must be involved in intervention for patients with severe cognitive impairments because these patients are not likely to be able to independently practice or transfer what they learn in clinical sessions to the home setting. Individuals with more mild cognitive problems will be better able to apply therapy recommendations in their daily lives with only the support of the therapist. In addition, the therapist considers the nature of the underlying condition that is causing the client's cognitive problems. For example, are the client's problems attributed to organic impairments in primary cognitive abilities or characterized as a shorter term cognitive inefficiency caused by transient stressors or circumstances? Is the client in the process of recovering, or is his or her condition likely to result in progressive deterioration? How are other systems, such as motor, visual, and perceptual systems, functioning (Schwartz, 1995)? To what extent is the client aware of the cognitive problems and motivated to improve function in this area? In general, patients must have some degree of awareness and motivation to benefit from strategy training, whereas even those with severe cognitive deficits have the potential to benefit from skill-task-habit training or changes to tasks and environments to match current capabilities.

Outcome Expectations, Setting, and Anticipated Contact Time

Where the patients are in their injury or illness trajectories will influence the overall outcome expectations of therapy and the amount of time available for patient–therapist contact—all of which should be carefully considered in developing the cognitive intervention plan.

During acute medical care, occupational therapists may only have a limited number of sessions with the patient; discharge planning is typically the focus. Inpatient rehabilitation may extend for a week to a month or so and focuses on impairment remediation and assuring competence in basic ADL. Patients typically receive an hour and a half of occupational therapy per day during this phase. Outpatient rehabilitation is often provided two to three times per week, and this may continue for weeks to months, depending on patient needs, goals, and insurance coverage.

It is imperative that clinicians are well versed in published cognitive rehabilitation guidelines and evidence-based reviews (Cicerone et al., 2000, 2005, 2011; Haskins, 2011; IOM, 2011) so that the most promising interventions are matched to patients' needs and goals at various points in the continuum of care. For example, a patient with a new stroke demonstrates forgetfulness during his kitchen evaluation immediately prior to discharge home from an acute medical setting. He would be best served if the therapist focused on task-environment modification (provision of recommendations to the patient and wife that the patient perform cooking tasks only when supervised by his wife). Broader memory concerns could be addressed by memory strategy training when he returns to occupational therapy as an outpatient.

Alignment with Scope of Practice, Clinician Competence, and Interdisciplinary Team

As introduced earlier, cognitive rehabilitation is an interdisciplinary enterprise. This means that there is the potential for complementary, overlapping, or conflicting roles with other disciplines. Often, the expertise of the clinicians at a given site will determine whether, for example, memory strategy training is provided by an occupational therapist or a speech language pathologist. Occupational therapists have the education and training to provide cognitive intervention and are accountable to their patients and the profession to employ occupation-focused, evidence-based cognitive intervention and to invest in ongoing learning in this important area of rehabilitation.

case example

D.B.: Using Multiple Approaches to Optimize Cognitive Functioning after Traumatic Brain Injury

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**
Patient Information	Appreciate the context	See Chapter 6 for description of the assessment process and client's background.
D.B., a 26-year-old man who is 3 months post traumatic brain injury, participated in an outpatient occupational therapy assessment, and the following problems were identified: (1) decreased initiation of activities of daily living (ADL) and instrumental activities of daily living (IADL), (2) decreased productivity because of poor stamina and limited repertoire of appropriate avocational outlets, (3) memory inefficiency and inadequate repertoire of memory compensation strategies, and (4) decreased awareness of cognitive deficits interfering with compensatory strategy use.	Develop intervention hypotheses	"I believe that D.B.'s cognitive problems are the most salient barriers to his occupational functioning at present, specifically his limited awareness of his cognitive deficits. I think that he could better adapt to his physical limitations if he employed an array of strategies to compensate for his cognitive limitations. His motivation and family support are real facilitators of his occupational functioning and recovery."
	Select an intervention approach	"I will develop an intervention plan that emphasizes compensation for deficits, because given the severity of his brain injury, D.B. will likely have long-term cognitive challenges (*strategy instruction*). D.B. will no longer need assistance from his brother if I help him reestablish an ADL routine (*skill-habit training*). I know that I will also want to work with D.B.'s family to change the social context so that they are not providing him more cues and assistance than is really necessary (*task-environment modification*). I will suggest some computer games that place demands on attention and memory that D.B. might enjoy during some of his free time (*cognitive stimulation*). I know that these games won't 'fix' his brain, but they may help him gain insight about his cognitive functioning, especially if I provide some guided reflection questions for him to complete afterward."
	Consider the evidence	"A recent systematic review (Cicerone et al., 2011) indicates that evidence supports helping patients with traumatic brain injury (TBI) learn to use compensatory strategies for memory and attention problems but that there is no empirical support for patient exposure to computer-based exercises, without a therapist. The literature also suggests that habit training results in improved independence, even with people who have more severe TBI (Giles & Clark-Wilson, 1988; Giles et al., 1997)."
	Reflect on competence	"D.B. reminds me of three or four other clients I've worked with in recent years. I'm a little concerned that I may not be able to satisfactorily address emotional or adjustment issues that might emerge as he gains insight, and so I need to start thinking about a counselor I might refer him to later."

Recommendations

The occupational therapist recommended two or three treatment sessions each week for 8 weeks. In collaboration with D.B. and his brother, the occupational therapist established the following long-term treatment goals: (1) D.B. will independently initiate and carry out all self-care and selected light housekeeping tasks (through use of external memory aids), (2) D.B. will increase his level of productive activity at home such that he initiates avocational activities at least three times per week, and (3) D.B. will follow through on intended tasks at least 85% of the time through use of external memory aids and strategies. D.B.'s brother indicated a willingness to provide transportation to appointments and to attend at least weekly.

Consider what will occur in therapy, how often, and for how long

Ascertain the client's endorsement of plan

"I think that a fairly intensive outpatient program is warranted because of the scope of our goals and D.B.'s motivation and potential to make progress. I have real hope for D.B.'s recovery for many reasons, including his level of cooperation, his cognitive strengths, and his brother's commitment to the therapy process. D.B. seems agreeable to the plan, but I really don't know how much he truly understood what I'm proposing and why."

Summary of Short-Term Goals and Progress

1. *D.B. will independently initiate note-taking when presented with occupational therapy homework (at least 60% of the time) and thereby improve his follow-through on intended tasks.*

    The therapist ascertained that D.B. would be most likely to carry a memory aid if it was highly portable. Therefore, she assisted D.B. in selecting a commercially available, pocket-sized week-at-glance planner. The therapist created opportunities for D.B. to practice filing and locating information in function-specific planner sections. The therapist used an event record to log each of the three to four homework assignments she presented to D.B. during all treatment sessions, taking note of the extent to which D.B. required cues to initiate note-taking. Any level of note-taking initiation was verbally reinforced. Progress in this realm was reviewed at each session, graphing both note-taking initiation and homework completion as reinforcement and to improve insight. During the last week of this period, D.B. averaged a 65% independent note-taking rate and a 70% homework completion rate.

2. *D.B. will initiate and employ consistent routines for self-care tasks (including medication management) through use of checklists and alarm cueing devices.*

    Based on the therapist's recommendation, D.B. purchased a container for medications taken each week as well as an alarm watch. The therapist set the alarm to sound at 5:00 pm as a prompt to refer to his medication checklist and take medications. D.B. required cueing and supervision with this system for 2 weeks, but by the end of the month, he took medications on schedule, once his brother filled the medication container. A "morning checklist" (D.B.'s hygiene sequence) was posted in D.B.'s bathroom, and after 1 month, he progressed to the point that he required his brother's cueing to initiate these activities only one or two times per week.

3. *D.B. will improve his attention to detail such that he has an error rate of less than 10% on pencil-paper tasks.*

    D.B. was highly motivated to "fix" his memory and eager to carry out any exercises that might help. To that end, he agreed to work on various attention-concentration worksheets as part of his homework while experimenting with various strategies that might help him focus on the task. For example, he tracked and compared his performance under various conditions: while watching television versus sitting in a quiet room; in the morning when rested versus after dinner; working in a space crowded with many papers and belongings versus a corner of his bedroom from which his "stuff" was not visible.

Assess the client's comprehension

Understand what he is doing

Appreciate the context

"At first when I started giving D.B. homework, he simply sat and nodded his head as if to confirm that he understood and would remember. It was hard for me to say nothing and 'let the chips fall where they may.' It was uncomfortable for a while when he would argue with me at our next session, telling me that I had not assigned him anything, but as I showed him my log and how to use his planner, he seemed to realize that it's o.k. to write things down rather than trying to memorize everything. I'm seeing progress."

"I am so glad that D.B.'s brother is part of the team. Ordinarily, I like to allow patients to go ahead and make forgetting errors as a means of helping them improve awareness, but I simply can't allow that when it comes to remembering to take medications on schedule."

Know the person

"D.B. would rather 'fix' his memory than learn to compensate for memory problems, but the research evidence just doesn't support the notion that repetitive cognitive exercises lead to functional changes. I don't want to create any false hope but have tried to both give him some activities to fill his time at home and create a structure in which he can think about his thinking. He still needs a lot of help to understand the circumstances under which he performs at his best, but he seems to feel that these activities give him something important to do during his days off from therapy."

Next Steps

Revised short-term goals (1 month):

1. D.B. will use his daily planner and planning checklists in order to schedule and carry out at least two housekeeping tasks and three avocational activities each week.
2. D.B. will be able to use compensatory strategies to independently take medications on schedule (once his brother sets up the medication box each week).
3. D.B. will demonstrate improved awareness of his current problems with memory by independently initiating note-taking to the presentation of homework at least 85% of the time and at least 75% of the time when his brother provides instructions.

Anticipate present and future client concerns

Decide whether he or she should continue or discontinue therapy and/ or return in the future

"D.B. has made great progress over the past month but is not yet ready to be living on his own, which remains his primary goal. He really needs to be able to handle self-care tasks (including medications) and perform critical household tasks in order to do so. I would like to help D.B. prepare himself to do some sort of volunteer work within the next couple of months, and he has indicated at least preliminary interest in doing so. He'll need to be quite proficient with his planner to be a successful volunteer."

Clinical Reasoning in Occupational Therapy Practice

Incorporating Task-Environment Modification Training into Occupational Therapy Intervention

D.B.'s brother was an important member of the rehabilitation team. Because D.B. had significant problems with memory and self-awareness, D.B.'s brother assumed central responsibility for trying to transfer and apply therapy recommendations in the home setting. Based on D.B.'s long-term goals, what information do you think that the occupational therapist should specifically teach D.B.'s brother? Provide some examples regarding how that teaching might take place.

Summary Review Questions

1. Describe the characteristics of the two systems people use for the control and execution of behavior. Keep a notebook with you for a day and write down the minutes that you spend in controlled effortful processing. How do you think this might differ it you are engaged in usual activities or in a new activity such as starting a new work environment?
2. How would your efforts to optimize cognitive function be different for a person with Alzheimer's disease compared with a patient in acute recovery from a traumatic brain injury?
3. Describe the pros and cons of process-specific training. Describe ways that this approach could be appropriately incorporated into an occupational therapy intervention plan.

4. Write down the steps to one of your daily routines or habit sequences. Now change the order of steps and, next time, try to follow this revised sequence. How do these changes affect your speed of performance and the attentional demands of the task? What does this experience teach you about helping patients establish daily routines?
5. Describe three changes you could make to your own living environment to decrease its cognitive demands.
6. Explain the ways in which metacognitive strategy training such as CO-OP is both similar to and different from external memory strategy training.
7. Consider practices or habits that optimize your memory performance and ability to concentrate, plan, and problem solve. How might these same strategies be used by an individual with cognitive impairment?

Glossary

Automaticity—The ability to perform activities or behaviors with little or no contribution from the conscious mind. Automaticity occurs as a result of practice of the behavior or skill.

Chaining—A task analysis breaks down complex tasks into a series steps or subtasks. In forward chaining, the client is taught to complete the first action in the task sequence; once mastery is achieved, the client is taught the first and second tasks and so on until all of the steps in the chain have been mastered and the complete task can be performed.

Cognitive rehabilitation—Multidisciplinary field and a broad category of intervention methods aimed at improving cognitive function.

Compensatory cognitive strategies—An array of tactics that are intentionally employed in order to optimize performance despite a cognitive limitation, such as using a metacognitive strategy to organize a project despite executive dysfunction or using an alarm watch to monitor the passage of time despite attentional problems.

Domain-specific strategies—Strategies people use to assist them to manage occupational performance problems related to a specific area of functioning (e.g., the person who has a tendency to leave needed items at home adopts the strategy of setting items he needs to take to work by the door).

Habits—The continuum of automatic physical, emotional, and social behaviors that become increasingly effortless with repetition within the same context.

Metacognitive strategies—Global tactics that people use to guide their approach to occupational performance problems. These strategies can be applied to a variety of problems and are applicable to many domains of functioning.

Press—Aspects of the person's physical or social environment that influence the challenge of an activity (activity demand). Reducing the press can make an activity easier to perform.

Routines—Semiautomatic sequences of activities that are prompted by physical context and are fairly consistent for each individual on a day-to-day basis (e.g., a person's morning ADL routine).

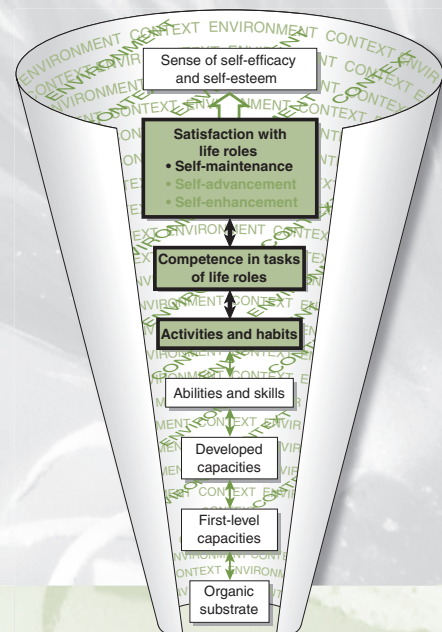
Restoring the Role of Independent Person

Anne Birge James

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Describe the use of occupation-as-end as a therapeutic medium.
2. Distinguish between activities of daily living (ADL) and instrumental activities of daily living (IADL).
3. State principles to restore adapted function to persons with varied impairments and activity limitations.
4. Modify tasks and the environment to promote participation in ADL and IADL for people with varied impairments and activity limitations.
5. Prescribe and evaluate the use of assistive devices to promote safe independence in ADL and IADL.
6. Articulate the clinical reasoning and demonstrate the implementation of solutions to unique situations for persons with a variety of impairments and activity limitations.
7. Develop appropriate teaching strategies for persons with varied impairments to maximize progress toward occupation-based goals.


People who are satisfied with their life roles have the resources and capabilities needed to accomplish their everyday tasks, whether or not they actually perform the task themselves. Self-maintenance roles include participation in activities of daily living (ADL) and instrumental activities of daily living (IADL) (Latham, 2008a). The occupational therapist is the rehabilitation specialist responsible for teaching the patient to accomplish these tasks. Most people want to care for themselves to the best of their ability, which may include directing and/or delegating to others tasks that are beyond their capabilities.

The term *activities of daily living* is synonymous with self-care. ADL include feeding, grooming, dressing, bathing, toileting, bowel and bladder management, personal device care, sexual activity, functional mobility, sleep/rest, and eating (chewing and swallowing) (American Occupational Therapy Association [AOTA], 2008). The first eight ADL are included in this chapter. Functional mobility, including bed mobility, transfers, and wheelchair mobility, is addressed in Chapter 26, and chewing and swallowing are addressed in Chapter 43. Although every human engages in most or all ADL to some degree, the way that each is done and the importance attached to each differ culturally. ADL are the focus of most insurance coverage for rehabilitation. Baseline measures and examination of progress is documented by such evaluative measures as the Functional Independence Measure (FIM™) (see Chapter 4).

Suggesting that people are independent in self-maintenance if they can complete their ADL gives a false impression of independence. True independence also requires participation in *instrumental activities of daily living*, including but not limited to management of one's own medications, food, shelter, and finances; caring for other people or pets; communication device use; and community mobility (AOTA, 2008). IADL include a range of diverse tasks that often require greater interaction with the physical and social environments and may have more demanding physical and/or cognitive demands than ADL (James, 2014).

OCCUPATION-AS-END

When remedial therapy can correct performance skills/patterns or client factors that interfere with ADL, patients are often able to resume meaningful tasks and activities as they become able. Intervention that targets ADL directly is necessary for those who do not regain full capabilities, prefer not to engage in remedial therapy, or require interim strategies to enable participation in ADL and IADL as they regain required capacities. Occupation-as-end is an intervention focused on learning how to accomplish the activities and tasks that constitute roles in an adapted way (Latham, 2008b). The therapist employs a modification approach that enables patients to accomplish activities by changing the task and/or environment and providing appropriate patient and/or caregiver education (AOTA, 2008). The modifications recommended by the therapist may be aimed at the patient and/or the caregiver (Chen et al., 2000). Intervention is frequently aimed at improving independence in ADL and IADL, that is, the person's ability to complete the task without assistance from others. However, intervention may also be used to address other important task parameters, including safety and adequacy conditions, such as perceived difficulty or ease of performance, pain, fatigue, or dyspnea precipitated by activities, length of time to complete a task, and the ability to complete tasks in a way that meets personal and societal expectations (Rogers & Holm, 2009). For example, a person with rheumatoid arthritis may be independent in cooking, but experience significant pain that makes her unwilling to engage in the task. The therapist may instruct her in the use of adapted methods of cooking that protect painful joints to help her cook both independently and without pain.

The extent and focus of services for a particular patient depends on the person's needs and the level of independence required in the anticipated context. Patients' perceptions of ADL capabilities may differ from others' perceptions or even actual performance (Goverover et al., 2009), affecting their investment in treatment. Therefore, identification of patients' perceptions, values, and goals is a crucial part of the evaluation process that can be done informally or via standardized assessments, such as the Canadian Occupational Performance Measure (COPM; Law et al., 2005) or the Melville-Nelson Self-Identified Goals Assessment (Melville et al., 2002) available at http://www.utoledo.edu/eduhshs/depts/rehab_sciences/ot/melville.html. Involving patients in setting goals not only supports the therapist's ability to develop an appropriate treatment plan, but patients tend to have better outcomes (Kristensen et al., 2011).

Independence in ADL may be sufficient for a person returning to a supportive living situation in which IADL needs are few and willingly assumed by others, but it is never enough for a person who expects to reintegrate into community life. This person not only must master ADL and common IADL tasks but also must learn to solve problems that interfere with performing new tasks. For some patients, however, independence in only one or a few activities, such as transferring and toileting, may determine whether discharge is to home or an institution. Therefore, full effort should concentrate on achievement of critical goal(s), and additional goals may be determined and addressed, as possible, at a later time.

Intervention by occupation-as-end, then, is a modify approach (AOTA, 2008) that uses education of adapted methods, assistive technology, and adaptation of physical and/or social contexts to enable people to participate in desired roles with a permanent or temporary disability.

EDUCATION

In the modify approach, the therapist and patient engage in a collaborative learning process. Although the therapist is the teacher and the patient and caregivers are the learners in this relationship, sometimes roles are reversed when engaged in a collaborative relationship. Both teaching and learning are active processes (Dreeben, 2010). The patient must be both ready and able to learn. Assessing a client's readiness to learn can help the therapist select appropriate tasks and educational methods to maximize client outcomes.

Readiness to Learn

Patients' self-efficacy can have a significant impact on learning and can be evaluated and addressed in the context of ADL intervention. Self-efficacy is defined as the judgments people have of their capabilities to do or learn a task (Bandura, 1977, 1997; Sanford et al., 2006). Self-efficacy is positively related to actual performance and helps people to persist in tasks, even when faced with tasks that are difficult or new (Dreeben, 2010; Sanford et al., 2006). Persons with a new disability may have low self-efficacy for engaging in ADL because they lack experience with their limitations in the context of familiar tasks. Self-efficacy can be measured by asking patients to predict their performance on a given task using a Likert-type scale (e.g., 1 = very unlikely to learn this task, 5 = very likely to learn this task). A baseline self-efficacy measure can be used to determine the need for intervention to address self-efficacy along with the ADL skills training to enhance goal achievement.

Depression is another factor that can impede learning and occurs concurrently with a wide variety of physical disabilities. Depression has been demonstrated to have a negative relationship with functional outcomes for persons with varied physical disabilities, e.g., stroke (Pohjasvaara et al., 2001) and Parkinson's disease (Weintraub et al., 2004). Depression may impact functional outcomes by reducing self-efficacy needed for learning. Identifying depression in patients and referring them to physicians for prescription of antidepressant medications may reduce depressive symptoms, enhancing functional performance (Chemerinski, Robinson, & Kosier, 2001; Lin et al., 2003). In addition, occupational therapy that directly addresses the patient's depression can enhance outcomes, e.g., providing structure that promotes initiation in ADL and selecting tasks that provide the patient with successes will increase self-efficacy for future performance.

Other factors may interfere with patient learning, such as cognitive deficits (see Chapters 6 and 24). Persons with severe cognitive deficits may not be candidates for ADL training. Instead, the caregiver should be taught appropriate methods for assisting the patient and told to seek reevaluation if the patient's cognitive status improves.

Patients with cognitive disabilities who have the capacity to learn often have limited insight into their ADL or IADL impairments. This may interfere with treatment because patients see little reason to work on tasks they believe they can do. Integrating self-awareness training into occupation-as-end–focused treatment can improve functional outcomes for patients with limited self-awareness, compared to treatment focused simply on skill acquisition (Goverover et al., 2007). Pain may interfere with attention and learning and should be addressed directly or by selecting adaptive methods that minimize pain.

Patients with receptive aphasia or who speak a different language from the therapist have communication limitations that may impact learning. Therapists should use demonstration for patients who do not understand verbal instructions. A translator can be used to support learning for patients who speak another language. Patients with low literacy will not be able to use written materials to supplement learning, so other methods must be explored that support carryover of new skills outside of therapy. Chapters 3 and 13 describe ways to accommodate low literacy.

Clients may require adaptive equipment to maximize independence in ADL; however, attitudes toward adaptive equipment can impede learning and performance. Persons with disabilities have reported that assistive devices have both positive and negative connotations (Skymne et al., 2012). People value a device if the task is important and cannot be done any other way (Wielandt & Strong, 2000), but they dislike the stigma associated with device use. Disabled persons reported that they not only had to learn to use the device, but they had to learn to go out in public with it (McMillen & Söderberg, 2002). Assessing a patient's "gadget tolerance" can help therapists tailor their approach when presenting adaptive equipment as an option. Patients with a low tolerance for "gadgets" may need more trust in their therapist before considering equipment. Building this trust may become an important component of the therapeutic intervention for maximizing independence (See chapter 14).

Finally, the motivation to learn is influenced by the learner's values, which guide actions and effort (Dreeben, 2010; Falvo, 2011). Therefore, therapists must collaborate with patients to identify those tasks that will be within their capabilities and are also consistent with their values and goals. Attending to the many factors that may impact a patient's ability to learn helps the therapist select the most appropriate teaching strategies to enhance patient performance of ADL.

Teaching Strategies for Effective Learning

This section will address points of effective teaching, which are also summarized in Procedures for Practice 25-1. Throughout the teaching and learning process,

Procedures for Practice 25-1

Effective Teaching

1. Identify the patient's goals and learning needs.
2. Determine what the learner knows.
3. Use active learning strategies.
4. Engage the patient and/or caregivers in a collaborative learning process.
5. Select learning activities that present the "just-right challenge."
6. Adapt the presentation to the learner's capabilities.
7. Provide opportunities for practice, considering context and schedule.
8. Facilitate the learner's use of internal feedback and provide appropriate external feedback.
9. Test the learner in the appropriate context(s) to confirm that learning has occurred.
10. Discuss progress toward goals with the patient and revise teaching–learning strategies, as indicated.

occupational therapists should look for and address potential barriers for learning. Some barriers that are intrinsic to the patient were discussed when considering readiness to learn, such as self-efficacy, depression, pain, and gadget tolerance. External barriers to learning related to the physical and social environment may also exist. Occupational therapists' skills in analyzing tasks in context and adapting environments can be applied to removing barriers to learning in the treatment environment (Smith & Gutman, 2011). Examples of barriers and how to minimize them are included in the teaching strategies below:

1. Identify patients' goals and what they must learn to reach their goals (James, 2014). These become learning objectives or goals expressed in behavioral terms, such as "The patient will brush his teeth independently in less than 5 minutes." Although patients' needs vary, toileting is often a priority (Clark & Rugg, 2005). Identifying realistic goals may be difficult, particularly for patients with a sudden-onset disability, e.g., a stroke or spinal cord injury, because they have not had time to experiment with solutions to functional problems. Setting goals supports the learning process, and patient goals that are poorly defined or unrealistic may present a barrier to learning. Occupational therapists can help patients identify goals by sharing their vision of what is possible or by helping patients see how smaller, more realistic goals serve as important stepping stones to goals that are unrealistic or require a long time frame.

2. Determine what routines and skills patients have retained and whether they do them safely, including the ability to figure out adapted methods independently. Embedding the learning in context facilitates retention of new information and skills.

3. Present the material in a way that requires patients to be active in the learning process (Dreeben, 2010). Verbal or written instructions and demonstration are passive learning strategies and are often insufficient for mastering a new task. **Active learning** requires learners to apply new knowledge to real-life problems. For example, patients learning energy conservation can be asked to describe a typical day, identify ways they could conserve energy, and then practice strategies in an actual task, e.g., cooking. Active learning is vital when the patient is learning a motor task, such as putting on a shirt with one paralyzed arm, and should be guided by motor learning principles (see Chapter 13).

4. Use a collaborative approach, recognizing that each participant in the learning process (therapist, patient, and/or caregiver) has experience and expertise to contribute to the learning task. Engaging patients and caregivers in the intervention process enhances problem-solving skills, increases "ownership" of functional gains, and enhances self-efficacy (Jack & Estes, 2010). Allowing patients to participate in the selection of equipment appears to have a positive influence on adherence (Wielandt & Strong, 2000). Peer learning can also be effective by providing psychosocial support, promoting self-management, and improving patient's self-efficacy (Packer et al., 2009).

5. Select the "just-right challenge." A "just-right challenge" is one that is within the outside limits of the patient's ability, ensuring success, but requiring effort. Initially, keep the challenge low to enhance self-efficacy by reducing anxiety and promoting success (Falvo, 2011). For example, if the patient is learning to eat with adapted utensils, begin with sticky foods that stay on the spoon and progress to more difficult foods, such as spaghetti and peas. Scaffolding is the technique of providing just the amount of assistance the person needs and then gradually removing assistance as the person can do more of the task (Thomas, 2012). The form of assistance can vary, including setup, verbal cues, or physical assistance (James, 2014).

6. Adapt the presentation of new information to the particular learner, given his or her abilities and deficits. For patients without brain damage and with average intelligence and literacy, teaching methods can include discussion, demonstration, and written instructions (Falvo, 2011). Printed materials and verbal instructions should be simple and direct, as almost half of the population in the United States has low health literacy, that is, their comprehension and ability to act on health-related information is inadequate (Smith & Gutman, 2011).

The availability of high-quality, online educational media is increasing rapidly. Libin et al. (2011) reported that social media, such as YouTube, provide a virtual context for sharing ideas for disability self-management in a forum that is increasingly accessible to people with disabilities. Occupational therapists can access a number of "how to" videos, produced by the National Rehabilitation Hospital for persons with spinal cord injuries at http://www.youtube.com/user/HealthyTomorrow. Not all information on YouTube or other nonprofessional sites is correct, therefore note the credentials of the source before adopting any method from these sites.

ADL and IADL training for persons with intact cognition should occur in varied contexts so they become independent problem solvers. Effective problem solvers have an accurate awareness of their abilities and limitations and the ability to identify and define problems. They can select appropriate solutions to a problem from past experience or create a new solution when prior strategies are inadequate. Finally, effective problem solvers assess the outcome of the problem solving, which helps them organize the learning experience so that it is accessible for solving problems in the future.

Patients with brain damage require a different approach to the teaching–learning process. If patients cannot do previously familiar tasks automatically using old habit programs, they are learning a new skill. Several learning approaches may be considered for patients with cognitive deficits. Impairment in self-awareness of abilities and limitations may need to be addressed, because patients are not likely to value or engage in learning for ADL or IADL they perceive themselves to be competent in. Self-awareness training in the context of ADL and IADL tasks can help patients identify performance errors and initiate self-correction strategies (Gillen, 2009). Consistent and systematic use of cueing may be effective in helping patients focus on relevant task cues to support performance (Wesolowski et al., 2005). Errorless learning is a teaching method in which the learner is prevented from making errors by the therapist. For example, providing step-by-step verbal cues during ADL training or handing patients the necessary adaptive equipment rather than allowing them to choose. Research on the effectiveness of errorless learning has been mixed and may reflect its application to different types of learning deficits. For example, errorless learning was effective for people with acquired brain injury in learning to use electronic aids to daily living (EADL) (Boman et al., 2007); however, Mount et al. (2007) found no difference between errorless learning and trial-and-error learning of ADL in people post stroke. Monitoring response to treatment can help the occupational therapist determine whether errorless learning is effective for a given patient.

Patients with acquired brain injury often have difficulty processing abstract information or large chunks of information at a time, so instructions should be reduced to one- or two-word concrete cues. Given consistently, these key word cues help the patient chain the task from beginning to end. For tasks that can be easily broken into isolated subtasks, it may be helpful for the patient to practice one step at a time, combining steps as learning progresses, e.g., begin brushing teeth with the toothpaste already on the brush. For some tasks and some patients, however, performance of the whole task will enhance learning (see Chapter 13). If the task will occur in different places, the patient must practice each task until it is learned within all the contexts in which it will be required.

Progress in learning ADL for those with brain damage may be slow (Boman et al., 2007). Given the economic constraints, it is unrealistic to expect to teach such patients in the brief period of treatment authorized. The therapist should teach the caregiver how to help the patient learn some ADL skills at home.

Patients with damage to their dominant hemispheres usually have difficulty processing verbal or written language but may benefit from demonstrated or pictorial instruction. Those with damage to their nondominant hemisphere may have difficulty with spatial relationships that make it difficult to interpret pictures and demonstrations but may be able to process step-by-step verbal instruction.

7. Arrange appropriate practice schedules. Motor skills are learned only through practice. Multiple studies have shown that motor skills were better retained when participants without neurological impairment practiced with contextual interference (random practice) rather than repetitive drill (blocked practice) (Lin et al., 2009). However, for patients with movement disorders, response to practice schedules may vary, and alternatives may need to be considered (Lin et al., 2007). Chapter 13 has a discussion of practice schedules.

8. Provide opportunities for internal feedback and use appropriate external feedback. External feedback comes from outside the patient, typically the therapist, and can be provided in many forms. Motivational feedback ("Looks good!" or "Keep trying!") has some benefit, but specific feedback about what was correct and what was not correct has more definitive benefit. Persons who are not aware of the outcome of their efforts benefit from external feedback so that they gain knowledge of the results of their efforts, a requirement for learning (Schmidt & Lee, 2011). Although external feedback from the therapist is an effective teaching method, patients must eventually respond to internal and task feedback, that is, feedback from their own sensory system or the outcome of task performance ("My pants are on, but twisted and uncomfortable"). Asking patients to articulate internal feedback before providing external feedback can support their ability to rely on internal feedback when faced with novel tasks outside of therapy.

9. Test whether the learner has acquired the knowledge or skill by requiring that it be done independently at the appropriate time and place.

10. Discuss progress toward goals and revise teaching strategy or goal as indicated. Gagné and Hoppes (2003) found that patients in a rehabilitation center who regularly discussed and updated their goals with their therapists made greater gains in ADL than patients whose treatment did not emphasize goal attainment.

ADAPTATION AND MODIFYING APPROACHES TO INTERVENTION

Adaptation is the process by which people change their approach to a task when faced with an occupational challenge (AOTA, 2008). It is a cumulative process that evolves over time. Older people therefore have a rich repertoire of adaptive strategies based on personal experience that may be helpful in dealing with disability.

A modifying approach to occupational therapy intervention means adapting the method of accomplishing the task and/or the environment to promote independence in occupational functioning by compensating for impairments (AOTA, 2008). Examples of modifying the task are to switch to loafers instead of tie shoes or to order from catalogs instead of going to the shops. Adapted methods of dressing for persons with loss of the use of one side of the body or weakness of all four extremities (discussed later) are examples of modifying the method of accomplishing a task. Installation of grab bars in the bathroom to enable safe transfers and storing often-used items within easy reach are examples of modifying the physical environment. Teaching wheelchair users ways of interacting with individuals who are not disabled so that they present themselves as self-assured, capable people is an example of adapting the social environment.

Prescription of and training in the use of assistive devices or adapted tools and utensils to enable occupational performance by persons who are physically disabled is a primary function of occupational therapy. Examples are adding extensions to keys and door handles to extend the force arm and reduce the force required to turn the key or knob (Fig. 25-1) and use of a button hook to button a shirt (Fig. 25-2). Grasp, a problem for many patients, can be helped by using enlarged handles and ergonomic designs that put the hand and wrist in optimal biomechanical alignment (Figs. 25-2 and 25-3). A therapist may experiment with adaptations to utensils by wrapping a washcloth, foam rubber, or other material around the handle and securing it with a rubber band. If enlarging the handle improves performance, permanent adaptation is prescribed and purchased or, if necessary, custom built. Low-temperature thermoplastic materials that bond to themselves can be used for this purpose (see Chapter 16), or thermoplastic pellets can be heated and shaped into handles.

Figure 25-1 Doorknob extension.

Adaptation entails the following seven aspects, summarized in Procedures for Practice 25-2:

1. Analyze the activity. Determine the essential demands of the activity. The activity demands are a combination of the performance requirements of a task, such as

Figure 25-2 Good Grips® button hook. (Courtesy of North Coast Medical, www.ncmedical.com.)

Figure 25-3 Garden tools with ergonomic handles keep the joints and musculotendinous units in optimal alignment, optimizing strength and protecting joints.

Procedures for Practice 25-2

Adaptation Process

1. Analyze activity demands, including performance and contextual requirements.
2. Identify the problem: what performance and/or contextual requirements prevent the person from accomplishing the task?
3. Know principles of compensation for the given limitation.
4. Creatively apply principles of compensation to solve the problem.
5. Select appropriate adapted methods and assistive devices, and specify environmental adaptations to implement the solution.
6. Check out all modifications to verify that they solve the problem.
7. Train in safe use of the assistive devices or modified environment.

lifting, reaching, and manipulating, and the contextual demands. Contextual demands include the physical environment, such as counter height or location of faucets in the bathtub, as well as social demands, such as the ability to communicate with others, and temporal demands such as the need to complete a morning care routine within 45 minutes in order to get to work on time. Performance requirements must be quantified: What is the weight to be lifted? How high must it be lifted? and so on. Examination of these objective dimensions of the activities suggests how the environment and equipment can be adapted to meet the capabilities of the person (Thomas, 2012). Studies have examined specific performance components of particular tasks, such as the minimal wrist ranges of motion needed to accomplish ADL (Ryu et al., 1991), pinch and grasp strength requirements for varied tasks (Rice, Leonard, & Carter, 1998; Smaby et al., 2004), effect of object width on hand muscle activation and grip force (Vigouroux, Domalain, & Berton, 2011), differences in cardiovascular demands of carrying a bag at the side versus against the chest (Irion et al., 2010), and the effect of reacher length on muscle strength needed to lift objects (Pinkston, Boersma, & Spaulding, 2005). Such studies can help occupational therapists set realistic goals and identify the need for adaptations more quickly and accurately.

2. Identify the problem. Why can't the person do what the task demands? It is helpful to consider the problem from two perspectives: patient limitations and contextual features. For example, the patient is unable use the left hand, but toothpaste with a screw cap requires the use of two hands. Or the patient has precautions against bending over so pots needed for cooking stored in low cabinets cannot be reached. Linking the performance limitations with contextual features helps the therapist identify appropriate solutions.

3. Know the principles of compensation. Principles of compensation for common functional limitations are presented in Procedures for Practice 25-3.

4. Propose solutions. Consider creative ways that the principles of compensation can be applied to a specific task to enable the particular person to do it. Collaboration with the patient or a group of similarly involved patients often generates solutions and increases compliance with assistive devices (Wielandt et al., 2001).

5. Know the resources for implementing the solution. For example, it is important to know what reliable and safe equipment is available to solve the problem. Sources of equipment are rehabilitation supply stores, web-based businesses, and gadget stores (see Resources 25-1). The occupational therapist needs to know and evaluate each piece of equipment being recommended. The fact that a piece of equipment is sold does not mean that it is

Procedures for Practice 25-3

Compensation Principles for Particular Impairments

Weakness

- Use lightweight objects, utensils, and tools.
- Let gravity assist.
- Provide external support, e.g., sit if trunk or lower extremities are weak, use a mobile arm support for proximal upper extremity weakness, or splint a weak wrist.
- Use assistive devices or methods to stabilize objects and replace lost functions such as grasp.
- Use power tools and utensils.
- Use biomechanical principles of levers (e.g., lengthen the force arm in relation to the resistance arm) and friction (e.g., increase friction to decrease power required for pinch or grasp).
- Use two hands for tasks ordinarily done one-handed.

Low Endurance and/or Fatigue

- Use energy conservation methods (see Procedures for Practice 25-4).
- Pace work to prevent fatigue.
- Use principles listed for weakness that reduce workload, such as lightweight utensils and power equipment.
- Match activity demands to ability.
- Avoid stressful positions and environmental stressors.
- Coordinate optimal breathing patterns with movement during activities to maximize oxygen exchange.

Limited Range of Motion

- Use long-handled tools and utensils to increase reach and/or eliminate the need for bending over.
- Build up handles to compensate for limited finger flexion range of motion.
- Store frequently used things closer to reduce reach.
- Use joint protection techniques for rheumatoid arthritis (see Chapter 39).

Incoordination

- Stabilize the object being worked on, including use of assistive devices that reduce slipperiness.
- Stabilize proximal body parts to reduce degrees of freedom, improving control of distal body parts.
- Use heavy utensils, cooking equipment, tools, and so on.
- Use adaptations that reduce or eliminate the need for fine motor skill (e.g., replace buttons with Velcro™).

Loss of the Use of One Side

- Provide assistive devices that substitute for the stabilizing or holding function of the involved upper extremity.

- Teach one-handed methods for activities ordinarily done two-handed.
- Provide assistive devices that change bilateral tasks into unilateral tasks.
- Improve dexterity of the uninvolved upper extremity if use of the dominant arm is impaired.

Limited Vision

Blindness

- Organize living space and stress the importance of putting everything in its place after use (e.g., in the pantry cabinets, on refrigerator shelves, and in the medicine cabinet).
- Use Braille labels or optical scanners to distinguish canned goods, medications, clothing colors, etc.
- Use devices that operate through voice commands.
- Use assistive devices that provide auditory, tactile, or kinesthetic feedback to compensate for low vision and blindness.
- Eliminate environmental clutter.
- Expect tasks to require extra time.

Low Vision

Some of the above principles are useful for those with low vision. Some others are:
- Provide high color contrast (e.g., white mug for coffee, colored towels in a white bathroom)
- Increase the light on a task by bringing the light closer, increasing wattage, or changing the background to increase contrast.
- Use techniques and devices that magnify type or images.
- Reduce visual clutter.
- Use organized scanning techniques (e.g., left to right or top to bottom) when functioning in a stationary environment.

Decreased or Absent Sensation

- Protect the anesthetic part from abrasions, bruises, cuts, burns, and decubiti.
- Develop habit of using areas with intact cutaneous sensation to test temperature, e.g., test bath water temperature with the forearm if finger sensation is impaired.
- Substitute vision for poor awareness of limb position and limb movement or to detect texture.
- Develop habits of directing attention to the affected part.
- Incorporate visual skin inspection into daily ADL routine.

Poor Memory and/or Executive Skills

- Use assistive devices that substitute for memory or poor organizational skills (e.g., pill minders, day books, sticky notes, or watches/phones/tablets with programmable alarms or reminder apps).

Procedures for Practice 25-3 *(continued)*

- Teach strategies such as writing memos to self, making to-do and other lists, and placing objects together at the point needed ahead of time.
- Develop habits regarding time use and how activities are to be accomplished.
- Teach self-awareness strategies to improve carryover of adapted methods or devices.

Low Back Pain and Post Back Surgery

- Teach body mechanics for moving and lifting (e.g., hold objects close to the body and squat to lower the body rather than bending over).
- Use long-handled or bent-handled equipment or sit to substitute for bending over.
- Change position frequently.

- When standing, put one foot up on a step to rotate the pelvis.
- Rest before fatigue results in awkward, careless movements.
- Avoid twisting the trunk, especially when lifting.

Obesity

- Ensure that adaptive equipment will accommodate the person's size (e.g., sock aids) and that durable medical equipment has been approved for the patient's weight.
- Use long-handled equipment to reach feet and perineum.
- Use compensation principles for decreased endurance and/or weakness, as appropriate.

Resources 25-1

The Internet has supported an explosion of online resources for persons with disabilities and the professionals who work with them. This section is organized by topic area. Books that are included in this section can all be purchased through an online book vendor, such as www.amazon.com or www.barnesandnoble.com.

General Online Resources

AbleData

www.abledata.com
Database sponsored by the U.S. Department of Education National Institute on Disability and Rehabilitation Research. It has information on almost 40,000 products including manufactured items, customized devices, and noncommercial prototypes.

The Boulevard

www.blvd.com/accent
Quarterly online magazine (previously *Accent on Living*) that addresses all aspects of living a full life with a disability and makes good suggestions for solving problems of persons with physical disabilities.

disABILITY Information and Resources

http://www.makoa.org/index.htm
Offers a wide range of links to information, vendors, and services. Maintained by Jim Lubin, a man with C2 quadriplegia.

NARIC (National Rehabilitation Information Center)

http://www.naric.com
1010 Wayne Ave., Suite 800, Silver Spring, MD 20910.
800-34-NARIC.
A bibliographical database of documents on rehabilitation that includes journals, unpublished documents, audiovisual materials, commercial publications, and government reports.

American Occupational Therapy Association

www.aota.org
AOTA's Occupational Therapy Buyer's Guide, a yearly supplement in *OTPractice*. Note: Access granted to AOTA members only.

Environmental Adaptations: Equipment, Modification, Installation Resources

The following sources focus on bathrooms, kitchens, and wheelchair lifts.

Accessible Environments, Inc.

http://www.acessinc.com/index.htm

Accessibility Professionals

http://www.ada-handicapped-showers.com/about_us.htm

Resources 25-1 *(continued)*

Barrier Free Architecturals, Inc.

http://www.barrierfree.org/

Online Vendors for Adaptive Equipment for Persons with Disabilities

Most vendors offer a wide array of products. Specialty vendors are indicated below, some with a brief description.

Active Forever

http://www.activeforever.com

AliMed, Inc.

http://alimed.com

Andicap

http://www.andicap.com

Be Adaptive Equipment LLC

http://www.beadaptive.com/
Adaptive equipment for hunting and fishing.

Dynamic Living.

http://www.dynamic-living.com
A range of daily living needs for people with varied disabilities and needs.

EnableMart

http://www.enablemart.com

Invacare

http://www.invacare.com/cgi-bin/imhqprd/index.jsp
Also a source for bathroom and other equipment for people weighing over 200 pounds.

North Coast Medical, Inc.

www.ncmedical.com

Patterson Medical
(formerly Sammons Preston Royalan)

http://www.pattersonmedical.com

Self-Wipe Toilet Aids

http://www.selfwipe.com
Sells a toilet aid for limited reach and grasp.

Online Vendors with Devices for the General Public

Several vendors are selling items aimed at making life easier for the general population. These products tend to be more "transparent" than those sold by medical vendors, and they are often less expensive because they cater to a much larger population.

Oxo International

http://www.oxo.com
Maker of Good Grips™ and many other products.

The Wright Stuff

http://www.wrightstuff.biz/

Comfort House

http://www.comforthouse.com/sicroomsup1.html

Carol Wright Gifts

http://www.carolwrightgifts.com

Dynamic Living

http://www.dynamic-living.com

Adaptations and Specialized Equipment for Activities of Daily Living for Specific Limitations

Resources and Products for Persons with Low Vision

Access-USA

http://www.access-usa.com
Supplier of Braille stickers (salt, pepper, food, beverage, and spice tags) and other Braille products, such as menus and maps.

Optelec

www.optelec.com
On-screen magnifier for low vision.

Lighthouse International

www.lighthouse.org

Independent Living Aids, Inc.

http://www.independentliving.com

Sight Connection

http://www.sightconnection.com

Resources 25-1 *(continued)*

En-Vision America

http://www.envisionamerica.com/

Resources and Products for Persons Doing Activities of Daily Living One-Handed

Mayer, T.-K. (2000). *One-handed in a two-handed world* (2nd ed.). Boston: Prince-Gallison, P.O. Box 23, Hanover Station, Boston, MA 02113-0001.

One-handed typing app

http://www.onehandkeyboard.org/

The Left-Hand Store

http://www.leftyslefthanded.com/

Resources for People of Exceptional Size

---

effective or safe. The therapist must know construction techniques needed to implement the solution when environmental modification is needed (e.g., anchor grab bars in studs) and should be familiar with local contractors who provide quality home modifications.

Procedures for Practice 25-4

Energy Conservation Methods (Carson, Gaya, & Milantoni, 2008; Matuska, Mathiowetz, & Finlayson, 2007)

- Rest.
  - Balance work and rest, including alternating heavy and light tasks.
  - Rest before fatiguing.
- Examine and modify standards and priorities.
  - Eliminate unnecessary tasks.
  - Combine or delegate tasks to reduce work.
- Reduce task demands.
  - Use good body mechanics.
  - Sit to work when possible.
  - Plan ahead. Organize work.
  - Use electrical appliances to conserve personal energy.
  - Use lightweight utensils and tools and assistive technologies.
  - Work with gravity assisting, not resisting.

6. Check it out. The assistive device or environmental modification should be checked out for reliability (always works as it should), durability (can withstand repeated use at the force levels the person will apply to it), safety, effectiveness, and patient satisfaction.

7. Train the person. The person must understand and be able to implement the safe use of the assistive device, environment, or method. Gitlin and Burgh (1995) suggested five aspects to device training: develop an activity in which to introduce the device, choose a site for instruction, determine the best time in the rehabilitation process to introduce the device, provide instruction that meets the patient's needs, and reinforce device use with the patient and caregivers. Guidetti and Tham (2002) reported that therapists also use important overarching strategies, such as building trust and motivating their clients, collaborating on goals, and selecting training methods uniquely suited to each client.

It is important to some people that assistive devices be transparent, that is, not call attention to the person as disabled or reveal the extent of disability. Use of conventional devices or gadgets that are sold to the general public qualify as transparent. Examples are felt-tipped pens, slip-on shoes, lightweight pots and pans, kitchen tools with large, grippy handles, and magnifying makeup mirrors. They become adaptive because of their specific application. This perception of transparency and its importance are unique to the individual. Transparency is becoming easier because the principles

of universal design focus on designing environments and products that are inclusive of the needs of all (Iwarsson & Stahl, 2003).

ACTIVITIES OF DAILY LIVING

This chapter describes methods and devices suggested by occupational therapy practitioners and former patients to enable independence in ADL and IADL. These suggestions are presented according to typical problems. Many patients have more than one problem. For example, persons with rheumatoid arthritis have weakness as well as limited range of motion. Persons with spinal cord injury have decreased sensation as well as weakness. The therapist will have to use information from pertinent sections for a patient with particular combinations of impairments. Procedures to enable ADL are presented. The need to do these activities and the task demands of each are fairly universal. However, because each person has unique constellations of IADL that describe their roles (James, 2014; Latham, 2008a), only representative IADL can be included as examples of solutions for particular problems.

All tasks that the patient expects to perform independently after discharge must be practiced as they will be done. For example, if a patient will bathe in a tub at home, it is inadequate to practice only sponge bathing while he or she is hospitalized. It is also crucial to address the more intermittent activities inherent in ADL, such as nail care, ear care, and menstrual care, and those ADL that are not universally engaged in, such as managing contact lenses, handling catheters, or flossing teeth. Do not assume that all self-care tasks that a particular person may need to learn are listed on an evaluation checklist.

Techniques and equipment for self-care presented in this chapter are not the only methods of accomplishing these particular tasks. This presentation is meant to provide the student or novice therapist with a repertoire of basic skills with which to approach patients with confidence. The principles of compensation for each problem are key pieces of information that allow the developing therapist to brainstorm a range of techniques or equipment that might meet the needs of a particular patient. For many tasks not mentioned here, either no adaptation is required or the adaptation can be extrapolated from the examples cited.

As each task is taught, all equipment should be close at hand. For early training in dressing, clothing that is a size too large should be used, because it can be managed more easily. The patient's attention should be called to design details of clothing, because persons with certain disabilities find some styles and/or fabrics easier to don. The details to be considered are the cut of the garment, sleeve style, type of fabric, and type of closure or fasteners (Dallas & White, 1982). Clothing especially designed for people with disabilities is now commercially available (see Resources 25-1).

Weakness

For other information and suggestions, see Chapters 12, 18, 26, 35, and 38 (see also Procedures for Practice 25-3).

Suggestions for Activities of Daily Living

When muscle weakness affects all four extremities and the trunk, the techniques and devices are extensive; therefore, this section focuses on compensation for whole body weakness. If the patient has lower extremity paralysis but has normal upper extremities, many of the techniques or devices are unnecessary. Often, compensation for trunk weakness is in the form of support to compensate for poor balance in sitting, standing, or both. Some of the principles described below apply as well to limited weakness, such as weak pinch secondary to osteoarthritis of the carpometacarpal joint.

When paralysis is extensive, a personal care assistant is needed to carry out ADL. The patient must learn to hire, supervise, instruct, compensate, set limits for, and terminate personnel (see "Management of Personal Care Assistants" in Resources 25-1).

Feeding. The problem with feeding is the inability to grasp and/or bring the hand to the mouth. A universal cuff can be used to hold the utensil if grasp is absent (Fig. 25-4). This cuff fits around the palm and has a pocket for insertion of the handle of a utensil for feeding, although it can also be used for other devices, as shown. Some universal cuffs include a wrist support if wrist extensors are weak. Alternatively, the utensil handle can be woven through the fingers, that is, index and ring fingers on top and middle and little fingers under, and held in place passively. A spork, a utensil that combines the bowl of a spoon with the tines of a fork (Fig. 25-5), can be used with the cuff to eliminate the need to change utensils. Some of these have a swivel feature to substitute for the inability to supinate. Gravity and the weight of the food keep the bowl level on the way to the mouth. If the patient has weak grasp, lightweight enlarged handles can be used. The patient may use a wrist-driven wrist–hand orthosis to increase the strength of palmar pinch (see Chapter 15), or an alternative design that was found to be effective in increasing lateral pinch strength and independence in a range of ADL (King et al., 2009). For cutting, a sharp serrated knife is used, because less force is needed, and it is less likely to slip. L-shaped rocker knives enable patients with weak grasp to apply force for cutting with stronger, larger proximal muscles.

An attachable open-bottomed handle can be added to a glass or soft drink can to permit picking it up in the absence of grasp. A mug with a T-shaped handle or a handle that allows all four fingers to be inserted (Fig. 25-6) provides leverage and stabilizes the fingers around the mug, allowing pick-up with a tenodesis grasp. A foam can insulator can be
Figure 25-4 **A.** Universal cuffs can be used to hold feeding utensils. **B.** They can also be used for many other items, such as grooming tools. (Both photos courtesy of North Coast Medical, www.ncmedical.com.)

used for a glass to provide friction to assist weak grasp. A long straw can be used to eliminate the need for lifting the cup to the mouth for drinking. *Safety Message: Using a cup with a lid, such as a commuter mug, minimizes the risk of spills in the event that the cup slips, reducing the risk of mess or injury for people with weak grasp, especially when drinking hot liquids.* Commuter mugs have the added benefit of being a transparent device.

A mobile arm support or suspension sling (see Chapter 15) may be required to enable patients with very weak proximal upper extremities to feed themselves. A table placed at axilla height offers support for the arm and eliminates the pull of gravity, allowing the patient with elbow flexors graded 3 or 3+ to bring the food to the mouth. As strength increases, the surface can be lowered. For patients who lack active upper extremity movement, powered feeders are available that are operated with a head or sip-and-puff switch (search "powered feeders" on AbleData's website, listed in Resources 25-1).

Grooming. Weakness in grasp and pinch are the most common barriers to grooming. Adaptations for makeup jars, tubes, and applicators have been suggested (Hage, 1988). Jar openers can be used to open twist-off caps, or products can be selected that open more easily, given the patient's capabilities, for example proximal muscles can be used to dispense toothpaste in a pump container. A universal cuff or a splint can be used to hold a rattail comb, toothbrush, lipstick tube, or safety razor if grasp is absent. A handcuff can be constructed to hold an electric razor. If grasp is weak, lightweight enlarged handles may be enough. Applying friction material to the utensil or tool can reduce force needed for maintaining a firm grasp and may be especially helpful for people with nerve

Figure 25-5 Spork (combination fork and spoon). This one also swivels to prevent loss of food when the patient cannot supinate.

Figure 25-6 Cup with large D-shaped handle assists drinking when grasp is weak. This cup has an oval shape that compensates for weakness or impaired motor control in directing liquid into the mouth.

Figure 25-7 Aerosol-can adapter that reduces the force needed to operate the spray.

injuries that also reduce sweating and limit the normal friction between the hand and task objects (Smaby et al., 2004). A small plastic brush with a cuff attachment may be used to assist in shampooing hair. Lengthening the force arm relative to the resistance arm may allow use of spray deodorant (Fig. 25-7) or nail care (Fig. 25-8, A & B).

Toileting. Transfers, proximal stability and balance while raising and lowering clothing, and weak pinch and grasp are common problems for people with significant weakness. Wheelchair users often require adaptations for the toilet, such as a raised toilet seat and toilet armrests. Alternatively, a commode can be used over the toilet, which both raises the height of the seat and provides armrests. People using a sliding board for transfers or who need to reach behind for toilet hygiene can use a drop-arm commode (Fig. 25-9). Commodes also offer flexibility; for example, they can be moved to the bedside to minimize transfers for people with mobility limitations who need to use the bathroom at night.

For people with spinal cord injury, concomitant loss of bowel and bladder control requires special procedures, including bladder irrigation, use of a catheter, or intermittent catheterization (Medline Plus, 2010a, 2010b). Generally, the person can push down the pants while in the wheelchair by leaning from side to side. If the person cannot stand or has precarious standing balance, it is necessary to transfer back to the wheelchair before raising the clothing after toileting. If the person uses an indwelling catheter or external drainage device, the collection bag can be emptied into the toilet without transfer or removal

Figure 25-8 Emery board and nail clipper with elongated handle stabilized to reduce force required (**A**) and for one-handed use (**B**).

Figure 25-9 A commode with the collection pail removed can be used in place of a raised toilet seat with toilet armrests. This commode has a "drop-arm" feature, which improves access for transferring and toilet hygiene.

of clothing. Usually, nurses or enterostomal therapists teach clean intermittent self-catheterization, but the occupational therapist should be aware of the process of this ADL:

1. Assemble the equipment.
2. Wash hands and penis or vulva and urethral opening. Clean gloves may be used, if desired.
3. Lubricate the catheter tip with water-soluble lubricant. Males hold penis at sides, and insert catheter with firm, gentle pressure. Females separate labia, palpate meatus or use a mirror, and insert catheter into the bladder.
4. Push catheter in until urine starts to flow.
5. Allow urine to flow until it stops, gently pressing on abdomen or bearing down to empty bladder.
6. Slowly remove the catheter, holding catheter tip as it is removed to prevent spilling.
7. Discard disposable catheters, or clean reusable catheters with soap and water, rinse, dry, and store in a plastic bag.
8. Wash hands with soap and water (Medline Plus, 2010a, 2010b).

Knee spreaders with a mirror help hold weak or paralyzed lower extremities in abduction and enable people with limited trunk control to see the urethral opening.

People on a bowel program may use suppositories or digital stimulation to initiate a bowel movement. Suppositories may be inserted while the person is in the bed or on the toilet. When people use digital stimulation or insert suppositories while on the toilet, a raised toilet seat with a space between the seat and toilet bowl rim is needed to allow them to reach the rectum. Suppository inserters for those with weak or absent pinch are commercially available and can be adapted with cuffs for patients who lack grasp. Some inserters have a spring ejector that releases the suppository after it is properly positioned in the rectum. An inspection mirror is needed if the patient lacks anal sensation. Bowel stimulators are available for patients who lack adequate digit control. People with weak grasp and pinch can wrap toilet tissue around the hand for use. For people with very limited hand function, bidets can be fit to the toilet to clean and dry the perineal area. Menstrual needs can be met by adaptations to positioning, pants, pad versus tampons, and aids such as mirrors and knee spreaders (Duckworth, 1986).

Bathing. The problems with bathing include the transfer, dynamic sitting balance, lack of lower extremity movement, and lack of pinch and grasp. Transfer tub seats (Fig. 25-10A), which have two legs in the tub and two legs

Figure 25-10 **A.** Transfer tub bench. **B.** For patients with a walk-in shower, a commode with the pail removed can double as a shower chair.

outside the tub, provide a safe means to transfer from the wheelchair to tub. For persons with a walk-in shower in their home environment, a commode with the pail removed can be used in the shower, eliminating the need for a separate piece of equipment (Fig. 25-10B). *Safety Message: Individuals who are prone to pressure ulcers need to use padded seats. Each person's requirements should be evaluated and a seat selected to fit him or her.* Users of tub seats (both patients and caregivers) have reported that safety, adequate support, stability of equipment, and comfort are some of the most important considerations in selecting appropriate equipment (Pain & McLellan, 2003). The tub seat must be placed so that the faucets are within reach. Grab bars help during the transfer and while the person is seated (Procedures for Practice 25-5). Nonslip material is used in the bottom of the tub. The faucets must have lever handles for ease in tapping them off and on with the fist or foot. A handheld shower that is adapted with a hook handle is used. *Safety Message: No-scald faucets and shower heads should be used, but if they are unavailable, water temperature should be regulated by turning on the cold water first and then adding the hot, which prevents scalding desensitized skin.* Soap on a string or in a wall-mounted dispenser is helpful. A bath mitt is used if grasp is weak or absent. The person dries off before transferring back to the wheelchair. A towel placed in the wheelchair seat will dry the perineal area and can be removed when the person transfers to the bed for dressing. Alternatively, some people don a terry cloth robe, which absorbs water without having to reach all areas. Bathing and drying the feet and legs are particular problems for people with poor trunk balance, and they may prefer to do foot hygiene while in bed (Shillam, Beeman, & Loshin, 1983).

A custom-made shower stall and shower wheelchair provide the easiest bathing solution for a person with tetraplegia, however, it typically requires an expensive home modification. The shower area should have a raised slope to prevent the water from running out but allow the person to enter the shower on a shower wheelchair. Prefabricated bath enclosures and remodeling designs are listed under "Environmental Adaptations: Equipment, Modification, Installation Resources" on Resources 25-1. Shower wheelchairs have commode seats and can be positioned over the toilet for bowel programs, reducing the number of transfers required for morning care. For people who prefer a bath, a number of electronic bath lifts are available that enable them to transfer onto a seat and then be lowered into the tub for independent or assisted bathing, depending on their needs.

Dressing. Dressing ability for persons with tetraplegia varies in both level of independence and time required. Individuals who are independent but require extensive additional time must decide whether this time requirement is acceptable or whether a personal care assistant is a better option. Problems with dressing include moving the paralyzed limbs to dress them, decreased sitting balance, and the need to compensate for the lack of pinch and grasp. Rudhe and van Hedel (2009) found moderate to strong correlations between dressing ability and both upper extremity strength and hand function. While in bed, people with spinal cord injuries at C6 and below can pull their knees up to dress the lower extremities by using their wrist extensors and elbow flexors. Loops of twill tape can be added to the cuffs of socks to facilitate pulling them on by hooking the thumb in the loop when pinch is absent.

A buttonhook attached to a cuff or with a built-up handle is used when fingers are unable to manipulate buttons (Fig. 25-2). The hook is inserted through the buttonhole to hook the button and pull it through the buttonhole. The other hand is used to hold the garment near the buttonhole. A loop of string or leather lacing may be attached to the zipper pull of pants or other garments so that in the absence of pinch, the thumb can be hooked in the loop to close the zipper. Alternatively, a zipper hook can also be used.

Adaptation of clothes should also be considered to facilitate dressing, undressing, and toileting; to regulate temperature; to increase comfort; and to increase feelings of self-confidence (Kratz et al., 1997; see Resources 25-1). For business people who are wheelchair users, suit jackets, pants, and skirts tailored to accommodate the sitting position look better than off-the-rack suits.

Initially, the occupational therapist may use the following adapted dressing techniques for persons with tetraplegia (Runge, 1967). Demonstrations of persons with spinal cord injury dressing, produced by the International Spinal Cord Society and Livability (2012), can also be viewed on the Internet, providing additional examples that underscore the need for an individualized approach to modifying self-care activities (see http://www.elearnsci.org/). You will need to establish a free account, which will give you access to many training videos embedded in educational modules for occupational therapists, including many on dressing.

Pants and Underwear

1. Have the patient sit in bed with the back against the head of an elevated hospital bed or against the wall. Pants are positioned with the front up and pant legs over the bottom of the bed.
2. The patient lifts one of his legs by hooking the opposite wrist or forearm under the knee, and puts the foot into the pants leg. The thumb of the other hand hooks a belt loop or pocket to hold the pants open. Working in a cross-body position aids stability for those with poor balance.
3. The other foot is inserted.
4. The palms of the hands are used to pat and slide the pants onto the calves and to get the trouser cuffs over the feet. The wrist or wrists are hooked under the waistband or in the pockets to pull the pants up over the knees.

Procedures for Practice 25-5

Grab Bars and Safety Rails for the Bathroom

Selection

Grab bars can be used in both the tub area and near the toilet, if it is close to a wall. Grab bars can be purchased from rehabilitation product vendors and many plumbing or home improvement stores. *Safety Message: Towel bars are NOT safe for use as a grab bar.* Grab bars must be able to support the person's weight, so recommendations should take the weight of the person into account. Grab bar specifications will include a weight limit.

Horizontal bars are for pushing up; vertical bars are for pulling up. An L-shaped grab bar that includes both vertical and horizontal legs is a good choice for the bathtub or shower enclosure. Clamp-on bathtub safety rails fix onto the edge of the tub, providing a secure handhold for stepping in and out of the tub; however, they cannot be used on fiberglass tubs because these tubs cannot withstand the stress.

The optimum diameter for grab bars is 1.25–1.5 inches for adults. The distance between the wall and the bar should be 1.5 inches (U.S. Access Board, 2004). A wider space is dangerous because if the arm slips, it may get caught between the wall and the bar and/or the person may fall.

Toilet armrests can provide the necessary support for using the upper extremities to transfer on and off the toilet. Some models are incorporated directly into a raised seat (Fig. 25-11), whereas other models bolt onto the toilet, providing more security for people with balance impairments who may weight the seat unevenly. Toilet armrests are easier to secure than wall-mounted grab bars and are typically better positioned than a wall-mounted bar, which may be too far away or available only on one side.

Placement

Locate bathtub grab bars where a person may be off balance, such as going into or out of the tub, turning in the tub or shower, or standing up from or sitting down on a bench or seat. One vertical bar outside the tub and one horizontal or diagonal bar on the wall along the length of the tub is recommended as a basic installation. An L-shaped bar can be substituted for the bar on the wall along the length of the tub. If an L-shaped bar is used, locate the horizontal bar 16 inches above the tub rim and the vertical bar approximately 32 inches from the corner of the tub or as the placement suits the height and transfer and bathing process of the user.

Installation

Grab bars must be mounted to the wall with 2-inch stainless steel screws driven into the wall studs. Use a stud finder to locate the studs. It may be necessary to locate the studs from the other side of the wall if the bathroom walls are tiled. The typical mounting flange has three holes for three screws. Drill a small pilot hole before drilling holes in ceramic tile, using an

Figure 25-11 Raised toilet seat with armrests to help with the transition to and from sitting.

eighth-inch masonry bit to drill three holes for the mounting screws. Only two screws will actually fit into the stud. Therefore, use a toggle bolt for the third screw. The length of horizontal bars must be the same as the stud spacing. Alternatively, existing walls can be cut into to add a horizontal 2 × 4 and then replace the wallboard in order to securely place a horizontal bar.

In new construction or during a renovation, double the studs where grab bars are to be fastened so there will be a 3-inch place to fasten the screws rather than the 1.5 inches offered by only one stud. For horizontal bars, add a 2 × 4 between the studs as a screwing surface or back a large area with plywood, which enables bars to be mounted in any place or desired orientation.

Suction grab bars are available for areas where it is not possible to secure a bar to the studs or a solid wall backing. These bars should be used with caution as weight capacity varies with security of the mounting surface and the direction of force on the grab bar. Suction grab bars are not ADA approved.

Toilet armrests attach using the bolts that hold the toilet seat in place. No alteration of the fixture itself is required.

5. The patient continues to pull on the waistband or pockets while returning to supine position to pull the pants up onto the thighs. This may have to be repeated. Hooking the wrist or thumbs in the crotch helps pull up the pants.
6. In a side-lying position, the thumb of the top arm is hooked in the back belt loop, and the pants are pulled over the buttocks. Then the patient rolls to the other side and repeats the process until the pants are on.
7. In a supine position, the pants can be fastened using a zipper pull loop and Velcro™ tab closing or button-hook.
8. The pants are removed by reversing the procedures and pushing the pants off.

An alternative method for getting the pant legs over the feet may be useful for patients with limited forward reach. The pants are positioned parallel to the patient's legs. The first leg is lifted and crossed over the other leg so the pant leg can be slid all the way over the foot, up to the knee. The leg is uncrossed and the second leg is slid in (Regional Spinal Cord Injury Center of Delaware Valley, 2001). To pull the pants over the hips, use the method described above.

Socks. Socks with tight elastic should be avoided. While sitting in the wheelchair or bed, the patient crosses one leg over the other and uses tenodesis grasp to put on the sock and the palms of the hands to help pull it on. If the patient cannot cross his or her legs, the foot can be placed on a stool or chair. Socks are removed by pushing them off with a dressing stick, long shoehorn, or the thumb hooked over the sock edge.

Shoes. Loafers that are a half to one size larger are most practical for people who cannot walk. Shoes are put on by crossing one leg at a time as for putting on socks. The shoe is pulled onto the foot by balancing the sole of the shoe in the palm of the hand. Then with the foot on the floor or on the foot pedal of the wheelchair, the foot is pushed down into the shoe by pushing on the knee. A long shoehorn may be helpful for getting the heel into the shoe. Shoes can be removed by pushing them off with the shoehorn.

Cardigan Garments: Shirts and Blouses

1. Shirts may be donned in either the wheelchair or bed. The shirt is positioned with the brand label of the shirt facing down and the collar toward the knees.
2. The patient puts his or her arms under the shirt and into the sleeves and pushes them up over the elbows.
4. The shirt is gathered up by using wrist extension and by hooking the thumbs under the shirt back.
5. The shirt is placed over the head.

6. The patient shrugs to get the shirt down across the shoulders and hooks the wrists into the sleeves to free the axillae.
7. The patient leans forward and reaches back with one hand to rub on the shirt back to pull it down.
8. The shirt fronts are lined up, and buttoning begins from the bottom button up, using a buttonhook. Alternatively, shirts can be adapted with Velcro™ fasteners.

A cardigan garment is removed by pushing first one side and then the other off the shoulders and then alternately elevating and depressing the shoulders to allow gravity to assist in lowering the shirt down the arms. Then one thumb is hooked into the opposite sleeve to pull the shirt over the elbow, and the arm is removed from the shirt.

With the exception of buttons, an overhead garment is put on in a similar manner and removed by hooking one thumb in the back of the neckline and pulling the shirt over the head. The sleeves are pushed off each arm.

Bra. Either a front- or back-closure bra can be used. Velcro™ can replace hooks for fastening, but some patients can manage the standard hook fastener if it is hooked in front at waist level. After the bra is hooked, it is positioned with the cups in front, and the arms are placed through the shoulder straps. Then, by hooking the opposite thumb under a strap, one strap at a time is pulled over the shoulder.

Sexual Activities. Many persons with disabilities have concerns about their sexuality and challenges to resuming sexual expression. Depending on the extent of weakness, patients may need help identifying positions that best support engagement in sexual expression. Much of the literature on sexuality and disability has focused on people with spinal cord injury and resulting impairment in sensorimotor function, including sexual function. Although they may not be ready to learn about the particulars of resuming sexual activities or procreation early in the rehabilitation process, knowing that they may have concerns about sexual expression and that there are a variety of sources of information for them when they are ready (McAlonan, 1996) should be discussed. Fisher et al. (2002) conducted a longitudinal study of people post-spinal cord injury that examined a range of issues, including the optimal timing of interventions addressing sexuality. Their findings suggest that people post-spinal cord injury are most interested in receiving information regarding sexuality in the 6 months following discharge from rehabilitation, suggesting that discussion during outpatient therapy or at follow-up appointments might be most appropriate for this population.

In a pioneering book, *Sexual Options for Paraplegics and Quadriplegics*, Mooney, Cole, and Chilgren (1975) explicitly

described methods of sexual expression for persons with spinal cord injury. They pictured the process of getting ready for sex (emptying the bladder, washing). They addressed how to handle a catheter that is left in place during sex (bend the catheter and fold it over along the shaft of the penis where it will be out of the way, but do not anchor it until the erection has taken place to avoid pulling out the balloon of the Foley catheter; be sure the tubing and collection bag are not leaned on to prevent the flow of urine). They presented positions for genital and orogenital sexual expression, alternative means of sexual expression (vibrators, touch, or talking), and how to achieve and maintain a reflex erection of the penis. They discussed fertility of men: ability to ejaculate depends on the level of the lesion, and production of sperm depends on healthy testicles. They pointed out that women remain fertile and therefore pregnancy is as possible as for able-bodied women. Although this book is out of print, it is available in many university libraries, and used copies are available through online booksellers, such as amazon.com and barnesandnoble.com.

Suggestions for Selected Instrumental Activities of Daily Living

For the persons with severe paralysis, high-tech adaptations as described in Chapter 18 offer opportunities to engage in communication, leisure, and work activities. Some low-tech adaptations are suggested here.

Handling a Book. The person with tetraplegia encounters problems with holding a book and turning the pages, with writing or recording notes in business or school, and possibly in telephoning. Some book holders support a book on a table, whereas others are designed to hold a book when reading supine in bed. If a person is reading while supine, and the book is not held directly above, prism glasses are needed to direct the vision to a 90° angle so that the book may be seen.

To turn pages, some solutions are as follows:

1. When wearing a splint, the person can use a rubber thimble or finger cot on the posted thumb.
2. A pencil with the eraser end down can be used in a universal cuff (typing stick) or hand splint.
3. Electric page turners automatically turn pages when activated by a microswitch or other means of control.
4. A mouthstick with a friction tip end may be useful. Mouthsticks may have flat mouthpieces or custom-molded mouthpieces that conform to the person's dentition. The mouthpiece has a lightweight plastic or aluminum rod to which an eraser or other type of end piece, such as pencil, pen, or paintbrush, can be added. AbleData has information on a wide range of mouthsticks (www.abledata.com).

An alternative is books that have been audio-recorded on tape, CD, or digital platforms, which can be obtained from libraries and bookstores. The Library of Congress has a large collection of tapes, including many current issues of magazines, and tape players that are available to the blind and the physically disabled for no charge through the National Library Service for the Blind and Physically Handicapped. Information about this service and a link to the catalog can be found at: http://www.loc.gov/nls/. Depending on a patient's limitations, an electronic reader may be easier to hold and manipulate than printed books. Some have a text-to-speech output feature that will read books for people and may be useful for those with severe weakness who are unable to lift and hold books or turn pages.

Writing. Extensive writing is usually done with computerized word processing. Keyboarding can be done with typing sticks or a mouthstick for hitting the keys. Voice recognition software is a better option for people who need to regularly create large amounts of text. If speed is important, as in taking notes in the classroom or in business, a tape recorder can be used.

Handwriting is important for legal documents and personalizing cards and typed notes. Splints that provide pinch can be used to hold a writing instrument. If pinch is absent, and the patient does not use a splint, a pencil holder (Fig. 25-12) that encircles the pencil, thumb, and index finger can be made of thermoplastic materials. Pens with textured grips provide friction to make a weak grip more effective. Felt-tipped pens require little pressure and are therefore easier to use than other types of pens. If the arms cannot be used, with practice a mouthstick with pencil attached can become an effective writing tool.

Opening Containers. Jar openers, including rubber sheets, clamp style, and mounted style, or pliers can be used to open jars, bottles, and pill bottles. In one study, a pop-off lid was found to require approximately 13 pounds of force to open, and medicine bottles required 2–6 pounds

Figure 25-12 Pencil holder made of thermoplastic material.

(Rice, Leonard, & Carter, 1998). If childproof containers are not necessary in a person's home environment, he or she can ask the pharmacist to use easy-open rather than childproof containers. Many over-the-counter medications and supplements can also be selected with easy-open caps.

Telephoning. As phone technology advances at a rapid pace, the occupational therapist exploring telephone options with persons with significant upper extremity weakness will need to identify what type of telephone is needed or desired. Home telephones frequently include a speaker feature, which eliminates the need to lift and hold the receiver. Buttons may be pushed with the eraser end of a pencil in a universal cuff or with a mouthstick. Speed dial options reduce the complexity of calls to commonly dialed numbers. Many mobile phones have voice-recognition features that enable the caller to dial through voice commands provided the person can activate the phone. Finally, voice-over-Internet calling provides another communication option for people who have accessible computers.

Turning Electrical Appliances On and Off. The expansive field of EADL, formerly known as environmental control units, includes remote control devices for TV, entertainment centers, VCR and DVD players, computers, cell phones, electronic tablets, lights, door openers, electric beds, and appliances. Voice-activated remote controls are available in specialty stores for operating the TV, VCR, and DVD player. See Chapter 18 for a discussion of high-tech assistive devices that are useful for persons with severe weakness or paralysis resulting from a spinal cord injury or degenerative disease such as amyotrophic lateral sclerosis. Many consumer electronics, such as tablets and mobile phones, offer features that enable access to people with a range of abilities, for example, many functions can be accessed through voice commands, making them accessible to people with limited hand function.

Low Endurance and Fatigue

For other information and suggestions, see Chapter 42. See also Procedures for Practice 25-3.

Suggestions for Activities of Daily Living

Endurance, a physiological characteristic, is the ability to sustain activity over time. General endurance is primarily a reflection of cardiopulmonary function and overall level of fitness. Fatigue is not simply low endurance, but a subjective experience of feeling tired or exhausted (Stout & Finlayson, 2011). Fatigue is multidimensional and includes cognitive, behavioral, and emotional components (Matuska, Mathiowetz, & Finlayson, 2007), as well as

physical factors. Patients of various diagnoses and circumstances (e.g., extended time in bed because of illness or injury) have low endurance and/or fatigue, which may be temporary or chronic. Many disorders cause a more or less permanent reduction of endurance to which patients must adapt, e.g., cardiac and pulmonary disease, or recurrent fatigue, e.g., multiple sclerosis, rheumatoid arthritis, and chronic fatigue syndrome. Patients with low endurance and/or fatigue may also have higher level cognitive impairments that impact learning. Fatigue can directly affect patients' memory, attention, and ability to process new information, whereas patients with severe cardiac and pulmonary disorders have reduced ability to use oxygen needed for muscle, including cardiac muscle, and brain functions. If oxygen deprivation is severe enough, neuropsychological changes involving memory, perception, and information processing may occur.

Adaptations for ADL and IADL for people with low endurance and/or fatigue involve education and training in self-management (Migliore, 2004; Taylor, 2004). People with low endurance learn to work within limits of cardiac and pulmonary capacity by reducing the energy demands of tasks and routines and by maximizing pulmonary function during ADL and IADL. *Safety Message: Cardiac patients are cautioned to stop activity when they have angina or shortness of breath (SOB). Patients with pulmonary disease may need to have blood oxygen saturation levels monitored with a pulse oximeter (see Chapter 42) during initial ADL training to establish levels of activity that do not reduce blood oxygen to harmfully low levels.* People who experience fatigue learn to monitor bodily signals to manage activity tolerance and to identify and manage cognitive-affective triggers of fatigue (Taylor, 2004).

Some activities require higher levels of energy than do others. One way to guide activity selection is to use metabolic equivalent (MET) tables. Most self-care activities require less than 3 METs. Ainsworth et al. (2011) have been compiling and revising a Compendium of Physical Activities since 1993 and now maintain a website with MET values for a wide range of activities at http://sites.google.com/site/compendiumofphysicalactivities/home. It should be remembered that MET charts are averages, do not account for particular circumstances, and therefore cannot be used without also monitoring the patient's breathing, heart rate, blood pressure, oxygen saturation levels, cognitive demands, or affective components. Dyspnea (SOB) is a signal for people with low endurance that the activity is beyond their cardiopulmonary capacity. Angina or excessive increase in heart rate (20 beats over resting rate) signals patients with a cardiac condition that they have reached their limit. Activity restrictions and precautions vary depending on the nature and severity of the cardiac disorder (Goodman & Smirnova, 2009). Adapted methods may be used to compensate for activity

restrictions, e.g., prolonged bending over may be avoided with long-handled utensils (described in this chapter in the section on limited range of motion). Patients with chronic obstructive pulmonary disease should learn to modify ADL methods to coordinate diaphragmatic and pursed lip breathing into activity routines to minimize dyspnea (Migliore, 2004).

Energy conservation is a primary intervention approach for patients with low endurance or fatigue. All patients with fatigue or reduced endurance are taught to take rest periods throughout the day and use other energy-conserving techniques. Principles of energy conservation are listed in Procedures for Practice 25-4 and elaborated on in Chapter 27. The principles themselves are relatively straightforward; however, they require people to change habits, which can be difficult to do but may be supported by having them set goals, monitor progress, and develop problem-solving strategies to promote goal attainment. In addition, adaptive methods, e.g., keeping frequently used items in the kitchen within easy reach, or adaptive equipment, e.g., using a long-handled sponge to eliminate bending in the shower, can support energy conservation strategies.

People with low endurance and fatigue should attend to getting sufficient sleep. Fatigue and sleep disturbances often coexist, creating a downward spiral of sleep deprivation and increasing fatigue. Sleep is identified as an area of occupational performance in the Occupational Therapy Practice Framework II (AOTA, 2008). Occupational therapists possess the skills needed for helping patients identify effective sleep hygiene, that is, habits that promote quality sleep. Strategies for the patient who is having trouble sleeping include developing a bedtime routine and schedule; avoiding consumption of alcohol, tobacco, and caffeine within 4 hours of bedtime; avoiding upsetting, important (e.g., paying bills), or stimulating activities (e.g., playing video games or answering e-mail) just before bedtime; and having a comfortable environment in which to sleep (Mastin, Bryson, & Corwyn, 2006).

Sexual Activities. The American Heart Association (2012) online article *Sex and Heart Disease* discusses the cardiovascular changes that occur during sexual intercourse, when the patient can resume sex after myocardial infarction or heart surgery, how other factors affect sex interest and capacity, guidelines for resuming sex, what to do if symptoms arise during sex, Viagra, and myths and misconceptions. The booklet can be helpful to both the patient and the health professional and can be ordered online at www.americanheart.org. Diaphragmatic breathing is facilitated in supine (Migliore, 2004), so individuals with pulmonary conditions may find dyspnea is easier to manage when lying supine during sexual activities. People with fatigue may need to plan sexual activities for a time of day or day of the week when energy levels are highest.

Limited or Restricted Range of Motion

For other information and suggestions see Chapters 36, 37, 39, and 40. See also Procedures for Practice 25-3.

Suggestions for Activities of Daily Living

Feeding. The most common problems with feeding that occur with limited range of motion are the inability to close the hand enough to grasp the utensil or inability to bring the hand to the mouth. Enlarged or elongated handles can be added to spoons or forks. Elongated handles may need to be angled to enable patients to reach their mouths. Remember that the longer the handle (resistance arm), the heavier and less stable the device; therefore, the handle should be only as long as is necessary and made of lightweight material.

A universal cuff, or utensil holder, can be used when grasp is not possible (Fig. 25-4). For some people, such as those with arthrogryposis, independent eating may only be possible with electric feeders. However, the device must be set up and cleaned up by an assistant, and some insurance carriers will not pay for both device and assistant. Another factor to be considered when prescribing this device: for an institutionalized person, being fed by another may be an opportunity for social contact that the device would eliminate (Hermann et al., 1999).

Grooming. The problems with grooming are the same as for feeding. Enlarged or extended handles can be attached to a comb (Fig. 25-13), brush, toothbrush, shampoo brush,

Figure 25-13 Long-handled comb. (Courtesy of North Coast Medical, www.ncmedical.com.)

lipstick tube, or safety razor. Aerosol deodorant, hair spray, powder, and perfume can be used by those with limited range. An assistant may be needed to wash and style hair if the person cannot reach the head to do it independently. A simple hairstyle may eliminate the need for blow-drying and styling.

Toileting. The problem with toileting is the inability to reach. The toilet tissue dispenser should be within reach. Wiping tongs can extend reach when using toilet tissue. If grasp is poor, the tissue can be wrapped around the hand, or wiping tongs with a cuff-shaped handle can be used. A bidet or personal cleansing system eliminates the need for wiping by hand. Gravity assists in pulling clothes down; loose clothes slide off easily. A dressing stick can be used to pull up the clothing (Fig. 25-14). Sanitary napkins with adhesive strips can be used more easily than tampons; the protective wrapper can be removed with the teeth. If limited range or movement precautions prevent the person from using a low toilet, a raised toilet seat may solve the problem (Fig. 25-11).

Figure 25-14 A dressing stick used to pull clothing up or around the body when reach is not permitted or possible.

Bathing. *Safety Message: Tub transfers are facilitated by grab bars. Nonslip material should be placed on the bottom of the tub.* A tub seat is used when a person is unable or not allowed to get down into the tub or up from the bottom of the tub (Mann et al., 1996). Different heights and styles of tub benches are available (Fig. 25-10A), and it is important to select the right one for each patient in terms of stability, ease of transfer, need for padding or back support, access to perineal area, and position of hips and knees. A handheld shower hose is used for rinsing if a tub seat is required; adding a strap can enable use by those with limited finger range of motion (Procedures for Practice 25-5). Alternatively, walk-in bathtubs have built-in seats and could be an option for people who prefer bathing to showering but are unable to get down into a standard tub. Whether using a tub seat or walk-in tub, it is essential to provide practice of strategies to bathe the back, feet, and perineal area when seated, especially if the patient also has impaired sitting balance. Lever handles on faucets are recommended because they do not require grasp and they allow better leverage for turning on and off. *Safety Message: For patients with hip precautions, it is important to position the tub seat so that faucets can be reached without excessive hip flexion.* It is helpful if the soap is on a string or to use soap and shampoo dispensers that can be fixed to the wall within easy reach. When grasp is limited, a sponge or terry cloth bath mitt works well. A long-handled bath sponge can be used to reach the feet or back; some are designed to hold the soap inside the sponge and others are designed especially for cleaning feet. A terry cloth bathrobe is effective for drying.

The following procedure is used for patients who cannot step over the edge of the tub and who require a transfer tub seat (Fig. 25-10A).

1 The patient walks to the side of the tub using assistive devices and weight-bearing precautions, as prescribed, and turns to face away from the tub.
2. The patient reaches for the back of the tub bench with one hand and the edge of the tub seat with the other.
3. The patient sits down on the tub bench and lifts both legs into the tub, turning to face the faucet, being careful to adhere to range of motion precautions for the leg(s), as appropriate.

Dressing. Lack of ability to reach and grasp, as well as restricted shoulder, back, hip, or knee range of motion, are limitations that cause problems in dressing. *Safety Message: Many patients post-total hip replacement will need to follow movement precautions for 2 months. A posterolateral surgical approach is commonly used, and while patients can typically bear weight as tolerated, they must avoid flexing the hip past 90°, adducting the leg past midline, or externally*

rotating the leg) (van Stralen, Struben, & van Loon, 2003). Other surgical techniques or complications may necessitate different precautions, so therapists must always confirm activity precautions prior to treatment (see also Chapter 36).

Reaching clothes from closets and dressers and dressing the lower extremities are common problems for people who cannot reach their feet or who are not allowed to flex the hip. A dressing stick can be used to pull clothing over the feet (Fig. 25-14) or to reach hangers in the closet. Reachers can be used to remove clothes from shelves, to start clothes over parts of the body, and to pick up objects from the floor (Fig. 25-15, A & B). People can don socks using a sock or stocking aid and use a dressing stick to remove socks (Fig. 25-16, A & B). To use a stocking aid, the trough is inserted into the foot of the stocking; the top of the stocking is pushed down below the top edge of the trough. While the strings are held, the stocking aid with stocking in place is placed on the ground, and the person's foot is moved into the trough until the toes reach the tip of the stocking. The aid is then removed by pulling the strings, bringing it out of the stocking behind the heel. This brings the stocking within reach so it can be pulled up the leg. Patients with a temporary range-of-motion restriction, such as those post-total hip replacement, may opt to go without socks for that time period. A long shoehorn assists in putting on shoes when the feet cannot be reached. Some long shoehorns have a hook on the opposite end that may be used as a dressing stick. *Safety Message: Positioning the shoehorn between the legs, rather than on the lateral aspect of the foot,*
Figure 25-15 **A.** Reacher with a pistol grip and suction cup tips. **B.** Reacher in use.

Figure 25-16 **A.** Stocking aid in use. (Courtesy of North Coast Medical, www.ncmedical.com). **B.** Socks are removed using the inverted hook on a dressing stick.

reduces the chance that the patient will move the hip into internal rotation when donning shoes. Slip-on shoes and elastic shoelaces avoid the need to tie shoelaces. Collaborating with patients to select the equipment they view as most helpful and providing adequate training with opportunity to practice increase the likelihood that patients will use the adaptive equipment effectively after discharge (Kraskowsky & Finlayson, 2001).

Dressing the upper body with limited upper extremity range of motion is easier when using button- or zipper-front garments rather than over-the-head garments. A dressing stick or reacher is used to bring the garment around the shoulders. Fasteners are particularly difficult, especially if limitation in the range of motion is accompanied by weakness. A study that examined the ability of 97 women with arthritis to manage clothing fasteners found that zippers were the easiest to use, especially easy-sliding, large-toothed plastic type. Snaps and buttons were rated as difficult, although vertical buttonholes made buttoning easier (Dallas & White, 1982). Velcro™ tabs can replace buttons, snaps, or hooks if limited mobility in the fingers prevents buttoning or fastening. Because few clothes come with this type of fastener, the patient's clothing must be adapted. To preserve the look of a buttoned garment, the buttonhole is sewn closed and the button is attached over the hole. The hook and pile Velcro™ tabs are sewn to replace the buttons.

Sexual Activities.   If a person's range of motion limitations are accompanied by pain and stiffness (e.g., with rheumatoid arthritis), the person should time pain relief medication so its effects are greatest during sexual activities. A warm bath may reduce joint stiffness as well as serve as a part of foreplay. Satisfying sex includes romance and intimacy even though engaging in intercourse may be too difficult or painful soon after injury or during a flare-up of arthritis. People should explore options for skin-to-skin contact that do not cause pain. The occupational therapist and patient can problem solve together to identify new, comfortable, and biomechanically safe positions for intercourse and other forms of sexual expression. For example, both partners may lie on their sides with a man entering from behind for a partner with hip problems; both partners may lie on their sides facing each other with one person providing most of the hip movement, for a partner with back problems (American College of Rheumatology, 2012).

Sexual activities such as touching, holding hands, and caressing can be resumed immediately after total hip joint replacement, but patients should follow their surgeon's guidelines for resuming intercourse. Positions during all sexual activities should be consistent with hip precautions. A booklet, *Sex after Joint Replacement*, is available for a nominal fee at http://mediapartnersinc.com/products/catalog/cat_JSEXBK.htm.

Suggestions for Selected Instrumental Activities of Daily Living

Writing.   If finger range of motion is limited, the size of the writing instrument can be increased by using cylindrical foam, passing the instrument through the holes in a practice golf ball, using commercially available grips that slip on the instrument, or using a comfort-grip pen.

Telephoning.   Cordless or mobile phones can be positioned near the person to reduce the reaching distance required. People who cannot grasp the phone or lift it to their ear may benefit from a phone with a speaker feature or from a hands-free device.

Shopping.   Online shopping is common, convenient, and economical. People who need to access shops can enlist the help of clerks. Many grocery stores offer this service to people with disabilities to help them get out-of-reach items too heavy to be obtained by use of a reacher (Fig. 25-15B). Shopping during the off hours might increase the likelihood that clerks are available to assist.

Gardening.   Strategies that reduce range of reach include the use of raised beds, wearing a carpenter's apron with pockets to keep tools in easy reach, and minimizing planting and weeding, for example, the use of low-maintenance perennial plants. Use tools with ergonomic grips (Fig. 25-3). Use of a rolling or stationary stool to sit while working reduces the range of motion in trunk and lower extremities required to work at the ground level.

Incoordination and Poor Dexterity

For more information and suggestions, see Chapter 35. See also Procedures for Practice 25-3.

Suggestions for Activities of Daily Living

Teach patients to use the body in as stable a posture as is possible, to sit when possible, and to stabilize the upper extremities by bearing weight on them against a surface or by holding the upper arms close to the body, or both (Gillen, 2000). Stabilizing the head may improve a person's ability to control the upper extremities. Friction surfaces, weighted utensils, or weighted cuffs (Fig. 12-14) added to the distal segments of the extremities, and the use of larger and/or less precise fasteners all contribute to increasing independence by lessening the effects of the incoordination (McGruder et al., 2003). For involuntary movements, for example, intention tremors or ataxia, splints may be used to stabilize selected joints, reducing the degrees of freedom that must be controlled by an individual during an activity (Gillen, 2000).

Feeding.   The plate can be stabilized on a friction surface, such as a damp towel or nonskid mat. A plate guard

or scoop dish can be used to prevent the food from being pushed off the plate. The utensil may be weighted for stability, have an enlarged handle to facilitate grasp, and/or be plastic coated to protect the person's teeth. Sharp utensils should be avoided. A weight cuff on the wrist is often chosen rather than a weighted utensil because the cuff can be heavier; also the cuff makes it unnecessary to weight each item that the patient will use. Weighted cuffs may improve food-to-mouth time, decrease spills, and diminish tremor during eating (McGruder et al., 2003), compared to feeding with no weight. A person may successfully drink from a covered glass or cup with a sipping spout or opening. Some may use a long plastic straw that is held to the side of the cup or glass by a straw holder attachment; the person moves the head to the straw but does not touch it or the cup or glass with the hand. People with incoordination may consider food choices that minimize spilling or staining (e.g., avoiding soups and foods with sauces), particularly when dining outside of the home. In the home, protecting the clothes with a cloth or bib may be desired to minimize soiling clothes and increase satisfaction with the feeding experience.

Grooming. Weighted cuffs on the wrists may help some patients gain greater accuracy while grooming. Standing in a corner enables people with incoordination to stabilize their trunk and head on the wall to the side, and their forearms on the wall in front for activities involving the face, such as brushing teeth, shaving, applying make-up (Gillen, 2000). Large lipstick tubes are easier to use than small ones. The arms must be stabilized to use lipstick. A simple hairstyle is the best choice. For a person who has difficulty holding a large-handled comb, a brush without a handle and with a strap attached across the back of it can be used. Stick deodorant is preferred to spray because it eliminates the risk of accidentally spraying the eyes. *Safety Message: An electric razor is preferred to a safety razor both because it is more easily held and because a safety razor can cut if it is moved sideways over the skin.* People with fairly good head control improve their accuracy shaving by holding the electric razor steady and moving the face over the cutting surface. An electric toothbrush is also useful both because it is heavier and because it can be held steady while the head is moved. This same principle can be employed when filing the nails: fasten the emery board to a flat surface and move each nail over the emery board. Cutting the nails may be unsafe for incoordinated patients, so filing is recommended.

Toileting. The principles described above can be applied to toileting. People with incoordination who require self-catheterization may have difficulty inserting the catheter into the urinary meatus. For women, the Asta-Cath female catheter guide (available online through many sources) helps spread the labia and guide the catheter accurately into the urinary meatus (Ryan & Sullivan, 2011). Sanitary napkins with adhesive strips to hold them in place may be easier to use than tampons.

Dressing. Clothes that facilitate independent dressing are front-opening, loosely fitting garments with large buttons, Velcro™ tape closures, or zippers. Wrinkle-resistant and stain-shedding materials enable the person to look well groomed throughout the day. To overcome difficulty with buttoning, a buttonhook with an enlarged and/or weighted handle, if necessary, can be used. A loop of ribbon, leather, or chain can be attached to the zipper pull so that the person can hook it with a finger instead of pinching the zipper pull. Velcro™ can be substituted to eliminate the need to fasten hooks on a bra. To don a bra, it is easier for the woman to put it around her waist, which is thinner and puts less tension on the garment, then fasten it in front where she can use vision to help guide movements, turn it around, put her arms in, and pull it up into place. Elastic straps or elastic inserts sewn into the straps make this relatively easy. If strength is adequate, a sports-style bra may be used, which eliminates the need for fasteners. A man who wears ties may choose to slide the knot down and pull the tie off over his head without undoing the knot.

Slip-on shoes should be worn, when possible. A shoehorn or foot funnel (available at http://www.footfunnel.com/) may be helpful, particularly for the person with lower extremity ataxia, to preserve the back of the shoe and aid in donning shoes. If tie shoes need to be worn, a variety of lacing aids are available, including elastic laces, which eliminate the need for managing any type of fastener, but create a tighter fit that may hinder slipping the shoe on and off.

Bathing. A person with incoordination may be able to shower or bathe independently but must adhere closely to safety precautions. Slipping is more likely, and often his or her ability to regain lost balance is delayed. Nonslip material should be used in the bottom of the tub, and a nonskid mat should be placed outside the tub to reduce the risk of slipping while stepping in or out of the tub. Safety grab bars should be placed where they would be most useful to the particular person's needs. A tub bench or seat can eliminate the difficulty of sitting in and getting up from the bottom of the tub or stepping over the tub to shower. Walk-in tubs are a practical, but expensive, option for people who have difficulty stepping into the tub, particularly if they desire a tub bath instead of a shower. Showering or bathing from a seated position reduces the risk of slipping and provides a stable position for people as they wash their feet. If a seat is used in the shower, a handheld shower spray is necessary.

Safety Message: Whether the person chooses to shower or bathe, the water should be turned on after

the person has transferred in and is seated to reduce the risk of slipping on wet surfaces and splashing water outside of the tub area. A mixer tap is ideal, but if it is unavailable, the cool water should be turned on first and the hot water added to prevent scalding. Soap on a string keeps the soap retrievable, or a bath mitt with a pocket to hold the soap is useful. The water should be turned off and the tub drained, if taking a bath, before the person attempts to stand to transfer out of the tub. An extra large towel or large terry cloth wraparound robe facilitates drying.

Suggestions for Selected Instrumental Activities of Daily Living

Communication. Writing and speech are problems for some persons with coordination deficits. See Chapter 18 for alternative communication systems and adaptations for computers that are appropriate for these patients. If a person's speech is intelligible, the use of a large-button phone reduces the fine motor requirements of dialing the telephone, or a speaker phone with voice-activated dialing can be used.

Playing Games. Board game pieces can be weighted or turned into pegs for stability. Game boards can be reproduced to enlarge the squares. Card holders and card shufflers are useful. Computer games that use keyboarding or switches rather than a mouse or joystick are appropriate.

Loss of Use of One Side of the Body or One Upper Extremity

For other information and suggestions, see Chapters 33, 37, and 41. See also Procedures for Practice 25-3.

Suggestions for Activities of Daily Living

The methods described here pertain to the person with hemiplegia who has lost the use of one side of the body. Some patients post stroke will retain or regain some functional use of the involved upper extremity, increasing the likelihood they will regain independence in their ADL. Techniques for weakness and/or incoordination may be useful for patients who can use the affected arm. However, other patients will have deficits that preclude use of one side of the body. Additionally, they may be prevented from developing independence by cognitive-perceptual impairments, especially of the less automatic tasks, such as one-handed upper extremity dressing (Árnadóttir, 2011; Fletcher-Smith, Walker, & Drummond, 2012; Walker & Walker, 2001). Motor planning deficits, such as ideomotor apraxia, may make learning new skills more difficult; however, patients have been able to learn a new motor process, such as one-handed shoe tying (Poole, 1998).

Figure 25-17 Rocker knife for one-handed cutting.

The methods and equipment described here may also be used by a person with a unilateral upper extremity amputation or temporary or permanent upper extremity limitations resulting from trauma. However, patients with upper extremity amputation or injury need fewer adaptations because they have normal trunk and lower extremity function and normal perception and cognition.

Feeding. Feeding is essentially a one-handed task, except for cutting meat and spreading condiments on bread, and these tasks can be done with assistive devices. Food can be simultaneously stabilized and cut by use of a rocker knife, a knife with a sharp curved blade that cuts when rocked over the food (Fig. 25-17). Condiments can be spread on bread if it is stabilized on a nonslip surface or trapped in the corner of a spike board (Fig. 27-2) and spread toward the corner. Soft spreads facilitate this process.

Grooming. Difficulties with grooming include care of the unaffected extremity and completing two-handed activities. Spray deodorant for the unaffected arm is easier to use than other types of applicators. Fingernails of the unaffected hand are cleaned by rubbing them on a small suction cup brush attached to the basin (Fig. 25-18). Fingernails of the affected hand can be trimmed with a stabilized nail clipper (Fig. 25-8A), and those of the unaffected hand, with an emery board fastened down to stabilize it. The fingernail is moved back and forth over the emery board (Fig. 25-8B). Toothpaste in pump bottles or a toothpaste dispenser can be used with one hand. A floss holder or disposable flossers enable patients to floss teeth one-handed.

Using another suction cup brush fastened to the inside of the basin, the person can scrub dentures by rubbing them over the brush. Partially filling the basin with water and laying a face cloth in the bottom cushions the dentures if they are dropped. Patients post stroke should use an electric razor for shaving because they are no longer able to hold the skin taut with one hand during shaving, increasing the risk of cuts.

Figure 25-18 Suction cup brush for cleaning nails or dentures one-handed.

Toileting. The primary difficulty with toileting is managing clothing, which is normally done with two hands. A grab bar mounted on the wall beside the toilet and/or a frame mounted on the toilet (Fig. 25-11) will assist transfers and maintaining standing balance. Once standing, pants are unfastened, and gravity pulls them down. If the person's standing balance is impaired, pants should be unfastened before standing and the affected hand placed in the pocket, which prevents the pants from sliding below the knees where they are difficult to retrieve. A woman in a dress can raise her dress on the affected side and tuck it between her body and the affected arm. Then she lowers her underpants to knee level and pulls the dress up on the unaffected side. The toilet tissue should be mounted conveniently to the unaffected side. A woman can manage menstrual needs by use of tampons or adhesive sanitary napkins.

Bathing. The bathing arrangements described for people with incoordination also apply to people with hemiplegia who may also find a long-handled bath sponge with a pocket to hold the soap useful to allow bathing of the unaffected upper arm and the back. The lower part of the arm of the unaffected side is bathed by putting the soapy washcloth across the knees and rubbing the arm back and forth over it, unless the patient has some return of function and can use a bath mitt on the affected hand. Pump bottles of liquid soap and shampoo are useful, as is soap on a rope. If sensory impairment exists, extra precautions should be taken to be certain of water temperature. Patients with hemiplegia should dry off as much as possible while still seated on the bath seat before transferring out of the tub.

A person with a unilateral upper extremity amputation can bathe using similar strategies. A bath bench enables individuals to place a washcloth on one leg to enable them to wash the unaffected arm without balancing on one leg, which may present a safety risk for people who lack excellent balance.

Dressing. Certain prerequisite abilities are considered important for successful dressing. These are ability to reach each foot, stand unsupported for 10 seconds, and maintain sitting balance when reaching down. The most difficult tasks for both men and women were found to be pulling pants up, putting the shoe on the affected foot, and lacing shoes (Walker & Lincoln, 1991). Many people can manage fasteners one-handed. Patients who have difficulty with one-handed fastening may prefer Velcro™ fasteners, which are easier to use.

Patients with hemiplegia should dress while seated on a stable surface with both feet on the floor to increase stability (Ryan & Sullivan, 2011). As a general rule, the affected limb is dressed first and undressed last.

Shirt or Cardigan Garment: Over-the-Shoulder Method (Ryan & Sullivan, 2011). The over-the-shoulder method is the most similar to the customary method of dressing and garments are less likely to get twisted than when using the overhead method that follows.

1. Put the shirt on the lap, label facing up, collar toward the abdomen, with the sleeve for the affected arm hanging between the knees (Fig. 25-19A)
2. Put the affected hand into the sleeve and lean forward to let gravity extend the elbow and to slide the sleeve onto the arm (Fig. 25-19B).
3. Grasp the collar at the point closest to the unaffected side (Fig. 25-19C).
4. Hold tightly to the collar, lean forward, and bring the collar and shirt around the affected side and behind the neck to the unaffected side (Fig. 25-19C).
5. Put the unaffected hand into the other armhole. Raise the arm out and up to push it through the sleeve (Fig. 25-19D).
Figure 25-19 Patient with left hemiplegia putting on a shirt. **A.** Position the shirt with the collar toward the knees and the sleeve for the affected arm hanging between the legs. **B.** Guide the affected arm into the sleeve, lean forward, and pull the sleeve up to the shoulder. **C.** Hold the collar tightly. Lean forward and bring the shirt up, around, and behind toward the unaffected arm. **D.** Put the unaffected arm into the armhole. Extend the arm out and up to push it through the sleeve. Straighten the shirt and button it.

6. To straighten the shirt, lean forward, work the shirt down over the shoulders, reach back and pull the tail down, and then straighten the sleeve under the affected axilla.
7. To button, line up the shirt fronts and match each button with the correct buttonhole, starting with the bottom button.

To remove the shirt, unbutton it and use the unaffected hand to throw the shirt back off the unaffected shoulder. Work the shirt sleeve off the unaffected arm, pressing the shirt cuff against the leg to pull the arm out. Lean forward. Use the unaffected hand to pull the shirt across the back. Take the shirt off of the affected arm.

Shirt or Cardigan Garment: Overhead Method (Brett, 1960). The overhead method for putting on and removing front-opening tops may be less confusing for a patient with selected perceptual impairments or limited reach in the unaffected upper extremity. This method is not suitable for coats.

1. Put the shirt on the lap, label facing up, and the collar next to the abdomen; drape the shirttail over the knees (Fig. 25-20A).
2. Pick up the affected hand and put it into the sleeve (Fig. 25-20B).
3. Pull the sleeve up over the elbow (Fig. 25-20C). If the sleeve is not pulled past the elbow, the hand will fall out when continuing.
4. Put the unaffected hand into the armhole. Raise the arm and push it through the sleeve as far as possible (Fig. 25-20D).

5. Gather the back of the shirt from tail to collar (Fig. 25-20E).
6. Hold the gathered shirt up, lean forward, duck the head, and put the shirt over the head (Fig. 25-20F).
7. To straighten the shirt, lean forward and work the shirt down over the shoulders. Often, the shirt gets caught on the affected shoulder and must first be pushed back over the shoulder. Then reach back and pull the tail down (Fig. 25-20G).
8. To button, line up the shirt fronts and match each button with the correct buttonhole, starting with the bottom button.

To remove the shirt, the patient unbuttons it, leans forward, and uses the unaffected hand to gather the shirt up in back of the neck. He or she ducks the head, pulls the shirt over the head, and then takes the shirt off the unaffected arm first.

Pullover Garment. The following steps are used for putting on a pullover garment.

1. Position the garment on the lap, bottom toward chest and label facing down.
2. Using the unaffected hand, roll up the bottom edge of the shirt back, all the way up to the sleeve on the affected side.
3. Spread the armhole opening as large as possible. Using the unaffected hand, place the affected arm into the armhole and pull the sleeve up onto the arm past the elbow. Alternatively, the sleeve may be positioned between the legs and as described above for the cardigan over-the-shoulder method.
Figure 25-20 Patient with left hemiplegia putting on a shirt, overhead method. **A.** Put shirt on the lap, label facing up, collar next to abdomen, shirttail draped over knees. **B.** Pick up the affected arm and put it into the armhole. **C.** Pull the sleeve well over the elbow. **D.** Put the unaffected hand into the armhole, and raise the arm to push it through the sleeve. **E.** Gather the back of the shirt from the tail to the collar. **F.** Hold the gathered shirt up. Lean forward and duck the head to put the shirt overhead. **G.** To straighten the shirt, lean forward and work the shirt over the shoulders. Reach back and pull the tail down and the front sides forward. Button it.

4. Insert the unaffected arm into the other sleeve.
5. Gather the shirt back from bottom edge to neck, lean forward, duck the head, and pass the shirt over the head.
6. Adjust the shirt on the involved side up and onto the shoulder and remove twists.

To remove, starting at top back, gather the shirt up, lean forward, duck the head, and pull the shirt forward over the head. Remove the unaffected arm and then the affected arm.

Bra. Some patients prefer to use a jogging bra and don it using the overhead method described for a shirt. If the woman prefers to use a regular bra, it is placed around the waist and hooked in front, where she can see what she is doing. Front-fastening bras are easier, because they do not

need to be twisted around the trunk once fastened (Ryan & Sullivan, 2011). One end can be tucked into the waistband of panties or under the affected arm until the other end is brought around, if needed. It is fastened and rotated to the proper position, the affected arm is placed through the shoulder strap, and the unaffected arm is placed through the other shoulder strap. The bra is pulled up into place. It is removed by reversing the process.

A plump woman may need an adapted front-closing bra if she cannot approximate the two edges of the bra to fasten it. The bra is adapted with a D-ring on the side of the bra opening on the involved side and a pile Velcro™strap on the opposite side. After the bra is around the waist, the strap is threaded through the D-ring and pulled to bring the two ends of the bra together. Hook Velcro™ must be stitched onto the bra so the strap can be fastened.

Pants. The following steps describe how to put on pants (Ryan & Sullivan, 2011). Modifications of the following method are used for men's and women's underclothing and pantyhose.

1. Sit. If a wheelchair is used, the brakes should be locked and the footrests should be up and/or swung out of the way. Move the unaffected leg beyond the midline of the body for balance (Fig. 25-21A).
2. Grasp the ankle or calf of the affected leg. Lift and cross the affected leg over the unaffected leg (Fig. 25-21, A & B). Alternatively, cup the affected knee in clasped hands to lift and cross the leg.

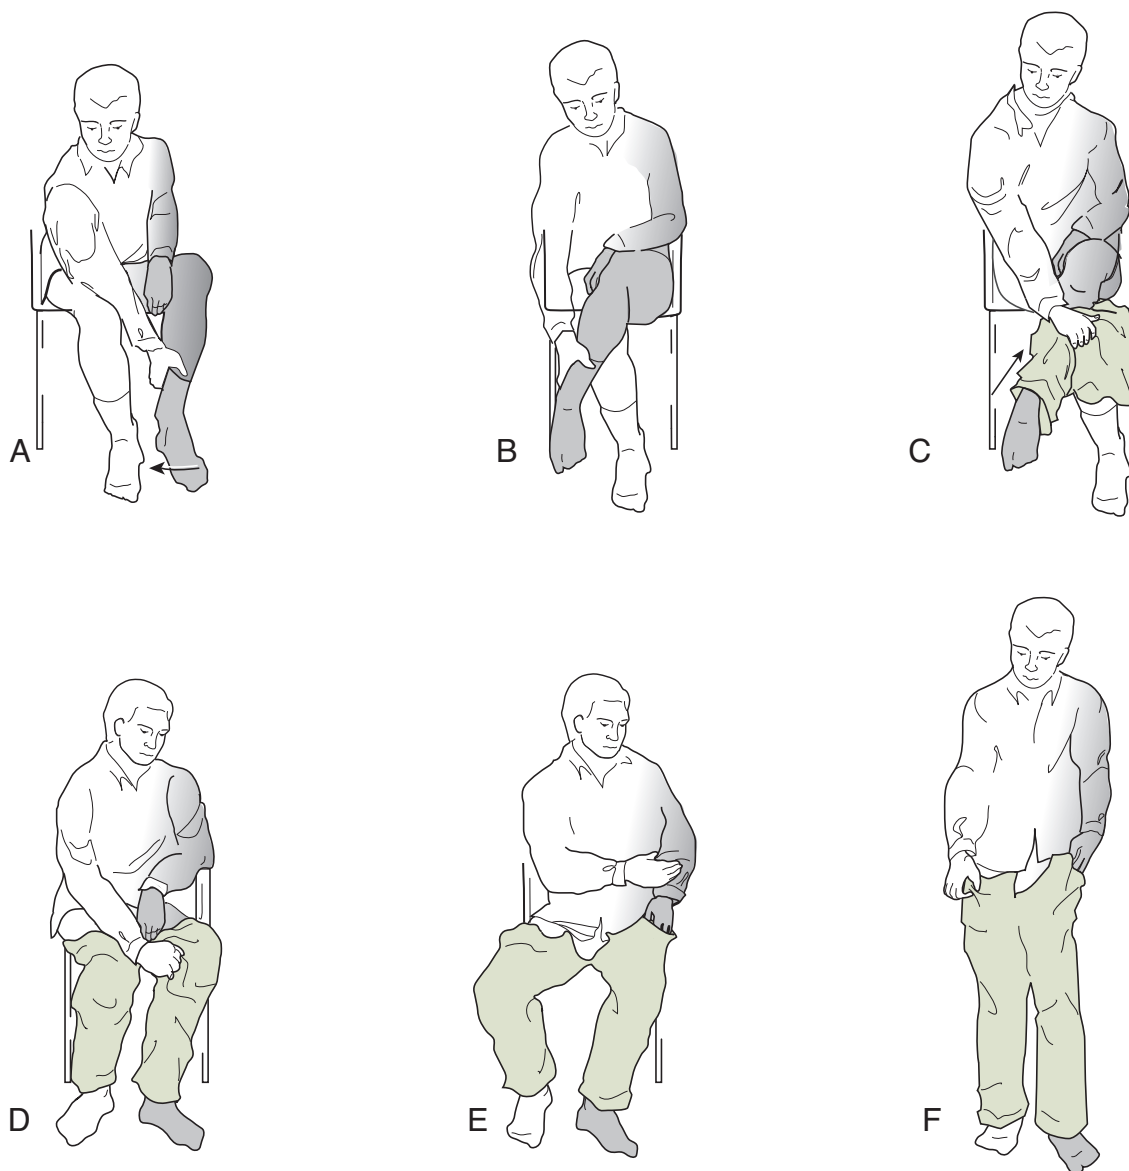
3. Pull the pants onto the affected leg up to but not above the knee (Fig. 25-21C).
4. Uncross the legs.
5. Put the unaffected leg into the other pant leg.
6. Remain sitting. Pull the pants up above the knees as far as possible (Fig. 25-21D).
7. To prevent the pants from dropping when standing, put the affected hand into the pant pocket or the thumb into a belt loop (Fig. 25-21E). Alternatively, use a pant clip to attach the pants to the shirt so they do not slide down. Pants with elastic waistbands are also less likely to slide when standing up.


Figure 25-21 Patient with left hemiplegia putting on pants while sitting. **A.** With knees bent, move the unaffected foot across the midline of the body toward the unaffected side. **B.** Grasp the ankle of the affected leg, lift it, and cross it over the unaffected leg. **C.** Pull the pants onto the affected leg up to but not above the knee. **D.** Uncross the legs, put the unaffected leg into the pants, and pull them up above the knees. **E.** To prevent the pants from dropping when the person stands up, put the affected hand into the pocket. **F.** Stand up. Pull the pants over the hips and fasten, or sit to fasten if balance is not good enough to do it while standing.

8. Stand up. Pull the pants up over the hips (Fig. 25-21F); button and zip pants while standing. Persons with poor balance may remain seated and pull the pants up over the hips by shifting from side to side; they should button and zip the pants while seated.

To remove, unfasten the pants while sitting. Stand and let the pants drop past the knees or push down if wearing elastic-waist garment. Sit. Remove the pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg. Uncross the legs.

Persons with poor balance should use this method: Place locked wheelchair or chair against a wall. Sit. Unfasten the pants. Work the pants down on the hips as far as possible by shifting weight from side to side in the chair. Use the unaffected arm to work the pants down past the hips. Remove the pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg. Uncross the legs.

Socks or Stockings. The following method is used to put on socks or stockings.

1. The affected leg is crossed over the unaffected as described above for donning pants. Or, if the patient has adequate flexibility, crossing the ankle over the thigh makes the foot easier to reach. The same process is used for the unaffected foot.
2. The sock is opened by inserting the thumb and index finger into the top and spreading the fingers.
3. The sock is put on the foot by slipping the toes into the opening made under the spread hand. The sock is then pulled into place, and wrinkles are smoothed.

People who cannot cross their legs can rest the heel on a small stool. People who cannot reach their feet may use a reacher to start the sock over the toes, but they will need to reach down to pull the sock over the heel. Although sock aids are effective for overcoming limited reach, getting the sock on most sock aids is difficult or impossible with one hand, so this device will not be helpful for most people with use of only one hand.

To remove, the leg is positioned as for putting the sock on. The sock is pushed off with the unaffected hand.

Shoes. A loafer is put on the affected foot with the shoe on the floor. The foot is started into the shoe, and a shoehorn is used to help ease the foot into the shoe. A tie shoe is put onto the affected foot after the leg is crossed over the unaffected one to bring the foot closer. If the laces have been thoroughly loosened, the person often can work the shoe on while the leg is crossed over by grasping the heel of the shoe with the unaffected hand and working it back and forth over the heel until it goes on completely. Sometimes it is necessary to insert a shoehorn while the leg is crossed over and then carefully lower the foot with the shoe half on and shoehorn in the shoe and finish putting on the shoe by repeatedly pushing down on the knee and adjusting the shoehorn.

Tying the shoes is a problem. It is possible to tie a conventional bow one-handed, but it requires fine dexterity and normal perception. The person with an amputation may prefer to do this or use loafers. The person with hemiplegia can use adapted shoe closures or learn a simple, effective one-handed shoe tie as illustrated in Figure 25-22. Putting the lace through the last hole from the outside of the shoe toward the tongue lets the tension of the foot against the shoe hold the lace tight while the bow is being tied. One-handed shoe tying is difficult for patients with cognitive-perceptual deficits to learn.

Ankle–Foot Orthosis. The posterior shell or molded ankle–foot orthosis (AFO) is usually easiest to don if placed in the shoe first (Ryan & Sullivan, 2011). The shoe laces should be quite loose to allow the maximum room possible for getting the foot into the orthosis and shoe. The orthosis acts like a shoehorn, as the foot slides into the shoe.

Sexual Activities. A helpful booklet, *Sex after stroke: Our guide to intimacy after stroke* (American Heart Association, 2011), can be requested from the American Heart Association via their website (http://www.heart.org/HEARTORG /Conditions/More/ToolsForYourHeartHealth/Sex-After -Stroke-Our-Guide-to-Intimacy-After-Stroke_UCM _310558_Article.jsp) or phone (800-242-8721). It discusses sexuality and body image, fears about resuming sex, specifics of sexual intimacy after stroke (bowel and bladder control, change of position to accommodate paralysis, birth control, pregnancy, ways to make love other than intercourse), and a list of additional resources.

Suggestions for Selected Instrumental Activities of Daily Living

Writing. Persons with only one functional arm have to stabilize the paper when writing with the unaffected hand. The paper can be secured using masking tape, a clipboard, a weight, the affected extremity, or other similar means. If the dominant hand is the affected one, writing practice for the nondominant hand, especially for the signature, is usually required. Alternatively, the patient can purchase a signature stamp. Using a computer or tablet with a keyboard may be an easier alternative for many writing activities.

Leisure Activities. Many devices for leisure activities are available for people who have lost the use of one hand, including devices for knitting, crocheting, embroidery, playing cards, and fishing. The list in Resources 25-1 includes sources where devices can be explored and purchased.

1. Tie a knot in one end of the shoelace. Thread the unknotted end up through the hole nearest the toe of the shoe on the left.

2. Take the lace across the tongue of the shoe and up under the flap on the opposite side of the shoe.

3. Continue to go across the tongue and up under the flap on the next highest hole on the opposite side until you reach the top (or go down through the last hole so the tension will be maintained for tying.)

4. Circle around toward the toe of the shoe and go under the part of the lace that is going across the tongue to the last hole.

5. Circle around toward the top of the shoe. Pull free lace through the loop down toward the ankle and out to the left side.

6. Pull loop tight

Figure 25-22 One-handed shoe tie for a person with left hemiplegia. For a person with right hemiplegia, start the lace on the right side of the shoe so that the lace ends on the left side at the top.

Lower Extremity Amputation with Prosthesis

Persons with lower extremity amputations can benefit from many of the adaptations described for people with limited mobility caused by weakness or decreased range of motion; however, lower body dressing for prosthetic users presents a unique challenge not previously addressed. Prior to dressing, a person should change the shoe and/or sock on his or her prosthesis to match the day's clothing. People with a transtibial (below knee) amputation with pants wide enough to pull up to the knee should dress while seated using the following steps:

1. Place pants over unaffected leg and amputated leg, pulling pants up as far as possible.
2. Patients who are stable standing on one leg can stand to pull the pants up, then sit down to don the residual limb stocking and prosthesis, exposing the area by sliding the pant leg up over the knee.
3. Patients who are not stable standing on one leg should remain seated and don the prosthesis before standing to pull up their pants so that they have the stability of both lower extremities when standing to complete the task.

Patients with a transfemoral (above knee) amputation or those with a transtibial amputation who wish to wear fitted pants that cannot be slid up over the knee should dress as follows:

1. Slide the end of the pant leg for the amputated limb down over the top of the prosthesis so that the prosthesis is dressed first. The shoe and limited ankle mobility will prevent the pants from being slid over the prosthetic foot.
2. Don the stocking and the prosthesis.
3. Place the unaffected leg into the pants.
4. Stand to pull up and fasten the pants.

Limited Vision

The suggestions listed here pertain to blindness (20/1250 to worse than 20/2500) and to low vision (20/80 to 20/1000) (Colenbrander & Fletcher, 1995). Organization and consistency in the placement of objects is necessary for persons with visual impairment to locate things efficiently. General strategies to enhance visual performance include enlarging objects, magnification, increasing contrast through better lighting or use of

color, and reducing glare in the environment (Ellexson, 2004; Smith, 2001). Other modifications eliminate or reduce the need for vision by substituting with auditory or tactile information, such as a talking clock or locating dryer settings with a raised mark (Ellexson, 2004). The American Foundation for the Blind and Lighthouse International are major sources for obtaining information and assistive devices for persons who are blind or visually impaired (see Resources 25-1). For additional information, see Chapter 23. A number of high-tech solutions are available for persons with impaired vision, particularly for computer usage (see Chapter 18; see also Procedures for Practice 25-3).

Suggestions for Activities of Daily Living

Feeding. When possible, food should be set in a consistent pattern, using a clock method of description, such as "Meat at 3 o'clock." When this is not possible, a companion or server can tell the person where food is located on the plate. When pouring liquid, the correct amount can be determined by inserting a clean finger over the rim to feel when the liquid is near the top or by using a liquid level indicator, which is placed on the rim of the cup and gives an auditory signal when the cup is nearly full. Food is cut by finding the edge of the food with the fork, moving the fork a bite-size amount onto the meat, and then cutting the food, keeping the knife in contact with the fork. For those with low vision, the plate, glass, and utensils should be a color that contrasts with both the table covering and the food.

Grooming. A major problem is identification of objects. This can be done through the use of touch (size, shape, and texture), location, and Braille or bar code labels used with a talking bar code scanner. The application of cosmetics or toiletries is another problem; fingers of the assistive (nondominant) hand can be guides, such as when shaving sideburns or applying eyebrow pencil. Aerosol sprays should be avoided as persons who have low vision cannot see the extent of the spray.

Dressing. Limited vision does not interfere with the physical aspects of dressing, but persons with impaired vision need a system to coordinate colors of clothes and compatibility of style, to determine when clothing is inside-out, and to identify spots or stains. Wrinkle-free, stain-resistant, no-iron fabrics are desirable, and clothes should be hung properly to prevent wrinkles and eliminate the need for ironing. Several adaptations, with the help of a sighted companion, can facilitate the selection of matching clothes, including storing clothes of like color together, putting matching outfits on the same hanger, or using tactile or high contrast identification tags on clothes or hangers to denote the colors

(Ellexson, 2004). Colorless wax polishes can be used to shine shoes.

Suggestions for Selected Instrumental Activities of Daily Living

Writing and Reading. Persons with visual impairment can use a signature or writing guide to stay within boundaries while writing in longhand. Using a black felt-tipped pen on white paper provides good contrast. Talking books and magazines can be used in place of written materials, and a variety of optical devices can enlarge print in newspapers, personal mail, etc. For those with moderately low vision, books, popular magazines, and *The New York Times* come in large-print versions. Many periodicals are available online and can be viewed with a screen magnifier, such as ZoomText (www.synapseadaptive.com/aisquared/zoom text_9/zoomtext_9_magnifier.htm) (Fig. 18-10). There are talking bar code scanners that can be used to identify products in the home and community and devices that scan medicine bottles and inform the person of the medicine in the bottle and the dosage schedule (www.envision-america.com).

Medication Management. Depending on the extent of visual impairment, some people may be able to manage their medications by using magnifiers or marking bottles with large, high-contrast labels or tactile identifiers. For those with significant visual loss, prescription bottle readers can be used to record information from the label. Talking blood pressure and glucose monitors are also available. The American Foundation for the Blind has ideas and resources on their website (http://www.afb.org/senior site.asp?SectionID=66&TopicID=305&Document ID=3271). Pharmacies can also organize and package medications for patients in blister packs so people with low vision can eliminate this challenging task.

Telephoning. People with very limited vision can use phones with tactile indicators on the touch pad, and those with low vision can use phones with large buttons. A phone with one-button automatic dialing is very useful, as are voice-activated phones.

Time. A person can tell time using a Braille or talking watch or clock. Many computer-based calendars and scheduling systems include alarms that can be activated to provide an audio signal when an appointment time is approaching.

Shopping. Persons with low vision may wish to shop using catalogs read by use of closed-circuit television (CCTV) or online with screen magnifiers. Portable CCTV is also available that can be taken out and used in the community. Talking barcode readers may also assist shoppers with visual impairments to identify items and prices.

Handling Money. Tactile discrimination enables the person to identify coins. Paper money can be discriminated by the way it is folded after it has been viewed by magnification or someone else has identified its denomination. Alternatively, people with blindness or low vision may prefer to use a credit card to minimize the need to identify and organize cash.

Playing Games. Braille and large print versions of popular games, such as Monopoly, Bingo, and playing cards, are available. Tactile bingo boards and markers are also available.

Decreased Sensation

For additional information, see Chapter 22. See also Procedures for Practice 25-3.

Suggestions for Activities of Daily Living

Problems of absent, decreased, or disturbed sensation affect performance of ADL and IADL because the automatic knowledge of limb movement and touch may be missing. Training and/or environmental modification to prevent injury is particularly important when interacting with hot or sharp items.

Bathing and Grooming. *Safety Message: To minimize the danger of scalding, hot water heaters should be set to a maximum of 120° Fahrenheit (49° Celsius).* Shower faucets that can be set to one temperature are also safer. When mixing hot and cold water, patients should be instructed to turn the cold water on first and then add hot water gradually. Mixer valves should be installed to compensate when decreased sensation is a permanent condition. Patients with intact areas of sensation can learn to test water temperature with those areas. Wall-mounted sinks give wheelchair users the best access. *Safety Message: but those with impaired lower extremity sensation should insulate hot water pipes and drains to prevent burns if their legs were to come in contact with the plumbing* (Fig. 25-23).

Dressing. *Safety Message: Wrinkles, seams, or bands on clothing that are sufficient to cause tissue damage may not be felt by people with impaired sensation and can cause pressure ulcers within a short time.* Clothing should be selected that is snug enough to prevent bunching, but loose enough to avoid binding or excessive pressure. Persons with insensitive skin should inspect clothing visually or with an area of intact sensation to avoid wrinkles. They must dress warmly in cold weather to prevent frostbite. Fine manipulation needed for fasteners may be affected by decreased sensation in the hand. Patients can learn to compensate visually or may benefit

Figure 25-23 Insulating the hot water pipes and drain under a sink prevents burns to the lower extremities of wheelchair users.

from larger fasteners or adaptive devices described for people with impaired coordination, such as button hooks.

Suggestions for Selected Instrumental Activities of Daily Living

Poor sensation interferes with graduated pinch and grip on tools and utensils to meet the demands of the task (Duff, 2005). The person may grip with excessive pressure (Johansson & Westling, 1984) or inadvertently let go, when the attention is directed away from the object being held. Devices discussed earlier for poor grip may help persons with impaired sensation for activities requiring sustained grip.

Safety Message: Activities that involve using hot objects, such as a riding mower or cooking at an outdoor barbecue, pose a threat because anesthetic lower extremities can be burned if allowed to rest against the hot engine cover or bottom of the barbecue. Objects should be insulated when possible and patients trained to be extra vigilant in positioning themselves near hot items.

Cognitive-Perceptual Impairments

See Procedures for Practice 25-3 and Chapters 23 and 24 for information concerning methods to compensate for cognitive or perceptual impairments in ADL.

Pain, Including Low Back Pain

See Procedures for Practice 25-3 and Chapters 27 and 36 for information concerning body mechanics to be used during occupational functioning for persons with low back pain. Adaptations for people with limited range of motion, particularly in reaching the feet, may also be effective for people with low back pain. Adaptations for people with weakness may also increase performance for those with upper extremity pain.

Considerations in Bariatric Care

Occupational therapists are treating increasing numbers of patients who are exceptionally large. Obesity is associated with a number of health problems and is a multidimensional problem that not only impacts physical engagement in daily activities, but affects psychosocial functioning as well (Forhan et al., 2010). Persons who are exceptionally large often have movement limitations that result directly from their size, so these patients often require occupational therapy (Foti, 2005). Several considerations warrant discussion regarding adaptations for these individuals. Excessively large individuals with a medical condition may have more occupational performance deficits than are typically seen because of preexisting limitations in strength relative to body mass, limited reach, and decreased endurance. A thorough functional assessment is needed to ensure that all problems are identified (Foti & Littrell, 2004). *Safety Message: Adaptive equipment must be carefully evaluated to make sure that it has been approved to handle the patient's weight and that it is sized appropriately to meet the patient's needs.* For example, many tub seats are approved to handle up to 300 pounds and cannot be used safely by a heavier person. Traditional sock aids may be too small to accommodate the patient's foot or calf and a soft variety may need to be used (Foti, 2005). The typical home environment may present a number of obstacles for persons of exceptional size, including narrow doorways or pathways that prevent the person from entering a room, particularly those using a wider walker or wheelchair. Bathrooms are commonly too small to be functional for persons who are exceptionally large, and they may find themselves confined to one or two rooms in their homes (Foti & Littrell, 2004). Caregivers may be limited in the tasks they can assist a person with because of risk of physical injuries, so lift equipment may be required in the home. Psychosocial issues may complicate the clinical picture.

Adaptive strategies described above for persons with weakness, limited reach, and/or endurance may all be effective in treating persons of exceptional size. A number of companies have equipment especially designed for the bariatric population that can help the therapist select appropriate and safe adaptations for these patients (see Resources 25-1; also, additional resources are included in the references by Foti [2005] and Foti & Littrell [2004]).

Service Dogs: An Adaptation Option for a Range of Performance Limitations

Service dogs are specially trained to meet the needs of persons with limitations in mobility and/or ADL caused by loss of vision, hearing, and physical impairments. Service dogs are trained collaboratively with the owner so that they learn skills suited to meet the individual's unique needs. The training is extensive and, therefore, expensive, so service dogs are appropriate only for persons with permanent disabilities.

Service dogs can assist people with a variety of tasks. Dogs for people with visual impairment are primarily used for mobility by acting as a guide. Hearing dogs alert their owners to auditory stimuli that require a response, e.g., doorbells, alarm clocks, oven timers, and smoke detectors. Other physical disabilities vary significantly from person to person, and the range of activities that service dogs can assist with is very large (Rintala, Matamoros, & Seitz, 2008). Dogs at Canine Companions for Independence (see Resources 25-1) learn about 40 commands, which can be adapted to individual circumstances. For instance, the tug command is normally used on doors and drawers, but can be used to remove socks or other clothes (Fig. 25-24). The most common activities include help with wheelchair and floor transfers, mobility in home and community, carrying items, operating switches (e.g., lights and elevator buttons), retrieving and moving items, and

Figure 25-24 Service dog is given the "tug" command to help remove his owner's sock. (Courtesy of Canine Companions for Independence, Santa Rosa, CA.)

opening doors, drawers, and cabinets (Allen & Blascovich, 1996; Rintala, Matamoros, & Seitz, 2008).

Service dogs are an adaptive tool; however, they do not seem to carry the same stigma as assistive devices and may even support social participation. Service dog owners have reported increased interactions with friends and people out in public, increased confidence, and enhanced feelings of safety (Camp, 2001; Fairman & Huebner, 2000). Allen and Blascovich (1996) conducted a randomized controlled study to examine the impact of service dogs on a number of variables, comparing an intervention group that received a service dog and a wait-list control group with no dog. The service dog group had higher scores on psychosocial variables (including self-esteem and community integration), increased participation in school and work, and a decrease of 68% in both paid and unpaid assistance hours. The wait-list group showed a similar pattern of improvement 18 months later when they received their dogs. While the cost of training a service dog was estimated at $10,000, the researchers estimated that savings in personal care attendants would reach $60,000 after 8 years, the average working life of the dog (Allen & Blascovich, 1996). Brashear and Rintala (2007) interviewed veterans with spinal cord injury and found that about one-third had no knowledge of service dogs and 42% desired getting additional information, suggesting that occupational therapists should be knowledgeable about service dogs as an option for enhancing independence and should educate patients about the possibilities.

EFFECTIVENESS OF THERAPY TO RESTORE THE ROLE OF INDEPENDENT PERSON

Evidence from selected quantitative studies, including meta-analyses, systematic reviews, and randomized controlled trials that demonstrate occupational therapy has a positive effect on client functional outcomes in ADL and IADL is summarized in Evidence Table 25-1. Over the past several years, there has been an increase in the number of published studies that demonstrate the efficacy of occupational therapy in improving ADL and IADL. Evidence varies widely in terms of population studied, specific interventions, and outcome measures used to examine changes in ADL and IADL. Four challenges face occupational therapy practitioners searching for evidence in using a modify/adapt approach or occupation-based approach to restoring the role of the independent person, including finding studies that (1) specifically examine interventions that focus on ADL or IADL, (2) examine the practitioners' population of interest, (3) describe the nature of the intervention in sufficient detail, and (4) use relevant outcome measures.

Although many occupational therapy intervention studies include ADL or IADL outcomes, often the intervention did not focus directly on regaining occupation-based skills. For example, Hoffmann et al. (2008) focused only on research evidence related to stroke and occupational therapy from randomized controlled trials and systematic reviews. They found 452 studies published between 1980 and 2006. Although 70% of those studies included outcome measures of ADL and/or IADL, only a small percentage of the studies were evaluating treatment specifically directed at ADL (8.4%) or assistive technology/adaptive equipment (4.0%). Many more studies examined treatment using a remediation approach, such as movement training (43.2%) or physical modalities and splinting (30.1%). Studies of interventions aimed at restoring underlying functions are important; however, direct treatment of ADL and IADL are at the core of occupational therapy practice, and more extensive evidence is needed to support practice.

The range of compensatory strategies for ADL and IADL is extensive, as is evident in the detailed descriptions in this chapter. Varied patient populations require different approaches to modifying tasks, but many research studies have focused on a single population. ADL and IADL outcomes have been extensively studied in adults post stroke, but practitioners may find limited evidence to support interventions in other populations. A few recent studies have included more heterogeneous populations (e.g., Gitlin et al., 2006), enabling practitioners to generalize results to more patient populations.

A common methodological weakness identified in several meta-analyses or systematic reviews (e.g., Legg, Drummond, & Langhorne, 2006; Steultjens et al., 2003) was that the nature of the occupational therapy was widely varied and/or poorly described, making it difficult for practitioners to apply specific interventions to practice. Variations in treatment to consider include the dosage of treatment (i.e., frequency and length of sessions, as well as overall duration), extent and type of client collaboration in goal setting and treatment planning, practice schedules, service delivery setting (e.g., home, hospital, or community), and individual versus group treatment. In many studies, variations in these approaches are not controlled for, making it difficult to identify key components of an effective intervention. Additionally, ADL and IADL outcomes are measured following multidisciplinary treatment, making it difficult to tease out the unique contributions of occupational therapy (Gitlin et al., 2006).

Finally, occupational therapists examining the evidence will find a wide array of ADL and IADL outcome measures, making comparison across studies challenging. For example, Hoffmann et al. (2008) identified 17 different ADL measures among 358 randomized controlled trials related to stroke outcomes. Different measures may conceptualize ADL in different ways, for example, the FIM™ requires the patient to gather clothing as part of dressing, whereas the Barthel Index does not.

In addition to the quantitative studies summarized in Evidence Table 25-1, qualitative studies can also provide insights that help guide occupational therapy interventions, particularly in terms of individualizing treatment

| Evidence Table 25-1 | Best Evidence for Occupational Therapy Practice Regarding Activities of Daily Living |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-specific practice of client-chosen activities of daily living (ADL)	Practice of specific tasks in a familiar context	Four hundred three stroke survivors (189 left cerebrovascular accident [LCVA], 194 right cerebrovascular accident [RCVA], 20 other); mean age = 72.7 years	Ranged from 1 to 15 visits over a period of 2 weeks to 5 months	Meta-analysis of four studies Level: I	Yes. The treated groups improved in ADL as measured by various ADL assessments.	Mean weighted effect size was r = 0.30, equivalent to a 30% success rate over control treatment.	Trombly & Ma (2002)
Home-based occupational therapy	In-home occupational therapy to clients with a diagnosis of stroke; "home" included own home or residential or nursing homes	Nine hundred sixty-five stroke survivors; mean age = 70.0 years	Ranged from 10 sessions to up to 5 months of intervention	Meta-analysis of five studies Outcome measure focused on instrumental activities of daily living (IADL) Level: I	Yes. The treated group showed small improvement on the Nottingham Extended ADL Scale.	Z = 2.97, p = 0.0003, effect size r = 0.10.	Walker et al. (2004)
Home-based occupational therapy for people post stroke	Treatment that directly addressed ADL, common to all studies included, delivered by an occupational therapist at the patient's home	Nine studies with 1,258 participants living at home post stroke	Wide range from two or three visits to 6-month programs of varying intensities	Systematic review of randomized trials Level: I	Yes. Participants who had occupational therapy were more independent in ADL at discharge and maintained capabilities more than those who received no care or usual care.	Standardized mean difference with a random-effects model was 0.18 (95% confidence interval [CI] = 0.04–0.32), p = 0.01, demonstrating more independence in ADL. Odds of death or declining ADL performance were lower in the occupational therapy group (odds ratio =.60, 95% CI = 0.51–0.87, p = 0.003).	Legg, Drummond, & Langhorne (2006)
Use of everyday life occupations, including "adaptive or compensatory occupation"	Varied, depending on the study described, but all included direct use of occupations as a therapeutic intervention	Review of 23 studies in stroke rehabilitation, published 2000–2007	Varied	Systematic review that included two meta-analyses, seven systematic reviews, four randomized controlled trials, with additional studies at lower levels of evidence Level: I	Occupation-based interventions resulted in better outcomes in ADL, IADL, and participation.	Not reported for specific studies nor for the review overall	Kristensen et al. (2011)

Intervention	Description	Participants	Dosage	Design	Results	Statistics	Citation
Occupational therapy and physical therapy at home	Problem-identification and problem-solving training, behavioral interventions (e.g., pacing), and environmental modifications	Three hundred nineteen community-dwelling adults older than 70 years of age who reported difficulties with two or more IADL and/or one ADL; 82% were female and reported a mean of seven health conditions	Six months, including four 90-minute occupational therapy visits, one 20-minute occupational therapy phone contact, and one 90-minute physical therapy visit	Prospective, two-group RCT (treatment and no treatment group) Level: IA2a	Yes. Participants with a range of chronic health conditions had better ADL and IADL performance after home intervention of occupational therapy and physical therapy (with five of six contacts conducted by occupational therapy).	There were statistically significant group differences at 6 months in ADL ($p = 0.03$) and IADL ($p = 0.04$), with biggest differences in bathing and toileting.	Gitlin et al. (2006)
Follow-up occupational therapy in the home after rehabilitation	Home occupational therapy visits for review of assistive devices for bathing introduced in hospital	Fifty-three adults with stroke who were discharged home with bathing equipment; mean age = 72.1 years	Control and treatment groups got inpatient instruction; treatment group got two or three home visits	Single-site RCT Level: IB1b	Yes. The treated group improved more in ADL as measured by the Functional Independence Measure (FIM™) than control group.	$t_{(51)} = 2.002, p = 0.051$, effect size $r = 0.27$, equivalent to a 27% success rate over control treatment	Chiu & Man (2004)
Home-based occupational therapy	Control: Conventional outpatient follow-up Treatment: Conventional plus 6 weeks of home occupational therapy	One hundred thirty-eight adults with stroke	Client-centered intervention; approximately ten 30–45-minute visits over 6 weeks	Single-site RCT Level: IA2a	Yes. Treated group reported higher performance scores on the Canadian Occupational Performance Measure (COPM).	Group differences measured with Mann Whitney U, $p = 0.0006$, $Z = 3.25$, effect size $r = 0.27$.	Gilbertson & Langhorne (2000)
Goal-specific outpatient therapy	Occupational therapy varied slightly at each site, but all included training in IADL; some also addressed ADL and work skills	Thirty-one adults with TBI, Rancho Level IV or higher, receiving outpatient occupational therapy at one of three sites	Mean hours of treatment were 13, 53, and 84 hours at the three sites; mean duration ranged from 12 to 20 weeks	Quasiexperimental pretest/posttest design with no control group Level: IIIB2a	Yes. Goal Attainment Scores (GAS) and COPM performance and satisfaction scores were higher. Gains were retained in follow-up, but no further gains were made. No change in Community Integration Questionnaire.	Improvement in treatment phase as follows: GAS, $Z = 7.52, p < 0.001$, effect size $r = 0.94$ COPM performance, $Z = 4.13, p < 0.001$, effect size $r = 0.71$ COPM satisfaction, $Z = 4.25, p < 0.001$, effect size $r = 0.76$	Trombly et al. (2002)
Inpatient rehabilitation	Occupational therapy "within nine areas of practice," delivered within a rehabilitation program; all participants received ADL training as part of their occupational therapy	Forty-three adults with stroke	Three hours of occupational therapy daily for the duration of the inpatient rehabilitation (average = 31 days)	Quasiexperimental pretest/posttest design with no control group Qualitative component to gather client perceptions of outcomes Levels: Quantitative = IIIB3a Qualitative = N	Yes. Quantitative measures demonstrated improvement in ADL and IADL from admission to discharge.	Significant improvement in ADL measured by the FIM ($t = -9.71, p = .000$) and IADL measured by the ALSAR ($t = 7.75, p = .000$). Clients also reported an improvement in ADL and IADL that they attributed to occupational therapy.	Unsworth & Cunningham (2002)

Evidence Table 25-1	Best Evidence for Occupational Therapy Practice Regarding Activities of Daily Living *(continued)*

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Occupational therapy, primarily a compensatory approach, including adaptive equipment and energy conservation	Inpatient occupational therapy, including instruction in compensatory strategies for ADL, home management, leisure; education in managing fatigue; and treatment to increase upper extremity function	Thirty adults (27 female, 3 male) with multiple sclerosis from one inpatient unit in the Midwest United States	One week of "intensive" inpatient treatment (daily treatment dosage not indicated)	Quasiexperimental pretest/posttest design with 6-week follow-up Level: IIIB2b	Yes. There was improvement in all six ADL (tub transfers, toileting, feeding, grooming, upper body dressing, and lower body dressing) from admission to discharge and improvement continued at 6 weeks, except for feeding, which had reached maximum level.	ANOVAs for repeated measures on all six variables showed significant improvement from admission to discharge (F ranged from 12.2 to 76.8, with p values for each variable < 0.01 or 0.001). Five variables (all except feeding) showed significant improvement from discharge to 6-week follow-up (F ranged from 4.17 to 20.90, with p values ranging from < 0.05 to < 0.001)	Mathiowetz & Matuska (1998)
Joint protection educational-behavioral program	Control: Standard program, including education on joint protection Treatment: Joint protection including strategies to increase adherence	One hundred twenty-seven adults with rheumatoid arthritis <5 years since diagnosis	Both programs included four 2-hour weekly meetings	Two-site RCT Level: IA1a	Yes. At a 48-month follow-up, treated group had significantly better ADL scores compared with the control.	Group differences measured with Mann-Whitney U, $p = 0.04$, $Z = 1.75$, effect size $r = 0.15$.	Hammond & Freeman (2004)
Service dog	Control: No dog (wait list for 13 months) Treatment: Received service dog 1 month into the study	Forty-eight individuals with severe, chronic ambulatory disabilities requiring wheelchair use; mean age = 25 years	Dog training was 6–12 months; training with participants was not specified	RCT Level: IB2b	Yes. Self-reported biweekly hours of both paid and unpaid assistance were significantly less in the treatment group, suggesting more independence in ADL and IADL performance compared with the control group.	Effect of a service dog on assistance was very large, $r = 0.98$ for paid assistance and 0.96 for unpaid assistance.	Allen & Blascovich (1996)

(Kristensen et al., 2011). For example, Eklund and Ivanoff (2006) evaluated the experience of learning in participants with macular degeneration in a low-vision rehabilitation program. Results included not only participants' reported mastery of content, but which aspects of the program were most effective, such as strategy learning that can be generalized across many homemaking tasks and the value of peer mentoring. These outcomes can be helpful for clinicians in developing new programs, with the understanding that outcome measures pertinent to their own setting and population should be used to verify that the interventions transfer to their setting.

Another qualitative study that can provide valuable insight into ADL and IADL interventions was conducted by Pettersson, Appelros, and Ahlström (2007), who described the complex and, at times, contradictory perceptions individuals have related to their adaptive equipment. Understanding the dual perception patients may have that adaptive equipment supports independence while at the same time highlighting their disabilities can help occupational therapists address barriers to adaptive equipment use that may facilitate ADL or IADL independence.

Consideration of the findings of the research summarized above and in Evidence Table 25-1 may help occupational therapists develop more effective intervention and may direct occupational therapy researchers to problems that require additional study.

Environment-Client Focused Activity Analysis Case Example
Environment-Client Focused Activity Analysis: Increasing Independence in Self-Feeding

Patient Information

Mr. W. is a 20-year-old, right-handed man who sustained a traumatic brain injury 1 month ago. He was in a coma for 2 weeks and spent 3 weeks in an acute care hospital before being transferred to a rehabilitation center. Mr. W. was NPO (*nil per os*, or "nothing by mouth") until a swallowing evaluation revealed that it was safe to begin eating orally (i.e., he can swallow all foods effectively), and the occupational therapist has begun to work on self-feeding. Mr. W.'s impairments include left hemiplegia (paralysis of the left side) with poor sitting balance and mild ataxia. He has significant cognitive deficits, including poor attention span, poor short-term memory, low frustration tolerance, and very limited awareness of deficits. He is easily distracted by auditory and visual stimuli in the environment. He can follow one-step directions but is unable to follow more complex instructions. He appears to be motivated to eat, grabbing at food that is placed within his reach; however, nursing has not been able to allow him to feed himself because he does not pace himself appropriately, "shoveling" food into his mouth without chewing and swallowing between bites. Although he can swallow safely, this behavior creates a choking risk.

Task Analysis Process		Intervention Planning	Therapeutic Transactions: Preparation for and Interactions at the Occupational Therapy Session	Clinical Reasoning: Example of Therapist's Internal Dialogue
S E L E C T I O N	Specify the task that the person needs or wants to perform in a given environment	Self-feeding is a very basic self-care skill, and Mr. W. is demonstrating motivation to feed himself by grabbing for food. When fed, he readily chews and swallows food and looks to the feeder for another bite.	The occupational therapist decided to work on feeding during lunch. The nursing staff and Mr. W.'s parents have stated he is not a "morning person." The occupational therapist also consulted with Mr. W. and his family to select foods that he both liked and would meet his nutritional needs.	"Mr. W. is easily frustrated and I want to work with him at a time when he is at his best and to select foods that will be motivating for him to eat."
	Specify the performance environments (environment in which the patient will perform the desired activity; environment in which the therapy session will occur)	The therapy session will occur in Mr. W.'s room in the rehab facility. Eventually, he will need to feed himself in a variety of places, including his home, others' homes, restaurants, cafeterias, outdoors, and other possible locations, such as the car.		"Being able to work with Mr. W. in his room, rather than in the patient dining area or clinic, will allow me more control over the environment, because he is very distractible. Once he is able to feed himself effectively in his room, I will make a plan to help him transition to eating in the patient dining room, which would be closer to eating with his family at home or out at a restaurant."

| A N A L Y S I S | Evaluate the barriers or enablers to performance of this activity in this environment:

1. Task

2. Environment

3. Person | Barriers:

1. Some aspects of feeding require bilateral hand use, e.g., cutting food, eating sandwiches or a hamburger, and opening containers. Eating includes some safety considerations, e.g., moderating the amount of food intake to prevent choking and managing hot food and drink to prevent burns.

2. Mr. W.'s family is very involved and is usually in the room at lunchtime, presenting a distraction. His hospital bed does not enable him to sit up straight enough to get close to the table.

3. Mr. W. has no use of his left upper extremity (UE) for bilateral tasks (such as cutting meat or picking up a sandwich). His sitting balance and posture is poor. He is impulsive and does not swallow before putting more food into his mouth.

Enablers:

1. Feeding is mostly a unilateral task, so he will be able to do most of it with his functional right UE. It is usually done seated, requiring minimal trunk control and no lower extremity function. The cognitive demands are not great. The length of the task is easily adjusted.

2. The hospital room can be modified to minimize distractions.

3. Mr. W. is right-hand dominant, so eating with the right hand will be familiar to him. Feeding is also a very well-learned task that he will likely be able to recall. | Materials required:

• Food tray with food items placed in individual dishes, including a tuna sandwich, potato salad, applesauce, and juice (in covered cup with straw)

• Wheelchair

• Bedside table

• Adaptive equipment: large-handled utensils, including a spoon with a small bowl, nonslip mat, covered mug

• Damp towel and hospital gown

Safety precautions:

• Eliminate hot foods and the need for sharp utensils (e.g., steak knife) for initial treatment sessions

• Present foods one at a time to reduce the chance of eating too fast, which could cause choking | "Before we get started, I want to optimize the environment by minimizing distractions. I explain to the family that I want to begin working with Mr. W. alone because he has a hard time focusing on eating when there are a lot of people in the room. I make sure to tell them I will invite them back at the end of the session to explain what we did and how they might be able to help Mr. W. when he is eating safely enough to do so with family, because I know they very much want to help Mr. W. but need some direction."

"I make sure the TV is off and the door is closed. I help Mr. W. transfer to his wheelchair, which has been set up to provide him with good trunk stability. The wheelchair will maintain a good posture for eating and allow me to put food on the bedside table close to him. He is dressed in jeans and a t-shirt, so I put on a hospital gown to protect his clothing, and I keep a towel nearby in case of spills, which could trigger frustration."

"To begin, I present only the applesauce with a spoon because (1) he is not distracted by other foods; (2) it is a limited amount, so is safer if he begins to 'shovel'; and (3) I can focus on his ability to use a spoon. I will present each food item independently and without adaptive equipment, unless I see something suggesting that the equipment might be helpful (e.g., the plate is slipping, he scoops too much onto a regular-size spoon, or he cannot control the volume of liquid when sipping through a straw). Adaptive equipment can be really helpful, but it is unfamiliar to him and I want to minimize its use." |

	Determine solutions that will enable performance: 1. Person 2. Environment 3. Task	Solutions: 1. Position upright and supported in wheelchair with table close and in front. 2. Minimize visual and auditory distractions 3. Present one food item at a time. Use softer foods to reduce choking hazard if he takes too large a bite. Have adaptive equipment available to intervene, if needed. In particular, a smaller spoon would limit how much food he could get in a single bite.		"I will not make small talk, because that would be a distraction. I will keep instructions as short and simple as I can and may need to remove the food from in front of Mr. W. when I am giving an instruction."
G R A D A T I O N	Specify task and environmental parameters to calibrate difficulty level: • Method of instruction • Nature and level of cueing • Objects and their properties (materials and equipment) • Space demands • Social demands • Sequence and timing • Required actions and performance skills • Required body functions • Familiar or novel task or environment • Known adaptations or specifics to design and build the needed adaptation	To progress Mr. W., reduce the number of verbal cues, increase the number of food items available at one time, decrease reliance on adaptive utensils (if used), and transition into more natural eating environments (e.g., the patient dining room). Feedback to increase self-awareness may be introduced, e.g., "Did you swallow the last bite before taking this one?" The family can be instructed in how to set up the environment and cue Mr. W. for safe and independent self-feeding.	Explain to Mr. W.'s family how to adapt the feeding task and environment so that he will pace self-feeding appropriately, including when and how to provide verbal, gestured, or tactile cues. Gradually increase the number of food items on the table in front of him. As Mr. W. becomes able to self-feed effectively in his room, the environmental demands can be increased, e.g., eat a meal in the dining room, gradually introducing more distractions (e.g., eat at a table at the edge of the room with one other person, then increase number of diners and/or change the placement within the room). Introduce adaptive methods for bilateral tasks (e.g., use of a rocker knife to cut meat) and/or begin to incorporate the left UE into feeding if he begins to get some active control.	"I want to provide Mr. W. with more opportunity for practice. His family really wants to help, but they do not know how to help him to avoid outbursts of frustration or control his impulsivity. Teaching them specific strategies will engage them effectively in his care. Plus they are also here for dinner, giving Mr. W. lots more practice. I will make sure to observe them to provide feedback and give them the confidence they need to carry through with this." "Right now, Mr. W. does not have the cognitive ability to problem solve, but I can start to ask questions about his self-awareness. I want to be careful not to trigger an angry response, but I want to monitor him so I can work more on that when he begins to show signs that self-awareness is emerging." "Mr. W.'s capacity for learning new tasks is limited right now, but when he shows some retention of new skills, I can teach him some news ways of doing things, such as cutting food with a rocker knife. I also want to look for any return of movement in his left UE because I can try to increase movement by having him use it in simple tasks, such as holding the dish while he eats dessert or using two hands to pick up his cup to drink."

case example

Mrs. C.: Adaptation and Training for Basic Activities of Daily Living

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Mrs. C. is a 50-year-old woman who was admitted to an inpatient rehabilitation unit 1 week after a decompression laminectomy with fusion of T5-T6 secondary to a metastatic spinal tumor with resulting paraparesis. The primary tumor was breast cancer, diagnosed and treated 3 years ago, and she was cancer free until the spinal tumor. The inpatient occupational therapy (OT) assessment revealed the following primary problems: (1) minimal to maximal assistance with bathing, dressing, toileting, bowel and bladder management, and transfers; (2) limited reach secondary to spinal orthosis, which restricts trunk and hip flexion (worn whenever upright for 8 weeks postoperatively); (3) significant trunk and lower extremity weakness (2–/5) leading to poor sitting balance; (4) persistent pain in the midthoracic area; (5) fatigue; and (6) possible depression.

Mrs. C. is in a stable and supportive marriage and has two teenage children living at home. She works as an elementary school nurse. Her husband works full time. She lives in a two-story home. All bedrooms are on the second floor. There is a half-bath on the first floor and a full bath on the second. Mrs. C. sought out both Western and complementary health care when treating her breast cancer, including acupuncture and yoga. Her immediate goal is to be able to return home without having to rely heavily on her family for assistance and to be able to cook for her family. Eventually, she wants to return to work.

Appreciate the context

"Mrs. C. has an incomplete spinal cord injury and it is hard to predict what her sensorimotor function will ultimately be. She will probably be discharged from inpatient rehabilitation within about 3 weeks, however, which means she will almost certainly still be relying on a wheelchair and will be wearing her brace for the first month she is home. Her home has some environmental barriers that will need to be looked at."

"Being diagnosed with metastatic cancer after being cancer free for 3 years must be very difficult for Mrs. C. It appears that she might have a reactive depression. I wonder if she is being treated for that. I wonder what her prognosis is. I should remember to look in her chart to find out the tumor grade and check my pathology books for a refresher on prognosis for metastatic cancer. Her active involvement in her prior treatment, such as using alternative treatments, suggests she might be anxious to work collaboratively in the rehab process."

"I wonder how her kids and husband are responding to all this. Mrs. C.'s goals suggest that she wants to return some level of 'normalcy' to their family routines as soon as possible."

Develop intervention hypotheses

"I think that the things interfering most with Mrs. C.'s ability to be independent in activities of daily living (ADL) are her limited reach (because of brace, lower extremity weakness, and impaired sitting balance), fatigue, and back pain. I am wondering if depression might be exacerbating her pain and fatigue. The home environment also presents some obstacles. Mrs. C.'s background as a nurse will support the rehabilitation process. Her prior routines that included healthy exercise (yoga) have left her with excellent upper extremity strength that she can use to compensate for her paraparesis. Her family is supportive, and her desire to return to her roles as wife and mother seems to be a powerful motivator for participation in treatment."

Select an intervention approach

"At this point, I will primarily rely on an approach that compensates for Mrs. C.'s deficits because her inpatient rehabilitation stay will be fairly short and it is important to her to minimize her dependence on her family when she returns home. Additionally, it is likely she will be using a wheelchair at discharge, and her home is not currently accessible. Modifying the physical environment will require some time and should be started right away. Although fatigue can be approached with a remediation approach to increase the physical component, I think that the level of activity required for learning compensatory strategies will be enough to increase activity tolerance without using a rote exercise program."

	Reflect on competence	"I have worked with many patients who are limited by a back brace, but I have not worked with many who also have paraparesis. I'll need to think more about how to combine methods to help Mrs. C. reach her feet for dressing and bathing that will work with lower extremities that lack functional movement. I am also not sure how to address the prognosis issue. Is she worried about her life expectancy? Should I invite her to talk about this, or would that be upsetting to her?"

Recommendations

The occupational therapist will see Mrs. C. twice a day for 45-minute treatment sessions. The following long-term goals were established for Mrs. C. to reach prior to her discharge home: (1) Mrs. C. will be independent in all ADL except donning shoes and socks and washing feet; (2) Mrs. C. will be independent in sliding-board transfers, wheelchair to and from bed, upholstered chair, toilet, transfer tub seat, and car; (3) Mrs. C. will be independent in planning and preparing simple, hot meals with a maximum of a 10 on the Borg Rating of Perceived Exertion at the completion of the task; (4) Mrs. C. will be able to access necessary facilities in her home, including bed, toilet, shower, kitchen appliances, and electronics (telephone, computer, TV, etc.); and (5) Mrs. C. will be independent in wheelchair mobility on smooth level surfaces and appropriately graded ramps.

	Consider the patient's appraisal of performance	"Mrs. C. seems to have a realistic view of her abilities and limitations. If anything, she seems to underestimate what she can do, for example, she feels she cannot do anything herself, but she can feed herself, complete grooming, and bathe her face, arms, and thighs."
	Consider what will occur in therapy, how often, and for how long	"I'm going to bring up the issue of depression in team meeting. I think she should be evaluated because if she is clinically depressed, antidepressants might help with pain management and reducing fatigue, which would allow her to participate more actively in treatment. Right now, it is hard to make the most of the 90 minutes I have allotted for treatment each day. In the meantime, I need to make sure I use the right balance of physically challenging tasks and those that rely on more of her cognitive abilities, such as making plans to improve the accessibility of her home. That way I can use all the valuable treatment time without overtaxing her."
	Ascertain the patient's endorsement of plan	"Mrs. C. strongly agrees with the goals, although she seems to doubt whether all this can be accomplished in just 3 weeks. Her sense of self-efficacy seems pretty low right now and will need to be addressed in treatment. It might help to also involve her family in this aspect of care so they can help her see her progress, no matter how small the steps seem to be at first."

Summary of Short-Term Goals and Progress

1. *Mrs. C. will require minimal assistance to don underwear and pants using adaptive equipment.*

   The therapist thought that donning the elastic stockings that Mrs. C. is required to wear and donning shoes would be very difficult to master while the back brace had to be worn. The therapist explained the challenges these tasks presented, and Mrs. C. agreed that it would be all right to have her husband help with shoes and socks until the brace was removed and she could reach her feet without adaptive equipment. Mrs. C. positioned herself in long sitting, resting against the elevated hospital bed. She was able to use a dressing stick to get her pants over her feet with minimal assistance and verbal cues to increase her effectiveness with the dressing stick.

2. *Mrs. C. will be independent in self-catheterization.*

   Mrs. C. could not see her urinary meatus because the back brace prevents trunk flexion. She was given a leg abductor with a mirror that enabled her to see.

	Assess the patient's comprehension Understand what he or she is doing	"Mrs. C. follows instructions well and remembers strategies that are taught to her (for example, the steps to doing a sliding-board transfer), but she still requires help to initiate problem solving. For example, she needed prompting to come up with ways to apply energy conservation principles to a cooking task. Again, this might be related to depression. She was diagnosed with clinical depression and started on medication, but we cannot really expect to see a change for 3 weeks or so, and by that time she will be home. So I just continue to use treatment that I hope will be extra motivating. She loves to be able to transfer to the couch with her family where they can sit close on the couch and visit or watch TV without the wheelchair as a barrier between them. She said she was also glad to be able to make a snack for her kids, 'just like a mom!'"

3. *Mrs. C. will require supervision for sliding-board transfers from wheelchair to/from bed and level, firm, upholstered surfaces.*

   Mrs. C. progressed quickly with sliding-board transfers because her upper extremity strength was excellent and helped her both maintain her balance and move her body along the board. The therapist now just provides supervision in case Mrs. C. loses her balance and pitches forward during the transfer. The therapist instructed Mrs. C.'s husband and children how to "guard" her during transfers, which enabled Mrs. C. to transfer onto the couch in the lounge when her family visited.

   | Compare actual to expected performance | "Mrs. C. is actually progressing a little faster than I expected with physical tasks such as transfers and lower body dressing. Maybe her experience with the difficult and controlled postures of yoga helps her adapt her movements to her 'new' body. She also is not afraid to experiment with movement and that might be why she progressed so quickly with transfers and maneuvering the dressing stick for lower body dressing. Maybe I can push her a little more with the physical activities, as long as I watch her fatigue level." |

4. *Mrs. C. will prepare brownies from a box mix with verbal cues and stand-by assistance with a max of 13 on the Borg Rating of Perceived Exertion.*

   Mrs. C. was instructed in energy conservation techniques prior to the cooking task and identified three strategies she could use to reduce the energy demands of the task with four verbal cues from the therapist. She used reachers, a rolling cart, and long oven mitts to complete the task. She reported her perceived exertion was a 12. She shared her brownies with her family when they came in later to visit.

5. *Mrs. C.'s husband will bring in a layout of the first floor of their home with measurements, as requested by the occupational therapist in preparation for home modifications to increase wheelchair accessibility.*

   Initially, Mrs. C. and her husband preferred to wait on the home modifications, hoping that she might be able to walk with a walker upon discharge. When Mrs. C. got into her second week, they realized that significant changes needed to be made at home and the husband brought in the requested information. Mrs. C. was especially upset to learn that the bathroom door was 1 inch narrower than her wheelchair.

   | Know the person

Appreciate the context | "Funny, I did not really expect the resistance to bringing in home plans and measures. I guess those kinds of changes drive the reality of Mrs. C.'s disability home for both her and her husband. Mrs. C. seems especially upset about the bathroom. I wonder if her husband or a friend is handy enough to reframe the door so she can get to the toilet. We are also going to have to address the issue of the bed. I think she would be better off with a hospital bed until the brace is off because it helps with bed mobility and sitting balance for dressing, but this might be a 'hard sell' for both Mrs. C. and her husband." |

Next Steps

- Continue to modify short term goals to progress patient toward ADL, mobility, and cooking using adaptive equipment and methods
- Make preliminary recommendations for home assessment, collaborating with Mrs. C. and her husband to determine the "best" solution and provide a home program to support follow-through with recommendations (see Fig. 25-25)
- Complete a home visit with Mrs. C. and her husband to examine accessibility and make final recommendations
- Provide training to husband and children (as appropriate— determined collaboratively with Mrs. C.) in any areas that required assistance or supervision
- Examine options for home-based occupational therapy and write a referral

| Anticipate present and future patient concerns | "I think Mrs. C. will progress well with independence in occupational performance. I expect the home modifications will be a bigger challenge. She wants to be able to access the full bathroom and her bedroom upstairs, but this would require an expensive stair glide, which may be premature (and Mrs. C. has also said she does not want 'such an eyesore' in her house). Intellectually, I think Mrs. C. understands the problems. Emotionally, the choices are hard. The temporary 'fixes' make her feel more disabled (changing the living room to her bedroom, replacing the bathroom door with a curtain so she can get to the toilet, etc.). This is an issue that she will continue to deal with after discharge." |

| Decide if he or she should continue or discontinue therapy and/ or return in the future | "I think home-based therapy would be best for Mrs. C. after discharge. She certainly has a lot of skilled occupational therapy needs as we had little time to address a host of instrumental activities of daily living (IADL), as well as work and leisure tasks. She would qualify for home occupational therapy as she is home bound. Additionally, it would be helpful to work with her in her actual environment where she might feel more comfortable problem solving. Once she is out of the brace, she will become more mobile and should switch to out-patient therapy, which might include a driving evaluation and treatment and possibly return-to-work training." |

Modifications for the 1st floor bathroom:

Purchase:
- Left-side toilet armrest
- Raised toilet seat
- Towel rack
- Small shelf
- Insulation for pipes under sink
- Curtain for doorway

Inaccessible

Current towel rack

Current medicine chest

Wrap any exposed hot water pipes to prevent burns →

Pedestal sink

← Add small shelf to hold toiletries

← Add towel rack here

Install raised toilet seat

Install left toilet armrest

Entry problems:
- Door opens in and can't be closed with w/c in BR
- Doorway 1" too narrow

Short-term solution:
- Remove door (allows w/c to pass)
- Hang curtain for privacy

Long-term solution:
- Widen doorway
- Replace conventional door with pocket-door

Remove w/c legrests before entering bathroom.

Modifications for living room (temporary bedroom for Mrs. C.):
- The existing family room will remain available for visiting, watching TV, etc.
- This arrangement allows Mrs. C. privacy while retaining space for quiet visiting.
- The current plan is for the arrangement to be temporary until it is possible for Mrs. C. to access the 2nd story where her bedroom and full bath is.
- Purchases and modifications:
  - 1 or 2 privacy screens to reduce visability of the bedroom portion of the living room.
  - Empty the existing bookshelf to use for everyday clothing.
  - Bring a nightstand down from the upstairs bedroom.
  - Purchase a touch-lamp for the bedside table.

Open entryway from dining rm.

No coffee table (↑'s accessibility) →

End tables provide necessary surfaces without reducing w/c access.

Window

Retain some living room furniture

Hook to hang reacher

← Stack pants and tops

← Keep socks and underwear out of sight and organized in baskets

Keep shoes on bottom → use reacher

See detail

Purchase decorative privacy screen

Additional privacy screen, if desired

Bookshelf

Use a low bookshelf for clothes to increase accessibility and minimize "bedroom" appearance

Open entryway from foyer

Night stand

Window

Put touch-sensitive lamp on night stand to decrease range of reach needed to operate lamp from bed without twisting trunk

Hospital bed - replace with day bed once TLSO is removed.

Window

Figure 25-25   Home program for Mrs. C.: modifications to maximize independence in the home upon discharge.

Clinical Reasoning in Occupational Therapy Practice

Kitchen Modifications to Increase Independence and Reduce Fatigue

The occupational therapist is preparing for a predischarge home visit and would like to be prepared to make recommendations that would improve Mrs. C.'s ability to access cooking items from her wheelchair and to apply energy conservation strategies. The information from Mr. and Mrs. C. suggests that they have a fairly large kitchen with an eating nook at one end.

What are some common accessibility problems for wheelchair users in a typical kitchen? What supplies and/or equipment should the occupational therapist bring on the home visit to optimize her ability to assess and treat Mrs. C. in her home environment? What are some common environmental changes that the occupational therapist could implement to increase accessibility and reduce the energy demands of cooking in the home?

Summary Review Questions

1. How is occupation-as-end used to improve occupational functioning?
2. Define and contrast IADL and ADL.
3. What conditions interfere with the patient's ability to learn new ADL and IADL methods?
4. What principle of compensation is implemented when a patient with limited or restricted range of motion uses a sock aid?
5. What device can enable use of utensils when a patient lacks active grasp?
6. What modifications may be necessary to enable a person with C6 tetraplegia to complete the tasks required of a college student majoring in journalism?
7. What principles of compensation are used for problems of incoordination?
8. State the steps a stroke patient can use to put on and remove a cardigan-type garment.
9. Name five energy conservation techniques and give an example of each that could be used by a patient with cardiac disease for home management.
10. Identify two ways the task and/or environment can be adapted to enable a person with low vision to efficiently identify spices during cooking.

Glossary

Active learning—A process in which a learner is engaged physically and/or cognitively in a learning task. Learners are engaged in finding a solution to a problem (e.g., identifying three ways cooking can be modified to save energy) and/or engaging in actual practice of the solution (e.g., practicing putting on a sock with a sock aid).

Adaptation—Process of learning to function in an environment. Occupational therapists enable that process by modifying a task, the method of accomplishing the task, and/or the environment to promote independence in occupational functioning.

Blocked practice—Practice consisting of drills that include many repetitions of the same task performed in the same way (Schmidt & Lee, 2011).

Errorless learning—Process of learning in which the teacher structures learning activities in a way that prevents the learner from making errors. In contrast to trial-and-error

learning, this approach is designed to prevent learners from recalling and repeating errors made during prior attempts of a task, which can impede learning, particularly in those with impaired memory (Gillen, 2009).

Random practice—Practice of several related tasks within one session; sequence of tasks varies randomly (Schmidt & Lee, 2011).

Self-efficacy—The judgments people have of their capabilities to do or learn a task (Falvo, 2011; Sanford et al., 2006). Self-efficacy is task-specific and is dependent, in part, on an individual's past experience with a task or similar tasks.

Task parameter—A property or characteristic of a task that can be measured and addressed in treatment. Independence is the most commonly used, but other parameters might include duration of task, quality of performance, or level of fatigue resulting from task performance.

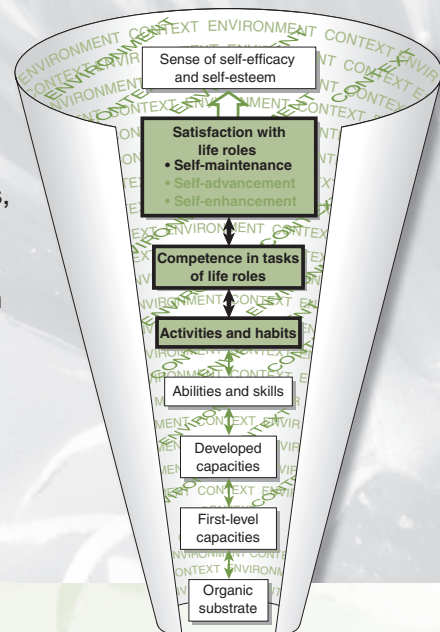
Restoring Functional and Community Mobility

Susan Lanier Pierce

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Explain why functional mobility and community mobility are considered an activity of daily living and instrumental activity of daily living.
2. Identify mobility issues to be addressed during the occupational therapy process and the role of the occupational therapy practitioner in goal setting and intervention.
3. State the hierarchy of mobility skills used to develop an intervention plan and describe how contextual and environmental factors influence performance.
4. Plan intervention to restore mobility through therapeutic activities and use of adaptive aids, devices, or alternative options and strategies.
5. Define the various meanings of community and how to identify barriers and enhance performance for safety in community mobility.


Mobility refers to moving about the home and community. Mobility is necessary for many activities and is therefore a key component of engagement in occupation. The Occupational Therapy Practice Framework (OTPF) identifies two types of mobility: functional mobility, defined as an activity of daily living, and community mobility, defined as an instrumental activity of daily living (American Occupational Therapy Association [AOTA], 2008).

Functional mobility relates to changing the position of the body, thus enabling a person to engage in chosen life occupations in the home and community. Functional mobility is defined as moving from one position or place to another during performance of everyday activities (AOTA, 2008). Functional mobility includes in-bed mobility, wheelchair or powered mobility, transfers (e.g., moving to and from wheelchair, bed, car, toilet, tub/shower, chair, floor) and ambulation while transporting task objects. Community mobility refers to moving around in the community including walking, driving, bicycling, accessing and riding buses, and using taxi cabs or other transportation systems (AOTA, 2008). Community mobility facilitates connectedness to others, to goods and services, and to the occupations of everyday life (Womack, 2012). Work, leisure, social, educational, religious, or political activities are examples of IADL that require mobility in the community. Restoring competence in functional and community mobility is a building block toward the end goal of supporting health and participation in life through engagement in occupations (AOTA, 2010). Both aspects of mobility must be addressed throughout the continuum of the occupational therapy process. Guidelines for the therapist in addressing functional and community mobility are summarized in Procedures for Practice 26-1. Evidence Table 26-1 presents the best evidence for occupational therapy practice regarding mobility.

DEVELOPMENT OF AN INTERVENTION PLAN FOR RESTORING MOBILITY

A person, whatever the age, client factor, or performance skill impairment, must be able to move about the surrounding environment to participate in the tasks and activities of the chosen life roles. Using a client-centered approach to mobility, the person and/or family contributes to goal setting and determination of successful outcomes in mobility. The therapist considers each client's individuality and personal circumstances and then customizes the therapeutic approach as necessary. The therapist must be an active listener to the client's thoughts and input during implementation of the plan and must be willing to modify techniques and strategies as needed.

During the process of obtaining an occupational profile, the therapist identifies the client's expectations for

Procedures for Practice 26-1

Guidelines to Address Functional and Community Mobility

- Gather and synthesize information from the occupational profile to identify specific areas of mobility that are important and meaningful to the client and identify his or her specific contextual factors.
- Select appropriate assessments to observe, measure, and identify barriers that hinder, or supports that facilitate, occupational performance as it relates to competence in mobility.
- Interpret all data collected to develop an intervention plan for safe mobility performance using the hierarchy of skill building as a guide (See Fig. 26-1).
- Select interventions that are based on available evidence and/or are considered best practice.
- Implement interventions that include improving performance skills to meet activity demands and/or applying assistive technology, adaptive devices, or compensatory strategies.
- Collaborate with other disciplines or specialists in the total care plan for successful outcomes to meet the client's mobility goals.

functional and community mobility so that the long-term goal for successful mobility becomes part of the intervention plan. The therapist analyzes the client's occupational performance; determines his or her capacities, strengths, and resources; and considers the contextual factors unique to the person (Womack, 2012). In the process, the therapist identifies circumstances that hinder or support mobility as related to activities of daily living (ADL). As particular mobility goals are identified within the client's chosen occupations, the therapist analyzes the specific activity demands.

After the therapist evaluates the client's occupational functioning and understands his or her occupational role(s), an intervention plan is developed that reflects the client's goals and occupational needs for mobility. The intervention plan for restoring competence in mobility must be developed in a sequence to reflect the hierarchy of skills of each mobility task and their increasing complexity as shown in Figure 26-1. Mobility addressed in BADL is followed by mobility addressed in IADL. Accomplishment in each area builds a foundation of performance skills that are required for the activity demands of the next higher level of mobility.

The performance patterns for ADL and IADL such as habits, routines, and roles may need to be modified or adapted to meet the client's current level of mobility skills.

Evidence Table 26-1	Best Evidence for Occupational Therapy Practice Regarding Mobility

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Review of assessment tools for predicting driving performance of persons with traumatic brain injury (TBI)	Systematic literature review of neuropsychological tests, off-road screening tests, self-reports and significant other reports, postinjury disability status, and comprehensive driving evaluation related to driving performance	Thirteen studies (5 experimental; 7 observational; 1 descriptive). Total sample size = 1,562. Exclusion criteria: published before 1995; not primary study; mainly qualitative or descriptive; if emphasized or established psychometrics; driving was not main outcome; included mixed diagnostic groups.	NA	Systematic review Level: IC2a	Recommendations based on each tool's ability to predict driving performance: Neuropsychological tests are not predictive of on–the-road performance. Simulator Testing: insufficient evidence. The Neurocognitive Driving Test (NDT), an off-road screening test: predicts on-the-road performance for people with moderate to severe TBI. Self-report and others' reports and disability status: provide low level of prediction. Comprehensive driving evaluation: insufficient evidence concerning prediction of safe driving performance.	Not reported	Classen et al. (2009)

Research Question	Description	Participants	Method	Study Design/Level	Results	Statistical Findings	Reference
Does Functional Capacity Evaluation, as part of a prevention program, predict at-fault crashes in older adults?	Functional Capacity Evaluation consisted of screening tools to detect loss of functional ability. The tools were: Motor-Free Visual Perception Test, visual closure subtest; Trail Making Test, part B; Delayed Recall Test; Useful Field of View Test, Subtest 2; Rapid Pace Walk Test; and Head-neck Rotation Test. First-time at-fault crashes determined from Maryland State Highway Administration data for individuals in the Maryland Pilot Older Driver Study (MaryPODS) over a 2-year period.	1,876 drivers from Maryland age 55 years and older who were randomly selected and then volunteered to participate	Volunteer participants were administered the Functional Capacity Evaluation in a one-time visit to the Motor Vehicle Administration.	One-group nonrandomized study Level: IIIA1a	Yes. Functional Capacity Screening can validly predict immediate and long-term risk of involvement in at-fault auto crashes in older drivers.	Odds ratios and chi-square tests were performed. Motor-Free visual Perceptual Test–visual closure subtest ($p < 0.001$); useful field of vision test ($p < 0.005$); rapid pace walk ($p < 0.001$); and delayed recall test ($p < 0.002$) were significantly valuable in predicting crashes shortly after the tests were administered. Delayed recall test and rapid pace walk were still predictive of crashes 1 year beyond test administration. The results indicate the need for periodic reevaluation, no more than 2 years apart.	Staplin, Gish, & Wagner (2003)
Does the environment influence walking speed and pedestrian safety in elderly people?	Participants took part in four randomly assigned trials. Two indoor trials were conducted on a level, tiled walkway and two outdoor trials were conducted on a simulated crosswalk. In one indoor and one outdoor trial, participants were told to walk a standard distance at preferred pace; in the other trials, participants were told to walk the same distance as quickly as possible.	Thirteen participants ages 77–88 years from independent-living resident facility. Exclusion criteria included deafness, history of stroke, myocardial infarction, and inflammatory arthritis.	One testing period; one trial per condition: 1. Indoor: preferred pace 2. Indoor: fast pace 3. Outdoor: preferred pace 4. Outdoor: fast pace	Randomized controlled trial Level: IC2a	For both pace conditions, significantly more time was required outdoors than indoors. Participants were significantly able to increase speed during fast-pace outdoor trial compared to the same condition indoors. The authors stated that these trials indicate that timing of crosswalk signals need adjusting to improve pedestrian safety for elders.	Not reported	Carmeli et al. (2000)

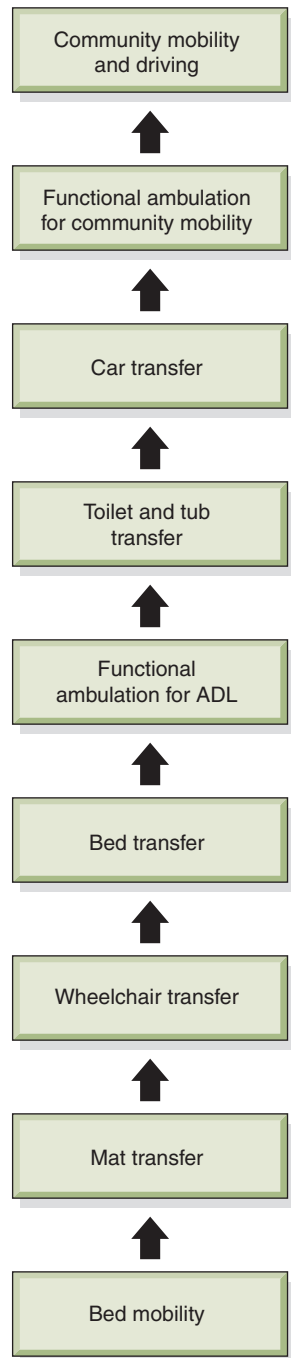
Evidence Table 26-1	Best Evidence for Occupational Therapy Practice Regarding Mobility *(continued)*					
Intervention	**Description of Intervention Tested**	**Participants**	**Dosage**	**Type of Best Evidence and Level of Evidence**	**Benefit**	**Statistical Probability and Effect Size of Outcome**	**Reference**
Usability of powered wheelchairs (PWCs) in home, school, or workplace, and community and outdoor environments	Assistive technology devices (includes PWCs) enable people with disabilities to function in multiple contexts and activities. The usability of such devices is indicative of the user's level of participation in multiple roles and occupations.	Seventy people of various diagnoses aged 18–65 years who used PWCs of various designs in small towns and suburbs of western New York. Exclusion: people who did not use their PWC outdoors and in the community	Each participant completed the Usability of Assistive Technology— Wheelchair Mobility (USAT-WM) questionnaire, which consists of 71 items in 7 subscales scored on a Likert scale. Participants' comments were also collected to explain ratings of ≤3 on the scales. One 45-minute interview session	Secondary analysis of data collected for psychometric evaluation of USAT-WM Level: IVA3a	Participants reported using their PWCs at home and work optimally, but issues of space and accessibility undermined their participation in these contexts. Usability issues were more apparent in community and outdoor contexts and had to do primarily with accessibility. Occupational therapists can document progress in PWC usability using the USAT-WM and can advocate for greater accessibility.	Qualitative and descriptive analysis only. Mean score for perfect usability = 5.0. PWCs were highly usable, with a mean score of 4.23 (standard deviation [SD] = 0.83) at home and 4.32 (SD = 0.59, *n* = 27) at workplace or school. Mean scores for the community and outdoor usability were 3.60 (SD = 0.77) and 3.74 (SD = 0.62), respectively. Mean scores for the user-wheelchair interaction subscales were high to very high at 4.25 (SD = 0.54) [ease of use], 4.36 (SD = 0.69) [seating] and 4.32 (SD = 0.56) [safety].	Arthanat et al. (2009)


Figure 26-1 The hierarchy of skill building for restoring competence in mobility is based on increasing activity demands of each task and illustrates the sequence for intervention planning. ADL, activities of daily living.

The therapist will explore the client's prior methods of accomplishing a particular occupation. For example, shopping for groceries entails moving out of bed, getting dressed, and having nourishment before moving outside the home and using a safe mode of transportation to the store. Once inside the store, the person must move safely through the store to shop, push a shopping cart, stand at a cash register, pay for and transport the items outside, load them into the transportation vehicle, return home, and unload and transport the items into the house for storage. Each of these mobility tasks requires a certain level of motor skills such as strength, coordination, and range of motion, as well as visual and cognitive skills such as peripheral vision, visual acuity, problem solving, decision making, and attention. The therapist will develop a plan, along with the client, to remediate those skills that can be improved, but achievement of safe mobility may also include intervention using assistive technology and adaptive devices and/or accommodations or compensatory strategies for an identified, unremediable barrier.

A client may have more than one area of impairment in performance skills combined with one or more client or contextual factors that hinders safe mobility. A person with rheumatoid arthritis, for example, may have decreased range of motion, weakness, and low physical endurance but also may be aging poorly with obesity and diabetes. A person with a spinal cord injury may have decreased sensation and paralysis in the lower extremities as well as tall body structure and poor trunk balance. A person who had a stroke or traumatic brain injury may have motor as well as visual and cognitive impairments that all hinder safe mobility. All impairments and contextual factors must be taken into consideration in developing the intervention plan.

With inpatient rehabilitation so brief, the level of mobility a patient achieves on discharge will not be the same level that the person can achieve 6 or 8 months postdischarge. The inpatient therapist should plan long-term postdischarge goals for mobility with the patient and the family so that outpatient intervention can carry on the identified goals for maximum independence in mobility. Independence in community mobility will more than likely be achieved during or after the outpatient rehabilitation process and intervention. Educating the client and family of this fact will prevent the client from becoming discouraged and will prepare the family to provide necessary transportation until the client is ready to pursue intervention goals for restoring competence in community mobility.

Environmental or Contextual Factors Influence Mobility

To holistically evaluate the ability of a person to move about in the world requires the therapist to consider not only the person's capacity for movement but also the desired destination and the context in which the mobility will take place (Womack, 2012). Mobility may be affected differently in the various environmental contexts of the individual; therefore, the therapist must consider mobility skills in all relevant environments. For example, a client who had a stroke may require a

wheelchair outside the home but be able to ambulate around the home with the assistance of an orthotic device such as a cane. Another client who had a stroke may require a wheelchair for mobility in, as well as out of, the home. For each of these clients, the wheelchair has to be considered as a necessary mobility device. Skill building strategies for mobility are listed in Procedures for Practice 26-2.

Functional mobility considers ambulation with or without an assistive device, manual wheelchair propulsion, or safe operating techniques for powered mobility. Initial mobility skill training in a controlled, therapeutic environment is the foundation for enhancing the client's safety and independent functioning eventually in the home, school, workplace, and other environments (Kirby et al., 2002). The first phase of functional mobility intervention will take place in the accessible environment of the hospital room or therapy clinic. The second phase considers the client's mobility relative to his or her actual home and chosen communities (see Chapter 10) which is crucial for discharge planning. The client's environmental context may not consist of the level floors, low-pile carpet, easy curb cuts, or nicely ramped entrances of hospitals and rehabilitation facilities. The outdoor terrain around the home may be soft dirt, sand, or thick grass. Functional ambulation with orthotic devices or mobility devices such as a wheelchair may be hindered because of a home's narrow hallways and doorways. The client may have to transfer onto a waterbed or soft mattress rather than the adjustable height surface of a firm hospital bed. There may not be a roll-in shower, so the client may have to learn to use a regular tub with a tub bench. Even if the client will be discharged to an assisted-living environment, maximum independence in mobility for that environment should be sought. Whether the client walks or uses a wheelchair and has an ideal situation or not, it is crucial to know the real-world environment for that person so the intervention plan for mobility and the final outcomes will be of real value and meaning to the client. The second phase of intervention, therefore, takes into consideration the actual environments to which the client will be returning so that realistic training can take place using mock environments set up in the therapy clinic or in simulated environments in or around the treatment facility.

The third phase of intervention addresses community mobility and must consider the client's definition of his or her community and the chosen or available modes of travel. The whole environmental context includes exit from the house, use of the yard, the neighborhood, and the community locations where the person, works, attends school; participates in public, cultural, or religious events; or participates in voting or shopping.

Interdisciplinary Team Approach Is Important

Teamwork between occupational therapy and other disciplines is important for intervention planning in mobility so that all disciplines can share a vision of targeted intervention outcomes for mobility that are realistic. Occupational therapy and physical therapy both may have goals related to mobility; however, each discipline will be addressing a different facet of mobility and will use different modalities and techniques to restore competence in mobility. For example, a physical therapist will address a patient's ability to stand while the occupational therapist will address the patient's ability to stand for a period of time to complete an activity such as washing dishes at the kitchen sink. A physical therapist will address a patient's ability to walk with good balance and good gait technique, while the occupational therapist will address the patient's ability to walk around in the kitchen to cook a meal or into a laundry room carrying the dirty linens.

Each discipline must know the other's intervention goals and strategies as they relate to planning for targeted outcomes in functional and community mobility. Communication between team members eliminates unnecessary duplication and promotes carryover of skills. The direction the occupational therapist takes in pursuing BADL should be influenced by the patient's achievements in physical therapy with lower extremity functioning and ambulation. Conversely, independence in bed mobility achieved in occupational therapy may influence balance and transfer training in physical therapy. Achievement of physical therapy goals that are precursor skills for functional mobility intervention may take several weeks, so during this time, the occupational therapist works on BADL that do not demand a high level of lower extremity

---

Procedures for Practice 26-2

Skill Building for Mobility

- Moving in the immediate space, such as rolling from a supine to prone position, repositioning the trunk and extremities, or moving from a lying to seated position
- Moving in the bed for body positioning or basic ADL such as dressing or skin inspection
- Moving out of bed and into the surrounding areas such as into the bathroom for hygiene activities
- Moving around the level, accessible environment of the therapy setting for intervention of performance skills or for other ADL such as kitchen activities or feeding
- Moving on the uneven terrain of the outdoor environment
- Moving around in the client's home and neighborhood environment
- Moving about the chosen community environment(s)

strength, trunk balance, and endurance. For example, a patient who is expected to walk at discharge will initially perform grooming or kitchen tasks while seated. When the patient has achieved standing tolerance and balance in physical therapy, the occupational therapist can incorporate standing in activities such as grooming activities at a bathroom sink and washing dishes at a kitchen sink. When it is determined that the patient will be using a wheelchair when discharged from the hospital, the occupational therapist works on teaching the patient how to propel the wheelchair and perform activities from the chair, such as dressing and cooking. If the patient will be a functional, but limited, ambulator with an orthotic device, the occupational therapist must incorporate the device into the intervention goals for functional and community mobility. For example, a person who uses a cane or walker has to learn to maneuver in the kitchen with this device while cooking.

INTERVENTION FOR FUNCTIONAL MOBILITY

The OTPF suggests that functional mobility pertains to taking care of one's own body. Functional mobility tasks occur throughout a person's daily routine under varying circumstances and within changeable environments. ADL and IADL require movements with optimal motor and sensory awareness, stabilization of the body in space, and postural control with varying static and dynamic balance demands. Intervention for functional mobility begins with the basics of moving in space, and then mobility in ADL performance is considered followed by mobility for IADL performance. As successful outcomes are obtained in the basic areas, the intervention plan is reassessed to include more complex mobility skills.

Intervention plans include the type or level of assistance needed for mobility, movement patterns/techniques to control an ambulatory device or wheelchair, and types of terrain in the patient's environmental context that may hinder safe functional mobility. Intervention focuses on performance skill impairments, client factors, and contextual factors that support or impede mobility. Strategies to enhance performance skills for safe functional mobility are evaluated and continually modified to assist the person in compensating for impairments in body structure or body functions that affect movement in space. Personal factors of age, health, and well-being may influence the selection of mobility interventions. Functional mobility will be addressed at varying degrees and level depending on the time constraints and venue. For example, a practitioner seeing someone in an acute care setting may concentrate on bed mobility tasks as they relate to basic self-care activities. The practitioner within a rehabilitation setting may approach functional mobility more comprehensively in relation to the more complex ADL and IADL (Kane & Buckley, 2011). The occupational therapist must evaluate and provide intervention

if necessary for the following areas related to functional mobility:

- bed mobility
- mobility using a personal mobility device (PMD)
- transfer mobility
- functional ambulation for ADL

Implementation of intervention will initially address therapeutic goals of the client regarding functional mobility such as moving around in bed, in and out of bed, into the therapy clinic, or onto a treatment mat. For example, a patient with quadriplegia who is working toward the goal of lower extremity dressing must achieve safe bed mobility performance requirements first that involve moving and posturing the body and limbs in addition to handling task objects such as pants, socks, or leg bag. Once the basic areas of functional mobility have been achieved, intervention is modified to address functional mobility of greater complexity that is involved during the performance of specific ADL. A hierarchy of skills exists within a specific area of functional mobility. For example, a patient learns to sit on a hard surface without support, such as a mat, before sitting on a soft surface, such as a bed, in order to eventually transfer to and from the bed. The occupational therapy practitioner will determine whether functional mobility aids are needed to enhance the patient's performance or safety. The functional mobility aids to be discussed in this chapter are leg lifters, bed rope ladder, transfer boards, and PMDs such as wheelchairs, walkers, canes, and body lifting devices.

Bed Mobility

Bed mobility is the ability to move the body in bed to perform activities in the various positions of supine, prone, side lying, or sitting. Bed mobility includes all of the tasks of rolling from side to side, rolling from supine to prone and back, and sitting up. These are basic functional mobility tasks that provide the basis for initial provision of medical care in a hospital, rehabilitation center, or nursing home setting as well as to allow an individual to engage in self-care activities at home. During bed mobility maneuvers, the individual must move the trunk, head, neck, and all extremities necessary for the position change and for postural control. A person must accomplish the goal of rolling his or her body from side to side before the goal of moving the legs over the side of the bed can be accomplished in preparation for sitting on the bedside. Similarly, there are performance requirements to move the body and limbs to the side of the bed in preparation for a transfer to a wheelchair. Bed mobility is also necessary for a person to posture the body for sleep, for changing positions to shift weight or reduce pressure on bony prominences that are prone to skin breakdown, and for using a skin

inspection mirror or bedpan. Basic functional mobility skills prepare for transferring out of bed. In goal setting for moving out of bed, the skills for rolling, coming to a sitting position and ability to stand up will determine whether alternative methods will be necessary for functional mobility out of the bed.

Bridging and Rolling in Bed

The first task to accomplish in bed mobility is bridging the hips. Bridging is simply lying supine on a surface and by using the back and hip extensors, the buttocks, upper legs, and lower back are lifted off of the supporting surface so that contact is only made with the upper back, shoulders, head, and feet (see Fig. 26.2). Strength in the back, quadriceps, lower abdominals, and gluteal muscles are important for this task as are ankle and knee stabilization. Bridging is a movement strategy that is taught by the occupational therapist to allow the patient to move the buttocks onto a bedpan, to pull pants over the hips, and to assist with moving the body laterally for changing bed positioning. A loss of motor or sensory function unilaterally or bilaterally will present a challenge to this task that will require the therapist to analyze the patient's impairment and enhance the bridging ability by strengthening, practicing, or learning a different technique. For example, a patient with lower extremity and abdominal/back muscle paralysis will not be able to perform bridging and will have to learn different strategies without hip bridging for donning pants. A patient with hemiplegia who is attempting to bridge the hips may cause an extension pattern in the affected extremity that does not allow for the necessary hip extension, knee flexion, or foot stabilization. The person may have to learn to compensate by bridging only with the stronger side.
Figure 26-2 The person illustrates hip bridging while lying on a bed with hips and knees flexed and feet flat on the mattress. Using back and hip extensors, the hips are lifted off of the bed to assist in pulling pants over the hips, moving the body laterally or moving onto a bedpan.

The second task to accomplish in bed mobility is rolling. Rolling of the body can involve moving the body completely from a supine to a prone position or rolling onto one side. Rolling the body is vital to weight shifting, to changing postures in bed for sleep, and to pulling pants over the hips in lower extremity dressing. Rolling is also a precursor for long or short-leg sitting in bed, which in turn is a precursor for moving out of bed whether to stand or transfer onto another surface such as a wheelchair. One of the most common movement strategies used to roll from supine to prone is a lift-and-reach arm pattern (Kane & Buckley, 2011). Movement of the head and trunk is initiated by lifting the shoulder girdle and reaching with the arm and hand in the desired direction. Typically, the momentum will cause the leg on the same side to lift and follow as the body rolls.

Sitting in Bed

Long-leg sitting is the posture in which the legs are extended straight out in front of the person on a flat surface and the hips are flexed to at least 90° (Fig. 26-3C). A position greater than 90° of hip flexion must be achieved to maintain balance in a long-leg sitting position when trunk and hip musculature are weak. Long-leg sitting can permit other activities in bed such as watching TV, reading, donning a shirt, or taking medication. Short-leg sitting is the posture in which a person sits with the hips flexed at least to 90° and the knees are flexed over the edge of the surface (Fig. 26-3F). The feet may or may not touch the floor, but stability is aided if they do. Short-leg sitting allows for activities to be performed while sitting on the edge of the bed such as donning a shirt, putting on shoes, or preparing to stand or to transfer to a wheelchair. Postural stability and balance are necessary for safe short- and long-leg sitting. Trunk length, leg length, weight, abdominal circumference, muscle tone, motor strength, cognitive status, vestibular reactions, and vision must all be considered by the therapist when evaluating stability and balance for sitting.

Intervention by occupational therapy focuses first on static sitting balance and then on activities to challenge dynamic balance in a sitting position. Intervention for sitting balance would begin on a flat, hard mat and then progress onto the soft bed mattress. Throwing or catching a ball or performing dressing activities are appropriate interventions to challenge and improve a client's sitting balance. Balance improves either because weak trunk muscles get stronger or because the patient learns adaptive strategies, such as balancing by lowering the center of gravity and using the neck muscles to right the body. *Safety Message: While the person is working on improving balance on the mat or in bed, the therapist must maintain close supervision and proximity to the client and be ready to catch the person if balance is lost in any direction.*

Figure 26-3 A person with C7 quadriplegia illustrates the steps for coming to a sitting position in bed without the use of assistive devices. **A.** The woman uses shoulder and scapula muscles to move to resting on elbows. **B.** Triceps and shoulder depressors in one arm are used to lift the upper trunk while balancing on the other flexed elbow. Then by straightening the bent arm, she pushes the whole trunk upright until she is in a long-leg sitting position. **C.** She can hold her balance by extending one arm behind her on the bed while using the other arm to reposition the legs as needed. **D.** Once she is close to the edge of the bed, she can lean on one arm, which is pressing into the wheelchair seat, to hold balance while she moves the outside leg off the side of the bed. **E.** She then moves the inside leg off the side of the bed. **F.** Once in a short-legged sitting position over the edge of the bed, she prepares for a sliding transfer to a wheelchair seat.

A client who does not have the ability to restore bed mobility competence will require the assistance of one or more persons to accomplish the tasks safely. One or more persons can assist with rolling the upper and lower body in the proper sequence or complete a log-roll technique that moves the entire body at once. Figure 26-4 shows a person with incomplete quadriplegia and proximal weakness in the shoulders and hips being assisted with rolling to one side. *Safety Message: The therapist must ensure that care partners learn and use good body mechanics.*

Assistive Devices for Bed Mobility

A person with motor impairment in the trunk or one or more extremities may require an assistive device to

Figure 26-4 A person is assisted in bed mobility by a caregiver. In preparation for sitting up in bed, the caregiver assists the person in initiating the movement of rolling the head and trunk by pulling his left shoulder toward her. Proper body mechanics by the caregiver are crucial with hips and knees bent and back straight.

pull on in order to begin rolling and then to assist with maintaining a side-lying position or with the movement toward sitting. Devices commonly used are a rope ladder, an overhead trapeze bar, a bed rail (see Fig. 26-5), or even a wheelchair positioned near the bedside. These devices can be used to give a person something to grasp with the hand(s) or forearm(s) so that rolling can be initiated or pulling to a seated position in a long- or short-leg position in bed can be accomplished. Good scapular, shoulder, and elbow strength are the minimum requirements for using these devices. Wrist flexion and extension and hand grasping capability are helpful, but a person with weak or no grasping capability can use the same devices by hooking the forearm or the extended wrist around the device and using strong wrist extensors and/or elbow flexors for the pulling action.

The rope ladder (Fig. 26-5A) is a device having two long parallel pieces of strapping connected by "rungs." One end of the ladder is attached to the foot of the bed or over the side of the bed. The person pulls with one or both upper extremities using each rung in progression

until he is at the desired position. The overhead trapeze bar (Fig. 26-5C) is a grab handle on a stable base that has adjustable positions and flexibility in the handle angles. This device can assist a person in rolling over, lifting the hips up to move onto a bedpan, scooting the body position in bed or in obtaining a long-leg seated position. The various configurations of bedrails of long and short length, portable or permanently mounted, can assist a person in rolling over, in body positioning for sleep or obtaining a short leg seated position on the side of the bed (Fig. 26-5B). A person can also use a locked wheelchair that is positioned next to the bed. By grasping a stable secure part of the chair such as the nearby armrest or push handle, the person may initiate rolling or sitting.

For rolling, the person grabs a rung on the rope ladder, bedrail, or wheelchair part with the arm closest to the side of the bed toward which he is rolling. Then by reaching with the other arm to grab the device and pulling, rolling of the body is gained, and the hip and leg will typically follow. If the hip and leg do not follow, the person can use an extended wrist or hand to push the knee or thigh to assist in moving.

If the patient's lower extremities are paralyzed, the person must manually move the legs over the side of the bed. For the dependent person, another individual swings the person's legs off the edge of the bed. A leg lifter is a device for moving one leg at time. This device has a large loop at one end that can be placed around the foot or thigh and a smaller loop or handle at the other end that a person can grasp for lifting the leg (Fig. 26-5D). The device is offered with the strap supported by a dowel stick or without that stiffness for a flexible strap. The flexible strap is ideal when moving a leg in a small space where knee flexion may be required such as when moving the extremity into a car seat. The device can be used to move paralyzed legs in bed or if the person has limited hip flexion and cannot reach the leg for moving it.

A hospital bed with powered head and knee controls can also assist a person with bed mobility and can be helpful for lower extremity dressing in bed. By raising the head and upper trunk, both hands are freed from holding one's balance to perform the task at hand. Contextual factors may influence this choice because not every patient can afford to purchase a hospital bed or chooses to use a hospital bed once at home. The occupational therapist will analyze the individual, task, and environment to determine the best method or device for the individual to use in accomplishing safe bed mobility.

If a patient is not able to move out of bed independently, there are a variety of lifting systems that can assist the person or caregiver in moving out of bed and to multiple locations such as to a toilet or tub

Figure 26-5 Devices that assist with bed mobility. **A.** Bed ladder pull-up. **B.** Bed rail assist. **C.** Overhead trapeze bar. **D.** Leg lifter. (Courtesy of North Coast Medical, Morgan Hill, CA.)

(see Fig. 26-6). The lifting systems can be on a movable frame, on a freestanding frame that hangs over the bed, or on a moving track that runs on the ceiling. The moveable frame lift requires one or more persons to physically move the lift with the person in it. Some lift systems can move the person from one room to another by way of ceiling tracks that run over the bed and through a doorway into the bathroom and then over the toilet, tub, and/or shower. A client who is able to attach the body support pieces of the lift and operate the remote motor control may have the capability to move independently out of bed into a wheelchair or over a toilet or into a tub. The occupational therapist must consider client factors (such as stature, weight, and postural stability), client performance skills, where the lift will be used and for what purpose, the activity demands of the lift system to determine the safest one for the client and the operation of the remote controls. The size and configuration of the seat sling or postural support offered by the system, the location of the body support pieces, presence or absence of underarm supports, and location and type of controls vary with each make and model. *Safety Message: Intervention must include careful instruction and multiple practices during ADL with the client and family to ensure safe use and operation of the lifting system.*
Figure 26-6 Motorized lifting systems assist physically challenged individuals or their caregivers in transfer goals for accessing the bed, shower, tub, toilet, or pool. (Courtesy of SureHands Lift & Care Systems, Pine Island, NY.)

Activities of Daily Living in Bed

Some persons may be able to, or choose to, dress while sitting on the edge of the bed or while standing. Persons with lower extremity or trunk paralysis may need to perform BADL such as dressing, skin inspection, self-catheterization, and/or a bowel program while lying in bed. Those persons that use a leg bag for urine management may need to disconnect tubing from a bed bag that collects urine during the night and reconnect the tubing to a smaller leg bag that is worn during the day. While dressing in bed, it is necessary to reach one's feet by flexing the hips and knees so that the feet are closer to the hands for preparing to don pants, socks, and/or shoes. Independence in rolling from side to side and reaching one's buttocks are important for performing manual bowel stimulation and clean up or using a long-handled mirror for skin inspection.

Bed mobility is illustrated in Figure 26-3 with a client with C7 quadriplegia who does not require the use of any assistive devices. Good strength in the deltoid, pectoralis major and minor, biceps, wrist extensors, and scapula muscles is key to support these tasks without assistive devices, so strengthening these muscle groups in therapy is preparatory to learning this technique. Even without trunk muscles, a person can perform safe bed mobility, but a sense of balance for sitting and transferring must be developed, practiced, and accomplished during intervention.

Transfers

A transfer is the means by which a person moves one's body from one surface to an adjacent surface (Definition 26-1). Therapists must consider transfers to all surfaces including the tub, shower, toilet, and eventually a transportation vehicle (Fairchild, 2013). Adaptive equipment, such as grab bars, a raised toilet seat, or a tub bench, can assist a person with easier and safer transfers. There are various techniques for safely performing a transfer, and the occupational therapist must work in conjunction with the physical therapist to determine the best method for each client.

Definition 26-1

Various Types of Transfers

Dependent Transfer

Person requires maximum assistance of one or more persons using a special technique or device to assist in moving from one surface to another.

Sliding Board Transfer

Person cannot bridge the gap between two surfaces without the use of a sliding board.

Standing Pivot Transfer

Person can stand up, pivot the feet and turn the trunk, and then sit down on the transferring surface.

Independent Transfer

Person can perform all steps of a transfer with no physical assistance from another person. A device may or may not be used.
Figure 26-7   Proper body mechanics for lifting an object are illustrated. The object is maintained close to the body. The person looks straight ahead, squats by bending the hips and knees and keeping the back straight. Lifting begins by straightening the knees and hips and keeping the object close to the body.

The transfer technique can be simple or complex and the method chosen depends on the patient's client factors, upper and lower extremity strength and range of motion, physical endurance, trunk balance, body type, orthotic devices, and/or wheelchair style. Skill building for transfers is necessary as the patient progresses through the rehabilitation process. A dependent transfer may be necessary until the person can begin learning assisted or independent transfers.

The intervention must include instruction and practice in a supervised environment until the patient is safe for less supervised situations. To prevent back injuries, the therapist must know and practice proper **body mechanics** during lifting, bed activities, and transfers, and furthermore must instruct and ensure that the family and patient understand the concept as well (Fairchild, 2013). Figure 26-7 illustrates proper body mechanics for lifting and basic principles of good body mechanics are listed in Safety Note 26-1. Back injuries must be avoided. After the first time one injures the back, it becomes vulnerable to future injury and can alter a therapist's or family member's quality of life and even livelihood.

A client must achieve competence in basic transfer skills for moving on and off a therapy mat and bed before working on the more difficult transfers such as to a toilet, to a shower chair, and perhaps eventually into a car. Transfers from the floor to a wheelchair or into a car are the most difficult of transfers because of the height discrepancy and space gap between the two respective seat levels. In addition, during a car transfer, the patient must handle both legs through the cramped space of a car door.

Dependent Transfer

A person who is too weak to move requires assistance from another person or persons for moving his or her body from one place to another using a dependent transfer.

Safety Note 26-1

Principles of Good Body Mechanics

- Pause and think before lifting or moving anything. Plan the path and technique.
- Keep the load to be lifted or carried close to the body at all times and if possible at the level of the belly button.
- Maintain a good posture and keep the whole body in straight alignment throughout the activity. Keep the entire back straight with the chest out and the shoulders level and squared back (not rounded or slumped forward), looking straight ahead. The hips should be in line with the shoulders and the ankles with the hips. Avoid twisting by rotating the whole body and changing directions with the feet.
- When picking up an object, squat down, bending at the hips and knees only instead of the waist so the leg muscles are used and not the weaker back muscles. If necessary, put one knee to the floor and the other knee in front bent at a right angle in a half kneeling position. After grasping the object firmly, lift the object while keeping the back straight, tightening the abdominal muscles and slowly straightening the hips and legs (see Fig. 26-7 middle picture).
- Position the feet shoulder width apart with one foot slightly ahead of the other for a wide base of support.
- If sliding an object, such as a client in preparation for a transfer, rock back on the heels while keeping the back straight with hips/knees bent so the physical lift or rotation uses the stronger muscles of the arms and legs to carry the weight and a strain on the back muscles is avoided.

Adapted from Dartmouth-Hitchcock. (2012). *Back problems: Proper lifting*. Retrieved September 1, 2012 from http://patients.dartmouth-hitchcock.org/health_information/health_encyclopedia/sig59692.

Figure 26-8 Proper body mechanics are used by a therapist during a simple and safe dependent wheelchair-to-bed transfer for a person with quadriplegia. The client must have the trunk flexibility to lean forward over the thighs, but this technique works for light to heavy weight clients. **A.** The therapist positions herself in a close proximity to the patient with feet apart, shoulders square and level, back straight, and hips and knees bent pressing around the patient's knees. The therapist slides the client's buttocks forward in the seat to eliminate proximity to the rear wheel during the transfer. **B.** The patient is leaned forward onto the therapist's outside thigh. If able, the patient can assist with balance with the left hand on the wheelchair tire. **C, D.** The therapist uses the strength in her arms and legs to rock the patient forward, placing her hands under the buttocks and lifting them off the wheelchair seat. With the patient's weight shifted forward, there is little weight to pick up, and the therapist rotates the client's buttocks onto the bed with relative ease, maintaining good body mechanics throughout the transfer.

A one-person technique entails standing in front of the patient and placing him or her in a forward flexed position with the chest lying on the thighs. This flexed position shifts the patient's body weight over the knees and ankles rather than on the buttocks, which allows the buttocks to be picked up and moved more easily. This method has proven worthy to teach family members because it enables the helper to control the movement of the patient's body while lessening the probability of hurting his or her own back (Fig. 26-8). Note that this method cannot be used for the patient with limited hip flexion, for example, those with a hip fracture or heterotopic ossificans or those who are posthip replacement surgery. For the patient with limited hip flexion, this technique is modified to sliding the buttocks toward the edge of the wheelchair (in a wheelchair to bed or toilet transfer) and placing the patient's knees between the helper's knees. Using proper body mechanics, the assistant squeezes the knees of the patient with his or her own knees while rocking the patient forward slightly and simultaneously pulling on the patient's pants or belt and rotating the hips to the surface being moved to. For a two-person dependent transfer, the first person stands behind the patient, threads his or her hands under the patient's axillae to hold onto the patient's flexed forearms, and lifts up to move the buttocks to the transfer surface while the second person moves the legs. A transfer board, sometimes called a sliding board, can be used to bridge the gap if the buttocks cannot be raised easily.

Sliding Board Transfers

A person who cannot stand but can slightly lift the buttocks off the surface by doing a push-up, can use a transfer board to slide the buttocks and bridge the gap between two transfer surfaces (Fig. 26-9). There are a wide variety of shapes, lengths, weights, and styles of transfer boards available from various manufacturers. A long transfer board may be needed for the difficult transfer into a car to bridge
Figure 26-9 Examples of different transfer boards available through suppliers. **A.** Transfer board with hand holes and notches allows transfers from either side. **B.** Offset transfer board fits around the wheel of the wheelchair when the armrest is removed. (Courtesy of North Coast Medical, Morgan Hill, CA.)

the large gap and the seat height discrepancy between a wheelchair and a car seat (Fig. 26-10A), but a shorter board can be used for transfer to the toilet or bed because the gap is smaller. A cutout on one end of the board may be needed to allow the person with a weak grasp to pick up the board. An angled or notched board, as shown in Figure 26-9B, may be best for maneuvering around the rear wheel of the wheelchair while transferring. A board made of high-density polished plastic, shown in Figure 26-9A, provides a slippery surface for bare skin while a board with a moving center disc allows easy sliding of the body.

Most transfer boards are positioned with one end under the patient's buttocks and thighs and the other end on the surface to which the person is transferring. Level surfaces greatly aid in the transfer, although one can use gravity to assist when sliding to a lower surface. A person may require a transfer board for a car or toilet transfer but not for other transfers in the home. The client with good

Figure 26-10 A sliding transfer with one person assist from a wheelchair to a car seat is illustrated. Assistance is required by this client for placement/removal of the transfer board as well as storing/unloading the manual wheelchair in the vehicle's trunk. **A.** The person leans to the outside of the wheelchair while the helper places the transfer board under the person's buttocks and on the car seat. The long transfer board is necessary to bridge the large gap between the wheelchair and car seat. **B.** The client extends her elbows and depresses the scapular, which lifts her weight from her buttocks and allows her to slide on the board moving sideways toward the car seat. **C.** This person found it easier to keep the legs outside the car until the transfer onto the car seat was completed. Then the left lower extremity is moved into the car with the right hand while balance is maintained by leaning against the dashboard of the car. **D.** The right leg is lifted into the car in similar manner.
shoulder/scapula muscle strength will be able to accomplish an independent sliding transfer using this device. The patient leans forward on extended elbows for balance and to shift weight from the buttocks. Using scapula depression, pushing with her hands on the wheelchair arm and seat, and maintaining balance, she slides her buttocks to the left from the wheelchair to the driver seat (Fig. 26-10, B). The person then handles both legs into the car (Fig. 26-10, C & D). Factors that can impede a safe sliding transfer include

- poor trunk balance
- spasticity
- excessive body weight or large, heavy legs
- inadequate upper extremity strength
- inability to lock elbows into extension
- joint contractures or tightness in the elbows or wrists that prevent full elbow extension and/or full wrist extension
- a low ratio of arm length to trunk length

Off-the-shelf boards do not always meet specific needs of clients, so therapists may have to custom-make or modify an off-the-shelf transfer device to meet a particular need. In Figure 26-3D, the client's occupational therapist made a custom board with plywood covered in high-density foam and vinyl to bridge the gap between the bed and the wheelchair seat. The client was able to easily manage placement of the board, and it fit the exact space gap for this transfer to enable the client to move safely and efficiently. The same idea for a custom transfer board was carried forward in community mobility goals when the client learned to drive an adapted van and needed to transfer onto the van driver seat. A similar but second custom transfer aid was made by the therapist to bridge the different space gap between the wheelchair and driver seat surface (see Fig. 26-11).

Stand-Pivot Transfer

A person with lower extremity deficits, who can support his or her weight on one or both legs, may be able to perform an independent or assisted stand-pivot transfer. An assisted stand-pivot transfer is performed with the helper standing in front of the patient and the transfer surface as close as possible. Generally, it is best to transfer the patient toward his or her stronger side. The patient should first be slid toward the edge of the surface from which the transfer is taking place, with care to protect the person from slipping off the edge completely, especially if there is lower extremity or trunk spasticity. The patient is assisted to a standing position (Fig. 26-12). The helper places his or her

Figure 26-11 A person with C7 quadriplegia demonstrates an independent sliding transfer from a powered-base wheelchair to a van driver's seat using a custom-made transfer board made by the therapist to bridge the gap between the two seats. **A.** The person maneuvers the wheelchair into the van backward and aligns the wheelchair seat adjacent to a van seat that is powered swiveled toward the rear of the van. The transfer board is covered in vinyl and wedge shaped to fit between the wheelchair seat and the driver seat, to create a flat, smooth surface and safe bridge for the client to slide on. The special board eliminates the hard task of putting a sliding board under the buttocks pretransfer and removing it post-transfer. **B.** The person prepares to transfer by leaning slightly forward onto the left arm. By pushing down on the right hand and using shoulder depression to relieve pressure under the buttocks, she lifts and slides her buttocks to the driver seat. **C, D.** She repositions each leg from the wheelchair footrest onto the van floor. The driver seat is then swiveled to the left to allow positioning under the steering wheel.

Figure 26-12 A patient with left hemiplegia is assisted to a standing position by one person. **A.** The patient places the unimpaired right hand on the therapist's shoulder for support. **B.** The therapist positions her knee in front of the patient's weak left knee to prevent the left knee from buckling as the person stands. The patient leans toward the therapist and the strong side to move the center of gravity forward. **C.** The patient uses the strength of the unimpaired side with the guidance of the therapist to extend the hips and knees to a standing position. (Reprinted with permission from Gillen, G. [2011]. *Stroke rehabilitation: A function based approach.* St. Louis: Elsevier/Mosby.)

knees in front of one or both of the knees of the patient to prevent the patient's knees from buckling upon standing. The patient wraps his or her arms around the helper's body or neck, but only for support, not to pull up. The helper bends his or her knees, keeps the back straight, and grabs the waist or belt of the patient's pants or a transfer belt. This belt with handles is wrapped snugly around the patient's waist and provides a handhold for the helper. The helper rocks the person back and forth several times and then using momentum pulls the person to a standing position. A patient can assist by using leg strength to stand or upper body strength to push off the wheelchair or chair armrest or bed rail to come to standing. By pressing against the weak knee or knees, the helper assists the patient to swivel or slide the heels toward the transfer surface while standing. The helper can then guide the patient's hips over and down to the transfer surface while again bending at the hips and knees rather than the back.

Independent Transfers

Patients with adequate strength to push up and move the trunk and to handle the lower extremities may learn to transfer safely and independently. Figure 26-13 illustrates one method that an individual with C7 quadriplegia used to accomplish her goal of independent bed transfers at home. This individual desired to live alone and did not want to use a hospital bed. She accomplished independence in this transfer after discharge as an outpatient and while working with a community-based occupational therapist in her home. A special soft-surfaced transfer aid was custom built to assist in bridging the space gap between the wheelchair and bed yet protect her skin by preventing her buttocks from sliding over the wheelchair wheel or getting stuck in this gap (Fig. 26-13, B & C). This special aid eliminated the need for the person to struggle to place or remove a transfer board from under her buttocks, which was time and energy consuming.

Patients with hemiparesis can learn to do a stand-pivot transfer independently as well.

Assistive Devices and Aids for Walking and Standing

For those individuals who are able to stand and walk, functional ambulation during task completion must be considered in addressing the more complex IADL such as caring for a child, walking a pet, home management, meal preparation and cleanup, moving about a yard for lawn care, or moving about a store for shopping. A person with balance difficulties or weakness in one or both lower extremities may require some type of orthotic mobility device to provide stability and support while ambulating. The physical therapist determines which mobility device the person should use; however, the occupational

therapist will have to address the client using the device while performing ADL. The device may only be used to assist a person in moving to a destination, or the device may be required for balance or endurance while in the process of performing the activity. The occupational therapist in collaboration with the physical therapist may need to adjust the device for the person's use such as adjusting the length of the quad cane or walker. Intervention would involve instruction and practice in the device's use during functional ambulation.

Assistive devices for ambulation come in various styles and shapes (Fig. 26-14). The type of cane chosen by the physical therapist depends on the person's balance and gripping ability, with personal preference considered. A straight cane is selected for a person with good strength, coordination, and balance who nevertheless requires a device for support. The four-prong or quad cane is chosen for a person who is weak on one or both sides, has increased muscle tone or ataxia, and needs a wider, more stable base than a straight cane provides. The hemiwalker, so called because it is often used by persons with hemiplegia, provides the greatest stability for a one-handed orthotic device and can assist with standing. A standard walker with four legs gives the user bilateral support for balance and stability while walking (Fig. 26-14, C). It does require the person to use both upper extremities, and the walker must be picked up with every step. With the standard walker, the user can simply rotate around the axis of the body and carry the walker during the turn. Various options are available that the therapist may recommend to assist the client with usability of the device during functional ambulation such as a folding frame, a fold-down seat for resting, or attached bag or pocket to carry items (Fig. 26-15, A & B). Also available are small front wheels that eliminate having to pick up the walker while ambulating, but dynamic balance is necessary.

A rolling walker with four small plastic wheels is effective for individuals with an ataxic gait, such as is seen in cerebral palsy or Frederick's ataxia, because it is easier to push the walker while walking rather than to pick it up for each step. A rolling walker is not indicated for a person who leans on the walker for support. A popular form of the walker for individuals who fatigue easily with conditions such as multiple sclerosis or arthritis is called a rolling walker with 6-inch wheels or a rollator. This device has four large pneumatic wheels that allow for easy ambulation with hand brakes and a fold-down seat to rest (Fig. 26-15, C). The user can even sit and propel it backward with stability or have someone else push them.

Some patients have the strength and balance to stand without an assistive device while performing light ADL. Patients who do not have the standing balance, strength, or endurance to stand at a work surface and use one or both hands may have to sit to perform ADL. If the activity requires the individual to carry items to various locations, then the therapist will have to consider this in addressing

Figure 26-13 Steps for an independent transfer from wheelchair to bed by a person with lower extremity paralysis. **A.** The patient positions the wheelchair close to the side of the bed and removes the left armrest. **B.** A custom-made transfer board between the wheelchair and bed fills the gap and prevents skin damage from bumping the wheel. **C.** Shoulder, triceps, and wrist extensor muscles allow the client to lean on her left arm for balance. She pushes off with the right arm, using triceps and latissimus dorsi muscles, to move her buttocks from the wheelchair to the bed. **D.** She steadies her balance once on the edge of the bed. **E.** Having moved her right hand to the wheelchair seat for balance, she picks up the left leg with her left arm. **F.** The left leg is placed on the bed. **G.** She straightens the leg. **H.** She repeats the process to move the other leg up onto the bed. Maintaining balance is the key to performing this move independently and without assistive devices.

Figure 26-14 Assistive devices are available to enhance safety and performance for functional ambulation. **A.** A quad cane has a wide base with four points of contact to the ground to provide stability. **B.** Forearm crutches allow a wide base of support for those who have leg weakness but good balance. **C.** A standard four-legged walker provides a stable base for standing and walking. Small front wheels can be used for ease in moving the walker while ambulating if the person has dynamic balance. (Courtesy of North Coast Medical, Morgan Hill CA.)

C

functional ambulation. The walker tray or bags can be used or a small stable cart on four wheels. If the person is a wheelchair user, the therapist may consider a wheelchair tray or a lap tray with a nonslip surface such as Dycem® that sits on the person's thighs to hold items while propelling the wheelchair around a room. The occupational therapist will eventually have to consider any assistive device from the point of view of storage and loading/unloading the device into a transportation vehicle for community mobility. Folding frames on walkers can promote easy loading and storage in a vehicle's back seat or trunk.

Mobility by a Personal Mobility Device: Wheelchairs & Scooters

For a person who cannot walk or has limited walking ability, a personal mobility device (PMD) such as a manual or powered-based wheelchair can assist with functional mobility in and outside the home. A manual wheelchair is appropriate for a person who can propel the wheelchair using two arms, one arm, the feet, or a foot and an arm together. A power-based wheelchair is recommended for the person who does not have the performance skills to

Figure 26-15 Available variations in walkers and optional features. **A** & **B**. Carrying trays and baskets on a walker. **C.** A rolling walker with 6-inch wheels is lightweight with hand brakes, a fold-down seat with curved back support and a basket. (Courtesy of North Coast Medical, Morgan Hill.)

propel a manual wheelchair. A popular PMD for those who can walk but only short distances is the three- or four-wheeled motorized scooter. The device enhances both functional and community mobility for individuals with multiple sclerosis, cerebral palsy, chronic obstructive pulmonary disease, cardiac conditions, obesity, and the elderly who have limited walking capacity. Personal requirements for a scooter are the ability to transfer, good trunk balance, and an ability to maintain an upright posture with little support. Persons who are dependent in manual wheelchair propulsion will require a manual wheelchair equipped with features to allow

another person to easily maneuver the wheelchair from behind. There are many models and styles of wheelchairs and scooters with a variety of standard and optional features (see Chapter 17).

The rehabilitation team that is prescribing a PMD for any person should *always* collaborate with all therapists and specialists to ensure that the device is suitable not only for functional mobility needs but also for community mobility needs when being transported in the chosen mode of transportation whether public or private. If a person cannot transfer from wheelchair seat to vehicle seat, a converted private or public vehicle will allow one to

Figure 26-16 This person with quadriplegia has the skill to push her manual wheelchair up a ramp into a modified minivan to enter the interior of the vehicle. This task is easy in a power-based wheelchair but can be difficult in a manual wheelchair.

maneuver a wheelchair into the vehicle. In Figure 26-16, a person with quadriplegia demonstrates the physical abilities and balance to safely ascend a ramp through the side door of a minivan.

Intervention for Wheelchair Mobility

Environmental barriers will most likely affect a person's mobility in a PMD at some point, and he or she should be taught to deal with such barriers. When a patient receives a new PMD, intervention for indoor and outdoor mobility is important so that he or she learns to handle and maneuver the chair in whatever circumstances are encountered, such as tight spaces, a curb or ramp, and rough and uneven terrain. A program graded toward independent mobility in a PMD should be a team effort among the nursing staff and physical, occupational, and recreational therapists with the practice of skills incorporated into all rehabilitation activities.

The initial stages of PMD intervention take place inside the rehabilitation facility where the patient learns how to maneuver on a smooth, uncluttered surface. The patient learns to operate and control the PMD and all of the movable parts, as well as how to transfer in and out of the device. For those who will be independent users, a second phase of training teaches the patient to use the PMD outside on various terrains such as uneven sidewalks, gravel, and sand. The patient then learns to negotiate obstacles such as curbs and steps. Once the patient can traverse outdoor surfaces, training continues in various interior environments of public buildings such as the airport, library, or shopping mall where the person learns to operate the PMD in crowded, narrow spaces. Development of a community mobility skills course will provide a framework for the practitioner in assessment and training with mobility device skills needed in the client's natural environment (Walker et al., 2010). The

occupational therapy practitioner can incorporate wheelchair mobility goals within other ADL intervention. For example, if a patient is taken to the grocery store to shop for food in preparation for cooking a meal, there is the opportunity to explore wheelchair mobility in a public environment while also carrying items or pushing a shopping cart.

Negotiating Ramps. A ramp enables a person using a PMD to overcome steps or a height discrepancy in a doorway or entrance. Ramps are constructed with many shapes, sizes, and dimensions and can be custom built or purchased and assembled from a kit. Federal guidelines specify how ramps in public places should be constructed in terms of length, slope, and texture. For every inch of rise, the ramp must have 12 inches of length (1:12 slope). For example, a 4-inch step will require the ramp length to be 48 inches in order for a person with a physical disability to safely negotiate the ramp. A ramp in a public place must have a surface with a detectable texture for persons with visual impairments. It must have railings that are not vertical but slope at 1:10 maximum. There must be 4 feet of level landing at the top of the ramp (ADA Standards for Accessible Design, 2010).

One safe technique to use in descending a steep ramp is to orient a manual wheelchair backward and lean forward to place most of the weight over the front caster wheels as the chair slowly descends the ramp (Fig. 26-17). If the wheelchair has a tendency to tip backward easily, a helper should stand behind the wheelchair and walk with the person to catch the chair should it begin to tip backward. For a manual wheelchair user to safely use a ramp, the following are necessary:

- Upper extremity strength and coordination, including grip strength
- Trunk mobility and awareness of the balance point of the wheelchair

Figure 26-17 A person with good arm and trunk strength can safely negotiate a steep ramp by moving backward down the ramp. By leaning the trunk and head forward, the center of gravity is shifted, and the chair is less likely to tip backward.

- Optional anti-tipping wheels to prevent the chair from falling backwards
- Optional hill climbers or grade aids to prevent the chair from rolling backward
- Level of visual and cognitive skills to make good decisions regarding movement on the ramp and in and around environmental factors such as traffic, other pedestrians, light poles, and the pedestrian walk signage.

Wheelchair Wheelie. Advanced manual wheelchair skills are important for the client to learn to maneuver the variety of terrains typical in a community. One such skill is called a wheelchair wheelie, which allows the user to move around on uneven terrain or surfaces such as sand, rocks, pothole, curbs, steps, and high door thresholds or down a steep hill or ramp (Kirby et al., 2006). A wheelie can also be used for resting against a wall, turning in a tight space, or moving down extremely unlevel or bumpy terrains. The goal of the wheelie is to balance on the large rear tires of the wheelchair and elevate the caster wheels in the air so they are not rolling over the surface or obstacle. This allows for smoother and more efficient operation of the wheelchair (PoinTIS SCI Physical Therapy Site, 2012; Somers, 2010). For this advanced wheelchair skill, a person must have the following:

- Basic wheelchair skills
- Upper extremity strength
- Good hand function with a strong grip
- Bilateral upper extremity coordination
- Understanding of the steps to perform the task and awareness of the center balance point of the wheelchair (which varies from chair to chair)
- Ability to maintain dynamic center of balance on the back wheels

The patient must practice a wheelchair wheelie many times on level surfaces before attempting uneven surfaces or the more difficult curbs and steps. In the clinic, a mat can be placed behind the wheelchair, or the therapist can stand behind the chair ready to catch the wheelchair should it tip too far backward. *Safety Message: Because of the danger of losing balance and falling backward, the therapist must be attentive and within close proximity of the wheelchair when the patient is practicing this advanced skill. Safety rigging may be necessary for the client to practice this skill independently.* Not all wheelchair users will be able to perform this advanced skill.

To "pop a wheelie," the first step is to grasp the hand rims posteriorly and pull them forward forcefully and abruptly, throwing the head back forcefully, if needed. Once the client learns to balance in and assume a wheelie position, then intervention focuses on instruction and practice in moving forward and backward in a wheelie position. Lastly, intervention covers dynamic wheelie skills over easy and then difficult obstacles. This wheelchair skill is better understood by seeing the task demonstrated in a dynamic mode. Multiple videos of wheelies and other wheelchair skills can be viewed at http://www.wheelchairskillsprogram.ca/eng/tests_video/php. One can also search "wheelchair wheelies" on *YouTube* for demonstrations by therapists and wheelchairs users; however, the therapist should view these videos with the understanding that they are not peer-reviewed demonstrations.

Negotiating Curbs. Since the passage of the Americans with Disabilities Accessibility (ADA) Standards in 1990, curbs on sidewalks at street intersections are becoming less of a problem as curb cuts proliferate; however, at times the wheelchair user may encounter a curb. Although some power wheelchairs can negotiate curbs well, ascending and descending a curb or step in a manual wheelchair will require proficiency with a wheelchair wheelie. First, the person approaches the curb or step, facing it. Once the wheelie position has been obtained, the casters are placed on the curb. The person leans forward to redistribute the weight and propels the large rear wheels up the curb or step with a hearty push. A person must have good balance, upper extremity strength, and hand function to perform this maneuver. To go down a curb or a step, the person approaches it backward, leans forward in the chair, and rolls the rear wheels over the step or curb. An alternative method for going down a curb is to approach the curb facing it, move into the wheelie position, and roll slowly down the curb using the back wheels. The person must have an excellent sense of the balance point of the wheelchair to perform this technique safely. If a wheelchair user cannot move up or down a curb or step or roll through grass or over uneven surfaces, another person can provide assistance as in Figure 26-18.

Negotiating Steps. Ascending or descending multiple steps in a scooter or powered wheelchair is impossible. A strong manual wheelchair user may be able to descend a couple of steps safely by performing a wheelie while moving down the steps. In an emergency, a person who can perform a wheelchair-to-floor transfer can get out of the wheelchair and "bump" up or down the steps while pulling the chair along. Skin protection during this task must be understood and practiced. *Safety Message: Instruction and practice to perform this difficult task should occur before an emergency arises.*

Moving a manual wheelchair and its dependent occupant up and down steps safely requires the assistance of two people. The back of the wheelchair should be positioned facing the steps with one person standing behind the chair and the other person in front of it. The chair is tipped backward, with one person holding the push handles and the other person holding the front of the chair by
Figure 26-18 Functional mobility is enhanced by an assisted wheelchair wheelie. **A.** A therapist performs an assisted wheelchair wheelie to roll a wheelchair through grass and uneven terrain. **B.** A therapist uses an assisted wheelie to place the front castor wheels of the wheelchair on a curb so the person in the manual wheelchair can be pushed over the curb and onto the sidewalk.

its frame or leg rests. While the person in front maintains balance of the chair, the person behind pulls the chair up step by step. That person should take care to keep his or her back straight and use leg strength to move the chair. To take a person down the steps, approach the steps with the wheelchair facing forward and with it tipped backward and balanced. The procedure is reversed, with the person in front of the chair holding onto the chair while guiding and controlling the speed of the chair down each

step. Moving a power wheelchair in this manner is impossible and not safe because of the weight of the chair.

For individuals who must negotiate multiple steps in a home and are unable to ambulate or have limited ambulation, a stair lift can move a person up or down the staircase safely and efficiently. There are various configurations of stair lifts that can be installed for straight and curved stairs in a private or public location (Fig. 26-19, A & B). The person must be able to transfer onto the seat

Figure 26-19 **A** & **B.** A powered stair lift allows a person to move up and down steps easy and safe on a stairway in a private residence and in a public place. (Courtesy of Acorn Stairlifts, Orlando, FL.)

surface and balance himself on the seat while the seat moves up or down the staircase. If the person cannot walk, a second wheelchair must be available at the top of the staircase for the person to transfer into. Another viable but expensive option is a small elevator, which meets the space and structural requirements, installed interiorly or exteriorly in a private or public building.

Mobility Devices to Assist with Standing or Sitting

Mobility devices are available to enable a person to perform the functional mobility tasks of standing or sitting. Some ADL requires supported standing or balance, use of two hands, and stability. Various mechanical and powered devices are available to raise a person vertically up and down. Other devices assist coming to a supported standing position or to rotate and swivel in preparation for standing/walking. Persons who have a powered up/down seat feature on a power-based wheelchair or scooter can reach work surfaces such as a sink or kitchen counter

Figure 26-20 This gentleman uses a powered vertical up/down seat on a power-based wheelchair to allow better height and close approach to the sink for grooming activities.

or tall cabinets (Fig. 26-20). This feature can also allow the user to engage other people at eye level and move around in the elevated position at low speeds. Wheelchairs can have features that enhance standing, such as a mechanically operated stand-up feature on a manual wheelchair or a motorized stand-up feature on a power-based wheelchair. This feature may be important to particular people because standing can improve circulation, renal and bowel functions, reduce lower extremity spasticity, and prevent effects of prolonged immobilization. The person using a power-based chair that has a stand-up capability can even move around in the standing position at low speeds (Fig. 26-21) to meet the task demands of a job when both hands are required for tasks, such as cooking in the kitchen or working as a beautician or pharmacist. The feature can prepare a person to walk by placing him or her in the standing position so the person can then just walk out of the device.

There are portable devices to assist in standing such as a swivel disk or seat that assists a person in preparation of standing (Fig. 26-22). The powered standing lounge chair is popular for persons with a variety of disabilities because the chair raises the person totally supported to a partial standing position to allow supported standing in preparation for walking or transferring (Fig. 26-23).

COMMUNITY MOBILITY

Community mobility includes all the ways in which people move about the world in order to access goods and services and remain engaged in occupations beyond their homes (Womack, 2012). Individuals move about their world as pedestrians, drivers, or passengers in motor vehicles or on public transportation, or even as users of a wheelchair or scooter. Viewed from this perspective, community mobility is an occupation that is essential to personal health and social well-being. Restricted mobility has been linked to the onset or acceleration of physical and mental health problems (Marottoli et al., 2000). Community mobility is valuable for every person of every age group because it facilitates engagement in important areas of occupation including leisure, work, and social participation (Stav, Hunt, & Arbesman, 2006).

Today, most people travel into the community for almost everything they need, although the virtual community created by the internet and social networking has expanded a totally different avenue for seeking and playing with friends, socializing, and even shopping online for such necessities as drugs, supplies, and clothes. These resources are inaccessible to some and can be unsatisfying in terms of social human interaction. The occupational therapy practitioner can offer a range of services to a client, a client's family, a local community, or a business or agency that is concerned with participation and safety in community mobility (AOTA, 2010). Guidelines for the

Figure 26-21 **A–C.** Permobil wheelchair options allow for many adjustable sitting and standing positions for activities at home and in the community. (Courtesy of Permobil Company, Woburn, MA.)

therapist in addressing community mobility are provided in Procedures for Practice 26-3.

The Meaning of Community

An occupational therapy practitioner must understand the value and need for community that exists in every person that receives occupational therapy no matter the age, cultural background, or setting in which they live. There are many ways to view "community." Merriam-Webster (2012) defines community as a "unified body of individuals" and lists various types of community as

- *family community*, which includes one's personal family members
- *neighbors*, or those that live in close proximity to an individual and collectively are called a *neighborhood*, a geographically local community
- *municipalities* or cities that consist of a collection of neighborhood communities
- *planned communities* that are developed to meet a specific need such as a retirement community

The value of feeling connected to one's environment cannot be understated. Participants in a study noted that their environment was more than just physical surroundings; it was the sense of belonging that came from doing, being, and living in place (Vrkljan, Leuty, & Law, 2011). A sense of community requires an ability to engage and interact not only with the family but also with persons outside of the home environment. This can be as simple as going to the knitting store where mothers gather after dropping their kids off at school, the local coffeehouse where friends meet for breakfast in the mornings, the hamburger joint where the local students gather, or the local senior center for weekly social gatherings. A community destination may include the courthouse in which one is called to serve as a juror on a legal trial or the church where one gathers with others of similar religious beliefs. Occupational therapy promotes greater participation in community by identifying barriers to performance and strategizing solutions with the client to overcome the barriers (Waite, 2011).

Accessible, Safe Environments Promote Alternative Modes of Travel for Community Mobility

For persons with disabilities or for those who cannot drive, having access and use of a sidewalk network is crucial for remaining active, interacting with others, and reaching vital destinations, such as shopping and medical facilities (Kihl et al., 2005). The physical characteristics of a

Figure 26-22 Mechanical devices to assist in standing up. **A.** Hydraulic action in this portable seat lift assists the person in rising. **B.** Portable and cushioned seat that swivels 360° and can be used in a vehicle seat or chair. **C.** A powered swivel/tilt passenger seat for a minivan. (Photos A and B courtesy of North Coast Medical, Morgan Hill, CA; Photo C courtesy of Braun Corporation, Winamac, IN.)

community often play a major role in facilitating personal independence. A safe pedestrian environment, easy access to grocery stores and other shops, a mix of housing types and nearby health centers and recreational facilities are all important elements that positively affect a client's health and well-being (National Highway Traffic Safety Administration [NHTSA], 2009). Poor community design, poorly maintained sidewalks, and physical barriers, such as busy highways and high walls, can make it difficult to remain independent and involved in the community (American Association of Retired Persons [AARP], 2005; Burkhardt, McGavock, & Nelson, 2002). AARP published a comprehensive survey entitled *Livable communities: An evaluation guide* that can identify barriers in mobility and safety in

a livable community (Kihl et al., 2005). The occupational therapy practitioner can provide consultation to a local community or municipality by using this survey as a guideline and structure.

Evaluation and Intervention for Community Mobility

The feasibility, safety, and personal control of community mobility must be explored early on in the occupational therapy process. The therapist finds out detailed information about the client's everyday routines by talking through the patient's typical day (Radomski, 2011). During the inpatient stay, the client may be allowed

Figure 26-23 The person is assisted to standing and a stand-pivot transfer to a power-based wheelchair by the dual features of a wheelchair with a powered vertical lift feature and a lounge lift chair with a powered base that raises and tilts the seat.

home visits on the weekends in preparation for discharge. Discussing the challenges met on these visits will focus intervention on meaningful goals. Furthermore, working on community mobility while the person is still in rehabilitation will prevent feelings of isolation and lessen feelings of loss during these visits and after discharge. Exploring

Procedures for Practice 26-3

Guidelines for the Therapist in Addressing Community Mobility and Driving

- Analyze the client and the activity demands of the specific mode of travel chosen to determine whether the client is capable of returning to the chosen mode of travel or requires alternative community mobility options.
- Determine whether the client has any questionable performance skills that would impede safe driving of a personal vehicle (car or low-speed vehicle [LSV]) if that is the goal, and ensure that the client meets all state licensing requirements.
- Analyze contextual and environmental factors to identify barriers to safe community mobility.
- Evaluate to determine whether a recommendation for continued driving or no driving is appropriate or if a referral to an occupational therapy driving specialist for a comprehensive driver evaluation is necessary because of performance skill deficits that may impair driving performance or bring to question safety issues.
- If the outcome of a driver evaluation determines that the person cannot return to driving, then identify community mobility alternatives that the client has the skills to use.

where, when, and how a person desires to interact in his or her communities will guide the therapist in setting appropriate goals and making recommendations that will allow the client to participate effectively and safely. The evaluation may include

- screening for safe community wheelchair skills and safe wheelchair transportation
- assessing safe pedestrian skills for crossing a street and negotiating curbs and sidewalks
- determining readiness and skills to use paratransit
- determining driver fitness to drive (Hunt, 2010; Hunt, Carr, & Barco, 2009)
- screening a client for referral to a specialist in driving if evaluation or intervention is necessary to determine driver safety or need for adaptive driving equipment (Pierce & Schold-Davis, 2013)
- determining safe alternative travel modes available in the community for the client who is not able to drive or must retire from driving
- screening for proper child passenger safety for disabled parents who will be transporting children (Yonkman et al., 2010)

A disability or health-related change can disrupt a usual pattern of community mobility and thus challenge habits (Dickerson et al., 2007). The occupational therapy process will explore all factors that support or hinder participation in necessary, desired, and routine community mobility. After evaluating these factors and exploring the meaning of community for the person, the occupational therapist provides intervention for community mobility goals during the occupational therapy process. Because the task demands for community mobility are higher than for any other ADL or IADL, the initial intervention plan should identify community mobility goals to be implemented later in the occupational therapy process as the last IADL to be addressed. When addressing community mobility, occupational therapy practitioners must employ interventions that address

- performance skills (cognitive, visual, and motor)
- performance patterns (self-regulation and self-awareness)
- context (role of passengers and family involvement)
- activity demands (adaptive devices and strategies) (Hunt & Arbesman, 2008)

Intervention for driving skills is not relegated to just the driving specialist anymore. General practice occupational therapists use a full range of interventions to improve driving skills as well as overall community mobility (Unsworth, 2011). Practitioners must think beyond driver rehabilitation as purely recommending and training in the use of adaptive equipment and use evidence-based interventions to improve the IADL of community mobility, including driving. Interventions must address cognitive and visual function, motor

function, driving skills intervention, self-regulation, and self-awareness, and the role of passenger and family involvement in the driving ability, performance, and safety of the adult (Hunt & Arbersman, 2008). The practitioner must provide intervention that addresses the impaired skills in vision, cognition, and motor function but also specific intervention that includes client education programs that aim to develop client self-awareness of driving skills (Hunt & Arbesman, 2008). Occupational therapy practitioners experienced in addressing community mobility needs recommend specific interventions be applied (Hunt & Arbesman, 2008; Pierce & Schold-Davis, 2013) such as follows:

- Provide education to develop self-awareness of driving skills.
- Provide education on the relationship between medical problems and driving.
- Use multiple training activities that excite different brain functions that are all necessary for safe driving.
- Provide education about compensatory strategies for maintaining driving skills such as changing habits and routines. For example, discuss alternative driving routes to avoid left turns, lane changing, and merging, and discuss changing habits that are known situations for frequent accidents. Discuss better times of the day to drive to avoid sun glare at dusk or dawn.
- Counsel drivers on cessation or limiting driving when it is necessary.
- Counsel families of older adult drivers on signs that indicate that driving is no longer an option.

Modes of Travel for Community Mobility

Community mobility is defined by the OTPF as "moving around in the community and using public or private transportation, such as driving, walking, bicycling, or accessing and riding buses, taxi cabs, or other transportation systems" (AOTA, 2008). Community mobility includes all of the ways in which people move about the world in order to access goods and services and remain engaged in occupation beyond their homes (Womack, 2012).

Walking

Walking enables people to get where they need to go under their own strength and energy without having to rely on another mode of travel. Whether the person walks in the community depends on specific environmental factors as well as the purpose for walking. For example, if the person needs to pick up multiple items and carry them to another location, then that activity must be considered in the mobility program. Sidewalks are the fundamental building blocks of a pedestrian network, and they allow mobility using a PMD and as such are important environmental

factors to be considered. Safety for pedestrians is enhanced by the separation of walkways from the roadway. The Federal Highway Administration provides information that includes pedestrian and bicycle safety tools (Federal Highway Adminstration, 2012). The Pedestrian and Bicycle Information Center (2012) provides planning and design tools to make roads, pedestrian crossings, trails, and separated pathways safer for pedestrians. The National Highway Traffic Safety Administration provides a booklet entitled *Stepping Out* that promotes the benefits of walking and pedestrian safety for adults aged 65 years and older, including tips for staying safe at intersections, in parking lots, in areas without sidewalks, and in bad weather (NHTSA, 2012).

Pedestrians aged 65 and older accounted for 19% of all pedestrian deaths and an estimated 11% of all pedestrians injured in 2010 (CDC, 2013). Elderly pedestrians are often hit in crosswalks or when crossing intersections and are generally hit when they have almost finished crossing. They are usually observing the law and not behaving dangerously. Many do not see the vehicle that hit them, and when they do see the vehicle, they usually believe that the driver has seen them and will avoid them. It follows that persons with walking impairments and those in wheelchairs may encounter the same dangers at intersections or crosswalks as the elderly do. Education about pedestrian safety could save lives (Classen et al., 2011). The occupational therapy practitioner can advocate for pedestrian safety by educating community planners and city leaders and encouraging changes in traffic signals at intersections, pedestrian walkways, and pedestrian warnings.

Using Nonmotorized and Motorized Personal Mobility Devices. PMDs are popular modes of travel in a neighborhood or local community as more communities are becoming accessible to bicycles, manual wheelchairs, and portable motorized chairs (three- or four-wheel scooters) or complex, power-based wheelchairs. These various nonmotorized and motorized PMDs assist a person with community mobility. If the person has the performance skills to ride a two- or three-wheel bicycle, he may be able to travel to a nearby store or facility. If the person has the strength and endurance to push a manual wheelchair for a distance and is able to handle the wheelchair in outdoor terrain, he may be able to use it to get to a local convenience store or down the street to a friend's home. If the destination does not exceed the powered device's battery charge, a person can use that device to travel to the store or visit a church in a nearby locale.

Using Personal Low-Speed Vehicles

Another type of private transportation is personal low-speed vehicles (LSVs), which are small electric or gas-powered cars designed for low-speed, local trips in areas

such as planned communities, resorts, college campuses, and even large industrial parks. As an alternative mode of transportation, the low-speed "street-legal" vehicle, or golf cart, is becoming popular especially among older persons, although not all communities allow them. Older residents see the carts as a form of transportation when driving privileges are suspended but limited mobility in their community is still allowed. Many planned retirement communities in year-round mild weather states now allow mobility by way of these vehicles that are simply a golf cart or simulate a golf cart. One such community in Florida called "The Villages" brags of as many as 50,000 carts and even set the world's record in 2005 for the "largest golf cart parade with 3,321 participants" (*Orlando Sentinel*, 2011). Under Florida law, a plain golf cart can be converted into a street legal LSV with the limitations that the top speed cannot exceed 25 mph, and it cannot be operated on streets with speed limits higher than 35 mph. The law further requires the cart to have specific features such as headlamps, brake lights, turns signals, seat belts, rearview mirror, windshield wiper, and horn (*Orlando Sentinel*, 2011). A neighborhood electric vehicle is another commonly used type of LSV with the difference that it has a driving range of up to 40 miles on a single battery charge (Lynott, Poncy, & Twaddel, 2011). The client in Figure 26-24 uses a power mobility device for functional mobility and enjoys community mobility with her companion assist dog within the planned retirement community in a modified golf cart with hand controls.

The occupational therapy practitioner can use information available from multiple resources when training a person to be mobile in the community via a wheelchair, cane, scooter, golf cart, or public bus. The occupational therapy

Figure 26-24   After learning to drive a personal van, Ms. S. desired community mobility via a golf cart in the planned retirement community in which she lived. The cart was specially modified to allow her to ride in a power-based wheelchair onto the golf cart, operate the cart with hand controls, and allow room for her companion assist dog.

practitioner can help city planners be more sensitive to the community mobility issues of people with special needs. Occupational therapy practitioners can advocate for their clients and consumers by working with local community leaders, planners, engineers, traffic safety and enforcement professionals, public health and injury-prevention professionals, and decision makers who are seeking ideas and solutions for changes to the physical environment that improve pedestrian, bicycle, and LSV safety.

Driving a Personal Vehicle

Most adults in the U.S.A., with or without disabilities, drive a car as the primary mode of transportation. People age 65 years and older make more than 90% of community trips in cars, as either drivers or passengers (Houser, 2005). When young adults cannot drive and older adults are no longer able to drive, occupational functioning is jeopardized. An occupational therapy intervention plan therefore may include addressing the IADL of driving a personal vehicle.

Driving is the most complex IADL because it requires good physical, visual, perceptual, psychological, and cognitive skills as well as an integration of these skills (Classen, 2010). Consequently, most patients are not ready for a driving evaluation before discharge from the inpatient facility, and it should be one of the last ADL resumed during rehabilitation (Pierce, 1996). There is clear evidence that clinical and community-based practitioners must realize their role and responsibility in addressing driving. A conversation about driving is not reserved just for a driving specialist (Hunt & Arbesman, 2008). The Multifactorial Older-Driver with Dementia Evaluation Model (MODEM) will assist the practitioner's clinical reasoning about fitness-to-drive decisions (Hunt, 2010; Hunt, Carr, & Barco, 2009).

Transportation needs, particularly for the wheelchair user, may have to be addressed long before driving because the person may not be ready for a driving evaluation until 8–12 months after discharge from a hospital or inpatient rehabilitation facility. A referral to the occupational therapy specialist in driving for the sole purpose of determining transportation needs may be appropriate before discharge so that the patient, family, and funding source can be guided toward the appropriate transportation vehicle and safe wheelchair transportation modifications. If the specialist determines that the patient may be able to drive later, vehicle selection and modifications for transportation can be made with future driving needs taken into consideration.

The Role of the Occupational Therapist in Addressing Driving

The role of the occupational therapist in addressing driving has been clearly defined in the past decade (Di Stefano & Macdonald, 2005). The American Medical Association

(Carr et al., 2010) has clearly delineated occupational therapists as experts who have knowledge and skill in this area. Referral to a specialist in driving for a comprehensive driver evaluation has been the common practice in the past; however, the number and accessibility of specialists in driving are inadequate to meet all driving needs in society (Classen et al., 2010). All occupational therapists who work with adults with physical dysfunction should have the knowledge and skill to accurately determine who is a safe driver presently, who is at risk for unsafe driving, and who needs further evaluation by a specialist in driving (Dickerson et al., 2011). In situations where the client is clearly at risk for unsafe driving, the role of the occupational therapist is to explain the dangers of driving and help clients and families resolve transportation options rather than prolong driving independence (Hunt, Brown, & Gilman, 2010). Ethical decision making is crucial for the therapist in ensuring the safety of the client, families, and others on the road.

Evidence is available that indicates therapists can use clinical testing to make an informed decision regarding driving and that not all clients need the services of a driving specialist (Dickerson et al., 2011). If the results of clinical testing indicate no functional performance impairments that correlate with driving risk, then the therapist can recommend to the physician and team that the person appears capable to resume driving without a referral to a specialist in driving. On the other hand, if the client has difficulty with other complex IADL, the occupational therapist practitioner can inform the team and client that he or she would be expected to also have difficulty with driving (Dickerson et al., 2011). If the client demonstrates performance impairments that correlate with driving risk, then the therapist must recommend cessation of driving and may plan interventions to improve the client factors that prohibit driving at this time. The client can also be referred to a driving specialist for a definitive decision concerning probable driving safety (Hegberg, 2007).

If the patient drives before he or she is ready, or after being told to cease driving, the therapist has an ethical obligation to protect the public welfare by reporting the person to the appropriate licensing authority in the manner dictated by the state of residency. Every state has specific procedures for reporting an unsafe driver, and the occupational therapist should know the procedure for reporting impaired drivers in his or her state and which functions a therapist is authorized, obligated, or responsible to perform. Individual state regulations for reporting can be found in *The Physician's Guide to Assessing and Counseling Older Drivers* (Carr et al., 2010). Although it is written with older drivers in mind, the material can apply to all age and disability groups.

The American Occupational Therapy Association provides guidance concerning the IADL of driving. The association provides practitioners, other professionals, as well as the public with educational opportunities through online courses, publications, and a dedicated website with useful and timely information about the occupational therapist's role in driving, older driver safety, driver evaluation resources, and community mobility throughout the life span (Schold-Davis, 2012) (see Resources 26-1). Occupational therapists are perfect community partners

to serve on city planning boards to assist in making transportation services more affordable and user friendly. Environmental factors can play a critical role in either facilitating or undermining the ability for one to move about in the community. The occupational therapist is well suited to address both the personal and environmental factors that enable communities to support independence and safe transportation.

When a Referral to a Specialist in Driving Is Necessary. If determination of driving competence requires a comprehensive and focused driving evaluation, the occupational therapy practitioner may need to consult with or refer to an occupational therapist with Specialty Certification in Driving and Community Mobility (SCDCM). These specialists may be on staff in an inpatient or outpatient facility or in a community private practice. A SCDCM is an occupational therapist with advanced knowledge and skill in evaluation and intervention specific to driving and community mobility. This specialist can provide a formal driver evaluation, driver training with specialized adaptive equipment, driver rehabilitation services for specialized driver education, or remediation for enhancing safe driving skills. The SCDCM can develop an occupational profile and perform a formal clinical and in-traffic evaluation of a person's physical, visual, perceptual, cognitive, and psychological functioning as it relates to driving, considering all contextual and environmental factors.

A fair and objective assessment by a professional is welcomed by families of older drivers or of younger potential drivers with acquired or congenital disabilities. The occupational therapy practitioner can steer the family toward the need for the driver competency evaluation and initiate the referral process to the SCDCM (Pierce & Schold-Davis, 2013). The general practitioner in occupational therapy should know the SCDCMs in the local communities, regions, and state to whom clients, patients, consumers, and agencies can be referred. A list of SCDCMs nationwide can be found on the driver safety link of www.aota.org.

The SCDCM will analyze each driving task for the person and determine the client's needs and desires and what specific aids are necessary for safe driving (Pierce & Schold-Davis, 2013). The SCDCM will take into consideration the particular contextual or environmental factors, the person's performance patterns, and the activity demands of the various driving tasks. The person's individual vehicle will be evaluated, as will the person's functional mobility in getting to and into the vehicle with any orthotic devices or mobility aids used. The client must be able to enter and exit the vehicle and store the wheelchair, scooter, or other orthotic device as needed. Figure 26-25 shows a person who accomplishes functional mobility by propelling a manual wheelchair with both feet and using an independent stand-pivot transfer into a personal vehicle she

Figure 26-25 A woman with juvenile rheumatoid arthritis illustrates how a powered device assists in loading/unloading and storing her manual wheelchair on top of her personal vehicle for independence. Figures A-C show the unloading process.

drives for community mobility. A powered device assists her in loading and unloading her folding-frame manual wheelchair.

Persons with physical deficits or mobility challenges may require special driving devices or aids to assist them with particular driving tasks. Driving technology can cost

as little as $85 for a steering device (Fig. 26-26, A), $800 for a left-foot gas pedal (Fig. 26-26, B), or $1,200 for simple mechanical hand controls (Fig. 26-26, C). A person with no lower extremity function and minimal upper extremity function may require a specialized high-technology modified van costing upward of $100,000 (Fig. 26-27).

When a SCDCM cannot be found to assist a patient, a commercial driving school instructor who has training in driver rehabilitation services may be available. A regular driving school instructor may not have the necessary medical background to understand the client's deficits and the medical implications for the driving task. Before referring the client to a commercial driving school or driving school instructor who markets services to persons with disabilities, the therapist should investigate the instructor's background and expertise concerning the medical condition or diagnosis of the client. When using a driving

school instructor, the occupational therapy practitioner should collaborate with this person and be involved with the final outcome. The therapist completes an occupational profile and performance skill assessment and share the results with the instructor prior to the person having the road test with the driving school instructor. After the road test, the therapist and instructor collaborate on the outcome and recommendations (Pierce & Schold-Davis, 2013).

When Driving a Personal Vehicle Is Not a Viable Option. If driving is not a viable target outcome for a client, it is very important that the occupational therapy practitioner address this with the client and family and then develop a plan for accessible and safe alternative transportation options in each person's context (Hegberg, 2007; Silverstein, 2008). There is no subject more entrenched in emotion and feelings than the topic of driving. The freedom and independence that driving gives a person is so tangible that an honest conversation about driving will only occur if the person directing the conversation shows compassion, understanding, and support. Unfortunately, many older adults faced with driving retirement have made no plans for alternatives to driving. Some of those who have not thought about alternatives expect to rely on friends and family for transportation rather than use other forms of transportation. The needs of older people who depend on public transportation are not being met. Of nondrivers 75 years old and older, 75% report satisfaction with their community mobility resources; however, most of these seniors use family members and friends for transportation (NHTSA, 2006). Seniors without access to family members or those living in nonurban areas are likely to have unmet needs that are greater than those of older people who live near family members (NHTSA, 2006). If driving retirement is the recommendation, then alternatives for community mobility must be presented that are based

on personal knowledge of the client's community and are perceived as real and practical by the client.

Nondriving options can include public transportation such as fixed-route rail, bus, paratransit, community transportation (e.g., community bus), demand-responsive transit (e.g., dial-a-ride), flex-route, independent transportation networks, volunteer services, taxis, bicycles or tricycles, and walking (NHTSA, 2006). An occupational therapy practitioner has the knowledge and skills to evaluate the person in using other community mobility alternatives for safe transportation. This IADL should be evaluated and treated in the same manner as the therapist looks at all other IADL (Pierce & Schold-Davis, 2013).

Environmental factors must be considered because every community has individualized resources for alternative choices for community mobility. Using public transportation may actually place more demands on the person than driving a personal vehicle. All requirements of using specific community mobility alternatives must

be considered. For example, a bus passenger must be able to understand a bus schedule and strategize a route and timing as well as have the fare, physically offer the fare, get to a bus stop, and then climb on and off the bus. The passenger must then recognize when he needs to get off the bus and appropriately notify the bus driver. Once off the bus, he must then get to his destination.

Each community mobility alternative has its own motor, sensory, visual, perceptual, cognitive, communication, and social skill requirement for safe use. Evaluation includes a client's performance skills related to the chosen community mobility alternative, community assessment to explore the person's contextual/environmental factors, and the availability of options and their usefulness to the person. If possible, the occupational therapy evaluation and intervention should take place near the person's home, on the chosen mode of transportation, and on the routes and paths that the person would be using.

case example

Mr. J.: Restoration of Functional and Community Mobility Following Stroke

Clinical Reasoning Process

Occupational Therapy Intervention Process	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mr. J. is 69 years old with right hemiplegia and expressive aphasia from a left cerebral vascular accident (CVA). Mr. J. has a good medical history except for the CVA and has good motor functioning in the left extremities and normal visual and cognitive performance skills. He was evaluated in an outpatient rehabilitation center, and the following problems were identified by the occupational therapist:	Appreciate the context	"Mr. J. is aging well in all areas and most importantly is motivated to improve his mobility skills so that he can be less dependent on his wife. His home and community environment as well as family support will enable him to reach his chosen goals for functional and community mobility."
1. Client can roll over and sit up in bed but has difficulty moving his right leg off the bed in preparation for transferring and dressing. 2. Client cannot complete a stand-pivot transfer independently because he needs assistance coming to standing. 3. Client can propel a manual wheelchair with a one-arm drive on level surfaces but cannot negotiate a ramp or uneven terrain. 4. Client cannot perform bathroom activities at home because his bathroom is inaccessible to a wheelchair. 5. Client has not driven since the CVA but is very anxious to begin driving again. He is concerned about loading his wheelchair into a car by himself. 6. He enjoys living in a planned retirement community and has access to other modes of community mobility but has not used them in the past.	Develop intervention hypotheses	"Mr. J. has significant physical deficits that may be permanent, but with his young age and good health, I believe that his occupational performance could be enhanced greatly by improving his functional and community mobility skills."

Select an intervention approach	"I will develop an intervention plan that emphasizes functional mobility first and community mobility needs second. I know that there are precursor mobility skills that are required in the areas of bed mobility, transfers, and wheelchair mobility, so I will need to address these performance skill areas first before I address the specific tasks that he is weak in, such as handling his legs in bed or propelling his wheelchair outdoors. It will enhance my intervention if I talk with physical therapy to see if they can work on improving his leg strength and his ability to stand up independently. I will need to explain to the client and his family that we will address his driving ability as a long-term goal after we have accomplished the short-term goals in functional mobility. I will explain how the skills in functional mobility will prepare him for the driver evaluation when the time is appropriate. I will let the family know that I can research community mobility options available in their community that he may be able to use in the meantime or in case the outcome of the driver evaluation is that he is not able to return to driving."
Reflect on competence	"As an occupational therapy generalist, I am concerned that I do not know all of my responsibilities in driving and community mobility. I need to research this area before I begin addressing the topic of driving and community mobility. I also need to find resources in my state for a SCDCM so I can talk intelligently about the specialist's services and purpose to the client and family as well as make a timely referral. In the meantime, I will research options in his community and use my OT skills to consider the activity demands of each option and evaluate Mr. J.'s ability to use alternative modes of travel similar to how I evaluated his skills in the kitchen and bathroom."

Recommendations

The occupational therapist recommended two sessions per week for 8 weeks. In collaboration with the client and his wife, the occupational therapist established the following long-term intervention goals:

1. Mr. J. will be independent in bed mobility and sitting on the edge of the bed.
2. Mr. J. will be able to perform a stand-pivot transfer independently.
3. Mr. J. will improve his ability to negotiate outdoor terrain and ramps with his manual wheelchair and be advised on motorized scooters for use in independent long-distance mobility in the community.
4. In collaboration with physical therapy, Mr. J. will be instructed in using his quad cane to walk into the bathroom and perform sink activities while standing.
5. Mr. J. will be referred to SCDCM once he is able to transfer in and out of his car.

Consider what will occur in therapy, how often, and for how long Ascertain the patient's endorsement of plan	"I do not believe that this client is aware of his potential for being more independent in functional mobility skills. Some of this may be related to his wife, who is overprotective of her husband as she is afraid that he will fall and hurt himself. She expresses concern about him driving again. I believe that he is motivated enough to be more independent and will have successful outcomes with client-focused intervention. I believe that when he sees that he can accomplish functional mobility goals and realize his potential to drive again, he will be highly motivated to work hard in occupational therapy. Mr. J. and his wife seem agreeable to the plan, and I hope that by including his wife that she will become more comfortable in letting him do tasks independently at home as he achieves each mobility skill."

Summary of Short-Term Goals and Progress

1. Mr. J. will be able to move his weak leg off the edge of a bed and come to a seated position with or without orthotic devices.

   The therapist ascertained after a week of occupational therapy that Mr. J. could move his weak leg off the bed using his stronger left leg by putting his left foot under the weak right foot and then moving both feet over the edge of the bed. She determined, however, that he would require a device to use to pull against to come to a short-leg sitting position on the edge of the bed. In the second week, various techniques and assistive devices were demonstrated to him, and it was determined that a portable half-bed rail worked best. By the fourth week, Mr. J. could come to a short-leg sitting position on the side of the bed independently. He was also shown how to use the bed rail to help him stand up and ready himself for a stand-pivot transfer.

2. Mr. J. will become independent in sink activities in the bathroom.

   The first week of therapy revealed that the client's standing tolerance and balance were not sufficient to perform sink activities while standing, even though he could walk short distances. In the second week, he was taught how to stand up from his wheelchair outside the bathroom door, walk into the bathroom using his hemiwalker and short leg brace, and sit on a tall-legged stool at the sink. The higher seat helped him come to standing when he pulled on the sink for assistance in standing up when ready to leave.

3. Mr. J. will be able to transfer into the passenger and driver side of his car independently.

   By the third week, Mr. J. could handle his leg on and off the bed and could stand up independently. In the fourth week, Mr. J. was instructed in getting in and out of the passenger side of a car. After he could perform this transfer, he was taught how to transfer into the driver's side of the car, maneuvering his legs under the steering wheel.

Next Steps: Revised Short-Term Goals (1 month)

1. Mr. J. will become independent in toilet transfers and tub transfers but will likely require some assistive technology such as elevated toilet seat, grab bars, and a tub bench.
2. Mr. J. will become independent in long-distance ambulation by using a motorized scooter but will require assistance for loading and unloading the scooter.
3. Mr. J. will be independent in driving himself to and from therapy.

In the sixth week, he was referred to a SCDCM that I found in the next town. He was instructed by this specialist to use a left-foot gas pedal and a spinner knob for driving, and the adaptive equipment was installed in his own car. In collaboration with the SCDCM, I decided that Mr. J. could not be independent in loading his wheelchair into his four-door sedan. He did not have the standing balance to use a wheelchair loader that is bumper or trunk mounted. He could, however, use a car topper that will electrically pick up, fold, and load his manual wheelchair into a box on the top of his car, all while he sits in the driver seat. By the time of his discharge, he had received all necessary in-vehicle training by the SCDCM and was beginning to drive around his own community.

"It has been very helpful for Mrs. J. to attend each of Mr. J.'s treatment sessions. As she has observed his weaknesses, she has been able to encourage him to complete his home therapy exercises and activities on days that he does not come to therapy. They have learned how to use the kitchen sink for support to let him work on standing tolerance three or four times a day. Mrs. J. has indicated that he will sometimes sit outside the bathroom and appear to long to just stand up and walk in. Mr. J. knows that they cannot afford to modify the bathroom doorway, so he understands that it is very important for him to have a good outcome with standing and this goal. He keeps asking me about a driving evaluation and is beginning to show some frustration in having to wait. Mrs. J. is very understanding of why this goal has been put off to later and has assured me that she will not let him drive before he is ready."

Understand what he is doing

"Mr. J. is accomplishing his goals quickly. I see him working very hard because he can tell that a driver evaluation is getting closer to becoming to reality for him. Through my contact with the occupational therapy driving specialist, I was able to discover that Mr. J. can use an adaptive equipment rebate from General Motors to help him purchase some of his driving equipment because his car was bought new 6 months ago. This will enable him to afford to buy the car topper as well as the devices he requires for driving. I introduced Mr. J. to another client of mine who also drives with adaptive equipment and went to the same occupational therapy driving specialist. This was very encouraging to Mr. J., and he actually went to see some driving equipment in this gentleman's car.

Anticipate present and future patient concerns

Decide whether the patient should continue or discontinue therapy and/or return in the future

"Mr. J. has made great progress over the past month. He does not seem as depressed as when I first saw him and is coming to therapy with more and more goals that he would like to work toward. I will update the intervention plan to incorporate the new goals. I have recommended that he obtain a referral for home health occupational therapy so that he can begin working in his own home environment. The home health occupational therapist can make sure he gets the right equipment in his bathroom and give him practice with his transfers in his own environment. He is totally agreeable to this plan. It was so great to see Mr. J. come into therapy after the first session of seeing the occupational therapy driving specialist. He was so excited and could finally see that he would be able to become much less dependent upon his family now. It was nice to hear him express his appreciation for my work, and he even admitted that he was glad I did not send him for a driving evaluation sooner. He is asking if he can drive now to and from his daughter's house, which is about 45 minutes away in another small town. I have referred him back to the SCDCM to address this issue with him. Mr. J. and I decided that he no longer needs outpatient occupational therapy but can be followed for his other goals by the occupational therapy consultant in the community."

Clinical Reasoning in Occupational Therapy Practice

Environmental Contextual Factors in Mobility

Mr. J. will be returning to his home with his wife on discharge, but the environment is rural, and according to his wife the home is not wheelchair accessible. How will these environmental factors influence intervention planning for functional mobility? What will the inpatient therapist request of the community-based therapist regarding follow-up for functional and community mobility?

Clinical Reasoning in Occupational Therapy Practice

The Importance of a Client-Centered Approach

During the initial occupational therapy evaluation, Mr. J. appeared depressed and unmotivated regarding therapy and the time and effort that would be required for intervention. What factors could be contributing to his attitude? What approach should the therapist take to improve this person's motivation and participation in goal setting?

Summary Review Questions

1. Define the two areas of mobility that are within the domain of occupational therapy, and list three specific subareas to be addressed under each main area of mobility.
2. Describe the hierarchy of intervention planning for mobility and the interdependence of functional and community mobility.
3. List precursor abilities and skills that a patient with lower extremity dysfunction must possess before learning to transfer into a wheelchair and how the principles of body mechanics must be applied during the transfer.
4. List the specific outdoor mobility skills in which a therapist would instruct a patient who uses a manual wheelchair.
5. Describe the process for evaluation and intervention planning for the IADL of driving a personal vehicle.
6. State when it is appropriate to refer a client to an occupational therapy specialist in driving and why.
7. Define three modes of travel that can be used for community mobility and three transportation alternatives available when independent driving is not an option.
8. Describe how occupational therapy practitioners can become involved in functional and community mobility issues in the communities in which they practice.

Glossary

Body mechanics—The way one moves the body, spine, and extremities during every day activities to protect the body, especially the back, from pain and injury. Good body mechanics refers to proper posture and body alignment when lifting or moving.

Community—"Unified body of individuals" that includes family, neighborhood, local communities, and groups that share the same interest or goals (Merriam-Webster, 2012).

Community mobility—"Moving around in the community and using public or private transportation, such as driving, walking, bicycling, or accessing and riding buses, taxi cabs or other transportation systems" (AOTA, 2008, p. 631).

Community mobility alternatives—Various modes of transportation chosen by an individual to move about a community that can include walking, bicycling, driving a personal car, driving a powered mobility device, or using

alternative modes of transportation such as private or public options of a subway, bus, or taxi.

Functional mobility—"Moving from one position or place to another (during performance of everyday activities), such as in-bed mobility, wheelchair or powered mobility, and transfers (e.g., wheelchair, bed, car, tub, toilet, tub/shower, chair, and floor). Includes functional ambulation and transporting objects" (AOTA, 2008, p. 631).

Functional mobility aids—Devices that assist a person with functional mobility such as a wheelchair, hemiwalker, leg lifter, bed rope ladder, quad cane, or transfer board.

Livable community—A community "that has affordable and appropriate housing, supportive community features and services, and adequate mobility options,

which together facilitate personal independence and the engagement of residents in civic and social life" (AARP, 2005, p. 4).

Mobility—The ability to move about the home and community.

Paratransit—An alternative mode of transportation for persons who qualify that uses taxis, minivans or small buses. It may be an on-demand, door-to-door service within a given service area or may follow a particular route. Also called community transport.

Personal mobility devices (PMDs)—Nonmotorized and motorized personal devices that assist a person with functional mobility and community mobility. Examples are a bicycle, an electric scooter, a manual or power-based wheelchair, golf cart, or low-speed vehicle.

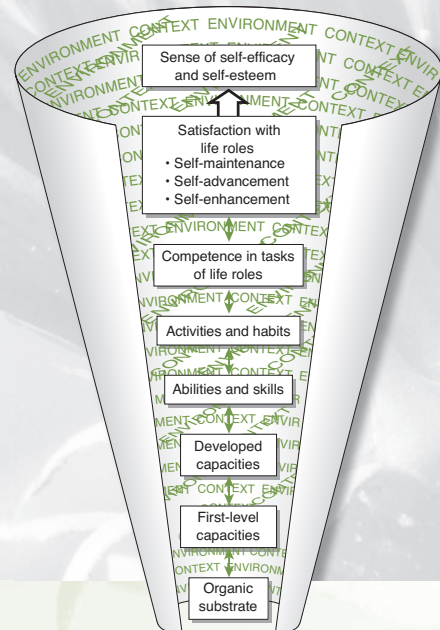
Restoring Competence for Homemaker and Parent Roles

Susan E. Fasoli

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. State the principles of compensation and adaptation.
2. State the principles of work simplification.
3. Identify adapted methods and equipment that enable persons with varied physical challenges and diagnoses to regain competence in homemaking roles.
4. Identify adapted methods and equipment that enable persons with varied physical challenges and diagnoses to regain competence in parenting roles.
5. Describe and teach proper body mechanics for homemaking and parenting tasks and activities.


Restoring competence in homemaker and parenting roles following a disabling event can greatly enhance one's sense of efficacy and feelings of self-esteem. Therapists typically address impaired performance of these life roles after a client has regained independence in basic activities of daily living (ADL) (e.g., self-care). Home management and parenting tasks, however, can be incorporated into the rehabilitation process at any time, depending on the individual's own priorities and needs.

Homemaking and parenting tasks may be used as both occupation-as-means and occupation-as-end, depending on the client's rehabilitation potential and desired goals. This chapter focuses on the use of occupation-as-end to restore a client's competence and participation in homemaker and parent roles. This treatment approach allows for addressing significant deficits in occupational performance skills (e.g., incoordination or visual impairments) via the principles for compensation and adaptation highlighted in Procedures for Practice 27-1.

Principles of work simplification and energy conservation can be taught to clients with physical impairments who lack sufficient endurance to accomplish daily life tasks. Work simplification and energy conservation principles are common-sense ideas to improve task efficiency and reduce energy expenditure during all occupational tasks and roles, including those related to homemaking and parenting (see Procedures for Practice 27-1).

HOMEMAKER ROLES AND TASKS: TREATMENT PRINCIPLES AND METHODS

An important role of the occupational therapist is to learn what life roles and tasks are particularly meaningful to the client (i.e., to explore his or her occupational identity) and to allow him or her the opportunity to grieve for what is lost or changed (Unruh, 2004). Many factors, including psychosocial adjustment, cognitive or

---

Procedures for Practice 27-1

Principles of Adaptation to Compensate for Functional Limitations

Principles for Compensation and Adaptation

- Limited range of motion (ROM): Increase the person's reach via extended handles and organize needed items within a compact work space.
- Weakness and low endurance: Use lightweight and/or powered equipment and allow gravity to assist. Employ work simplification and energy conservation techniques.
- Chronic pain: Reinforce use of proper body mechanics and pacing during physical tasks.
- Unilateral loss of motor control and limb function: Use affected limb to stabilize objects when possible. Use adapted methods and/or assistive equipment to perform bilateral activities with one hand.
- Incoordination: Stabilize at proximal joints (e.g., elbow) to reduce degrees of freedom necessary for control. Use weighted objects to minimize distal incoordination.
- Visual impairments: Use senses of smell, touch, and hearing to substitute for low vision. Enhance performance of visual tasks by improving lighting, reducing glare, or increasing contrast.
- Cognitive limitations: Employ visual and auditory aids to enhance memory and organization. Plan steps prior to beginning task. Work in familiar environment (e.g., home kitchen) to enhance cognitive performance during homemaking tasks.

Principles of Work Simplification and Energy Conservation

- Limit the amount of work. When possible, avoid overfatigue by assigning heavy homemaking tasks (e.g., vacuuming and cleaning bathrooms) to family members or a housekeeper.
- Explore ways to reduce homemaking demands and expectations, such as using packaged mixes or frozen foods to decrease time and energy for meal preparation.
- Plan ahead. Schedule homemaking, child care tasks (e.g., changing bed linens and giving tub baths), and community outings (e.g., shopping and doctor visits) to distribute energy-demanding tasks throughout the week. Prioritize to complete important tasks before fatigue sets in.
- Use efficient methods. Organize work areas and store frequently used supplies in a convenient location. Avoid standing when it is possible to sit while doing the task (e.g., ironing). Slide objects across a counter or table rather than lift them. Identify needed items at the beginning of a task to avoid extra trips. Use a utility cart to transport items.
- Use correct equipment and techniques. Use assistive equipment (e.g., long-handled reachers) to decrease bending and stooping. Avoid prolonged holding by stabilizing items with nonskid mats. Adjust work height and use tools most appropriate for the job. When physical limitations are present, choose equipment that does not promote further deformity.
- Balance daily tasks with rest breaks. Clients are advised to perform energy-demanding tasks early in the day, when they are most rested. Encourage self-pacing of tasks ("Don't rush!") to avoid fatigue. Frequent rest periods of 5–10 minutes can greatly enhance functional endurance during homemaking and parenting tasks.

perceptual impairments, and physical limitations, can influence a client's ability to take part in homemaker roles and tasks.

Psychosocial Adjustment

When faced with the onset or progression of physical disability, a client and family may have a variety of psychological responses. These reactions may be characterized by lack of motivation and refusal to participate in therapy, expressed feelings of hopelessness or anger, and denial. For persons with chronic conditions, such as scleroderma or rheumatoid arthritis, the challenges encountered during household chores can strongly affect levels of life satisfaction and well-being (Sandqvist, Akesson, & Eklund, 2005). The family's expectations and reactions must also be considered when occupational therapists are setting intervention goals and establishing plans for treatment. These psychological reactions must be acknowledged and addressed by the occupational therapist if identified goals are to be achieved. A client-centered approach involves sensitivity and planning. These highly individualized concerns should be addressed on a timely basis that is guided by both the client's illness trajectory and psychosocial adjustment to disability. For example, a client may find it easier to tackle unfamiliar or nonpersonal tasks early in therapy because this can ease his or her confrontation with loss. By involving the client and family in the choice of activities during treatment planning, the therapist can better individualize interventions and establish rapport and trust.

Barriers to Effectiveness

The occupational therapist must identify factors, in addition to psychosocial concerns, that can interfere with the effectiveness of intervention and inhibit performance during homemaking tasks. These factors include, but are not limited to, cognitive and perceptual impairments, poor vision, and environmental constraints, including lack of family support.

Persons with cognitive impairments as a result of central nervous system disorders may have more difficulty learning compensatory techniques than persons with musculoskeletal or peripheral nervous system disorders. The client needs good memory, judgment, and problem-solving abilities to learn how an assistive device is used, when it is needed, and how it can safely enhance task performance. Cognitive demands are increased when the adapted methods greatly alter the way the task is performed (e.g., ordering groceries online or learning to use a utility cart to transport items). The occupational therapist works to educate the client's caregivers in ways to best structure tasks and provide cues to enhance performance (see Procedures for Practice 27-2). Supervision and feedback are given to reinforce use of these techniques during varied situations. Refer to Chapter 24 for other cognitive strategies that can be used during homemaking and parenting tasks.

In the absence of intact cognitive abilities, clients may be able to learn new task methods, such as how to operate a microwave oven for meal preparation, if they can follow visual cues or instructions. The occupational therapist must ensure that the client can safely perform the task

---

Procedures for Practice 27-2

Managing Homemaker Roles with Cognitive Limitations

Clients with cognitive limitations may be unable to structure daily homemaker routines for many reasons, including impairments in attention, memory, sequencing and organization, problem solving, or executive functioning. Assessments such as the Canadian Occupational Performance Measure (COPM) (see Chapter 4) are used to identify important homemaker tasks and can assist the client and family in setting reasonable goals for intervention. The occupational therapist teaches the client and family ways to compensate for cognitive impairments while successfully returning to homemaker roles. Several examples of cognitive strategies include the following:

- Progress from gathering all needed materials and setting up tasks for the client to having him or her list and gather needed ingredients and kitchen items (e.g., cutting board, pot, utensils, etc).

- Break multistep tasks (e.g., preparing a meal) down to smaller components. Depending on the level of impairment, the family might involve client only in peeling potatoes, gather items needed for salad preparation so client can assemble salad, or assist as needed with step-by-step directions when making a casserole dish. Consider the impact of cognitive and physical limitations on the client's fatigue and motivation to participate.
- Grade difficulty of task and the amount of verbal cues and physical assist given. Preparing a peanut butter and jelly sandwich is easier than simple hot meal preparation (e.g., making scrambled eggs and toast), which is less complex than following directions to bake a cake from a prepared mix. Allow for independence, satisfaction, and success before moving on to more complex tasks.
- Set automatic timers on appliances to remind client to check cooking food or care for dishes or laundry when the cycle is complete.

with the prescribed adaptations and meet unexpected challenges encountered during task performance.

Perceptual impairments, including poor figure-ground skills, poor spatial orientation, and visual neglect, can also interfere with one's ability to manage homemaking tasks independently. Limitations in perceptual processing can interfere with one's ability to find needed items in the cupboard, decrease the safety of pouring hot coffee into a cup, and increase the likelihood of falls when vacuuming or sweeping floors. In addition, poor visual processing, such as the loss of central vision or decreased contrast sensitivity, can inhibit safety during homemaking tasks. Environmental changes, such as increasing available lighting throughout the home and enhancing contrast (e.g., pouring coffee into a light-colored mug), can improve performance.

The support of family or friends can be instrumental for carrying out recommended adaptations, reinforcing the use of assistive devices, and identifying additional concerns in need of intervention. When family assistance is not available, other support services (e.g., home health aide or companion) may be employed to ensure safety in homemaking tasks.

Preventing Decline in Homemaker Role and Tasks

Occupational therapists are often involved with preventing disability in persons who are at risk for developing impairments, activity limitations, and restrictions in the performance of life tasks and roles. Prevention programs for elderly persons include exercise classes to reduce physical limitations in balance, range of motion, and strength, in addition to group activities that exercise cognitive abilities, such as judgment and problem solving (Clark et al., 1997; Jackson et al., 1998). Homemakers may be instructed in home safety tips directed toward reducing clutter, removing loose rugs, and arranging furniture to clear walkways and allow access to electrical plugs and windows. Environmental modifications, such as the installation of grab bars and railings, can significantly decrease the occurrence of falls.

Occupational therapists can be instrumental in identifying hazards in the home and providing ideas that may enhance a person's safety and continued independence (see Resources 27-1). Many limitations encountered by well-elderly persons during homemaking tasks may be prevented or alleviated by relatively simple and inexpensive solutions.

Homemaking: Techniques and Therapeutic Aids

Competence in the role of homemaker can be attained in either of two ways, depending on the client's level of physical and cognitive ability: by managing and directing others to perform homemaking tasks or by direct participation.

Although persons with severe physical disabilities may not be able to perform many homemaking tasks without assistance, they can be effective home managers. For instance, individuals with high-level spinal cord injuries can independently manage household tasks by directing family members or paid housekeepers, managing finances, and overseeing shopping. Computerized banking systems and shopping services are accessible to those with Internet access and are relatively easy to use. Occupational therapy at this level may focus on organizing how household tasks may be scheduled, instructing the client in computer use, or identifying service resources in the community. Homemaker services, personal care assistants, and Meals on Wheels may provide the support necessary for a person with limited abilities to remain at home.

Persons who can physically participate in homemaking tasks can benefit from a variety of interventions that maximize role performance. The following sections discuss equipment and adapted methods for homemaking.

Equipment Considerations

A number of factors contribute to the selection and use of assistive devices and adapted equipment for homemaking. Simple modifications in the way a task is performed sometimes eliminate the need for an assistive device, and this is the preferable solution. When equipment is recommended, a primary concern is that the assistive device satisfies the needs of the client and enables the person to accomplish tasks that are otherwise impossible or difficult. The person must be comfortable with the idea of using an assistive device and satisfied with its appearance.

When making equipment recommendations, the occupational therapist must consider both the immediate and long-term needs of the client. Individuals with a progressive disease, such as rheumatoid arthritis or multiple sclerosis, benefit from equipment that can enhance current functional performance and provide for anticipated changes in physical status. In contrast, persons with nonprogressive conditions, such as acquired brain injury or spinal cord injury, often use fewer assistive devices as they regain physical abilities or learn alternate ways to accomplish their tasks without equipment.

Generally, assistive devices should be simple to use and maintain, as lightweight as possible, and dependable. If a client has mild cognitive impairments that interfere with equipment use, family members may be taught ways to enhance carryover at home. Insurance providers generally do not pay for assistive devices and adapted equipment. For those who cannot afford to purchase such items, loaner equipment may be available from local organizations, including disability support groups and senior citizen centers.

Meal Preparation, Service, and Cleanup

Efficient work areas, adapted techniques, and assistive devices can greatly enhance a client's safety and participation in meal preparation tasks.

Kitchen Storage and Work Area. Kitchens are best organized so that frequently used items are within easy reach of the place they are most often used. On average, persons who use a wheelchair can reach to retrieve items between 15 inches (low reach) and 48 inches (high reach) from the floor. Those who are ambulatory but have difficulty bending generally can reach 30 inches (low reach) to 60 inches (high reach) from the floor, depending on the person's height.

Pull-out shelves and turntables in cabinets can compensate for limited reach and maximize usable storage space. Pans, dishes, and so on may be stored vertically to alleviate the need to move unwanted items to obtain the one underneath. Pegboards with hooks can be attached to the back of closet doors to hold pots, pans, and utensils for easy access. Shelves attached to the inside of cabinet doors are handy for holding assorted wraps, canned goods, and cleaning supplies. Items that are seldom used should be removed to eliminate unnecessary clutter.

Procedures for Practice 27-3

Principles of Correct Body Mechanics

Principles of correct body mechanics that should be used during homemaking and parenting tasks include the following:

- Keep the shoulders and hips parallel and facing the task. Do not twist the trunk when lifting.
- Maintain good balance by positioning the feet shoulder distance apart with one foot forward.
- When standing for long periods, reduce pressure on the lower back by placing one foot on a low stool and changing positions frequently.
- When sitting or standing, maintain a neutral position in the lower back by tilting the pelvis slightly forward to maintain the natural curve of the spine. Use this neutral back position when lifting as well.
- Use the strongest or largest muscles and joints when lifting (e.g., use legs rather than back and palms rather than fingers).
- Keep the back upright and bend at the hips and knees rather than bending forward at the waist when reaching for low items.
- Push before pulling, and pull before lifting.
- While lifting or carrying, keep the object close to the body.
- Avoid rushing. Proper body mechanics are more effectively used when working at a comfortable pace.

Safety and independence in the kitchen can be enhanced by the availability of clear and accessible workspaces. For persons in wheelchairs, work counters should be 28–34 inches from the floor and have a depth clearance of 24 inches underneath to allow room for wheelchair leg rests. A work area that is at least 30 inches wide is recommended to provide sufficient space for needed items during meal preparation (ADA and ABA Accessibility Guidelines for Buildings and Facilities, 2004).

Gathering and Transporting Items. An important role of the occupational therapist is to help the client solve problems about gathering and transporting items at home by using work simplification principles and proper body mechanics (Procedures for Practice 27-1 and 27-3). Long-handled reachers can be helpful but should be used primarily for retrieving lightweight unbreakable items.

The wide range of assistive devices for transporting items around the home includes cup holders and walker or wheelchair bags. Homemakers who use a wheelchair may benefit from using a lap tray that easily slides on and off the wheelchair arms (Fig. 27-1). A variety of wire baskets and trays that attach to a standard walker are available for purchase, but many of these devices accommodate only a few things at a time, such as a sandwich and covered beverage. Individuals who perform homemaking tasks either from a wheelchair or ambulatory level may prefer to use a wheeled utility cart because of its larger carrying capacity. The therapist can help clients learn to maneuver the cart efficiently. Homemakers who use an assistive device or adapted methods to transport hot foods and beverages must follow strict safety precautions to avoid burns.

When limited income inhibits a client's ability to purchase assistive aids, the creative therapist can work with the client to identify inexpensive workable alternatives. No-cost solutions, such as attaching a plastic grocery bag or used bike basket to a walker, can add to independence in transporting certain items.

Food Preparation. The use of assistive devices and adapted equipment can make food preparation easier and more enjoyable. Homemakers who have lost the use of one arm following stroke or fracture find an adapted cutting board extremely useful when peeling or cutting vegetables, fruit, or meat. A raised edge along one corner of the board can stabilize a slice of bread for spreading butter or jam (Fig. 27-2).

The occupational therapist helps clients with physical limitations to solve problems such as the safest way to open cereal boxes and juice cartons. Some persons can open packaged food with one-handed techniques, while others prefer to use adapted scissors with a looped handle (Fig. 27-3). Homemakers with weakness and impaired hand function may find it easier to open plastic milk jugs than cartons. Smaller containers are generally easier to manage than large ones. Nonslip mats or suction holders may be used under jars or bottles to hold them steady for opening with one hand and to reduce sliding or turning of bowls when mixing.

Figure 27-1 Woman eating her lunch on a clear acrylic wheelchair lap tray that allows her to observe her lower body. (Photo by Robert Littlefield.)

Figure 27-2 Spiked cutting board with corner guards. (Photo courtesy of North Coast Medical, Inc., Gilroy, CA.)

Figure 27-3 Looped scissors. (Photo by Robert Littlefield.)

Figure 27-4 Ergonomic right-angled knife. (Photo by Robert Littlefield.)

Figure 27-5 One-handed egg crack. (Photo by Robert Littlefield.)

Knives, vegetable peelers, and other kitchen tools are available in many shapes and sizes. Clients with rheumatoid arthritis benefit from using utensils with ergonomically designed handles that require less hand strength and reduce ulnar drift (Fig. 27-4). Incoordination caused by ataxia may be somewhat alleviated by the use of weighted utensils and tools. Freestanding or mounted jar openers can be helpful to persons with a variety of physical limitations. Homemakers can be taught adapted methods for cracking eggs (Fig. 27-5; Procedures for Practice 27-4).

Electric equipment, such as food processors, blenders, can openers, and electric knives, can conserve energy by reducing the physical demands and time needed for meal preparation. To be truly beneficial, this equipment must be easy to use and maintain and suited to the person's disability. For example, some one-handed cordless can openers are available only in right-handed models and therefore are not convenient for persons with significant right hemiparesis after stroke.

Homemakers with limited mobility or reach often find a side-by-side refrigerator more accessible than other models. Loops of webbing or rope can be attached to the door handles to enable clients with limited hand function to pull the doors open. Heavy items should be stored on a shelf that is level with a lapboard or wheeled cart so they can be moved in and out with minimal lifting.

Cooking. Most persons with physical impairments find lightweight nonstick pots and pans to be the easiest to handle and maintain. Ergonomically designed cookware with easy-to-grip handles can be ideal for persons with limited distal strength. The use of double-handled casserole dishes, pots, and pans can enable joint protection by evenly distributing the weight of the pan between both hands.

Ambulatory clients with back or lower extremity pain or limited endurance can save energy by sitting whenever

Procedures for Practice 27-4

Methods for Breaking Eggs

Individuals with weak grasp can grossly hold the egg, throw it sharply into the bottom of an empty glass or metal bowl, where it will split in two, and then remove the shell.

Clients with functional use of only one hand may prefer to use the chef's method, as follows. Place the egg in the palm with one end held by the index and middle fingers and the other end held by the thumb to form a "C" around the egg. Sharply crack the egg on the side of a bowl, and then in one motion, pull the thumb down and the fingers up to pull the two halves apart (Fig. 27-5).

Figure 27-6 Oven push-pull stick. (Photo by Robert Littlefield.)

possible while preparing meals. Individuals who prepare food from a wheelchair can use a mirror mounted at an angle over the stove to keep an eye on cooking foods. Persons with hemiparesis may use a suction holder to stabilize pot handles while stirring. Homemakers can conserve energy when straining vegetables or pasta by placing a french-fry basket in the pot before cooking or by using a slotted spoon. This practice eliminates the need to carry a hot pot to the sink to drain it. Those who can safely transport and drain hot foods at the sink can reduce the need for lifting and holding and enhance stability by resting the pot on the sink's edge when pouring. An adjustable strainer that clamps onto the top of a pot or pan can also be used.

Homemakers who prepare meals from a wheelchair will find a self-cleaning stove with front-operated controls and a low wall oven (30–42 inches from the floor) to be the most practical to use and operate.

Individuals with limited proximal arm strength or grasp should not remove hot items from a wall oven higher than waist level without supervision because of the potential for burns caused by spilling or dropping. An oven push-pull stick may be used to manage oven racks or reposition hot dishes safely during baking (Fig. 27-6). If a client is planning to buy a new stove, the therapist may recommend a gas rather than electric range to reduce the risk of burns because the gas flames provide a visual cue that the burner is on.

Microwave ovens provide a cost-effective and safe alternative to conventional ovens and stoves. Elderly persons with arthritis, visual impairments, and limited endurance can be taught to use a microwave instead of a conventional stove to cook meals more easily and in less time.

Dishwashing. Dishwashing can be made easier for individuals in a wheelchair by placing a removable wooden rack in the bottom of a standard sink to reduce its depth to approximately 5 inches. The under-sink cabinet doors can be removed to allow persons in a wheelchair to face the sink head-on, with any exposed piping insulated to protect lower extremities from burns. A swing-away faucet with a single control lever can enhance the ability of a person with limited hand function to adjust water flow. Installing this faucet beside rather than at the back of the sink further increases accessibility for persons in wheelchairs.

Dishwashing in a double sink should be organized to allow the person to work from one direction to the other: dirty dishes, wash water, rinse water, and drying rack. Homemakers with hemiparesis may wash dishes with greater ease when the rinse water and dish rack are on their unaffected side. Suction bottlebrushes and scrub brushes can be attached to the sink to allow for cleaning glasses or silverware with one hand. A rubber mat at the bottom of the sink prevents plates from sliding when they are washed and reduces breakage. Persons with limited grasp may prefer to use a terry cloth mitt or sponge mitt when washing dishes.

Work simplification includes air drying versus towel drying dishes and reusing them directly from the dish rack or dishwasher. Use of an electric dishwasher aids energy conservation, particularly when little prerinsing of soiled dishes is required.

Whenever possible, the homemaker can eliminate unnecessary cleaning by using oven-to-table ware or by serving directly from the pot. Pans can be lined with foil to reduce washing after baking or broiling. It is recommended that individuals clean as they prepare the meal and soak hard-to-clean dishes while eating to reduce the amount of cleanup required when the meal is over.

Grocery Shopping. Persons with physical impairments or limited endurance can more easily participate in grocery shopping with a few task modifications or assistive devices. When transportation is readily available, individuals may find that frequent visits to the market are more manageable because they can purchase and carry smaller quantities of food items at one time. Shopping at a small local market, although sometimes more expensive, can be easier and less energy consuming than shopping at a superstore. Grocery shopping can become a social event when done with a friend. Shopping together may provide an additional advantage if the friend can assist with reaching items on high and low shelves or carrying the bags.

Planning. A well-organized shopping list is necessary to make the most efficient use of time and to conserve energy at the store. Individuals should keep the list in a convenient location at home, so that needed items can easily be added between shopping trips. Store maps, available at the customer service desk of many large grocery stores, can be used to organize the list. The homemaker or occupational therapist can arrange the items on the list (e.g., produce, dairy, and meats) according to the store layout, aisle by aisle. Copies of this list can be used between store visits to record the items needed under each category.

The client should plan ahead and shop during off-peak hours, when the store is not crowded. Once at the store, he can use the grocery list and signs above the aisles to find needed items.

Carts. Ambulatory persons with mild balance impairments can use a standard grocery cart when shopping; however, they should not use it for support when bending to reach items on low shelves. Individuals who use a wheelchair may find that adapted shopping carts that attach to the wheelchair are more convenient than a standard cart; although some have found that these attached carts interfere with their ability to reach items. When this is the case, homemakers who are independent with wheelchair mobility may prefer to leave a standard cart at the end of an aisle, gather needed items in a small lap basket, and transfer them into the cart before proceeding to the next aisle.

Large stores sometimes have motorized carts for shoppers with limited endurance and mobility. These carts are handy for getting around the store, but it may be necessary to call the store in advance to reserve one. The baskets on these carts are generally small, which may be problematic if the person is planning to purchase a large order. The client may need help to figure out the safest and most effective ways to obtain items from high or low shelves from a motorized cart.

Selecting and Retrieving Items. It is wise to shop for items that are easy to open and require little preparation. Persons with limited endurance can increase the ease of meal preparation by selecting frozen rather than fresh vegetables and skinless or boneless meats.

Individuals who have limited upper extremity range of motion or who use a wheelchair find it difficult or impossible to reach items on high shelves. A reacher can be used to retrieve lightweight unbreakable items, but assistance may be needed for heavier objects. Most stores provide an employee to assist with shopping if asked. Some persons may feel comfortable asking people in the aisle for occasional help to increase opportunities for socialization.

Some individuals with traumatic brain injury or cerebrovascular accident have cognitive or visual-perceptual problems that interfere with their ability to locate items (e.g., attention, hemianopsia, or impaired figure-ground skills). These persons can be taught to find objects more easily by scanning shelves in an organized manner, top to bottom and left to right. A person with severe visual impairments needs assistance to ensure safety and effectiveness while shopping.

Transporting Items Home. Generally, plastic or reusable grocery bags are easier to manage than paper. Foam tubing can be placed around the bag handles to reduce joint stress. At the checkout counter, the client should ask the clerk to keep grocery bags as light as possible and to bag refrigerated foods separately. Several half-filled bags are easier to manage than one or two full ones. Most stores provide assistance for transferring groceries into the car,

Figure 27-7 Using wheeled cart to conserve energy when transporting items.

but store workers should be instructed to place them within easy reach.

At home, a wheeled cart can be used to transport groceries into the house (Fig. 27-7). Persons with limited endurance can leave nonrefrigerated items in the car until later, when the person has rested or a family member is available to bring them into the house.

Computerized Shopping. Clients with physical limitations and limited endurance may find computer shopping to be a wonderful, energy-efficient alternative to conventional shopping. Persons with Internet access find that grocery orders can be easily placed online. Deliveries are made directly into the home, eliminating transportation and accessibility issues that may arise at the grocery store. The occupational therapist can help the client identify which method of shopping is most practical based on the individual's priorities, physical limitations, knowledge of computer use, and financial situation.

Clothing Care. When a homemaker identifies clothing care as an important goal, the occupational therapist can help the person modify the way laundry tasks are performed. Even persons with severe physical impairments can engage in some aspect of clothing care (e.g., sitting at table to fold clothes).

Figure 27-8 Kneeling to keep back straight when removing laundry from dryer.

In-Home Appliances Versus Self-Service Commercial Laundries. Although top-loading washers decrease the amount of bending required to load and unload clothing for persons who are ambulatory, they provide an additional challenge for persons in a wheelchair. Front-loading laundry machines are easier for seated individuals to access, but persons who are ambulatory may need training in body mechanics, particularly when loading or unloading wet clothes. For example, it is recommended that ambulatory clients with low back pain kneel on one knee, bending at the hips and knees and keeping the back upright, when loading or removing clothes from a front-loading machine (Fig. 27-8). Homemakers with limited hand function caused by spinal cord injury or rheumatoid arthritis find it easier to use knob turners to set machine dials (Fig. 27-9).

Individuals who use a self-service commercial laundry for clothing care should bring needed coins and premeasured packages of soap for each load. Many laundries have rolling carts available for carrying wet clothes from washer to dryer. If possible, persons with physical impairments should choose a staffed laundry. These individuals can be called on for assistance if problems arise.

Collecting and Transporting Clothing. Ideally, the home laundry room should be on the same floor as the bedrooms
Figure 27-9 Knob turner. (Photo by Robert Littlefield.)

to minimize the need to carry clothes up and down stairs. When this is not an option, family members can assist as needed to transport clothing to and from the laundry area.

Soiled clothing can be placed in a hamper lined with a plastic or cloth bag with handles. Seated individuals with good upper body strength can transport clothes to the washer by lifting the bag out of the hamper and either carrying it on their lap or hooking the drawstrings on the wheelchair handles. If the person is ambulatory but has difficulty bending, a clothes basket can be kept on a waist-high table or shelf to collect soiled laundry. A wheeled cart is handy for transporting clothes for persons at an ambulatory level.

Washing and Folding. Laundry detergents and bleaches should be kept within easy reach of the washing machine. Hand washing can be eliminated by laundering delicate clothing in a mesh laundry bag in the machine. Persons with visual impairments can fasten paired socks with large safety pins when they are taken off so they do not have to be sorted when clean.

A person in a wheelchair can use a handheld mirror and reacher to remove clothes from the bottom of a top-loading washer. Homemakers with very limited grasp caused by spinal cord injury have found that stubborn items can be more easily removed from the washer tub after a wet towel or shirt is put back into the washer and the spin cycle is restarted. Movement of the wet towel inside the spinning washer can loosen clothes that are stuck to the tub.

Clothes can be folded while the person sits or stands at a table. An adjustable rod 42–60 inches high is convenient for hanging permanent-press items as they are removed from the dryer. Large items, like sheets and bath towels, can be reused immediately after cleaning so they do not have to be folded. Those who choose to fold sheets may find the task easier if they use the bed as a work surface.

Ironing. One challenging task for homemakers with physical impairments is to fold and unfold an ironing board. When possible, it is best to leave the ironing board set up in a convenient, out-of-the-way place. The board surface should be at waist level for persons who stand when ironing to reinforce good posture and body mechanics. Persons who iron while seated in a wheelchair will find a

work surface of 28–34 inches high comfortable (ADA and ABA Accessibility Guidelines for Buildings and Facilities, 2004). A heat-resistant pad can be placed at the end of the ironing board to eliminate the need to stand the iron up while arranging clothes on the board.

When buying a new iron, individuals should select a lightweight model with an automatic shut-off switch. A cord holder can reduce effort and keep the iron cord from getting in the way. Permanent-press clothing requires less care than cotton or linen fabrics and thus reduces ironing needs. Persons who iron only occasionally may prefer to use a small tabletop ironing board if they have sufficient upper body strength to store and retrieve it from a closet easily.

Sewing. Homemakers may enjoy sewing as a hobby or may only make occasional alterations or repairs. Persons who have hemiparesis after a stroke can still sew with an electric machine by using the unaffected leg to operate foot or knee controls. Persons who do not have use of their lower extremities can place the foot pedal of an electric sewing machine on the table and use one hand or elbow to depress it. Sewing is generally most successful when there is an adequate workspace and adapted methods to stabilize materials when cutting or stitching.

Persons with limited use of an affected arm can hand sew by using an embroidery hoop attached to the edge of a table or counter with a C-clamp (Fig. 27-10). To minimize sewing needs, sticky iron-on tape or fabric glue can be used for hems and small repairs. Rotary cutters, instead of scissors, can make cutting fabric easier.

Indoor Household Maintenance. The occupational therapist helps clients identify effective ways to do household maintenance tasks, such as bed making and floor care.

Figure 27-10 Embroidery adapted with use of a hoop that fastens to the table; requires only one hand. (Photo courtesy of Maddak, Inc.)

Adapted techniques and assistive devices can help the client to safely perform necessary chores without assistance.

Bed Making. Bed making can be simplified by straightening the sheets and blankets as much as possible before rising in the morning. Homemakers with limited mobility or impaired upper extremity function find it easier to make the bed by completing one corner at a time, starting with the head of the bed. If the individual is working from a wheelchair, the bed should be positioned so that both sides are accessible. Persons with chronic back pain must adhere to proper body mechanics when making beds, being careful to eliminate excessive forward bending.

When changing the sheets, a person can reduce extra work by carefully pulling blankets and spreads toward the foot of the bed, trying not to dislodge them from under the mattress. In this way, the person will not have to expend unnecessary energy to find and reposition the top edge of the blankets or bedspread. Although the bottom sheet should be fitted, it should also be loose enough to be easily applied.

If the client or a friend is handy at sewing, several adaptations can be made to standard sheets to increase the ease of bed making. Fitted sheets can be adapted by opening the two fitted corners at the bottom end and sewing Velcro™ straps onto each side. When fastened, these straps securely hold the bottom corners together. Persons with limited upper body strength or hemiparesis may find lightweight blankets and spreads and satin pillowcases easier to manage.

Dusting. Physically challenged homemakers can dust hard-to-reach places with assistive devices. Persons with limited upper extremity reach because of orthopedic or neurological changes can use a commercially available long-handled duster that is lightweight and easily extended to reach high places. Individuals with good hand strength may prefer to hold a dust cloth with a long-handled reacher or use a vacuum cleaner attachment to clean hard-to-reach places. Persons who cannot afford assistive devices may find that a dust cloth secured to the end of a yardstick or dowel with a rubber band meets their needs. Clients with limited grasp or fine motor control may find that an adapted spray handle (see Fig. 25-7) attached to the furniture polish can and an old sock or duster mitten significantly enhance their independence in dusting.

Floor Care. Heavy homemaking tasks, such as floor care, are often the first activities that elderly persons or individuals with physical impairments find difficult because of the amount of strength and endurance required. When the client's goal is independence in floor care, the occupational therapist must determine how this can be safely and efficiently accomplished.

Cleaning supplies can be conveniently stored and transported in a handled bin or canvas bag with a shoulder strap. When feasible, duplicate sets of equipment can

be kept around the home to reduce the need to carry items. A number of lightweight, wet or dry floor-cleaning tools are commercially available and easy to use for quick cleanups. A sponge mop with the squeeze lever on the handle minimizes bending and can be used with one hand. Individuals with limited hand function but adequate proximal arm strength can use a grasping cuff to help maintain a closed fist around mop or broom handles. Persons working from a wheelchair may find it best to start at the farthest corner and work backward out of the room. Furniture should be fitted with casters or Teflon slides if moved regularly.

Lightweight upright vacuums provide a good alternative to using heavier canister-style models because they work well and are easier to manage for both those who are ambulatory and those who use wheelchairs. A lightweight carpet sweeper is another good choice because it is maneuverable, is relatively inexpensive, and does not have to be plugged into an electrical outlet. Although the carpet sweeper is easier to push, more repetitions are generally needed to clean the same area. Long-handled dustpans and brushes can ease cleanup because they eliminate the need for bending and stooping (Fig. 27-11). If the client has

Figure 27-11 Use of a long-handled brush with dustpan. (Photo by Robert Littlefield.)

good hand function, cordless handheld vacuum cleaners are handy for cleaning up small messes within easy reach.

Bathrooms. After a disabling event, a homemaker who cannot afford a housekeeper or does not have family members to assist may have to learn adapted ways to clean the bathroom. Cleaning needs can be reduced by rinsing the sink or tub immediately after use to wash away soap residue. Spray-on chemical products clean bathroom fixtures with little effort, substantially reducing physical demands. Toilet cleaning tablets can be dropped into the toilet tank to reduce the growth of bacteria between thorough cleanings. A long-handled mop with a small head is useful for cleaning inaccessible areas behind the toilet.

Many homemakers with physical impairments find that cleaning the bathtub is difficult or impossible. These suggestions may make it possible. Persons with limited endurance or balance concerns should sit to clean the tub. Cleaning sprays and foams can be easily applied and rinsed off from a seated position, particularly if a long-handled shower hose is used. A long-handled bathroom cleaner with a nonscratch scrubbing sponge can enable persons with limited reach to clean tubs and shower enclosures without assistance (Fig. 27-12). Replacing sliding doors with a plastic shower curtain can make the bathtub more accessible for bathing and cleaning. The plastic curtain can be laundered in the washing machine or inexpensively replaced when it becomes soiled.

Hard to Manage Tasks. No matter how creative the occupational therapist and client are, some household tasks may be impossible for persons with physical impairments. However, a large number of assistive devices are

Figure 27-12 Cleaning bathroom tile using a long-handled cleaner. (Photo by Robert Littlefield.)

available to ease the physical requirements of previously difficult tasks. Electric outlet extensions can be plugged into existing baseboard outlets and secured to the wall to eliminate the need to bend when inserting or removing a plug. Devices that make it easier to replace hard to reach light bulbs are also available. The adaptive therapist is well able to analyze task demands and identify modifications or assistive devices that promote independence. When a client cannot accomplish household tasks despite adapted methods, the occupational therapist can initiate a referral to homemaker services.

Outdoor Household Maintenance. When a client's goal is to do outdoor household maintenance, such as yard work or gardening, the occupational therapist can offer suggestions to increase safety and independence.

Yard Maintenance. Persons with mild physical impairments can return to some level of outdoor home maintenance if desired. Individuals with good endurance can mow with a self-propelled lawn mower and accomplish small projects, such as maintaining a patio area. To reduce the risk of back injury when mowing, individuals should avoid stopping and turning the mower. For this reason, a lawn with rounded rather than angled corners is easier to mow (Yeomans, 1992). Rechargeable battery-operated edgers are more convenient than models that must be connected to an electric cord when operated. Numerous ergonomically designed products have been developed to reduce injury during outdoor work. For example, bent-handled shovels reduce excessive back strain and forward bending by altering the fulcrum of movement (Fig. 27-13).

Figure 27-13 Protecting the back while shoveling by using an ergonomically designed shovel with bent handle and lifting with the legs, not the back.

Gardening. Homemakers who are physically challenged need not give up the joy of gardening. Tools can be adapted, flower and vegetable beds can be raised, and wider walkways or wheelways can be created to increase a person's access to the garden. Container gardening is also feasible for persons with limited mobility.

Gardeners with limited hand function can adapt ordinary hand tools with inexpensive foam pipe insulation, which is available at most building supply stores (Yeomans, 1992). This foam, presplit for easy application, can significantly enhance the comfort of grasping and holding the tool. In a randomized study, Tebben and Thomas (2004) reported that a garden trowel labeled as "ergonomic" did not elicit better wrist positions during use when compared to an ordinary trowel. This reinforces the need to carefully assess whether "ergonomic" garden tools truly enhance body mechanics and positioning for a given client.

Individuals who garden from a wheelchair can increase their reach by using long-handled spades, shovels, and pruners. Persons with limited trunk mobility or balance may increase their safety by sitting on a garden stool and using long-handled tools. Gardeners who are fairly mobile can use a kneeling bench, with handles that assist them in getting up and down. Tools can be transported around the yard in apron pockets, a backpack, or a child's wagon, depending on the person's needs and available options. Tools with brightly colored handles are easy to see and therefore less likely to be lost in the garden (Yeomans, 1992).

Homemakers who return to gardening need to take care of themselves while caring for their flowers. Stretching exercises before and after gardening can reduce muscle stiffness and prevent injuries (Adil, 1994; Yeomans, 1992). Work simplification, energy conservation, and proper body mechanics are essential. Gardeners should keep themselves safe by using sun and insect protection, drinking plenty of fluids, and carrying a medical-alert button or whistle around their neck in case they encounter unexpected problems when alone in the garden.

TASKS AND ACTIVITIES OF THE PARENTING ROLE: TREATMENT PRINCIPLES AND METHODS

The occupational therapist and client work closely to identify adapted methods and equipment that enhance participation and independence in parenting tasks. A holistic approach addresses parent and family needs within the home and community.

Psychosocial Adjustment

Parents whose physical limitations are due to an acute event, such as spinal cord injury or acquired brain injury, may initially lack a sense of competence, not only in their ability to care for themselves but also in their ability to care for their

children. The impact of the client's impairments on family responsibilities and expectations must be considered when establishing a treatment plan (see Procedures for Practice 27-5). The occupational therapist also must be sensitive to the client's psychosocial concerns about changes in family relationships and roles. Restoration of parenting roles can be challenging for the client, the family, and the therapist.

Parents with diminished physical abilities following an acute event (e.g., spinal cord injury) are likely to have different intervention needs than parents with a chronic or progressive disease or disorder (e.g., rheumatoid arthritis or multiple sclerosis). Persons subjected to the acute onset of physical or cognitive impairments are confronted by sudden and sometimes drastic changes in the ways they can participate in important life roles and tasks. In contrast, individuals with progressive conditions and their families can gradually learn adapted ways to cope with changing abilities and levels of role participation over time. The child's age and developmental stage will greatly impact parent/child relationships in both acute and chronic situations. It is important to recognize that parenting needs and concerns evolve as the child grows and as the parent's disability changes. Even small changes in physical status (e.g., transition from use of a walker to scooter for a mother with multiple sclerosis) can have significant effects on all family members. Children who were accepting of a parent's physical disability at a younger age may become more sensitive to peer pressures and their parent being "different" as they approach teen years.

During the evaluation, the occupational therapist asks clients to list their concerns and identify which parenting tasks they highly value, as well as which tasks are necessary for them to resume their parenting role. The client should then prioritize parenting goals in a way that addresses both valued and necessary tasks in a balanced way.

Barriers to Effectiveness

Barriers to a client's ability to return to parenting tasks and roles are similar to those for homemaker responsibilities. A client's child care needs within home and community environments must be identified and addressed. Factors such as the child's age, activity level, and behavior greatly influence the challenges encountered by the parent with physical impairments. The occupational therapist works to identify the barriers that interfere with a client's ability to accomplish important parenting tasks, devises adapted methods that reduce or remove these constraints, and assists the individual in regaining competence in his or her parenting role by addressing physical, cognitive, and psychosocial needs.

Child Care: Techniques and Therapeutic Aids

Caring for young children under the age of 4 years is physically demanding and can contribute to musculoskeletal pain, even in parents without physical disabilities (Sanders & Morse, 2005). Parents with rheumatoid arthritis, spinal cord injury, and stroke find that child care tasks that require lifting and carrying are the most challenging, followed by tasks that demand fine motor dexterity and/or grip strength. A national survey of parents with physical disabilities revealed that parenting tasks such as traveling outside the home with a child, recreational activities, and chasing and retrieving children require the greatest assistance from others (Barker & Maralani, 1997). Although researchers have shown that adaptive baby care equipment can reduce fatigue and increase parent satisfaction (Vensand et al., 2000), funding for adapted parenting equipment and

Procedures for Practice 27-5

Managing Parenting Roles with Cognitive Limitations: Structuring Age-Appropriate Play Experiences

Positive play experiences are key to parent/child bonding and facilitating child development. The therapist can use Internet resources and parenting texts to help the client with cognitive impairments choose age-appropriate activities for the child. Activities should allow for gross and fine motor play, creativity, and cognitive exploration through varied sensory modalities (visual, auditory, and tactile).

- Help parent to recognize and respond to the child's needs and interests. Being attuned to the child's energy level and interests will help the parent choose appropriate play activities (e.g., bean bag toss or push toys when active; manipulatives, puzzles, or story time when calm or tired).
- The client's physical and cognitive challenges must be considered when planning play time activities. For example, ball toss with a toddler can be frustrating when the parent lacks the physical ability to catch or retrieve stray balls. Kid-sized basketball or bean bag toss games may be more satisfying, particularly when the child's job is to gather balls for the next round of play.
- Various card and board games involve sustained attention, memory, or use of strategies and problem solving, so are good therapeutic activities for the parent facing cognitive challenges. Select games carefully, so they are fun and engaging to both the child and parent while providing the "just-right challenge" in light of the parent's cognitive impairments.
- Trips to the playground are among the most challenging for parents with physical and cognitive impairments. Small play groups with friends, or offered through community education programs, can provide great opportunities for socialization and support, physical assistance when needed, and modeling of appropriate parenting behavior.

personal assistance services to help with child care is extremely limited. Therefore, the parent and therapist must work together to identify adapted methods and inexpensive solutions that best address parenting needs.

Equipment Considerations

The occupational therapist and client should initially explore whether simple adaptations to the way child care tasks are performed can enhance performance. When these simple solutions do not work, the client and therapist should evaluate whether commercially available child care equipment can feasibly meet the needs of the parent and child. If not, more creative solutions and adaptations must be devised.

The occupational therapist should consider the cost of the adapted equipment and whether it is acceptable to the client in terms of appearance and ease of use. In addition, the therapist must understand that the appropriateness of any equipment changes over time as the child grows and develops (Vensand et al., 2000).

Transitional Tasks

When working with parents of infants, the occupational therapist must first address transitional tasks that occur before or between baby care activities such as feeding or dressing. These transitional tasks are holding, carrying and moving, transfers, and positional changes. The occupational therapist works with the parent to identify the safest methods for managing these transitions, including use of proper positioning techniques and holding devices such as wedge pillows or slings, alternate means for carrying that may include securing infant seats to rollator walkers, or emphasizing good body mechanics and use of lifting slings or harnesses during transfers and positional changes (Rogers & Kirshbaum, 2011).

Adapted equipment that provides alternative ways of carrying the infant or young child or reduces the need for multiple transfers can greatly enhance the parent's satisfaction and ability to care for the child. Parents with distal weakness and pain, as seen with rheumatoid arthritis, benefit from wearing wrist supports to reduce joint stress when lifting and carrying their child (Nordenskiold, Grimby, & Dahlin-Ivanoff, 1998). Many clients prefer to practice lifting and carrying techniques with a weighted doll before trying to manage an active child.

A variety of cloth infant carriers and child front packs are available. Although these carriers allow the parent to transport a small child while leaving hands free, they may be contraindicated for persons with chronic back pain because the shoulders and back carry the weight of the child. Individuals who use wheelchairs may find child front packs handy for holding the infant while performing other homemaking tasks. Ease of use is important: adaptations may be needed to enable the parent with physical impairments to get the baby into and out of the infant carrier. The straps can be modified to reduce the parent's coordination needs

Figure 27-14 A mother confined to a wheelchair using a safety strap for an older baby while gathering items from the refrigerator.

(Vensand et al., 2000). Older babies with good neck and trunk control can safely ride on their parent's lap with only a safety belt attached to the wheelchair (Fig. 27-14).

Bathing

Parents need to be sure that all necessary equipment and clothes have been gathered and are within easy reach before they begin bathing their infant or young child. A terry cloth apron worn during bathing can protect clothing and dry the baby after the bath. Persons who are ambulatory may find that bathing the infant in a portable plastic tub in or near the kitchen sink is a good option because the height of the sink or counter minimizes bending and the tub can be easily filled and drained at the sink. Parents who use wheelchairs, however, may find this arrangement inconvenient because it is too high for safely lifting the baby in and out of the tub. Persons in wheelchairs also find it difficult to bathe the infant if the baby tub is in a regular bathtub because it is too low (Vensand et al., 2000). An alternative is to secure the baby bathtub to a sturdy table or computer table placed near a sink. A portable hose can be connected to the sink faucet for filling the tub, and a separate hose can be used to drain the bath water (Vensand et al., 2000). It may be easier for the parent to use this arrangement to bathe the older infant until the child is mobile enough to help with getting in and out of a regular bathtub. This diminishes the parent's need to lift a wet, slippery child from a low tub.

Diapering and Dressing

Commercially available changing tables are usually inaccessible for persons who use a wheelchair because the wheelchair does not fit under the table for diapering or dressing

the child. In addition, the surface may be too high for a seated parent to lift and transfer the baby safely, particularly as the infant grows (Vensand et al., 2000). The client and therapist should work together to determine the changing surface that most effectively and safely meets the individual's needs. Concave diapering pads that keep the baby from rolling off the changing surface can be adapted and safely attached to a computer table or dining room table to allow better wheelchair access (Rogers & Kirshbaum, 2011).

Safety straps should always be used to secure the active baby to prevent falls. These straps are particularly helpful when the parent needs extra time to manipulate diaper or clothing fasteners because of diminished fine motor control. A mobile attached to the changing surface and assorted toys can keep the baby distracted during changing.

Although adapted fasteners for diapers and baby clothing can require initial assistance from family or friends, they can greatly enhance one's independence in child care during the day. For example, Velcro™ attachments on diaper wraps that hold either cloth or disposable diapers can be adapted by attaching metal or plastic key rings that are more easily managed by parents with limited hand function. In addition, many disposable diapers now have Velcro™ fasteners which, unlike tape closures, allow for easier repositioning and handling. Small pieces of Velcro™ can also be sewn onto a variety of infant and baby clothes. Ideally, clothing should have full-length openings with closures that the parent can manage. When a zipper pull is used, zippers are easier to manipulate than snaps. Many caregiver techniques that emphasize baby collaboration with the parent can be explored. For example, simple physical cues such as gently pushing on the baby's elbow can facilitate arm extension into the sleeve during dressing (Rogers & Kirshbaum, 2011).

Feeding

Mothers with physical challenges may choose to nurse or bottle-feed their baby. After an initial adjustment period, breast-feeding can be easier than bottle-feeding because it eliminates formula preparation. If the mother is taking medications, it is important that she check with her physician before deciding to breast-feed to be sure that the medication will not harm the nursing infant. The mother should sit in a relaxed, comfortable position, using pillows to support the holding arm and baby while nursing. Pillows that are specifically designed to support the nursing infant are commercially available. When needed, wheelchair lap trays with foam padding can be fabricated to assist with infant positioning while nursing.

Some parents find bottle-feeding easier and more convenient with the older infant in a child seat, although others prefer to hold the child close to them when feeding (Fig. 27-15). Individuals with limited grasp may be able to hold a bottle and feed their infant after slipping their hand
Figure 27-15 Alternative feeding position for mother with mild left hemiparesis following cerebrovascular accident.

through a loop of webbing material attached to the bottle (Vensand et al., 2000). Many different types of bottle holders are available on the internet. Lightweight plastic bottles with screw-on lids are recommended over glass bottles.

Older babies can be spoon-fed by a person with tetraplegia when the parent's wrist cock-up splint is adapted by attaching a Velcro™ loop to the palmar surface. The spoon is inserted into a utensil pocket made of Velcro™ hook and attached to the splint at the best angle for feeding (Vensand et al., 2000). An insulated baby dish can be used to keep food warm throughout the meal. Spoons should be rubber coated to protect the baby's gums and teeth if bumped while feeding.

Parents with impaired grasp and arm strength may not be able to attach or remove the tray on commercial high chairs (Vensand et al., 2000). In addition, it may be difficult for the parent to lift the child in and out of a standard high chair. Options to make high chairs more accessible for parents with physical limitations include altering the chair height, designing swing-away trays, and adding a climbing ladder to encourage the older infant to climb into the seat with supervision only (Vensand et al., 2000).

Play

Parents with physical impairments may find that their ability to play with their young children is hindered because they cannot sit on the floor or bend to reach into standard playpens. Although infants can be entertained while they are sitting in a bouncy seat, older babies need a larger safe play area to develop gross motor skills. If cost is not an issue, a play care center, essentially a raised playpen that allows wheelchair access, can be built in the corner of a room (Vensand et al., 2000). If the center is equipped with swing-away or sliding doors, the parent can wheel up to the play center and easily reach into it to play with the baby. This play area can also be used for the child's naps during the day, eliminating extra transfers in and out of the crib (Vensand et al., 2000). Walking toddlers and their parents may find that a child's table approximately 18 inches high is a convenient place to play while the parent is sitting in a wheelchair or standard chair.

Cribs

Standard cribs are inaccessible for parents who use wheelchairs, and they require ambulatory parents to bend forward when putting the baby in or out of bed. A standard drop-side crib can be adapted in several ways, depending on the parent's physical needs.

Persons who are ambulatory but have difficulty bending because of chronic back pain can raise the crib by inserting leg extenders or blocks of wood under the crib legs. The crib mattress can also be raised to the highest setting but should not remain in this position once the baby is old enough to sit or to climb over the crib rail.

Parents who use a wheelchair will find it easier to transfer the baby in and out of the crib if the rail is adapted. One suggestion involves extending the legs of the crib to allow wheelchair access under the mattress in its lowest position. The drop-down rail is cut to form two gates that open at each end of the crib. Hinges for the gates are attached to a center post that is connected to two horizontal bars that run between the head and foot of the crib. Latches that are inaccessible to the child secure the gate when the baby is sleeping (see http://www.disabled parents.net/?page_id=95). Another option is to adapt the crib rail so that it slides along a horizontal channel (Dunn, 1978; Versand et al., 2000). Whatever crib design is used, the release mechanism for the crib rail must be child resistant yet manageable for the parent to manipulate with one hand or with limited coordination and dexterity. When planning adaptations, the structural integrity of the crib and baby safety during transfers are major considerations. For example, babies who are mobile are at a greater risk for falling when a parent backs away from the crib to open a gate that swings outward. Horizontal bars that add structural support above the crib rail may pose a bumping hazard for older babies who pull up to stand before transferring out of the crib. Adapted cribs should be checked frequently to assure that they safely meet needs of both parent and child (Rogers & Kirshbaum, 2011).

EFFICACY AND OUTCOMES RESEARCH

Although the number of studies on occupational therapy outcomes continues to grow, there continues to be little evidence concerning specific effects of occupation-as-end on homemaking and parenting abilities. Much of the research describes interventions that either combine occupation-as-means (task-specific training in ADL or meal preparation) with occupation-as-end (task adaptation or environmental modification) (e.g., Clarke et al., 2009), or reports effects of a multidisciplinary approach in which the impact of occupational therapy cannot be distinguished from that of physical therapy (Gitlin et al., 2006; Ziden, Frandin, & Kreuter, 2008). An American Occupational Therapy Association (AOTA) critically appraised topic (CAT) paper on the effect of occupation and activity-based interventions on instrumental activities of daily living (IADL) in community dwelling older adults highlighted the need for stronger evidence of best practice. This is a challenging issue that must take into account the client's performance skills and patterns, the activity demands of the task at hand, and the complexities of context and environment (AOTA, 2010). Although one cannot expect to find a "one size fits all" intervention to improve IADL performance in clients with physical and/or cognitive impairments, it is important to identify which therapy approach is most effective based on the client's personal situation and needs. This CAT reported limited evidence to support the use of a compensatory approach to improve IADL in frail community dwelling adults and highlighted the need for more specific and sensitive outcome instruments to better assess IADL performance and change (AOTA, 2010).

Generally, occupational therapy outcomes are based on more global measures of ADL or IADL, such as the Frenchay Activity Index or the Nottingham Extended Activities of Daily Living Scale. As can be seen from the studies described in the best evidence table, the effects of occupational therapy intervention on homemaking, meal preparation, or household management abilities are often embedded within these broader IADL scales, making it challenging to discern specific changes in task performance. In addition, two of the three studies in Evidence Table 27-1 combined treatment approaches (occupation-as-means and occupation-as-end) or therapy disciplines (occupational therapy and physical therapy), making it difficult to interpret research findings.

Research is needed to further examine the degree to which adapted methods and equipment (i.e., occupation-as-end) contribute to one's satisfaction and competence in homemaker and parenting roles after a disabling event. Empirical support for the cost effectiveness of adapted equipment and supportive services may lead to improved reimbursement from third-party payers.

| Evidence Table 27-1 | Best Evidence for Occupational Therapy to Restore Competence for Homemaker and Parenting Roles |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Home-based, client-centered occupational therapy targeting limitations in ADL & IADL, mobility, and home safety	Occupational therapy methods included task-specific practice, reducing task complexity or demands, and/or altering environment through adaptive aids. Control group received occupational therapy after completion of trial.	Parkinson's disease, $n = 39$; mean age = 73 years	Six 45-minute sessions of occupational therapy over 2 months	Randomized controlled trial (RCT) pilot study with cross-over design Level: IC2b (small group sizes; blinding not reported; unclear whether sample was representative of Parkinson's disease population and what theoretical support was for intervention)	Yes. Mean group difference in Nottingham Extended ADL Scale at 8 months was 3.5 (95% confidence interval = 3.2–10.2) favoring the intervention group. Strong correlations were found between PDQ-39 and other measures.	Formal statistical analysis not completed because of small sample size.	Clarke et al. (2009)
Home-based, client-centered occupational therapy/physical therapy intervention to reduce functional difficulties	Treatment group: occupational therapy focus on training of cognitive and behavioral strategies for problem solving/pacing and environmental modifications. Physical therapy intervention was one visit (90 minutes) that addressed balance, strengthening and fall-recovery techniques. Control group did not receive intervention.	Adults aged 70 years and older, $n = 319$, reporting difficulty with two IADL or one or more ADL	Over a 6-month period, treatment group received four 90-minute occupational therapy visits and one 20-minute phone call in addition to one 90-minute physical therapy visit. During the 6 months that followed treatment, three follow-up phone calls were made to reinforce use of strategies and a final home visit was conducted for closure.	RCT, prospective two-group trial Level: IA1a	Yes. At 6 months, the intervention group was significantly better than control in IADL, with fewer home hazards, increased use of adaptive strategies, and better self-efficacy (confidence in managing ADL) as compared to control group. Benefits sustained for most outcomes at 12 months.	At 6 months, change in IADL scores were significantly better in treatment group ($p = 0.04$); unable to calculate effect size from study report.	Gitlin et al. (2006)

Evidence Table 27-1	Best Evidence for Occupational Therapy to Restore Competence for Homemaker and Parenting Roles *(continued)*

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Community-based energy conservation course	Energy conservation course for adults with fatigue caused by chronic illness; lectures, goal setting, and assignments applicable to everyday tasks. Control group received delayed intervention.	Multiple sclerosis, *n* = 169; of these, *n* = 131 compliant participants (attended at least five of six sessions)	Six sessions over a 6-week period	RCT, cross-over design Level: IA2a (study evaluators not blinded)	Beneficial effects of energy conservation training were maintained 1 year postcourse.	Intention to treat analysis showed significant benefits for training group on Fatigue Impact Scale ($p = 0.05$) and SF-36® ($p = 0.02$); unable to calculate effect size from study report. Benefits were maintained at 12 months.	Mathiowetz et al. (2007)

Activity-Focused Analysis
Baking Chocolate Chip Cookies

Task Analysis Process			Example
Describe the task demands	Objects used	Properties of the utensils, tools, materials and their locations relative to the person	Ingredients as listed on recipe (including flour, baking soda, sugar, eggs, and chocolate chips)
			Measuring cups and spoons
			Mixing bowls, spoons for mixing and placing dough on baking sheet
			Electric mixer
			Baking sheet, spatula, cooling rack, and timer
	Environmental demands	Characteristics of the environment in which the activity usually is carried out, including possible environmental barriers and enablers	Clinic kitchen in rehabilitation facility or client's own kitchen at home
			Familiarity with location of needed items in kitchen cabinets; kitchen size and distance items will be transported
	Social demands	Nature of and extent to which the activity involves others and/or holds particular meaning associated with social roles	May be performed alone or with family/child participation; may hold personal meaning when preparing warm cookies for friends or loved ones
	Contextual demands	Nature of and extent to which the activity or the way it is carried out holds particular meaning to certain cultures or age groups	Appropriate for a wide range of ages; type of cookie may be adapted to cultural backgrounds and likes
	Sequencing and timing	Monological task (requiring a singular sequence in order to be performed correctly) or a multilogical task in which a variety of sequences will work	Monological: combining ingredients and baking cookies allow for little variation in sequencing of task
		Extent to which the task involves temporal requirements or timing requirements	Small batches of cookies can be prepared within one therapy session. Baking time must be closely monitored.
	Required actions	Steps that comprise the activity	1. Preheat oven.
			2. Gather all needed ingredients and kitchen items (bowls, measuring cups/spoons) for mixing dough, baking, and cooling cookies.
			3. Measure and combine dry ingredients in a small bowl.
			4. Use electric mixer to combine butter, sugar, vanilla, and eggs.
			5. Gradually add and beat in flour mixture with wet ingredients. Add chocolate chips.
			6. Drop by rounded tablespoons onto ungreased baking sheets.
			7. Bake until golden brown (9–11 minutes).
			8. Cool on wire racks and eat!
			9. Clean up work space.

	Prerequisite capacities, abilities, and skills necessary to successful task performance	Sensorimotor: range of motion, strength, motor control, postural control, endurance, coordination/dexterity	Volitional functioning of at least one upper extremity; shoulder flexion, abduction; elbow flexion/extension; forearm supination/pronation; wrist flexion/extension; grasp/release
		Vision-perceptual: visual acuity, visual scanning, visual perception, awareness of extrapersonal space	Visual acuity for reading directions; visual scanning to locate needed items, spatial awareness when placing uncooked batter on cookie sheets
		Cognitive: attention, memory, executive functioning, problem solving, self-awareness	Ability to follow step by step directions and sustain attention for 20–30 minutes; ability to sequence task and detect errors/omissions of ingredients and self-correct; demonstrates divided attention when baking multiple batches of cookies
		Emotional, relational	Varied; can be completed in isolation or with others. Although baking cookies with others will increase interaction and socialization, the client may be distracted and require additional cues/support.
	Safety precautions	Nature of safety considerations if performed in a therapy context	Clients who perform task in standing may need supervision related to balance and/or endurance; closely monitor safety when using oven and hot baking sheet
Identify the primary therapeutic aspect of the task; adapt task demands to align with therapy goals	Sensorimotor	Range of motion	Ingredients are located in overhead cabinets to encourage reaching
		Strength, motor control	Heavier objects (canisters of flour, sugar, large mixing bowl) are carried from cabinet to work surface.
		Postural control, endurance	Client uses postural control and weight shifting when reaching for ingredients that are located on the counter/table. Client is required to stand for increasingly longer times between seated rests. Client has to bend to reach oven racks/door.
		Coordination, dexterity	Use teaspoons versus tablespoons to increase number of repetitions when scooping and dropping cookie batter onto baking sheet.
	Vision-perceptual	Visual scanning	Client needs to locate needed ingredients and supplies within kitchen space. Increased number of distracters (e.g., needing to find needed items on crowded shelf) requires greater figure ground/perceptual processing.
		Visual perception, extrapersonal space	
	Cognition	Attention, memory	To reduce attention/memory demands, instructions can be written out and checked off when each step is completed. Client may be asked to retrieve two or more ingredients at a time to increase memory demands. Client is challenged to work in an increasingly distracting or noisy kitchen. Therapist may interrupt client to determine whether he or she is able to return to task efficiently. Increase needs for divided attention by asking client to keep track of when baking cookies will be done while preparing the next batch for the oven.

		Executive functioning, problem solving, awareness	Client is given general cues to monitor performance and check for errors (missed ingredients, sequence of steps, etc).
			Client predicts what task components will be most challenging and then assesses performance after task to check predictions and identify ways to optimize performance during future cooking activities.
	Emotional-relational	Mood, engagement, interactions with others	Client performs task with others, working in parallel or cooperatively to reach task goal.
Modify task demands to calibrate difficulty level	Objects used		Use of prepared mix or unbaked, packaged cookies versus recipe from scratch reduces number of ingredients and steps involved.
			Location of items (within reach, fewer visual distractions).
			Have adaptive equipment available for clients with physical challenges (e.g., oven pull, dycem to stabilize bowl when mixing, etc.).
	Space demands		Quiet versus busy kitchen environment
	Social demands		Working alone or with others; may involve family/caregivers
	Contextual demands		Working in clinic versus home kitchen.
			Preparing cookies for family or friends may increase personal meaning and motivation.
	Sequencing and timing		Reduce task complexity by providing initial setup (e.g., gather needed ingredients for client)
			Prepare only one batch to reduce attentional demands

case example

Mrs. B: Treatment to Improve Homemaking and Child Care Abilities

		Clinical Reasoning Process
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information	Appreciate the context	"Mrs. B. is ordinarily a fairly active woman who has been caring for her 6-month-old granddaughter since she was a month old. She truly values the time she spends with the baby and is frustrated and somewhat depressed by her present limitations. Although her daughter has offered to find another child care provider while her mother recovers, this has been difficult to arrange in their small community. Mrs. B.'s prior level of independence, combined with a strong desire to help her daughter and care for the infant, have motivated occupational therapy goals to optimize homemaking and child care abilities."
Mrs. B. is a 54-year-old widow referred for a home occupational therapy (OT) assessment following recent exacerbation of rheumatoid arthritis (RA). She lives alone in a ranch house and ordinarily cares for her 6-month-old granddaughter 3 days a week while her daughter works. Prior to her exacerbation, she was fairly active and able to manage all household and child care tasks independently with the exception of yard work. An avid gardener, she spent a good deal of time in her greenhouse prior to her exacerbation. She is able to use joint protection principles (e.g., avoiding positions of deformity, such as ulnar deviation) during functional tasks.		

As a result of this exacerbation, she has decreased strength and dexterity in her hands and wrists, increased pain during activity, and a significant decrease in overall endurance. The OT evaluation identified the following problems: (1) moderately decreased ability to perform the household management tasks needed to maintain her independence at home, with fatigue after 30 minutes of activity; (2) moderate impairments in her ability to care for her granddaughter secondary to decreased strength and pain during resistive activities, such as opening baby food jars and attempting to lift the child; and (3) poor use of body mechanics and a tendency to rush through tasks when fatigued.

Develop intervention hypotheses	"I think that Mrs. B.'s weakness, pain, and reduced endurance are the biggest barriers to her independence right now. Although she can tell me how to protect her joints during homemaking tasks, her pain and resulting fatigue are causing her not to use proper techniques. She tends to hurry through tasks so she can rest, and I'm concerned about her safety. I expect that, as her pain lessens, she'll do much better overall."
Select an intervention approach	"I will develop an intervention plan that emphasizes compensation for deficits; this will help to protect her from injury long term. By engaging her in important home and child care tasks, we will use occupation-as-means to improve her physical abilities as well."
Reflect on competence	"Mrs. B. reminds me of a couple of other clients I've worked with in home care. It will be really important to involve her in problem solving of ways to best accomplish important tasks. This way she'll gain skills in handling unexpected situations outside of therapy."
Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan | "I think that occupational therapy in the home will be the most effective means of addressing Mrs. B.'s current needs, especially because she is highly motivated to make changes that will optimize her home and child care abilities. Her house is pretty accessible, and I think small changes will really help improve her independence and safety. We should be able to accomplish a lot in the next 4 weeks." |

Recommendations

The occupational therapist recommended three treatment sessions each week for 4 weeks. In collaboration with Mrs. B. and her daughter, the therapist established the following long-term treatment goals: (1) Mrs. B. will independently perform all indoor homemaking tasks, except floor care, with only occasional complaints of fatigue, using energy conservation and work simplification techniques; (2) Mrs. B. will independently care for her granddaughter for 4-hour periods with only occasional complaints of pain, demonstrating appropriate use of assistive devices to protect joints during resistive activities; and (3) Mrs. B. will use proper body mechanics when lifting and carrying her granddaughter and performing household tasks, such as meal preparation and laundry (see Home Program in Procedures for Practice 27-6).

Procedures for Practice 27-6

Home Program for Body Mechanics

Mrs. B., please focus on using proper body mechanics during all of your daily tasks. Below are specific ideas for you to incorporate every day:

- Be sure to have a broad base of support when lifting your granddaughter. Keep feet shoulder distance apart, and place one foot forward of the other to help with balance.
- Face the task you're doing, and don't twist your trunk when lifting.
- When doing tasks around the house that take a while (like feeding your granddaughter or repotting small plants) sit instead of standing to conserve energy. Sit up straight, and think about keeping a neutral position in your lower back by tilting the pelvis slightly forward.
- When doing laundry, use your rolling basket to help transport clothes. When you do need to lift clothes, use your strongest muscles (legs versus back) and bend at your hips and knees to avoid straining your back.
- Don't rush! It's best to take rests before you feel tired, and it's much easier to use good body mechanics when working at a comfortable pace!

Summary of Short-Term Goals and Progress

1. Mrs. B. will independently and safely prepare a light meal for herself without complaints of fatigue, using work simplification and energy conservation principles after initial instruction.

   The therapist and Mrs. B. first reviewed work simplification principles in the context of preparing a hot beverage, taking the opportunity to organize work areas in the kitchen so frequently used items were easily accessible. They identified ways Mrs. B. could conserve energy during meal preparation, such as by retrieving all items needed at one location (e.g., refrigerator) before moving on to the next and sitting when possible to prepare foods. After instruction in self-pacing, Mrs. B. was more willing to take brief rests during meal preparation before fatigue or pain began to worsen. After practicing proper body mechanics, she was better able to obtain and carry items safely around the kitchen without increasing pain. In addition, use of a jar opener significantly reduced the discomfort in her hands. To reduce preparation time and effort, Mrs. B. decided to use frozen rather than fresh vegetables until her endurance improved. Mrs. B. found that these strategies greatly reduced her level of fatigue during meal preparation, and she began to apply these techniques to other tasks around the house.

2. Mrs. B. will safely and independently transfer her granddaughter from the infant seat to changing pad on the kitchen table with good body mechanics and safety and no complaints of discomfort.

   Mrs. B., her daughter, and the occupational therapist determined that the need for lifting and carrying the infant could be minimized by organizing essential child care materials, such as the infant seat, changing pad with straps, diapers, and toys, on one side of the oversized kitchen table and nearby hutch. Mrs. B. found that bilateral wrist supports greatly reduced pain in her wrists when she lifted the baby.

   Proper body mechanics were reinforced and practiced, such as standing close to the child with feet staggered and placed shoulder distance apart and using stronger muscles (legs rather than back) when lifting. Mrs. B. progressed from requiring minimal assistance to lift and transfer the baby safely to performing the task independently. As she gained confidence in her abilities, her body mechanics improved and complaints of discomfort decreased.

Assess the patient's comprehension	"Mrs. B. has cognitive strengths that I expect will help her to readily integrate new techniques with her current knowledge of joint protection."
Understand what she is doing Compare actual to expected performance	"I was a bit concerned about her rushing through tasks when we first started therapy, but I think that was partly related to her desire to show us that she 'could do it.' I see that, as we gain rapport, she is becoming more comfortable with voicing her concerns about the long-term changes she is experiencing from her arthritis and her fears about losing independence."
Know the person Appreciate the context	"Mrs. B. is lucky to have such a supportive daughter; she has helped to identify creative ways for her mother to manage the baby's care. I sense that she is concerned about her mother's chronic RA and the physical changes that Mrs. B. is facing now. I wonder what their long-term plans will be regarding living arrangements, etc."

Next Steps

Revised goals include the following: (1) Mrs. B. will use work simplification techniques and proper body mechanics to do laundry independently, and (2) Mrs. B. will safely and independently lift and transfer her granddaughter from a stroller to the infant seat with good body mechanics and will prepare and feed the child a warm meal without assistance.

Anticipate present and future patient concerns Decide if the patient should continue or discontinue therapy and/or return in the future	"Mrs. B. has been very responsive to therapy and has made great gains over the past couple of weeks. She is much more confident in her abilities, and her pain is being better managed through medication and the compensatory strategies she has learned to use. She is now ready to practice work simplification techniques during more physically challenging tasks. With a bit more therapy, she will be able to care for her granddaughter independently once again."

Clinical Reasoning in Occupational Therapy Practice

Effects of Fatigue on Upper Extremity Functioning and Instrumental Activities of Daily Living

Since her recent RA exacerbation, Mrs. B. reported that end-of-day fatigue is more significantly impacting her arm and hand strength and coordination. She reports that it is more difficult to complete needed tasks, such as cleaning up after dinner, transferring laundry from washer to dryer, or holding her pen well when paying bills or writing cards to friends.

What further adaptations may be made to improve her ability to manage these daily tasks? How might you help her to prioritize and best manage her time for needed tasks throughout the week?

Summary Review Questions

1. Describe how work simplification and energy conservation techniques can help persons with low endurance and shortness of breath caused by chronic obstructive pulmonary disease with meal preparation and household maintenance tasks.

2. Identify at least three principles of correct body mechanics that a person with chronic back pain should use when doing laundry and transporting groceries from the store.

3. Describe how a homemaker who has pain and weakness in her hands and wrists caused by rheumatoid arthritis can use adapted methods or assistive equipment when preparing brownies from a mix.

4. Using the principles of compensation and adaptation, what recommendations would you make to a client with limited upper extremity coordination and strength caused by multiple sclerosis when gathering the items needed to prepare breakfast from a wheelchair?

5. Give two examples of adaptations that may assist a paraplegic parent with spinal cord injury at T4 (see Chapter 38) to lift and carry an 11-month-old infant from the crib to the changing area.

6. Describe how a mother with upper extremity weakness and limited hand function in her right arm after a stroke can use one-handed techniques and assistive equipment to prepare a bottle and feed her 5-month-old infant.

7. How would you recommend that a parent set up a baby bathtub and needed supplies to bathe a 2-month-old infant from a wheelchair?

8. Discuss proper body mechanics for a person with general pain related to fibromyalgia who is playing with a 10-month-old baby and putting the baby to bed.

Restoring Competence for the Worker Role

Valerie J. Rice

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Understand and articulate the reasons people work.
2. Recognize and verbalize the unique role of occupational therapy in the return-to-work process.
3. Describe job analysis and how it is used in the return-to-work process, and identify other possible applications for the results of job analysis.
4. Describe functional capacity evaluations and considerations in selecting appropriate evaluations for clients.
5. Recognize how return-to-work evaluation tools can be used as treatment tools.
Two people meet for the first time at a social event. After introducing themselves, the inevitable question is asked: "What do you do?"

The focus of this chapter is on returning a worker who has been incapacitated in some way to the workforce. The intervention begins after an individual has been identified as being unable to meet the requirements of his or her job. Thus, the primary roles for the clinician are *evaluating* the individual's functional performance, strengths, and impairments as compared with the job requirements; *treating* the client; *matching* the client-worker with the job (enabling and integration process); and *reevaluation.* To understand the progression, it is first necessary to understand why people work, recognize how occupational therapists view work and their role in work rehabilitation, understand how the work role can be interrupted, and become acquainted with a few work-related assessments. An extensive explanation of the evaluation process is provided to enable a thorough understanding of the process and permit tailoring of the intervention to both the individual and the context in which the individual will work. With this knowledge, the occupational therapy process can be understood and implemented within the appropriate context.

WHAT IS WORK?

"He who complains against his work knoweth not life; work is an uplifting force by which all things may be moved. Repose is death, and work is life!" (Jastrzebowski, 1857/1997, p. 1)

Although we may not all agree with Jastrzebowski's enthusiastic assertion that work is uplifting and *life itself*, there is some merit in his declaration. Used in the broadest sense of the term, everyone must work. It is part of life. Work, as seen in the first definition in Definition 28-1, consists of any physical or mental effort or activity directed toward the purposeful production or accomplishment of something. This means that work occurs in the home, in schools, as part of one's employment, during volunteer work, and as part of one's leisure. To work is *to do*, to accomplish. With this definition, returning the worker to work encompasses occupational therapy as a whole, as clinicians assist their clients to achieve their fullest capacity in all aspects of life. In this chapter, however, returning the worker to work refers to helping a client reenter the workforce, go to a place of employment or job (including volunteer positions), and/or develop a means to earn a livelihood.

MOTIVATIONS FOR WORK

Why would an individual want to reenter the labor force? Why do people work in the first place? For most

Definition 28-1

Work-Related Definitions

Work (noun)

1. Physical or mental effort or activity directed toward the purposeful production or accomplishment of something: labor. **2.** Employment: job. **3.** The means by which one earns one's livelihood. **4.**a. Something that one is doing, making, or performing, especially as part of one's occupation: a duty or task. b. The amount of effort required or done.

Work (verb)

1. To exert one's efforts for the purpose of doing or making something: labor. **2.** To be employed. **3.** To perform a function or act: operate.

Work (synonyms)

Business, employment, job, occupation. Core meaning: what one does to earn a living. Work, the most general of these terms, can refer to the mere fact of employment or to a specific activity.

Career

1. Chosen profession or occupation. **2.** The general progression of one's life, especially in one's profession.

Job

1. An action that needs to be done: task. **2.** An activity performed regularly for payment, especially a trade, occupation, or profession. **3.** A specific piece of work to be done for a set fee. **4.** A position in which one is employed.

Occupation

Any activity or task with which one occupies oneself, usually specifically the productive activity, service, trade, or craft for which one is regularly paid.

Vocation

A regular occupation or profession, especially one for which an individual is particularly suited or qualified.

people, work is an economic necessity. In earlier times, people traded their wares and their abilities to attain the goods they needed by bartering. Although this practice still exists in some communities, most residents of industrialized countries have distinct employment and pay for their goods and services with money earned at their jobs.

Self-Creation and Self-Identity through Work

We work to finance lives, homes, families, education, and fun. However, especially in industrial societies, we do not have to work from dawn to dusk to earn a living, and we are also not required to enter jobs dictated by our birth or heritage. For the most part, we have choices. We can choose our line of work according to our own values. Occupations are key, not just to being a person, but to being a particular person and to creating and maintaining an identity (Matuska & Christiansen, 2009; Unruh, 2004). The use of one's time during the day provides a sense of purpose and structure, as well as building an identity. We create ourselves through our actions. Although we may define ourselves daily through our work, we may also fulfill other needs. Our values and the meaning of our lives arise from (and are seen in) our work and how we spend our leisure, home, self-care, and family time.

Work can fulfill our primary motivations (needs), as defined by some of the great psychologists and psychiatrists of our time. Work can fulfill the need to find meaning in life as asserted by Frankl's (1984) logotherapy. Work can fulfill the need to find pleasure, on which Freudian psychology is based. Work can also fulfill the need for power or striving for superiority stressed by Adlerian psychology (Stein, 2002). The point is that work can meet a number of needs. For some, work meets multiple needs of financial achievement, a sense of accomplishment and competence, socialization and status within society, pleasure and gratification, a sense of meaning and purpose, self-respect, and an identity. For others, work answers a singular need, leaving them to meet other needs elsewhere in their lives.

Matching Personal Values with Work Requirements

If our work forces us to behave in ways that directly conflict with our view of ourselves, we feel discomfort and are motivated to change our line of work. This is because people try to maintain positive views of themselves and refute or avoid feedback that is negative or disagrees with their ideal self (Alicke & Sedikides, 2009; Swann, Chang-Schneider, & Larsen, 2007). As an example, Enid DuBois worked as a telephone solicitor for a newspaper. Often, the solicitors were told to tell the potential customers that a portion of their money would go to a particular cause to encourage people to subscribe. "After a while, I didn't care. Surely I could have fast-talked people. Just to continually lie to them. But it just wasn't in me. The disgust was growing in me every minute. I would pray and pray to hold on a little longer" (Terkel, 1974, pp. 94–97).

We have seen a change in the desires of the workforce. In addition to the emphasis on pay and security, workers value and expect their work to be psychologically meaningful. They expect to participate in decisions that affect their work lives (Hendrick & Kleiner, 2009). The current, better-educated workforce in industrialized nations seeks challenges, advancement, and a voice in their work lives.

Balance is particularly important to the younger generation entering today's workforce. Occupational balance refers to the integrating of one's work, home, and leisure activities (Anaby, Backman, & Jarus, 2010; Matuska & Christiansen, 2009). Other work-related values of younger persons in today's workforce include independence, autonomy, self-expression, recognition for their work, and continual learning (Chester, 2005; DuToit & Coetzee, 2012). Younger workers need to feel valued and prefer work environments where they are mentored, treated with respect, and allowed to try some of their own ideas (even if they fail occasionally). More than past generations, they need to understand why things need to be done in a particular way, and they need to believe in and value the product, service, or mission they help to deliver (Chester, 2005; DuToit & Coetzee, 2012). They value their social interactions at work as well as their own perception of the importance of the product created by their work (Murphy & Patrick, 2007; Polanyi & Tompa, 2004).

Employers are recognizing the importance of meaningful work, because the psychological well-being of workers is enhanced when they are engaged in work considered meaningful to them (Arnold et al., 2007; Cheney et al., 2008). In fact, meaningful work is associated with personal hardiness and people often derive personal benefits from even difficult work situations, such as military deployments (Bartone et al., 2008).

The importance of occupational involvement and the characteristics of work most valued differ according to one's culture (Kuchinke et al., 2009) and personal values. In fact, the importance of work within a single culture and perhaps within an individual can vary over time. As discussed earlier, some researchers note that work alone is considered as a declining value, replaced by a high value of success in both personal and professional life and valuing leisure, friends and family, especially among the younger generation (Buddeberg-Fischer et al., 2008; Klaghofer et al., 2011). Similarly, people's values change over time, and their view of work can change accordingly. Thus, in rehabilitation, the therapist and the patient/client must explore the perceptions and values of the client, discover the client's occupational identity, and create an appropriate occupational balance intervention (Anaby, Backman, & Jarus, 2010; Matuska & Christiansen, 2008).

INTERRUPTIONS IN THE ABILITY TO WORK

People's ability to work may be interrupted by changes in physical, psychological and behavioral, or socioeconomic status.

Physical Status

Mr. L. worked in a collision repair shop. His brother was fond of saying that he "banged on cars" for a living. The job required him to stand and manually remove the dents from car fenders using specialized tools. He was physically strong because his job demanded it. He wasn't prepared for what happened after he broke his leg. It never seemed to heal correctly. He developed what they called reflex sympathetic dystrophy. The term didn't matter. All he knew was it hurt all the time and he couldn't stand or even sit for long periods. He received workers compensation and wondered if he'd ever work again (D. Rice, personal communication, 2000).

Injury or illness may result in permanent or temporary inability to resume work activities because the worker cannot fulfill the physical, cognitive, or emotional demands of the job. This mismatch between requirements and performance has been traditionally addressed by retraining the individual. The focus was on improving the deficits; thus the therapist worked to diminish individual shortfalls in strength, dexterity, coordination, range of motion, endurance, or cognitive functioning. Whatever interrupted the client's ability to resume normal activities was addressed. More recently, the focus has broadened to include altering or redesigning the job to realign its requirements to the individual's residual abilities through ergonomic intervention.

Not all injuries or illnesses that disrupt the ability to work are the result of a sudden injury or illness. Nontraumatic injuries may also interfere with a person's ability to work. Nontraumatic injuries thought to be related to workplace demands include work-related musculoskeletal disorders (WRMDs). These injuries are typically thought of as transient, although they can result in permanent disability. WRMDs include a wide range of health problems arising from repeated stress to the body encountered in the workplace. These health problems, which may affect the musculoskeletal, nervous, and neurovascular systems, include the various occupation-induced cumulative trauma disorders, cumulative stress injuries, and repetitive motion disorders. Examples include damage to tendons and tendon sheaths and synovial lubrication of the tendon sheaths, bones, muscles, and nerves of the hands, wrists, elbows, shoulders, neck, back, and legs. Specific diagnoses include chronic back pain, carpal tunnel syndrome, de Quervain's disease, epicondylitis (tennis elbow), Raynaud's syndrome (white finger), synovitis, stenosing tenosynovitis crepitans (trigger finger), tendinitis, and tenosynovitis. (For additional information on WRMDs, see Barbe & Barr [2006] and Koh & Takahashi [2011]; for WRMD low back pain, see Pransky, Buchbinder, & Hayden [2010]; for upper extremity injuries, see Roquelaure et al. [2009] and Sommerich, Marras, & Karwowski [2006]).

Traumatic injury, aging, or progressive disability may also alter self-perception and personal identity. When a person loses his or her sense of identity, life becomes less meaningful, which may lead to depression so severe that it can interfere with a person's ability to carry out daily work (Bender & Farvolden, 2008). Thus, it is not always the initial injury that prevents a return to work; the resulting psychological adjustments can also interfere (Iles, Davidson, & Taylor, 2008; Sullivan, Simmonds, & Velly, 2011). For example, recovery expectations and fear avoidance can be predictive of failure to return to work (Iles, Davidson, & Taylor, 2008). Unless both the physical and psychological problems are addressed, the individual may not develop the skills needed to return to work (Snodgrass, 2011).

Cognitive Status

People's cognitive abilities directly influence their ability to do a job and the type of job they can assume. For example, individuals who have had a brain injury (including mild to moderate traumatic brain injuries and strokes) can have difficulties with memory, concentration, sustained attention, decision making, and reasoning and may also experience changes in their sensory processing and/or communication skills. After injury, they may suffer from depression, anxiety, or personality changes. All of these symptoms can interfere with return to work (Bender & Farvolden, 2008; Shames et al., 2007).

Adults who have attention deficit hyperactivity disorder (ADHD) also experience thought and behavior patterns that contribute to reduced work quantity and quality (deGraaf et al., 2008). The association between adult ADHD symptoms and functional impairments is quite high (0.83–0.85) (Mannuzza et al., 2011). A therapist who specializes in working with adults who have ADHD in the workforce can help them recognize their strengths and the types of jobs or job structure that will take advantage of their skills and give them a good chance of success. For example, many adults with ADHD are innovative, energetic risk takers who can do well in jobs that permit multitasking, self-determination of scheduling, physical action, and outsourcing of time-intensive detailed tasks.

Psychological and Behavioral Status

Psychosocial events may interrupt a person's ability to work, either temporarily or permanently. Divorce, severe illness, death of a family member, or change in job status sometimes triggers underlying psychopathology such as a mood or anxiety disorder. The disruption may be due not to underlying psychopathology but to the expression or manifestation of a normal reaction to a difficult situation. Each individual reacts differently to life situations, and adaptation may come more quickly for some than for others. Examples of an individual's inability to meet work requirements include disruptions in the ability to concentrate and follow complex directions, react quickly to emergencies (psychomotor retardation), attend to detail, or handle the pressures and anxieties associated with the

work environment. Although there is less information on individuals returning to work after a psychological disorder compared with after physical injuries/illnesses, this is no less a problem than is a physical injury. In fact, it may be more difficult to return to work because of the attitudes and lack of knowledge and empathy of employers and coworkers, in addition to the fears and concerns of the workers themselves.

Depression is predicted to be one of the fastest growing maladies of the 21st century and is often associated with physical injury or loss of work. Although treatment for depression and other psychological and emotional disturbances has vastly improved, there are definite implications for the individual's ability to work (Sullivan, Simmonds, & Velly, 2011). Work seems to mitigate the rate of mental health deterioration, with employment status being more important for men than women (Llena-Nozal, Lindeboom, & Portrait, 2004). In addition, Schene et al. (2007) found the addition of occupational therapy intervention in the treatment of depression accelerated and increased clients' return to work. Finally, adding a work-focus to cognitive behavioral therapy increased full return to work by 65 days and partial return to work by 12 days, compared with cognitive behavioral therapy only, saving approximately estimated at $5,275 U.S. dollars per individual (Lagerveld, et al., 2012).

Even when a physical injury or illness is the primary reason for ceasing work or ones' inability to return to work, there are typically associated psychosocial aspects that need to be addressed. For example, targeting psychosocial risk factors while providing physical rehabilitation increased return to work likelihood after whiplash (75% versus 50%) (Sullivan et al., 2006), and incorporating psychosocial interventions along with physical treatments decreased disability among back pain patients (Sullivan & Adams, 2010).

Socioeconomic Factors for Individuals with Disabilities

One reason that individuals with disabilities may choose not to work is their fear of losing their government-funded health coverage, i.e., Medicare and Medicaid benefits. In the United States and other countries, fewer than 1% of those who receive government disability ever leave that system, and few who receive a temporary disability pension ever return to work (Ahlgren et al., 2005). Many long-term sick-listed individuals (46%) move from vocational rehabilitation to permanent pensions rather than returning to work (Ahlgren et al., 2005). However, in the United States, disabled Americans are guaranteed the ability to keep their government-funded health coverage when they accept a paying job because of the Ticket to Work and Work Incentives Improvement Act of 1999 (http://www.chooseworkttw.net/). The Ticket to Work program underwent a major overhaul in 2008, with new

regulations revising employment networks so beneficiaries receive more money as they make progress toward employment. Whereas personal stories of success are noted on the Social Security website (http://www.choosework.net/index.html), criticisms of the program have also been raised, especially regarding the cost of the program. According to one news story (Adams, 2011), beneficiaries doubled under the program between 2007 and 2010, employment network approvals increased by nearly 100%, and costs increased from $3.8 million to $13 million. One might imagine this is good news for the beneficiaries but a concern to the taxpayers who foot the bill.

Aging and age discrimination may also prevent workers from continuing to work or from returning to work following physical or psychological problems or following a downsizing. This problem may become more evident as the proportion of older workers increases, because Americans aged 65 years and older will comprise approximately 20% of the population by 2030 (Centers for Disease Control and Prevention, 2007).

WORK AND AGING

Society is challenged to consider three questions regarding older workers: (1) Can our nation "afford" older individuals who do not work? (2) Do older workers stand in the way of younger workers? (3) Are older workers less productive, slower, harder to supervise, less cognitively aware, and less physically able to do a job?

Today's workforce is multigenerational (Pitt-Catsouphes & Smyer, 2007), as well as older (Gibbs, 2011; Pitt-Catsouphes & Smyer, 2007). Strategic planners in varying industries, governments, and rehabilitation services are investigating plans to counter the impending shortage of workers as the current graying workforce retires, including consultant roles and part-time positions for older workers and mentoring programs to assist older workers with transferring their knowledge to younger workers (Bazley, 2012; Sanders, 2012). In fact, in the United States, those aged 55 years and older have increased their employment by more than 14% between December 2007 and April 2012, perhaps because of the increase in the population of persons in that age range (Rix, 2012). Despite the fact that an increasing number of older people remain in the workforce, barriers stand in the way of their working. There are concerns about the safety of both older workers and their colleagues, their ability to learn and retain information, and the quality of their work, all of which sometimes leads to age discrimination (Johnson, 2007). Also, although older workers are not laid off more often than younger workers, once laid off, it takes older workers longer to find a job compared with their younger counterparts (35 weeks versus 26 weeks) (U.S. Government Accounting Office, 2012). In recent years, job seekers of age 55 years and older comprised 16.2% of the unemployed, accounting for approximately 2 million individuals (Rix, 2012).

Who Are Our Older Workers and Why Do They Work?

The proportion of the population that works decreases with age. However, the most recent data suggest that more older individuals are working than ever (Tables 28-1 and 28-2). The retirement patterns among older workers appear to be changing, with 60% moving to short-duration or part-time employment (bridge jobs) before leaving the labor force entirely (Giandrea, Cahill, & Quinn, 2008). Also, a number of older workers leave and reenter the labor force (approximately 15%) (Cahill, Giandrea, & Quinn, 2011; Maestas, 2010).

Although some older workers choose to work in order to remain active and productive, to do something fun, and for access to money and health care (American Association of Retired Persons [AARP], 2006), others do so out of economic necessity (Rix, 2012). At the beginning of the recession of 2008 in the United States, 826,000 individuals aged 55 years and older reported wanting a job; that number had grown to 1.2 million by June 2009 (Rix, 2012). Those who would like to work but cannot find a job report believing that work is not available, those hiring would consider them too old, they lack necessary training, or they are experiencing discrimination (Rix, 2012).

McLaughlin, Jette, and Connell (2012) found that only 3.3% of those in their study could be considered as "aging successfully" according to the following definitions provided by Rowe and Kahn (1999): (1) being free of disease, risk factors for disease, and disability; (2) having high physical and cognitive functioning; and (3) being socially and productively engaged. They suggested lowering the criteria, such as eliminating active engagement and risk factors for chronic conditions, which can increase the prevalence of those experiencing healthy aging from 3.3% to 35.5%. However, healthy aging is a multidimensional and complex concept, with both cultural and individual influences, and active engagement can be an integral part of one's life satisfaction. If, indeed, active engagement (such as having close

Table 28-2 Expected Years of Retirement for Men

Country	Years of Retirement

personal relationships or pursuing activities of meaning) is an important component of healthy aging, then continuing to work may lead to greater satisfaction with life and perhaps even a longer life of higher quality. In fact, Hao (2008) found that productive activities, in the form of full-time and low-level volunteering, had protective effects against decreases in self-reported psychological well-being.

Paid Employment, Volunteer Work, and Occupation of Time

It is intuitive to expect that an individual's occupational identity and the meeting of his or her needs and values (mentioned earlier) can be met through paid employment, volunteer work, or meaningful activities that occupy time, but few researchers have investigated this concept. However, both Hao (2008) and Schwingel (2009) found that seniors who work or volunteer maintain a higher (and healthier) state of mental health compared with those who do not work or volunteer. Those who continued to work or volunteer demonstrated better cognitive performance, fewer symptoms of depression, and higher self-satisfaction ratings than those who neither worked nor volunteered (Schwingel, 2009).

WORK AND OCCUPATIONAL THERAPY

Adolph Meyer (1922) advocated a "freer conception of work, a concept of free and pleasant and profitable occupation including recreation and any form of helpful enjoyment as the leading principle." He said the "whole of human organization has its shape in a kind of rhythm," and through structured use of time, people could achieve well-being (pp. 1–2). By assisting the client to achieve a balanced lifestyle in work, play, rest, and sleep, early occupational therapists helped clients achieve a sense of homeostasis and health. Meyer broadly defined the term *occupation* as purposeful activity within the full spectrum of a person's life.

Table 28-1 The Aging U.S. Workforce (Selden, 2008)

Year	Average Working Age
1980	35 years
2008	41 years
2015	One in five workers will be 55 years or older

Impact:
- Fewer available workers
- Need to reduce staff turnover
- Need to keep older workers engaged/employed

Occupational therapy, based on the concept of returning the injured worker to work, was founded on the belief that merely eliminating the disease or providing immediate treatment for traumatic injury was insufficient for full recovery and ability to assume life roles. Instead, a client should be guided through a strengthening and training process, both physically and mentally, to prepare him or her to resume occupational status in society (Committee on Installations and Advice, 1928; Rice, 2007). Therapists used "crafts" in their treatment. What were once called crafts are today considered jobs. The term *craft* included activities such as carpentry, metal work, and bookbinding, all of which were full-time vocations. Initially, a wide variety of crafts or jobs were used in occupational therapy clinics. Occupational therapists believed, however, that carefully chosen occupation-based activities resulted in a transfer of training to almost any occupation the recovered client chose to pursue. This is opposite the current trend of work hardening, which simulates specific job tasks that will be required of the client upon return to work. The latter certainly has greater face validity, but to date, no published outcome research clearly supports one approach as superior to the other. Occupational therapy as a treatment intervention has been shown to be effective in assisting with a successful return to work process, but the components of the therapeutic programs vary, which makes comparisons difficult (Désiron et al., 2011).

Occupational Therapists' Unique Contributions

Occupational therapists, with their solid background in the full spectrum of human performance (physiological, biomechanical, psychosocial, and behavioral), are uniquely qualified to help clients return to work. A fundamental goal of occupational therapy is to facilitate the client's highest level of functional status in all occupations and contexts of life, including physical, emotional, social, cognitive, and communicative dimensions. Occupational therapists recognize that successful return to work is likely to depend on adequate function in many aspects of life, not solely task performance at a work site. Occupational therapists apply their knowledge of human performance and the human mind to determine whether the impediments to returning to work are physical, psychosocial, or both and to integrate appropriate interventions.

The application of the full spectrum of human performance elucidates the unique contributions of occupational therapists in returning the injured worker to the workforce. This holistic approach is instrumental in a successful return to work process (Désiron et al., 2011). Indeed, a systems approach integrating aspects of biomedical, psychosocial, and economic models may be the most effective (Schultz et al., 2007).

Burwash Model

There are a number of models depicting the return to work process (Schultz et al., 2007), but few that focus specifically on occupational therapy. However, one overarching model is shown in Figure 28-1. A more specific model, which focuses on occupational therapy intervention, is presented by Burwash (1999) and is shown in Figure 28-2 and further described in Table 28-3. Although this is an older model, it is clear, concise, and easy for therapists and for clients to understand. Returning to work is seen as one of the triangles representing concerns of clients. To facilitate a return to work, however, the therapist may be involved in each of the eight areas. For example, the client may be leaving one line of work because of disease or disability and need to reevaluate his or her values to explore and choose another career. While building the requisite physical and cognitive skills for the chosen job or career field, the client may also need to develop skills in searching for work along with the work habits needed to sustain a successful career.

The therapist must understand the client's value of work and self-perception as related to work (such as self-definition and self-esteem), so as to design the rehabilitation process and identify short-term goals and techniques to motivate the client. This client-centered approach to evaluation and treatment involves joint identification of goals and priorities by the therapist and the client. For example, therapists can help clients ascertain whether they want their work to be a job rather than a career (see Definition 28-1) by examining where they fulfill their social, emotional, and achievement needs.

THE RETURN-TO-WORK PROCESS

Returning to work entails three main procedures: evaluation, intervention, and reevaluation.

Functional Work Assessments

Functional work assessments include evaluation of both the individual client and the work requirements the client will encounter. Individual evaluations incorporate the standard occupational therapy assessment, a delineation of the conditions preventing the client from returning to work, and a functional capacity evaluation (FCE). The evaluation of the work requirements is often referred to as a functional job analysis, or simply job analysis.

Job Analysis

A job analysis is a systematic evaluation of the job that identifies its physical, cognitive, social, and psychological requirements. Conducting a job analysis entails going to the job site, observing workers performing their tasks, measuring equipment and equipment placement, and

Figure 28-1 Return-to-duty decision pathway.
Figure 28-2 Work Practice Model (Burwash, 1999). The circular shape suggests many entry and exit points; intervention may progress in a linear fashion around the circle; or only one or two areas of concern may be addressed. The director's chair in the center is a reminder that focus is on the individual and his or her values, and the individual, rather than diagnosis or age, should be the director. The eight triangles represent concerns expressed by clients and are part of occupational therapy's professional heritage and within therapists' competencies. The pentagons suggest artists' palettes as a reminder that the intervention requires both art and science in dealing with productivity issues. The double-headed arrows represent environmental factors that influence and can be influenced by the client and therapist; they include social, cultural, and political factors, among others.

interviewing those who perform the job and their supervisors. Some of the tools employed in the job analysis are video cameras, tape measures, scales, goniometers, stopwatches, dynamometers, still cameras, and strain gauges. The results of a job analysis can be used in several ways, as seen in Procedures for Practice 28-1.

Basic Components of Job Analysis. The components of any job analysis include the job title, basic description or objectives of the job, number of employees performing the job, the work and break schedule, a description of any rotation or enrichment program, and output requirements for the workers. A description of the environment should include temperature, available space, a list of fixed and movable equipment, personal protective equipment, and a sketch of the area. A sequential description of each task (essential function) and the component steps to complete it are also necessary. This should include measurements such as heights, weights, durations, distances, and so on.

Rationale for Conducting Job Analysis. The reason for conducting the job analysis dictates its questions and procedures. The purposes of conducting a job analysis include returning a person with a disability to work, identifying musculoskeletal risk factors, matching a rehabilitated or new worker with job demands, and developing assessments such as FCEs and preplacement screening tests.

For example, if the results are to be used to return an individual classified as disabled according to the Americans with Disabilities Act (ADA) (Federal Register, 1991) to his or her work, the job must be described in terms of its essential functions (Definition 28-2). Therapists whose responsibilities include industrial rehabilitation and returning injured or disabled workers to the workforce or helping employers to advertise jobs should be well versed in Title I of the ADA. Therapists should refer to the regulations and guides (ADA Title I Regulations, 1991; Americans with Disabilities Act, 1990; Equal Employment Opportunity Commission, 1992). The U.S.

Table 28-3   Examples Using the Burwash Model (1999)

Model Segment	Client Concerns	Therapist Resources: Assessment Tools, Techniques, and Programs	Environmental Considerations
Valuing	"Why work?" "How does work fit into my life?" "What are my personal values and what types of work fit?" "Why am I not happy in this work?" "Is working worth it?"	Work Values Inventory, Life Roles Inventory, work values auction, a spirituality of work questionnaire, Occupational Performance History Interview	Family and social group attitudes toward work; economic considerations for persons on disability pensions; religious beliefs about work; work and gender issues
Exploring	"I don't know what I'm physically capable of." "Are there any occupations that match my interests?" "What am I good at?"	Functional Capacity Evaluation, Self-Directed Search, work samples, computerized career exploration systems	Role definition of occupational therapy versus other team members (career counselors, vocational rehabilitation counselor, or teachers); family expectations
Keeping	"How is this health problem going to affect my work?" "I hurt so much after a day at work!" "I'm about to take stress leave; all of these changes are really getting to me." "I can't figure out how to get ahead at work; I'm really feeling stuck." Returning	"Will I be able to work again?" "How do I prevent reinjury?" "How do I deal with coworkers' comments about my illness?" "If I'm hurting at work, how do I cope with the pain?"	Work Environment Impact Scale, Worker Role Interview, graduated return-to-work programs, work hardening and chronic pain programs, assertiveness skills, Loma Linda Activity Sort, other resources as noted in the Exploring row above	Laws on injured workers and employers' responsibilities to them, job market, funding for retraining, family responsibilities, possible financial settlements, advice from lawyers and others, employer–employee relations

Procedures for Practice 28-1

Ways to Use Job Analysis Data

- Develop FCE
- Match injured workers' capabilities to job task requirements
- Place workers on light duty
- Return previously injured workers to work
- Identify risk factors associated with work-related musculoskeletal disorders
- Develop preplacement, postjob offer screenings which enable companies to place new hires in positions that minimize potential future injuries
- Write job description (possibly using ADA terminology)
- Describe and advertise jobs

Definition 28-2

Essential Functions

Fundamental, Not Marginal, Job Duties

Some considerations in determining whether a function is essential include

- whether the position exists to perform that function
- the number of other employees available to perform the function or among whom the function can be distributed
- the degree of expertise required
- whether past and/or present employees in the job have performed the function
- the time spent performing the function
- the consequences of not performing the function

Reasonable Accommodations

Modifications of the work environment include job restructuring and providing adaptive or adaptable equipment and similar modifications to enable equal opportunities for employment by individuals with disabilities.

government maintains an excellent website, with guidance, suggestions, and publications available and updated regularly (http://www.ada.gov/). Another useful website is http://www.disabilityrightsca.org/pubs/506801.htm).

If the reason for performing the job analysis is to identify risk factors that may predispose a person to musculoskeletal disorders, listing the essential functions is not compulsory. A job analysis primarily geared to injury prevention, such as WRMDs, should include descriptions of observed risk factors, such as repetitive motions, force, static postures, awkward postures, mechanical compressions, vibration, and the acceleration and velocity of dynamic motions, noted for each body part and quantified. For example, the duration of static hold using a pinch grip is noted in seconds. Literature on job analysis related to injury prevention can be found in several excellent sources (Brannick, Levine, & Morgeson, 2007; Cronin et al., 2011; Lysaght & Shaw, 2011; Singh, 2008).

For matching workers' capabilities with the job requirements, placing workers on light duty, or returning previously injured workers to work, tasks (i.e., essential functions) are broken into their component steps and quantitatively described in enough detail to permit them to be matched with the worker's residual capabilities (Procedures for Practice 28-2). The therapist who only occasionally participates in returning injured workers to the workforce may prepare a unique job analysis for each client using various tools (Brannick, Levine, & Morgeson, 2007), whereas those who work full time in industrial rehabilitation generally keep a file of job descriptions that lets them quickly determine whether a client can return by comparing the results of the FCE with the job description (Isernhagen, 2006). One benefit of having occupational therapists involved in job analysis is the ability to combine these purposes for conducting job analysis and developing a comprehensive database for an industry's use.

Use of Job Analysis in Developing and Selecting a Functional Capacity Evaluation. A job analysis should be conducted *prior to development or selection of an FCE.* An FCE consists of two parts: a general evaluation of physical abilities and a job-specific evaluation. Before one can decide whether to use solely the general evaluation versus the job-specific evaluation, the therapist must know whether the client intends to return to a specific job or type of job. If so, the information from the job analysis can be used to develop one of two types of FCE using criterion-referenced tasks. The first uses task components, whereas the second uses work simulations (both discussed later in the chapter). In both cases, the initial information is gathered during the job analysis.

Predicting Work Performance. Although general tasks such as lifting (Gouttebarge et al., 2009) or general mental ability (Lang et al., 2010) can be predictive of return to work, the fidelity of the prediction is enhanced when multiple constructs

are used (Lang et al., 2010). During a well-constructed job analysis, job tasks are broken into component parts, often by construct. (An example of component tests and a work simulation can be seen in Procedures for Practice 28-3.) Successful predictions also tend to use multiple assessment techniques, such as interviews with ratings of key tasks for frequency, duration, and difficulty; direct observation; videotaping; measurements of masses moved and forces exerted; and identification of pace and frequency.

Job Analysis Conclusion. The ability to conduct a thorough job analysis is an essential skill for an occupational therapist working in an industrial setting. In other practice settings, the prudent therapist conducts a similarly comprehensive analysis of the job of a homemaker, athlete, or child. The instruction in task analysis (activity analysis) received during entry-level training for occupational therapy provides an excellent basis for building expertise in job analysis. However, job analysis for guidance in the cognitive, psychological, and social requirements of work is neither well-defined nor illustrated by a large number of case studies.

One important concept is that, although the job analysis is part of the evaluation, the results are used to develop the treatment intervention and establish the end goals. In traditional occupational therapy, the treatment intervention and goals are based solely on the evaluation of the client and his or her desires, not on evaluation of the work site and the job demands.

Functional Capacity Evaluations

A variety of assessments are available for evaluating work performance, with the majority coming under the classification of an FCE. An FCE is a systematic process designed to assess a client's physical capacities and functional abilities. Identification of an individual's capabilities also reveals his or her limitations. The FCE uses information available from traditional occupational therapy and medical evaluations along with performance-based evaluations.

The information gained from an FCE can be used in a number of ways: (1) to match the individual's residual capacities with the demands of a specific job as a basis for establishing work or work site modifications or accommodations, (2) as evidence in the determination of disability or compensation status, and (3) as a baseline for noting the physical capabilities of new employees. FCEs can be used in a variety of circumstances, including in industrial settings for preemployment and postoffer screenings, in clinical settings for setting goal and treatment regimens, and for determining a worker's ability to resume his or her job duties. Although an FCE can be used in determining whether a claimant is eligible for Social Security disability benefits, the results of an FCE are based on many factors including the therapists' expertise and the clients'

Procedures for Practice 28-2

Matching Job Analysis with Functional Capacity Evaluation

Job Title: Meat Grinder (ground beef, chicken, pork, turkey)

Job Analysis

Tasks	Physical Requirements
1. Load grinder	Standing, walking, climbing stairs, carrying, lifting, stooping, handling, reaching, grasping
2. Grind and load meat tubs	

Steps for Task 1	Physical Requirements for Task 1
Remove top from tub of meat	Lift 0.5 pound
Place top of tub to the side	Lift, hold, turn, and place 0.5 pound
Lift tub from stack	Lift 70 pounds
Carry tub up stairs	Carry 70 pounds 5 feet, climb three stairs
Empty meat from tub into grinder	Lift 70 pounds to height of 4.5 feet
Walk down stairs	Climb down three stairs carrying empty tub, 1.5 pounds
Place empty tub on stack	Walk 3 feet behind grinder, stack tub
Steps for Task 2	**Physical Requirements for Task 2**
Retrieve empty tub	Walk 6 feet, lift weight 1.5 pounds
Place tub beneath grinder spigot	Stoop, place 1.5 pounds beneath spigot
Turn on grinder	Turn handle, 0.8-pound resistance
Visually supervise grinding	Stand
Guide beef from spigot	Use handle of large metal spoon
Spread beef in tub	Use handle of large metal spoon
Turn off grinder	Turn handle, 0.8 pound resistance
Lift tub	Lift five full tubs, 28 pounds each
Carry tub(s) either up the stairs to reload grinder (repeat steps 4–6 for task 1) or to packaging area	See steps 4–6 Carry five tubs at 28 pounds each a distance of 15 feet

Functional Capacity Evaluation Results	FCE Results Match Job Requirements
No limitations standing, walking, climbing, and descending stairs	Yes
Vision: 20/20 with glasses	Yes
Upper extremity reach and manual dexterity within normal limits as measured by Purdue pegboard	Yes
Grasp: 50 pounds	Yes
Lifts	
Single lift of 29 kg to height of 4 feet	Yes
Repetitive lift to height of 4 feet	Yes
One lift of 20 kg every 8 minutes	Yes

Procedures for Practice 28-3

Example of Component Tests and Work Simulation for Military Medic Task: Stretcher Carrying

Job Title: Military Medic

Task

Carrying stretcher containing a wounded soldier to and from medical transport vehicles as part of a two-person team

Task Description

Maximal height a stretcher must be lifted is 135 cm, based on ground and air ambulance loading platform heights. Literature review revealed weight of 50th percentile male U.S. Army soldier as 84.2 kg (Paquette, Gordon, & Brandtmiller, 2009). The stretcher weighs 6.8 kg. When unloading air ambulances, patients must be carried to a ground ambulance, typically approximately 50 m.

Task Components for Functional Capacity Evaluation

1. Lift and lower a box approximately 91 kg to and from a 135-cm height.
2. Perform isometric grip strength test.
3. Run 1 mile in 10 minutes or perform aerobic treadmill testing.
4. Carry handheld weights approximately 35.5 kg for 50 m.

Work Simulation for Functional Capacity Evaluation

Soldier walks or runs 50 m on treadmill carrying a stretcher holding an 88.6-kg mannequin. Soldier dismounts treadmill and walks or runs 5 m to a weight stack machine adjacent to treadmill and lifts weight equal to the patient's load to 135 cm to simulate loading patient into ground or air ambulance. Soldier gets back on treadmill and walks or runs 50 m to retrieve next patient. Treadmill speed is self-paced using toggle switch attached to stretcher handle.

motivation and perceptions (Chen, 2007). FCEs based on the specific job requirements themselves may be more advantageous for determining current capabilities and future work sustainment, because FCEs with predetermined lifts (not related to the specific job) generally have low to moderate predictive ability (Gouttebarge et al., 2009). For example, some FCEs use a lift from ground level to 4 feet, with no twisting, to determine lifting ability, but the job may require a lift from a height of 2 feet, a partial turn, with placement at 4 feet. The closer the evaluation can replicate the task, the more accurate the assessment.

Most FCEs include a review of the client's medical record, an interview that includes a work and educational history and sometimes a self-administered questionnaire, a basic musculoskeletal evaluation, performance evaluations, and a comparison of the findings with the job requirements (Isernhagen, 1995). As mentioned previously, the two performance categories are a general evaluation of physical abilities and a set of job-specific evaluations. Some therapists include psychosocial aspects; however, this remains more of an exception than the rule unless the individual has specific mental health or neurological concerns. Both the psychosocial and cognitive aspects of FCEs are ripe for exploration, implementation, and research.

General Evaluation of Physical and Cognitive Abilities. Physical and cognitive abilities are evaluated to examine basic functional abilities thought to be common to a number of jobs. The evaluation is conducted to give baseline information and is a special concern when the job to which the individual will return is unknown. The general evaluation of physical abilities may include measures of flexibility, strength, balance, coordination, cardiovascular condition, and body mechanics. It should also include the individual's ability to sit, stand, walk, lift, carry, bend, squat, crawl, climb, reach, stoop, and kneel and any limitations with those activities. WRMDs have become prevalent; therefore, the individual's ability to do particular types of repetitive motions should also be noted. Documentation should specify weight limits, duration of activity tolerance, unambiguous environmental restrictions, and the exact side effects of medications. Subjective findings, such as reported degree and frequency of pain, along with any observations (grimacing), should be noted.

Job-Specific Evaluations. The second part of an FCE is job specific. This means that specific work tasks are designed to simulate the critical tasks associated with a specific job or set of jobs (described previously in the Job Analysis section as either task components or simulations). For example, the International Association of Fire Fighters uses a two-part system, the "Wellness/Fitness Initiative" and a "Candidate Physical Ability Test Program." The former uses peer fitness trainers to enhance cardiovascular respiratory fitness, muscular endurance, and flexibility. The latter is a preemployment test composed of job-specific tasks, including a stair climb, ladder raise and extension, hose drag, equipment carry, forcible entry, search (searching for victims while crawling through dark spaces), rescue drag, and a ceiling pull (to simulate locating fire and checking for fire extension) (International Association of Fire Fighters, 2012).

Identifying Task Components. Task component testing means that the most difficult and important functions of the job are identified, and an evaluation or treatment plan is developed using the task components. An example of selecting the most difficult essential task is when a person must lift tools weighing 10 pounds and a 50-pound toolbox. The criterion task includes the more difficult of the two tasks

on the assumption that a worker who can accomplish the more difficult task is also competent for the lesser one. The criterion tasks, in the form of task components or work simulations, are used because they are believed to predict job performance. It is assumed that testing applicants on single aspects of job performance that are critical to job success is a valid approach to determining work performance, as the content requirements are used. Often, several criterion referenced tasks are used in the assessment. For example, an assembly job might require perceptual-motor performance for fitting pieces together, balance as one reaches for parts, and upper body strength to tighten components; therefore validated assessments of perceptual-motor abilities, balance, and grip strength might be used as criterion tasks. An example of the development of criterion-referenced tasks using both the task component and work simulation techniques can be seen in Procedures for Practice 28-3.

Work Simulations. Work simulations differ from task components in that they replicate essential series of tasks required on a job. For example, a firefighter's task of removing a hose, attaching it to a nozzle, and holding the hose during spraying is one task simulation. The same task series analyzed according to its task components might include only two portions: lifting an item that weighs the same as the hose and pushing a sled whose weight equals the amount of hose pressure. Work simulations frequently combine multiple constructs, such as strength, balance, and agility, and they have greater face validity.

Psychosocial Behaviors. Some evaluations include the individual's psychosocial behaviors as they apply to work habits and motivation; however, this is not consistently part of the process. This part of the FCE should describe the client's limitations in comprehension, recall, and ability to follow instructions. Other psychosocial issues, such as the ability to handle work pressures, respond to supervision, and relate to coworkers or customers, should also be noted.

Many FCEs use an evaluation called the detection of sincerity of effort, which is said to be an indication of a client's motivation to perform optimally during an FCE. Although it is suspected that a client who is not sincere will have a different recovery pattern and perhaps even receive unwarranted disability payments, the ability to detect insincerity of effort remains elusive. In a review on assessment of effort, response bias, and malingering, neuropsychologists offered little to uphold such claims and instead encouraged continued research on the topic, admonishing researchers to adhere to recommended procedures and statistical evaluations (Heilbronner et al., 2010).

Because alterations in mood and affect commonly coexist with and exacerbate physical problems, these issues should be included in the assessment. A brief screening tool can be used in conjunction with clinical observations to determine the influence of any psychosocial problems.

The Generalized Contentment Scale is a quick 25-item paper and pencil measure of nonpsychotic depression that is useful in determining the extent of mood alterations associated with loss of the work role (Hudson, 1982). Other mood scales are also available (Heuchert & McNair, 2012), and therapists should select the appropriate scale for the client and the circumstances. If significant test results are obtained, assistance from psychological services may be indicated. Therapists should select the type of assessment(s) that best suit the client and the situation, for example targeting anxiety, depression, general health attitudes, etc.

Selecting a Functional Capacity Evaluation. More than 55 FCEs are available, and selection of an appropriate one can be difficult. They differ in the physical and psychological factors they assess and the way the measures are administered. They also differ in the training required for competency in administration and interpretation. Some use a battery of tests that may or may not be based on a specific task analysis of the job in question. Such a battery may include strength, flexibility, and endurance tests. Others use actual simulations of the tasks required of the job. Although test–retest reliability can be high (Brouwer et al., 2003; Gibson et al., 2010), few FCEs have undergone rigorous examination to determine whether the evaluation predicts actual job performance (Chen, 2007).

Cheng and Cheng (2011) found that job-specific FCEs demonstrated superior predictive value, when used with specific injuries, such as distal radius fractures, than when used with less specific injuries. They also found that job-specific FCEs were of benefit in evaluating the employment status of individuals with nonspecific, chronic low back pain (Cheng & Cheng, 2010).

The Isernhagen work system was the only FCE found showing good predictive validity in the systematic review by Gouttebarge et al. (2004) of the four most used FCEs: the Blankenship system, Ergos work simulator, Ergo-Kit, and the Isernhagen work system. Although some systems appear to show promise (Lechner, Page, & Sheffield, 2008), others fall short of expectations (Gouttebarge et al., 2009). Although it may seem easy to select an FCE based on the availability of workshops and related products, the decision-making process should be performed carefully, with a thorough knowledge of the current research literature.

Payment

In general, functional capacity assessments and work hardening are paid for by worker's compensation insurance, individual insurance, or managed care plans, state or local agencies, or private pay (American Occupational Therapy Association [AOTA], 2012). In general, such assessments and training must be medically necessary and meet certain medical criteria, delineated by insurance company policy statements. Precertification of the service and fee verification are advised (AOTA, 2012).

Functional Work Assessments Conclusion

Knowledge of the two primary means of assessment in industrial rehabilitation, job analysis and functional capacity assessment, sets the stage for intervention. Individual clients' goals, work site design alterations, and bringing the capabilities of the worker closer into alignment with the demands of the job are all built on a well-performed set of assessments. The practitioner must integrate into the intervention process the detail the assessments provide, and the results of the FCE should be used to indicate a client's potential to work. This information should be clearly communicated to the employer and to the client. The bottom line is this: The best "evaluation" is one that is holistic; it examines the work, the work environment, and the workers needs, interests, desires (motivations), behaviors (habits and lifestyle), and personal characteristics. Additional research is needed to demonstrate the success of FCEs in returning injured workers to work, and predicting their success. At this time, keeping one's own records about the predictive success (or failure) of FCE interventions may be the best method to demonstrate potential effectiveness to clients.

Intervention

Intervention that is specific for returning the individual to the workforce builds on traditional occupational therapy intervention, taking it a few steps further into the daily work requirements of the client. Throughout intervention, the therapist should maintain communication with the client's work supervisor and iteratively determine the potential for work site modification to match the levels of performance being discovered during the evaluation. These modifications may continue throughout the process, permitting the client to return to a work setting much earlier and encouraging personal identification as a contributing, competent worker.

Work Conditioning

Work conditioning generally follows acute care and precedes work hardening. Like traditional occupational therapy intervention, work conditioning focuses on remediation of underlying physical or cognitive deficits to improve function. The difference between traditional rehabilitation and work conditioning is that the intervention is focused on functional requirements of a job or employment setting rather than on life skills required at home or for recreational activities. Restoration of flexibility, strength, coordination, and endurance may be addressed. Work conditioning should increase physical abilities, engineer successful performance, and provide realistic feedback regarding the client's capabilities (Fig. 28-3). The client's day may include a regimen of warm-up exercises tailored to the activities planned for the day, conditioning exercises based on job requirements, and job-related tasks using work samples that replicate essential task components of a job. A program

Figure 28-3 Work conditioning using a simulated work task. This is an initial simulation, because the requirements for bending and stooping have not yet been added.

may begin with sessions of an hour or two and progress as the client-worker's condition improves to 8 hours per day.

Work Hardening

Work hardening is a multidisciplinary structured treatment designed to maximize a client's ability to return to employment. Work hardening includes all aspects required for the client to return to full employment function, such as psychosocial, communication, physical, and vocational needs. Although general physical abilities are addressed in work conditioning, work hardening is aimed more specifically at a particular job or classification of jobs and therefore tends to involve work simulation. Considerations added during work hardening include productivity (speed, accuracy, and efficiency), safety (ability to adhere to safety principles and use of safety equipment and algorithms), physical tolerances for specific tasks (endurance and ability to carry out the repetitive task requirements), organizational skills, and decision making. Work hardening differs from work conditioning in the following ways: use of real or simulated work activities in a graded fashion, building to work over periods comparable with those in actual work settings, the full spectrum of work-related intervention, and involvement of a multidisciplinary approach (Isernhagen, 1988). Disciplines included in work-hardening programs can include occupational and physical therapy, psychology, vocational rehabilitation, social work, and social services. Other professionals participate full time or as needed including drug and alcohol counselors, nutritionists, and educators (special education or educational evaluators).

Work hardening environments should replicate the workplace as closely as possible. Sufficient space is needed for both traditional equipment for work conditioning and specialized equipment that may be brought from a job site. Also, the behaviors and interactions required of the clients should replicate a work setting, such as arriving

and leaving on a set schedule, working with fixed breaks, having supervisors who give positive and negative feedback on performance, performance standards, and so on. Returning a client to a part-time or full-time light-duty assignment during rehabilitation may help the client feel like part of the team. It may also assist employers by building their confidence in the process and by letting them observe firsthand the capabilities of the client-worker.

All involved parties should be kept informed of the process. This includes employers, supervisors, insurance representatives, occupational health nurses, and the physician.

Reevaluation of the Client and Program Evaluation

Two types of intertwined evaluations should be conducted. Individual clients should be reevaluated, and the program as a whole should be evaluated. Monitoring clients' progress and annotating whether they have achieved functional goals should occur as in traditional occupational therapy during clinic-based treatment. Follow-up evaluations with the client and the client's supervisor are suggested so that, in case of a problem, the therapist can intervene before reinjury or exacerbation of the injury occurs. In addition, it is important to combine this information (having removed individual identifiers) with that of other clients to determine whether overall program goals are being met. It is important to know whether the program is meeting the needs of individual clients as well as those of the referral sources (employers). Tracking information such as the rate of successful return to work, the length of limited-duty time, and the subjective responses of past clients and their supervisors enables the therapist to improve the program. This information is important for showing the cost-benefit value of the services and should be available if reimbursement questions arise. The same information can be used in marketing strategies.

A CLINICAL IMPLEMENTATION OF THE RETURN-TO-WORK PROCESS

This chapter contains basic information about work-related assessment, intervention through work conditioning and work hardening, and reevaluation of both the individual and the program, along with background information on work motivation, interruption of work, and ways occupational therapists can intervene. Still, the application of this knowledge can be confusing without a framework. Therefore, this section describes a decision pathway and an example of an FCE (Fig. 28-4). The interventions identified in this decision pathway are closely aligned with the interventions articulated in the second edition of the Occupational Therapy Practice Framework: Domain and Process (American Occupational Therapy Association, 2008). These interventions are therapeutic use of self, education, consultation, and therapeutic use of occupations (occupation-based activity).

These interventions are broad based, and it is probably beyond the scope of this chapter to present a meaningful discussion of their merits or limitations.

The return-to-work decision pathway shown in Figure 28-1 presents work rehabilitation processes in the larger context of injury, medical management, and acute rehabilitation. Because cost containment is a paramount issue in any health care organization, the decision pathway encourages a logical process to return the client to the workforce in a time-efficient manner. The decision pathway begins with an interruption of the work process, includes medical and rehabilitative intervention, incorporates the return-to-work process of evaluation and intervention, and offers several junctures at which the client may return to work.

The FCE in Figure 28-4 is composed of measures that are routinely available in most clinical settings (Resources 28-1). Additional tests can be added as available and desired. The many available off-the-shelf FCEs all have some limitations as well as merits, and therapists should be broad minded in their selection of tools for the FCE. It may be most efficacious for therapists first to develop an understanding of the return-to-work evaluation and intervention process and then to develop a structured evaluation system composed of available components that are specific to individual patients and the specific environmental context to which they must return.

The first page of information seen on the FCE contains the evaluation of the findings, an explanation of the discrepancies between the job requirements and work performance, and recommendations. This arrangement seems to put the end (the results) at the beginning before permitting the reader to follow and understand the evaluative process. The format is designed so the "bottom line" is immediately available for the employer and/or client to read. Background information in the form of the evaluative process is then provided as substantiation of the findings. Each section of the decision pathway and FCE is explained in the next section. Also refer to the Case Example, which further demonstrates the use of the FCE.

Medical Management and Acute Rehabilitation

The return-to-work process begins as soon as a patient enters the medical system for treatment. Medical management concerns the use of medical and surgical treatment to control and remedy acute medical problems that have interrupted the work role. Acute rehabilitation naturally follows medical management when medical problems and their treatments have caused physical debilitation, muscle weakness, impaired joint motion, decreased flexibility and/or coordination, or other limitations. Acute rehabilitation for physical injuries can involve the use of physical agents,

<u>**Recommendations**</u>

☐ Demonstrated work capacity matches job requirements

☐ Perform target job at full capacity

☐ Full time

☐ Part time _____ hr/day _____ days/week

☐ Demonstrated work capacity approximates job requirements and demonstrates client's

potential to return to work.

☐ Perform target job with limits or light duty

"Safe" performance recommendations are calculated as maximum infrequent exertion/movement/lift (◄1/hr in optimal position/conditions) calculated at 60% of measured maximum demonstration where applicable.

☐ Two-hand floor to thigh level lift # _____

☐ Two-hand thigh to shoulder lift # _____

☐ Two-hand shoulder to overhead lift # _____

☐ Push (waist level) # _____

☐ Pull (waist level) # _____

☐ Overhead pull to shoulder level # _____

☐ Sit ☐ Unlimited ☐ Limit to _____

☐ Stand ☐ Unlimited ☐ Limit to _____

☐ Walk ☐ Unlimited ☐ Limit to _____

☐ Bend/stoop ☐ Unlimited ☐ Limit to _____

☐ Reach overhead ☐ Unlimited ☐ Limit to _____

☐ Precision tool use ☐ Unlimited ☐ Limit to _____

☐ Hand/power tool use ☐ Unlimited ☐ Limit to _____

☐ **Work Site Modification**
Ergonomic work site evaluation with recommendations for job pace/process or equipment modifications

☐ **Work Conditioning**
Structured, supervised work activity to physically and psychologically condition client for return to work

☐ **Retest Functional Capacity**
Following resolution of psychosocial and or physical issues

Figure 28-4 *(continued)*

exercise, and education to restore abilities impaired by injury, illness, surgery, or enforced inactivity. Both medical management and acute rehabilitation entail evaluation, diagnosis, and procedures to remedy pathological conditions. At the end of each of these processes, a decision as to the potential for the client to return to work must be made. If the client is able and willing to return to work at these junctures, intervention is discontinued. Many clients with minimal residue of injury or illness and high internal motivation return to work without further intervention.

Work Rehabilitation

If medical management and acute rehabilitation do not result in a return-to-work status, efforts focus on the feasibility of returning the client to work. The method to determine return-to-work feasibility is the functional work assessment, which includes general medical information, a job analysis (if the job or type of job is known), an FCE, and an assessment of the client's perceptions of his or her abilities.

In addition to being evaluative, the functional work assessment forms the framework within which the therapist builds intervention strategies to bring about the return to work. The FCE used here can be carried out in seven steps.

Step 1: Preevaluation Information

As indicated in Figure 28-4, information is recorded about the client's job, along with demographics and information regarding the client's medical condition and symptoms. Details about the job can be obtained through the client's self-report, a written job description, interviews with the employer, and/or an on-site job analysis.

Job Demands. The evaluator seeks to determine the specifics of the job in terms of physical, cognitive, and social demands. Careful review of the job description and interviews with client and supervisor allow the therapist to form a picture of the demands of the job. The therapist may also choose to conduct a job-site analysis so that objective measurements and observations can further elucidate the demands. These job demands are key in setting up work samples later in the evaluation.

Medical History and Current Symptoms. In addition to a complete review of the medical record, the client is asked to describe his or her medical history, including medical treatment, surgery, rehabilitation, and time off work. Information about the client's current symptoms is gathered. The Current Symptoms Relating to Work Situation grid on the FCE allows the client to describe symptoms and rate them on intensity. Clients are encouraged to state their desired resolutions to the current work/disability situation so as to enable the therapist and client to establish goals jointly. Even though the evaluation is in the early stages at this point, there is usually sufficient information to initiate treatment that can coincide with the continuing evaluation.

The therapist should determine whether the cluster of symptoms presented by the client matches those usually associated with the diagnosis or disorder. Significant variances between diagnosis and expected symptoms can be a sign of a client being overwhelmed by the situation or an early indication of symptom magnification. At this point in the FCE, the process may change from evaluation to intervention. The therapist may now choose to use a consultation intervention in which the client is assisted in explaining the discrepancies between conflicting findings. Although the client may not be intentionally misrepresenting symptoms or diagnosis, conflicting findings should be addressed at once. During this intervention, it is appropriate to provide the client with additional information about the medical condition and its usual presentation and course in rehabilitation. It is important to allow the client a face-saving way out, such as the opportunity to restate or discuss symptoms. The purpose of the consultation process is to help the client to either clarify information or adjust behavior according to new information presented by the therapist. Alignment of symptoms may also help to delineate those who have a well-defined WRMD versus those who may have signs and symptoms of overuse that are not yet at a stage of clinical diagnosis. This process may also assist the client to accept and understand his or her symptoms.

Step 2: Work Performance Measurement

In accordance with the job demands identified in step 1, the therapist determines which of the available work performance measures best simulates the demands of the current or target job. Although testing of ability components can be fairly general and applied to many jobs and tasks, if the job to which the client will return is known, the evaluation should be tailored to it. Figure 28-4 has a reporting format for selected work performance measures, including the following:

- Valpar 1: Small tools; fine motor dexterity
- Valpar 4: Upper extremity range of motion; prolonged use of both hands in confined space with awkward angles (Fig. 28-5)
- Valpar 9: Whole-body range of motion; reaching, bending, and stooping while using hands
- Valpar 15: Electrical circuitry and print reading requiring attention, memory, new learning, and hand dexterity (Fig. 28-6)
- Valpar 19: Dynamic physical capacities; reaching, lifting, reading, decision making, and following directions (Fig. 28-7)

Methods Time Measurement (MTM) scoring criteria are used with all of these work performance measurements (Valpar International Corp., 1992). MTM compares work sample performance with a standard that relates to competitive performance rather than to normative data. The standards were developed by an engineering company and are designed to mimic the real pace of work rather than the burst activity common to clinical testing. MTM grades performance in a percent rate of work from 0% to 150%. The percent rate of work is scaled against the following competitive work standards:

- Performance exceeding work standards
- Performance meeting work standards
- Performance below work standards with potential to meet standard
Figure 28-5 Valpar Work Sample 4: Upper extremity range-of-motion work sample.
Figure 28-6 Valpar Work Sample 15: Electricity circuitry and print reading.

- Performance below work standard with minimal potential to reach standard

MTM can, at first, be confusing to clinicians accustomed to using only standard normative data, but it is essential for the therapist to understand it for proper analysis of work performance measurement data and to explain the results to the client and employer.

Figure 28-7 Valpar Work Sample 19: Work dynamic physical capacities.

In the event that the client's work sample performance falls below competitive standards, steps 3 and 4 of the evaluation are used to discover the deficits responsible for the impaired work performance. Deficient work performance is generally the result of disconnects between job demands, internal motivation based on perception of ability, and/or performance and ability levels. If, however, demonstrated work performance on job-specific work samples meets the competitive standards, steps 3 and 4 can be omitted, and the therapist can proceed to data analysis and recommendations.

Step 3: Client's Perception of Ability to Work

Figure 28-4 shows two methods for gathering information regarding clients' perception of their abilities. The Employment Potential Improvement Corporation (EPIC) Hand Function Sort (HFS) and the Spinal Function Sort (SFS) (Fig. 28-8) are ratings of perceived capacity. These sorts require the client to view pictures of work situations (62 for the HFS and 50 for the SFS) and then sort them into four categories based on his or her perception of ability to perform the task within the situation. The categories include "able," "slightly restricted," "moderately restricted," and "unable."

The picture sort results can be analyzed in depth with the data compared with normative standards. The results can also be recorded in the format illustrated in Figure 28-4 as to the client's reported ability within each of the four physical demand characteristics categories of sedentary, light, medium, and heavy work. The second method of gaining the client's perception of ability is a self-rating of performance on a variety of common work tasks. Careful analysis of picture sort results and self-reports of ability give important information about the client's perception of his or her ability in relation to the diagnosis, presented symptoms, and the measures of ability that follow.
Step 4: Ability Measurement

Figure 28-4 incorporates tests and measures of ability, including body range of motion; static posture tolerance; hand sensation and dexterity; extremity strength; lifting, pushing, and pulling strength; physical endurance; mood and affect; and cognitive problem solving. These are measures of performance skills and client factors that may affect an individual's capabilities at a number of jobs rather than being tailored to any particular job or set of tasks. Examples include the following:

- Body range of motion, assessed by observing functional movements of the trunk and extremities to include reaching, touching hands to back of neck and middle of back, and bending or stooping toward the floor.
- Tolerance to the static postures of sitting and standing, observed and documented as the client performs other components of testing that require sitting or standing for extended periods.
- Physical strength, documented using both static strength and dynamic lift tests. A device such as the work simulator (Baltimore Therapeutic Equipment Co., 1999) can accomplish both static and dynamic lifting tests and allow comparison of strength between body sides and comparison against normative standards (Fig. 28-9).
- Physical endurance, using either a step test (Tuxworth & Shanawaz, 1977) or treadmill testing if available. *Safety Message: Before any strength or physical endurance testing, it is essential to ensure that the patient's medical record has been reviewed and that the referring physician has given clearance for physical testing.*
- Hand dexterity and function, using any of a number of tests. The Jebsen-Taylor Hand Function Test is a standard in most clinical settings and can rapidly gather information on hand function using common objects rather than pegs or pins (Jebsen et al., 1969).

Figure 28-8 EPIC Hand Function Sort and Spinal Function Sort. Patients sort cards based on their perceptions of ability to perform work tasks.

Figure 28-9 BTE Work Simulator used for dynamic strength testing.

- Mood and affect; alterations can exacerbate physical problems. This aspect of function should therefore be included in the assessment. A brief screening tool can be used in conjunction with clinical observations to determine any potential psychosocial problems. (See previous discussion of the Generalized Contentment Scale.) If significant findings are obtained, referral to psychological services may be indicated.
- Cognition should be tested to determine whether difficulties with attention, memory, vision, reading skills, and problem solving are contributing to work deficits. The Mini Mental Status Exam (Folstein, Folstein, & McHugh, 1975) is a brief paper-and-pencil test that can give the clinician a quick look at the client's cognitive functioning. A score of less than 24 without obvious external confounding factors would strongly suggest the need for more formal cognitive testing before proceeding on in the evaluation. In addition, the PSI Decision Making Test is a 5-minute standardized paper-and-pencil test measuring attention, immediate memory, reading, and judgment (Ruch et al., 1981). Either or both of these tests can give the evaluator a general idea of cognitive function and help in determining whether further specialized testing is indicated. Still a third alternative is the Barrow Neurological Institute Screen for Higher Cerebral Functions (BNIS). The BNIS is a screening method developed for identifying cognitive dysfunction. The BNIS has been shown to be related to activities of daily living abilities for patients who have experienced a stroke or anoxic brain injury, as well as to return to work (Hofgren, 2009).

Step 5: Summarize Test Data

The complexity of work demands and human behavior requires that therapists approach evaluation and intervention in a structured manner. If a structured approach is not used, there is a risk of being overwhelmed by the sheer amount of data or by the difficulties inherent in multifaceted behavioral interventions. To help manage information and use it as the basis for analysis, treatment, and recommendations, the sample FCE uses grids for summarizing and recording perception of ability, actual ability, and performance and work data. The evaluator summarizes observations from the tests and converts raw data to standard scores using either normative or MTM criteria. Completion of this section begins to paint a comprehensive picture of the patient's perceptions, abilities, and demonstrated performance in sample work situations. This information is the basis for the analysis in step 6.

Step 6: Analyze Findings

Under Assessment of Evaluation Findings, Figure 28-4 shows the variables to be considered in analyzing the results of test data. The first opinion relates to the quality of the FCE. Was this an incomplete or invalid evaluation, and if so, why did the therapist perceive it as such? The therapist annotates the

client's demonstrated work performance to the job requirements on the Department of Labor Physical Demands of Work Level chart (U.S. Employment Service, 2011). If work performance in sample testing does not meet competitive standards of job requirements, the therapist explains the difference in terms of the client's abilities and/or motivation. In essence, this is a return-to-work equation involving several variables. The therapist must look for matches and disconnects in the data collected during the evaluation to present a meaningful analysis and recommendations.

1. The first match is between the diagnosis and the symptoms. A given diagnosis usually results in a constellation of symptoms. The therapist must decide whether the symptoms match the diagnosis.
2. The next match is the agreement between the symptoms and the client's perception of his or her ability to work as expressed in the picture sort. An example of a disconnect is for the client to report hand paresthesias but not to indicate problems with precision tools on the card sort.
3. Next is assessment of the degree of agreement between the client's perception of ability to work and his or her demonstrated physical and cognitive abilities (potential to work). Examples of disconnects include the client who indicates an inability to use heavy tools on the card sort but shows above-normal strength and endurance during physical testing.
4. The therapist compares the client's physical and cognitive abilities (potential to work) with actual work performance demonstrated during work simulations or task component testing to determine the level of agreement. Demonstrated physical and cognitive abilities should be close to those demonstrated during performance of work samples.

The analysis in this section is the basis for flowing the evaluation process seamlessly into treatment. Problems in incorrect perception can be addressed and reconciled through consultation and education about the pathophysiological aspects of the injury or disorder and expected course of recovery. Education in techniques such as joint protection, energy conservation, and body mechanics can increase the client's ability to deal with symptoms and limitations. Instruction in movement and stretching exercises can provide further skills for managing symptoms and limitations. Work conditioning can be initiated. Work conditioning using work samples can increase physical abilities, engineer successful performance, help the client to recognize his or her abilities, and assist the client to develop realistic goals.

Step 7: Recommendations

Figure 28-4 incorporates recommendation statements that can be supported from the information gathered in steps 1–4, summarized in step 5, and analyzed in step 6. The first section of recommendations concerns the client who can return to either full duty or limited or light duty. The referring

physician may well use evaluation recommendations to determine the parameters of light duty, so it is important to base the definition of the limits of light duty on the results of test data and to include what the individual can do as well as what he or she cannot do. The recommendations section also addresses clients who are not ready to return to work but who may be brought to work standards with interventions such as education or work conditioning and hardening. Finally, for clients who do not appear to have the potential to return to target-level work or the preinjury job, the practitioner may recommend prevocational testing and vocational exploration of jobs within the client's physical demand capability.

SPECIALIZED OCCUPATIONAL THERAPY PRACTICE

Return-to-work evaluation and therapeutic intervention are complicated yet fascinating and rewarding. Work-oriented therapy, also known as industrial therapy, pushes the envelope of professional practice by demanding the blending of expert skill in assessment and data gathering with clinical reasoning and behavioral treatment. Applying occupational therapy skills and knowledge to the process is equally challenging because of the necessity of using physical and biomechanical knowledge along with cognitive and psychosocial knowledge. One particular benefit of practicing in the return-to-work field is being able to see the results of therapeutic efforts beyond those seen when practicing exclusively within the confines of a clinic.

Although the core of occupational therapy practice can be used as a basis for work rehabilitation and following step-by-step procedures should greatly increase the probability of seamlessly moving clients through the return-to-work process, this is considered to be a practice area that requires specialization. Therapists who specialize in return-to-work rehabilitation must develop observational and communication skills that are clearly understood by the client-worker, the work supervisor and/or the occupational health physician at the work site, the insurance representative, and medical professionals within the health care setting. Therapists must become comfortable in the work settings of their clients, just as they are comfortable in clinic settings. Occupational therapists specializing in this area have the potential to contribute to the growth of empirical evidence regarding outcomes of work-related interventions.

Désiron et al. (2011) conducted a literature review in which publications on the effectiveness of multidisciplinary return-to-work programs were evaluated. Their criteria were specific, requiring that the intervention programs evaluated include occupational therapy and be conducted between 1980 and 2010, that the studies be randomized, controlled trials or cohort studies, and that work-related outcome measures be used. Only six studies met the criteria. Although all six studies demonstrated a positive effect on return to work, comparisons were difficult because of differing interventions, patients, follow-up periods, and

definitions. Also, the contribution of individual professions could not be delineated. Although their review concluded that multidisciplinary return-to-work programs that include occupational therapy improved return to work, they also strongly suggested the need for additional research that includes uniform terminology and specific descriptions of therapeutic contributions (Désiron et al., 2011).

Snodgrass (2011) examined interventions for individuals with work-related low back pain and illnesses. Seven studies examined therapeutic exercise as an intervention, concluding that insufficient evidence exists to support or to refute the effectiveness of therapeutic exercise or other conservative treatments for subacute or chronic low back injury. The author recommended occupational therapists' use of multiple intervention strategies, and a holistic, client-centered, biopsychosocial approach in which psychological, social, and physical impairments and interruptions to function are considered (Snodgrass, 2011).

Briand et al. (2007) adapted a return-to-work rehabilitation program designed for use with individuals with musculoskeletal injuries for use with clients with mental health problems. Although they did not report on the effectiveness of the program, they delineated and described the elements from the musculoskeletal program that appeared to be relevant for mental health patients, such as psychological, work-environment, and stakeholder involvement. Using the approach with eight workers, they retrospectively documented their pathway through the program, providing rich information on program content. Four primary steps and their associated objectives and clinical activities were identified: evaluate the work disability situation, increase the readiness to return to work, support commitment (mobilization) to return to work, and maintain work (once the client is back in the workforce). The associated tasks are very similar to those described in this chapter including exploration of obstacles, perceptions, physical and mental conditioning, meeting with stakeholders (supervisors, occupational health practitioners), cooperative planning and goal setting, ergonomic evaluation and fit, etc.

The dynamic interplay between evaluation, intervention, and maintenance; the complexity of the return-to-work process; and the multiple professionals involved may explain the relatively weak body of evidence regarding return-to-work programs. Evaluating the effectiveness of such a program can be a challenge! Evidence Table 28-1 showing such results can be seen at the end of the chapter.

Most important to remember is that return-to-work rehabilitation programs using a comprehensive, multidisciplinary approach provide improved service to clients, guiding clients through the medical and rehabilitation processes without abandoning them along the way to fend for themselves in their quest to return to meaningful employment. The needs of both client and employer are addressed, one by one, until the client is a client no more, having once again become a worker and a valued contributing member of the workforce and of society.

Evidence Table 28-1 | Best Evidence for Occupational Therapy Practice Regarding Efficacy of Return-to-Work Programs Including Occupational Therapy

Intervention	Description of Intervention Tested	Participants	Dose	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Care as usual (CAU) versus integrated care. Integrated care included participatory ergonomics, graded activities based on cognitive behavior principles, and occupational therapy (OT). Those receiving care as usual were seen by physician and/or allied health professionals.	Occupational therapy contribution: functional capacity assessment, workplace intervention, graded activity, and input during monthly team meetings; also contributed to participatory ergonomics	One hundred thirty-four adults aged 18–65 years sick listed with low back pain for ≥12 weeks	Occupational therapy: assessment, workplace intervention, 26 graded activity sessions, monthly input. Measures taken at baseline and 3, 6, 9, and 12 months	Level: IA2b Randomized controlled trial, unblinded	• Integrated care reduced time off work (disability): 88 days compared with 208 days in CAU group • Integrated care effective in return to work • After 12 months, clients in integrated care improved more on functional status • No difference in pain	$p = 0.003$ $p = 0.004$ $p = 0.01$ $p > 0.05$	Lambeek et al. (2010)
Multidisciplinary return-to-work program including OT (two groups: treatment as usual (TAU) and TAU + OT)	Occupational therapy contribution: multidisciplinary team member. Assessment: occupational history, videotape of a role-play work situation, contact with work site occupational health physician with joint reintegration plan	Sixty-two adults with major depressive disorder and history of absenteeism (mean absenteeism = 242 days)	Diagnostic: five contacts (occupational history, video observation, contact with employer occupational physician, and work reintegration) Therapeutic: 24 group sessions and 12 individual sessions. Follow-up: individual visits (three). Measures taken at baseline and 3, 6, 12, and 42 months	Level: IB2a Randomized controlled trial	For those who did not work at baseline: reduced time between baseline and resuming work for those who participated in OT at 18 months, but effect disappeared over follow-up to 42 months. The addition of OT to TAU had a 75.5% probability of being more cost effective than TAU alone. Addition of OT did not affect depression or increase work stress.	$p < 0.05$ $p > 0.05$	Schene et al. (2007)

Compared multidisciplinary return-to-work programs	Cognitive-didactic versus functional-experiential rehabilitation therapy integrated into inpatient traumatic brain injury programs Occupational therapy contribution: multidisciplinary team member (no specifics mentioned)	Adult veterans or active duty military personnel with moderate to severe traumatic brain injury (*n* = 360)	Participants in both groups received 1.5–2.5 hours of protocol-specific cognitive-didactic versus functional-experiential rehabilitation therapy in addition to usual care. Measures taken via telephone calls at 1, 6, 12, and 24 months	Level: IA2b Randomized controlled trial; single blinded	No difference between groups on global outcome measures at 1 year. Cognitive-didactic participants improved more in immediate posttreatment Exploratory subgroup analyses suggested that at 1 year post, younger participants in the cognitive group had higher rates of return to work or school than those in functional group, whereas those age 30 years or more with more education in functional group had higher levels of independent living than those in cognitive group.	*p* > 0.05 *p* = 0.01 Vanderploeg (2008)

case example

Mr. B.: Return to Work after Hand Surgery

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**

Patient Information

Mr. B. is a 37-year-old married civil service employee. He works as an audiovisual support assistant and has a 2-year history of right dominant radial wrist pain. Mr. B. was intermittently treated for stenosing tenosynovitis of the first dorsal wrist compartment (de Quervain's disease) during the previous year. Conservative treatment, including activity limitations, limiting wrist motion with a thermoplastic thumb spica-type splint, superficial heat and cold, deep heat using ultrasound, and trials of transcutaneous and percutaneous corticosteroid medication via phonophoresis, iontophoresis, and injection, did not relieve symptoms to a level allowing Mr. B. to work at full capacity. About 10 weeks prior to referral for functional capacity evaluation (FCE), Mr. B. underwent a surgical procedure to release the right first dorsal wrist compartment. The surgery and postoperative recovery period were unremarkable. By postoperative week 10, however, Mr. B. could not return to work because of continued pain in the radial wrist during job-specific tasks. His supervisor referred Mr. B. to occupational health services, and Mr. B. was subsequently referred to occupational therapy for FCE and recommendations for return to duty.

A review of Mr. B.'s medical record and results of an initial interview revealed that he was in reasonable health and, excluding de Quervain's tendonitis, was without significant pathological medical history. Mr. B. had not been working for a total of 10 weeks, including the postoperative phase of his treatment. He was now back to work and on unofficial light-duty status administered by the good graces of his supervisor.

Appreciate the context

"I believe that Mr. B. has received a reasonable standard of treatment for the diagnosed condition. He has progressed through an expected treatment regimen with invasive (surgical) treatment initiated only when conservative had failed."

"Mr. B. seems to have a good working relationship with his supervisor as evidenced by the allowance of nonmedically directed light duty."

Description of Assessment

Mr. B. gave the therapist a specific listing of job tasks that included infrequent lifting and carrying of 50-pound items and fairly frequent lifting of approximately 25-pound objects. As part of his additional duties, Mr. B. was required to lift with one hand and carry a flagpole base weighing 17 pounds. The lift and carry were usually done with the right wrist slightly flexed and in radial deviation. Aspects of Mr. B.'s job description were verified by review of his written job description, an interview with his supervisor, and on-site observation.

Mr. B. stated that any use of his right hand caused wrist pain. He could perform all basic and instrumental activities of daily living but could not perform his job except for answering the phone and doing paperwork. He stated that it had taken "the doctors" 2 years to figure out his problem and that the surgery had not fixed it. When asked about his desired outcome, he replied that he needed either to be trained for another kind of job or receive disability for this work-related injury.

Based on his job demands, the occupational therapist decided to use the Valpar 1 (small tools), Valpar 9 (whole-body range of motion), and Valpar 19 (dynamic physical capacity) to sample Mr. B.'s actual work performance. Mr. B. performed at the Methods Time Measurement (MTM) rate of 95% on the Valpar 1, 90% on the Valpar 9, and 78% on the Valpar 19. Work performance on the Valpar 1 and 9 met competitive work standards; performance on the Valpar 19 was below competitive work standards.

Planning the evaluation

"My task is to try to discover the reason this medical condition continued to limit Mr. B.'s successful return to work despite successful surgical treatment and hand rehabilitation. I will need to consider his medical history in light of the job demands and try to determine his motivations regarding recovery and return to work. I will need to assess his ability to perform work tasks to see whether he is actually 'work ready.' If he is not able to perform at job standards, then I will need to assess his physical, cognitive, and behavioral potentials to try to understand the 'why' of his work inability."

Interpret observations

"The severity level of Mr. B.'s symptoms does not seem to match the expected response to surgical treatment and recovery for de Quervain's disease. Mr. B.'s perception of his performance ability does not match the severity of his reported symptoms either but does match measurement of physical and cognitive abilities. Work sample performance was greater than I expected from the evaluation of his physical abilities. Finally, I don't think that the sample work performance fully met target job requirements."

The therapist gathered subjective and objective data about Mr. B.'s abilities to examine the possible causes of the discrepancy between his abilities and the test and job demands. The EPIC Hand Functions Sort and the Spinal Function Sort allowed Mr. B. to express his perceptions of his ability to perform common work and leisure tasks. The results of these two sorts revealed that he perceived he could perform 80.5% of the tasks at normal or subnormal rates and intensity (categories A, B, and C); 19.5% of the tasks were rated as unable to perform in his present condition. Many of the tasks in both categories that were reported as not performable did not fall into the work domains usually associated with hand and wrist pain.

Measurement of physical abilities revealed body range of motion, ability to maintain static postures, and hand sensation as within normal range. Three of the seven subtests on the Jebsen-Taylor Hand Function Test were significantly below the mean. Static isometric strength testing using the BTE Work Simulator indicated that the right arm was below the 1st percentile, whereas the left arm showed average strength ratings at the 60th percentile. Lifting, pushing, and pulling ability of both arms using the BTE dynamic lift tests was below the 1st percentile. The general contentment scale score was 62. Cognitive performance under time pressure (decision-making test) was at the 45th percentile. Physical endurance using the step test was three standard deviations below the mean for age group.

Recommendations

The occupational therapist interpreted Mr. B.'s potential for return to work as moderate and recommended that Mr. B. participate in a work rehabilitation program. Skillful application of physical and psychosocial therapeutic interventions would be required to meet the long-term goal of return to full-time work. Mr. B.'s perceptions regarding his ability and performance would probably have to change to restore Mr. B.'s work role competency.

Summary of Short-Term Goals and Progress

In 1 month, Mr. B. will be able to do the following:

1. Use principles of body mechanics, energy conservation, and work simplification to perform work simulations
2. Improve his endurance and work tolerance so that he can use his right hand and wrist during work activities
3. Problem solve with the therapist regarding necessary adaptations to work tasks and work area

Here is a summary of Mr. B.'s formal work rehabilitation. The therapist provided several lessons on anatomy, pathophysiology, and wound healing, which related to Mr. B.'s surgical procedure. A focal point was that wound healing is a multiple-month process and that some pain during that process is normal.

Based on recommendations from the FCE, the referring physician assigned Mr. B. to an official light-duty status that specified physical demand limitations, with Mr. B. participating in work in accordance with FCE results.

"In general, I am seeing mismatches between diagnosis and symptoms, symptoms and abilities, and abilities and performance. I believe that this fits a pattern of psychological overlay that limits the application of ability to work performance. Combined with this situation, there is a general physical debilitation from several months of inactivity. The duration of his symptoms and perceived slow postoperative recovery are no doubt influencing symptom intensity and may be limiting his willingness to exert full effort during ability testing. At this time, he does not appear ready or willing to return to full duty."

"At no time during the evaluation did Mr. B. appear to be exerting himself to the full extent of his ability, as would be evidenced in concentrated facial expression, sweating, or grimacing with effort. At no time did he express pain or appear to be in pain."

Consider the patient's appraisal of performance	"Before we started treatment, I thought it would be important to review the results of the test data with Mr. B. and encourage him to explore and explain the variances in the data. Selective retesting (requested by Mr. B. and agreed upon by the therapist) allowed Mr. B. to clarify conflicts in data and demonstrate higher performance levels."
Consider what will occur in therapy, how often, and for how long	"I am recommending that Mr. B. participates in daily work rehabilitation sessions for 1 month, with each session lasting 1–2 hours initially and increasing until he can tolerate a full 8 hours (as is required at his job)."
Ascertain the patient's endorsement of plan	"Mr. B. readily agreed with my recommendations, and I am pleased, because this appears to signify a real engagement in this process."
Assess the patient's comprehension Understand what he is doing Compare actual to expected performance Know the person Appreciate the context	"The plan and goals were devised in conjunction with Mr. B. so as to increase his compliance. The goals specifically avoided the psychosocial issues and focused on tangible items such as knowledge of the healing process, body mechanics, and increasing endurance. I wanted Mr. B. to have the opportunity to change his perceptions about his work ability by experiencing successful activity rather than psychological analysis." "Analysis of the job tasks indicated that there were tasks that could cause a reoccurrence of wrist symptoms. I felt that it was important that Mr. B. know that the problem was not just related to his physical abilities but also to the job demands and that those job demands could be modified by changing the pace of work and by using adapted equipment."

Mr. B. participated in daily 90-minute work conditioning treatment activities with emphasis on regaining physical endurance and progressive use of the right hand and wrist during work activities. A secondary purpose was to arrange for progressive successful work experiences, so Mr. B. would begin to habituate a positive work role.

Mr. B. was provided training in body mechanics, energy conservation, and work simplification, especially as they related to his FCE results and the demands of his job.

A formal work site and job analysis provided the work site supervisor with sufficient information to modify task and pace to match Mr. B.'s abilities.

The occupational therapist fabricated an ergonomic tool adaptation to correct the identified injury-producing task. This modification corrected the extreme hand posture of radial deviation, allowing a more neutral posture. The device was adopted shopwide in Mr. B.'s work area.

Next Steps

Following 1 month of work conditioning, Mr. B. completed a partial FCE. Testing with the Valpar work samples indicated ability to work at target job standards. Mr. B. subsequently returned to full duty.

Anticipate present and future patient concerns	"I am pleased as to how Mr. B. responded to intervention. We succeed in helping, in part, because at no time during the evaluation or intervention phases of Mr. B.'s participation in the return-to-work process was there any attempt to confront, catch, or expose his psychological issues. I was careful to remain neutral and request only that he try to explain the variances in the data. Mr. B. was always given "wiggle room" and face-saving avenues in all interactions. Over the course of the rehabilitation, the combination of education, nonjudgmental interactions, and successful repetitive work experience encouraged Mr. B. to choose to alter his perceptions of ability and performance and regain work role competency."
Analyze patient's comprehension	
Decide if the patient should continue or discontinue therapy and/or return in the future	

Clinical Reasoning in Occupational Therapy Practice

Work Rehabilitation

Right dominant radial wrist pain was the central feature in Mr. B.'s inability to return to work. At the time of the evaluation, Mr. B. had been out of work for 10 weeks following minimally invasive wrist surgery. He returned to work but reported continued pain with work-related activities that have not resolved. His supervisor permitted unofficial light duty. He voiced feelings of disappointment and discouragement. He did not attend therapy during his initial recovery period. How should the therapist interpret Mr. B.'s emphasis on his wrist pain? Is it "real" or enhanced? Should Mr. B. have been given a longer period of protection from physical work stressors following surgery? What are the possible consequences of an extended recuperation period? What other psychosocial interventions might therapists have considered, given the possibility of a psychological component to his inability to return to full duty?

Summary Review Questions

1. List four reasons people work, and explain how each might affect their ability to return to work.
2. List four reasons older persons choose to work, along with four methods of attracting older workers to continue working.
3. Describe the unique contributions of occupational therapy to the return-to-work process.
4. Describe how job analysis is used in both the evaluation and treatment phases of the return-to-work process.
5. Describe other potential uses for the results gained from a job analysis.
6. Compare and contrast the two types of performance evaluation suggested in an FCE.
7. Using the job of grocery store clerk and scanning, keying, and bagging as the essential tasks, write a brief description of a treatment program based on task components and a description of a treatment program based on work simulation.
8. Use the return-to-work decision pathway to develop an evaluation plan for a 42-year-old diabetic who has intermittent retinal bleeding (loss of sight) and who has recently lost his job as a computer systems analyst.

Glossary

Functional capacity evaluation (FCE)—Systematic process designed to assess a client's functional abilities. Functional abilities may include all physical and psychosocial abilities required in a work setting, such as musculoskeletal (strength, range of motion, etc.), cognitive, emotional, and communication abilities. The two performance categories include a general evaluation of physical abilities and an evaluation of job-specific capabilities.

Functional work assessment—Entire return-to-work evaluation process, including evaluations of (1) the individual client (traditional occupational therapy and FCEs) and (2) the requirements of the job or potential jobs (job analysis).

Job analysis—Systematic evaluation of a job; a physical evaluation of the job site, observing workers performing their tasks, conducting a task analysis of the criterion tasks, measuring equipment and equipment placement, reviewing work-related documents such as job descriptions, and interviewing those who perform the job and their supervisors.

Task component testing—Functional capacity testing that identifies criterion tasks based on the most difficult, essential components of a job and develops specific evaluations or training programs based on those components. It is assumed that evaluating or training using task

components critical to job success is a valid approach to determining work performance, because the content requirements of the job are used to develop the evaluation or training.

Work conditioning—Treatment program focused on functional requirements of a job or employment setting; incorporates basic physical conditioning such as restoration of flexibility, strength, coordination, and endurance. Work conditioning is conducted after completion of acute care and before work hardening.

Work hardening—Multidisciplinary structured, graded return-to-work treatment program that progressively introduces greater rehabilitation requirements on the client-worker to achieve full capability of the worker to meet the demands of a job. Work hardening includes all aspects required for the client to return to full function in employment, such as psychosocial, communication, physical, and vocational needs, and typically incorporates work simulation as part of the treatment process.

Work-related musculoskeletal disorder (WRMD)—Wide range of health problems arising from repeated stress to the body encountered in the workplace; may affect the musculoskeletal, nervous, and neurovascular systems and include the various occupationally induced cumulative trauma disorders, cumulative stress injuries, and repetitive motion disorders.

Restoring Competence in Leisure Pursuits

Carolyn Schmidt Hanson

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Define leisure in a conceptual and pragmatic fashion.
2. List physiological and psychological benefits of engagement in active and quiet leisure.
3. Describe how leisure can be integrated into occupational therapy practice.
4. Identify various leisure assessments, and describe how they are used.
5. Discuss barriers and challenges for clients and therapists engaging in leisure activities.
Activities of daily living (ADL), work, and play/leisure are core aspects of occupational therapy intervention that promote self-efficacy and self-esteem. Although information concerning the use of play/leisure in occupational therapy is scarce compared to ADL and work, play/leisure is incorporated into key models that inform practice. In the Occupational Functioning Model, engagement in play/leisure is categorized as a self-enhancement role under the control of and chosen by the individual (see Chapter 1 of this text). Participation in social roles (including that of leisure) is a key concept in the International Classification of Functioning, Disability and Health (Brachtesende, 2005; World Health Organization, 2002), and the Occupational Therapy Practice Framework (American Occupational Therapy Association [AOTA], 2008) endorses participation in leisure activities as a legitimate goal in occupational therapy treatment.

Terms such as play, leisure, and recreation are often used interchangeably. Leisure can be viewed as the adult version of play, because many similarities are present. Also, leisure is viewed as a more encompassing concept than play or recreation and is the term most frequently used in the occupational therapy literature. Recreation is often used to describe how we occupy time that is not devoted to work or self-care. Therapeutic recreation specialists, professionals who are trained to use recreational activities to improve the quality of life for patients, have played a major role in developing leisure programs in medical settings. The profession of therapeutic recreation (TR) gained prominence and became more formalized after World War II, as recreational activities were used in the treatment of disabled war veterans. The history of TR is similar to the history of occupational therapy because our profession was launched after working with veterans from World War I. The distinguishing difference between the two professions is that treatment protocols for TR always use recreational activity as the primary form of treatment. Occupational therapists concentrate on the overall functioning of the individual, of which recreation is only one component.

The purpose of this chapter is multifold: to briefly review the use of leisure with persons with disabilities, to highlight particular leisure assessments, to recommend the development of specific leisure programs and activities for adults with physical disabilities, to discuss the evidence regarding the psychological and physiological benefits of leisure (see Evidence Table 29-1), to discuss barriers for both therapists and clients, to present a case study regarding the use of leisure in occupational therapy, and to provide leisure resources.

DEFINING LEISURE

A precise definition of leisure is elusive because our attitude toward a given activity shapes our perception of it as leisure or work. For example, sewing may be leisure for one person but considered work by another. Work and play are not always dichotomous experiences, however. Sometimes they become blended, and hopefully they are balanced. The Life Balance

Figure 29-1 Recreational activity: billiards.

Model explains the essential nature of everyday activities (see Chapter 4 for specifics). Balancing work and leisure is crucial for mental and physical health. When balance occurs, life is viewed as less stressful and more satisfying. However, excessive time spent in work at the expense of leisure or vice versa may lead to occupational imbalance, which may aggravate health and quality of life, resulting in injury or illness (Wilcock, 1998).

Law et al. (1994) have partitioned leisure into three major categories: active leisure, which consists of recreational activities incorporating physical exertion such as wheelchair sports and travel; quiet leisure, which incorporates activities such as watching television, reading the newspaper, and crafts; and socialization, which consists of visiting, correspondence, and Internet communication. Both quiet and active leisure activities appear to contribute to occupational balance, self-esteem, and wellness for persons with disabilities (Fig. 29-1).

Quiet Leisure

Generally, adults with physical disabilities tend to engage in quiet and passive activities (Law, 2002), such as needlecrafts, reading, video games, and playing cards (Fig. 29-2).

Figure 29-2 Large-print playing cards typify leisure adaptations available to elders. (Photo by Laurie Manuel.)

Evidence Table 29-1	Best Evidence for Leisure

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Leisure versus home visit	Leisure education program (experimental) versus a friendly home visit (control)	Sixty-two stroke survivors: 33 in experimental group, 29 in control group	Once a week for ~60 minutes for 8–12 weeks	Randomized controlled trial Level: 1A1 a	Leisure program members spent more time recreating and engaging in more activities according to Leisure Satisfaction Scale and Individual Leisure Profile; reported less depression	Statistical significance between groups. Improved participation in leisure and satisfaction with leisure and reduced depression for experimental group	Desrosiers et al. (2007)
Leisure rehab versus instrumental activities of daily living (IADL) treatment	Leisure group: sports and games, gardening, and entertainment IADL group: mobility, transfer training, dressing, cooking, and bathing	Three hundred nine stroke survivors	Median number of sessions = 10; median duration of sessions = 55 minutes	Randomized, controlled trial Level: 1A1 a	No difference between leisure rehab group and IADL group on outcome measures of leisure participation or functional training	No statistically significant differences between groups; no improvement in outcome in either group	Logan et al. (2003)
Intensive Tai Chi versus wellness education for fall prevention	Discussion of wellness strategies versus active participation in Tai Chi	Two hundred ninety-one women and 20 men residing in congregate living facilities; ages 70–97 years	Wellness group, 1 hour per week; Tai Chi group, 2 days per week; sessions were between 60 and 90 minutes for 48 weeks and then a year later follow-up testing session	Randomized, controlled trial Level: 1A1b	No significant difference in number of falls sustained by either group	Overall, no statistical differences. However, during 4–12 months, Tai Chi group showed early significant lower risk of falls, but wellness group showed steady decrease over the 2-year study.	Wolf et al. (2003)
Leisure activity; in-home treatment	Leisure activity training versus leisure discussion about effects of stroke	Forty stroke survivors (20 per group) survivors; mean age = 69.6 years	Sixty-minute sessions once a week for 5 weeks	Randomized controlled trial Level: IB2b	No. Leisure activities training group did not have significantly increased scores on Katz Adjustment Index. The conclusion was that low dose of therapy is ineffective.	No significant differences between groups on activity level and satisfaction with free-time activity	Jungbloed & Morgan (1991)

Another type of quiet leisure, horticulture therapy (HT), refers to gardening for therapeutic reasons. Occupational therapists have traditionally used HT to facilitate leisure and occupational skills in diverse populations. Gardening assists in enhancing the emotional well-being of patients by affirming life and establishing a sense of peace in addition to improving range of motion and endurance (Harnish, 2001). Raised flower boxes enable wheelchair users to employ gardening skills while improving functional, emotional, cognitive, and physical skills. Various tools are designed to allow people with arthritis and upper extremity weakness to garden (Resources 29-1).

Various programs as well as equipment offered.

Fishing Has No Boundaries, Inc.
http://www.fhnbinc.org
Gear and programs for everyone.

Active Leisure

People with chronic musculoskeletal diseases may be afraid to engage in activities that require physical exertion and believe that their leisure options are limited to quiet activities. Occupational therapists may inadvertently contribute to this misperception. Therapists may not introduce active leisure to clients because exercise recommendation guidelines have not been fully developed for people with physical disabilities. Sports for those with disabilities, however, have been connected to rehabilitation efforts since the 1940s when archery was used as therapy for paraplegic war veterans. Wheelchair sports now include wheelchair basketball, tennis, and quad rugby as a few of the better established popular activities (Fig. 29-3). In fact, people with physical disabilities are engaging in vigorous and demanding sports such as marathons, rock climbing, and downhill skiing. As you will see, evidence demonstrates that strenuous physical activity is not only well tolerated by those with disabilities, but it has beneficial effects.

ACTIVE LEISURE AND HEALTH FOR PEOPLE WITH DISABILITIES

Developing active leisure outlets is important to health and wellness for all people, including those with disabilities

(Buchholz et al., 2009). Active leisure minimizes the consequences of a sedentary lifestyle and advances health and wellness in a number of ways.

Consequences of a Sedentary Life

Despite the increased growth of wheelchair sports and opportunities for engagement in various leisure activities of all types, many people with disabilities lead sedentary

Figure 29-3 Active leisure: wheelchair basketball.

lives. Motl and McAuley (2010) stated that "there is an alarming rate of physical inactivity among older adults, particularly those aging with a disability" (p. 299). Research has shown that cardiovascular disease is the leading cause of death for people with spinal cord injuries (SCI) as well as the able-bodied, although people with SCI are affected at a younger age (Warburton et al., 2010). Participation in regular daily living activities alone is insufficient in promoting health and warding off cardiovascular disease (Warburton et al., 2010). Exercise and active leisure have been relatively unexplored methods of reducing the decline and deconditioning that most people with physical disabilities experience (White & Dressendorfer, 2004). To combat this spiral of physical decline, Painter (2003) emphasized that physicians play a role in encouraging their patients with chronic diseases to become physically active to improve function and quality of life. Occupational therapists can certainly encourage clients to improve their health by providing active leisure experiences, recommending adaptive techniques/equipment, and connecting people to existing activity programs.

Health Benefits of Active Leisure after Physical Disability

Evidence suggests that active leisure (such as sports and exercise) has many potential benefits for people with disabilities. In fact, there is beginning consensus concerning the imperative need for exercise and active leisure for people with physical disabilities in order to improve mental and physical health. It could be said that people with a disability have more to lose if they do not maintain a suitable level of fitness.

White and Dressendorfer (2004) advocated for exercise programs that focus on increasing cardiorespiratory fitness, muscular strength, and mobility for people with multiple sclerosis (MS). They discovered that not only are secondary disorders reduced (e.g., pressure sores, joint stiffness, and weight gain) but also people who engage in aquatic exercise and other aerobic activity attest to better quality of life and improved lifestyle. Exercisers with MS and other disabilities commonly mention the psychological benefits inherent in activity participation. Disabled veterans in a wheelchair games event testified that sports participation enhanced their disability acceptance, improved their mobility skills and added greatly to their life (Sporner et al., 2009).

In the Northern Manhattan Stroke study of 1,000 elders, those who engaged in physically active leisure were found to have a decreased incidence of ischemic stroke (Sacco et al., 1998). Researchers of this study stressed that physically active leisure should be emphasized in stroke prevention campaigns. Tai Chi, which is available in many communities, is an example of active leisure that has

health benefits for elders and those with stroke. Known as a soft martial art, Tai Chi involves moving the body slowly and smoothly through its range of motion. There has been an exponential increase in randomized controlled trials on the effects of practicing Tai Chi. In a meta-analysis performed by Klein and Adams (2004), 17 clinical trial studies were critically reviewed with all showing statistical significance in at least one outcome measure. Typical outcome measures included the positive effects Tai Chi had on quality of life and physical function. In addition, Tai Chi was credited in improving pain management and balance. People with stroke who practiced Tai Chi for several months had less depression than a control group (Desrosiers et al., 2007), and Tai Chi has been associated with better balance, lower blood pressure, and improved mood (Taylor-Piliae & Haskell, 2007).

Not only does active leisure such as exercise offer specific physiologic and psychological benefits, improved fitness may enable other aspects of active participation in life. Adults with SCI who enrolled in a 12-week fitness and weight management class reported that they hoped that losing weight and becoming more fit would enable them to more safely and frequently engage in leisure pursuits that required improved strength and stamina (Radomski et al., 2011). Many participants limited their leisure activities, such as travel, for fear of encountering an unexpected barrier that they did not have the capacity to manage. It was found that the same weight loss strategies used by people without disabilities, such as exercise, good nutrition, and behavioral techniques, benefitted individuals with SCI, who have a higher than average rate of developing heart disease.

In summary, engagement in leisure activities is essential to health and wellness for all people. Therefore, occupational therapists incorporate this area of functioning into the assessment and intervention process.

ASSESSMENT TOOLS

Before recommending specific leisure activities or using leisure as an intervention, one should assess the patient's interest in leisure. The following are instruments that identify the types of activities that are meaningful to clients. Although this is not an exhaustive list of the leisure assessments available in the fields of occupational therapy and TR, the following sections present some of the better known instruments.

The Canadian Occupational Performance Measure

Designed by occupational therapists, the Canadian Occupational Performance Measure (COPM) detects self-perceived change in occupational performance over time

(Law et al., 1994). The COPM contains three sections: self-care, productivity, and leisure. The leisure section is divided into quiet recreation, such as hobbies, crafts, and reading; active recreation, such as sports, outings, and travel; and socialization, such as visiting, phone calls, and correspondence. Individuals are requested to identify any problems in the three sections and to rate the importance of each activity on a scale of 1 to 10. Then five of the most important problems are identified, and individuals rate their performance and satisfaction with performance on these five problems.

Interest Checklists

Occupational therapists have developed and used many interest checklists. The Nottingham Leisure Questionnaire, developed in England for stroke patients, is a 38-item list of activities ranging from watching television to doing sporting activities (Drummond & Walker, 1994). A 5-point scale is used to describe frequency of doing the activity, ranging from regularly (every day) to never. In obtaining test–retest reliability scores, 21 subjects completed the same questionnaire on two occasions within a 2-week period. Based on Cohen's kappa coefficient, reliability was determined to be excellent (0.75–1.00) and good (0.60–0.74) for 23 of the 38 items and fair (0.40–0.59) for another 6 items. Inter-rater reliability was tested using the ratings of two occupational therapists and showed excellent agreement on 40 items and good agreement on 1 item; the total was more than 38 items because of write-ins of other activities not specified in the questionnaire (Drummond & Walker, 1994).

The Interest Checklist (Matsutsuyu, 1967) consists of 80 items grouped into the following categories: ADL, manual skills, cultural-educational, physical sports, and social recreation. The rating given to each item ranges from no interest to casual interest to strong interest.

Kautzmann (1984) developed an interest checklist for persons with arthritis that uses similar categories, as well as games, organizational activities, and entertainment. This instrument consists of 64 items rated according to their importance, ranging from none to high, and their relevance to the person with arthritis (importance of activity and whether there is a priority for further development) (Kautzmann, 1984).

Finally, the Lin Interest Check List (LICL), developed in 1991, contains 151 interests and activities within six categories: sports, physical activities, and nature; crafts; games; sociocultural and entertainment activities; community and education; and hobbies and miscellaneous. The level of interest, frequency, and history of participation are to be identified for each item. The LICL has high content validity and good test–retest reliability (Lin, 1991).

Occupational Therapy Assessment of Leisure Time

The Occupational Therapy Assessment of Leisure Time (OTALT) was based on a review of the leisure literature in occupational therapy and provides a frame of reference specifically for leisure (Soderback & Hammarlund, 1993). The purpose of the OTALT is to enable the client to use leisure time more effectively and to improve satisfaction with leisure activities. Using open-ended questions, the therapist interviews the client on the dimensional concepts of time, intrinsic motivation, and free choice of leisure activity; capability; structure of social and cultural environment; engagement in leisure activity; pleasure for pleasure's sake; goal self-fulfillment, goal diversion, recreation, and relaxation; leisure role; leisure behavior; and influence on his or her leisure role and leisure behavior. Although multiple questions are provided for each dimension, therapists are encouraged to structure the interview the best way they see fit.

Leisure Questionnaires from Therapeutic Recreation

Beard and Ragheb (1980) have developed four leisure questionnaires that are commonly used by TR specialists in medical settings. The Leisure Satisfaction Measure contains 51 statements about how patients perceive their needs being met through leisure. The Leisure Attitude Measurement contains 36 items that quantify the patient's attitude in three areas: cognitive, affective, and behavioral (Ragheb & Beard, 1982). The Leisure Interest Measure identifies patients' interest in the following eight domains: physical, outdoor, mechanical, artistic, service, social, cultural, and reading (Beard & Ragheb, 1990). The Leisure Motivation Scale contains 48 items regarding motivation to engage in leisure activities and reflects four areas: intellectual, social, competence-mastery, and stimulus avoidance (Beard & Ragheb, 1983). As a whole, reliability and validity are good for these measures because items and domains have been analyzed extensively according to the test manuals for the four aforementioned assessments.

Physical Activity Scale for Individuals with Physical Disabilities

The Physical Activity Scale for Individuals with Physical Disabilities (PASIPD) was developed to obtain information on the physical activity habits of people with physical disabilities. The PASIPD was based on and then modified from the Physical Activity Scale for the Elderly (PASE), a 10-item instrument administered in person or via the phone. Using the PASE as a starting point, qualitative interviews were conducted with 15 people with disabilities

along with four rehabilitation professionals. Goals for the new instrument included a brief time to complete, administered by self or interview, and targeted quantitative areas previously unexplored in the disabled population (Washburn et al., 2002).

Three hundred seventy-two people completed the PASIPD to determine its construct validity and represented the following conditions: postpolio, quadriplegia, cerebral palsy, and other locomotor impairments (Washburn et al., 2002). Descriptive characteristics of this sample population revealed an average age of 50 years, well educated, Caucasian, and a moderately high annual income—not necessarily representative of people with disabilities. However, information gleaned from this sample revealed that younger respondents reported higher levels of activity (the exception being questions regarding home and garden maintenance) than older respondents. Individuals who rated their health as "excellent/very good" reported significantly higher total activity scores than those individuals who rated their health as "good" or "fair/poor."

The resulting brief scale consists of 13 items representing five distinct categories: home repair/lawn and garden work, housework, vigorous sport and recreation, moderate sport and recreation, and occupation/transportation. Respondents are provided with four options to indicate how many days and hours per session they engage in the aforementioned activities. Based on the option selected, a specific multiplier related to energy expenditure is used to determine a value for each of the 12 questions. The first question is not scored because it taps sedentary activity and is meant to familiarize the person to the survey format. All of the values are summed for a total activity score with the highest being a maximum of 199.5.

OCCUPATIONAL THERAPY INTERVENTION TO RESTORE COMPETENCE IN LEISURE PURSUITS

Based on the results of the occupational therapy assessment, occupational therapists help clients resume premorbid leisure interests and explore new options (see Procedures for Practice 29-1). Social networking, in particular, is a quiet leisure outlet that is of increasing interest to those with disabilities.

Computers can provide extensive leisure outlets for people with disabilities from video and online arcade gaming to dating and blogging. Popular YouTube, Google, and Facebook platforms have allowed people to easily communicate with others globally and to learn instantaneously about events taking place in another hemisphere. Individuals with physical disabilities can form friendships with people who are simply online but may live thousands of miles away. Several websites specialize in matching people with disabilities who are interested in

---

Procedures for Practice 29-1

Strategies to Promote Leisure

- Elicit enthusiasm and support from health professionals through in-service education that links leisure, health, and quality of life.
- Elicit support from family and friends.
- Identify interest and enjoyment in activity via leisure assessments and interviewing techniques.
- Evaluate for special needs and assist in choosing an appropriate activity based on current abilities.
- Provide exposure to activity and establish a schedule to learn.
- Set basic goals for activity that can be mastered early, and establish more challenging goals with progress.
- Follow up to evaluate success and to make possible adjustments.
- Create opportunities to reinforce engaging in activity that may be extrinsically or intrinsically motivating (longer lasting effect).

---

dating and in offering entertainment opportunities (see Resources 29-1). Although distinctly having many advantages, computers may encourage individuals to be sedentary and remain in one position for extended periods. As with any activity, moderation is the key. Frequent breaks and repositioning are crucial.

As described earlier, moderate to strenuous activity may reduce functional decline, improve cardiorespiratory function and possibly decrease depression and fatigue for people with disability. A greater amount of time spent in physically active leisure pursuits has been associated with lower chronic disease risk (Buchholz et al., 2009). Therefore, this section focuses on helping people with disability engage in active leisure.

Guidelines for Exercise Regimens

Research data on the activity patterns of those with disabilities are scarce; insufficient evidence is available to determine exactly what activity is best for an adult with a physical disability based on safety, effectiveness, and outcome measures. Using the research on the able-bodied, we know that a properly designed physical activity program includes aerobic, flexibility, and strength components (Durstine et al., 2000). The exercise dosage (intensity, frequency, and duration of the physical activity) may need to be modified for persons with disabilities to maintain a training effect that does not cause abnormal clinical symptoms/signs or injury. For example, it

is recommended that adults with physical disabilities lower the intensity of the exercise but increase the duration and the frequency of the activity (Durstine et al., 2000). Exercise guidelines have recently been proffered for elders by Elsawy and Higgins (2010).

Active Leisure Options for Various Diagnostic Groups

Research of the past 15 years provides ideas regarding activities that may be appropriate for certain patient populations. As can be imagined, this area of research is lacking and is a fertile field for those interested in contributing to the leisure literature.

Persons with Spinal Cord Injury

Researchers surveyed 160 persons with SCI regarding their postdischarge activities (Hoffmann et al., 1995). On the basis of their activity level, respondents were placed in an active or an inactive group. Over a 1-year period, the active individuals spent, on average, 3.2 days in the hospital compared with 10.7 days for the inactive individuals. Inactive individuals were more than 2.5 times as likely to have pressure sores as the active ones. The results of this study underscore the cost-saving benefits of being physically active.

One hundred forty-three individuals with SCI from 18 to 55 years of age were surveyed regarding their engagement in physical activity before and after their injury (Wu & Williams, 2000). Individuals who participated in sports such as wheelchair basketball, rugby, and tennis were shown to have less depression, improved social interaction, and less incidence of rehospitalization. The participants in this study reported that they engaged in sport because it was fun and provided a means to be fit and healthy and a means to interact with a variety of people. Peers with disabilities, as opposed to therapists, were invaluable in introducing newly injured people to wheelchair sports. Wu and Williams (2000) emphasized that therapists should take a more active role in educating clients about sports training and leisure activities (see the Case Example about K.J.).

Persons with Joint Replacements

Individuals with modern joint replacement can expect to have their joints last at least 10–15 years. This does not apply to people with hip and knee joint replacements who regularly jog or hike because this type of activity may endanger the integrity of the prosthetic components (Kuster, 2002). Because there are no prospective, randomized studies on physical activities after total joint replacement, the conservative opinions of orthopedic surgeons have guided current recommendations on suitable leisure activities. In general, speed,

prior sport experience, and joint impact are factors when considering load or joint stress. High-impact activities requiring speed, such as football, soccer, and handball, are discouraged, whereas low-impact activities, such as swimming, cycling, and walking, are encouraged. Technically demanding sports (snow skiing, mountain biking) are not suggested for those individuals who have never engaged in these activities prior to their joint replacement. The rationale is that the learning curve for technical sports is too demanding on the replaced joints (Kuster, 2002).

Persons with Rheumatoid Arthritis and Osteoarthritis

Three hundred nine individuals with rheumatoid arthritis (RA) enrolled in a randomized controlled trial and participated for 2 years in either an exercise program of high intensity or usual care (standard physical therapy) (de Jong et al., 2003). The high-intensity exercise program was more effective at improving functional ability in this population. In addition, it also demonstrated that exercise did not increase radiographic damage of the large joints. Bulthuis et al. (2007) found that short-term exercise immediately after hospital discharge of RA and osteoarthritis (OA) patients had results of improved function. Aerobic exercise (particularly swimming) and strengthening regimens are viewed as being beneficial for people with joint problems (Esser & Bailey, 2011). In an older but still relevant publication, Minor and Lane (1996) noted that people with RA are prescribed rest and medication for their condition, which is appropriate for the acute condition but harmful in the chronic state. People with RA and OA often stop engaging in leisure and recreational activities. Unfortunately, inactivity produces the same symptoms as the rheumatoid disease process: muscle weakness, decreased flexibility, fatigue, incoordination, depression, and lowered pain threshold. People with RA who do engage in aerobic exercise may experience a significant reduction in swelling, which is attributed to increased synovial blood flow. Minor and Lane (1996) emphasized that vigorous activity is only supported in people with no joint inflammation; otherwise, joint damage may ensue. Developing strong muscles by engaging in mild resistance training may also take pressure off of joints.

Persons with Multiple Sclerosis

Prescribed exercise does not appear to increase or exacerbate the condition of MS. Aquatic exercise, especially, may decrease the incidence of obesity, heart disease, and diabetes—all leading problems associated with inactivity. Salem et al. (2011) found that a 5-week community-based aquatic program augmented rehabilitation efforts and was beneficial for people with

MS. Yoga is also deemed an appropriate activity because it assists in improving range of motion and balance. In dealing with this condition, it is essential to alternate periods of rest and activity and to monitor heat tolerance. People with MS commonly have more energy in the morning, so activity may be better tolerated earlier in the day before fatigue occurs.

Elders

In addition to a variety of sports, physically active leisure, such as walking, armchair or wheelchair aerobics (exercising the upper extremities while seated), swimming, and weight training (using light weights or machines; using resistive bands), is ideal for increasing endurance and tone in elders. As elders constitute more of our population, it behooves us to create and promote leisure and socialization opportunities in assisted-living facilities and retirement homes.

Sports Camps/Specific Sports Clinics

Camps have been developed to introduce sports and leisure activities to people with disabilities and to facilitate engagement in physically active leisure and to promote health (Hanson, 1998). Focus may be on one particular sport, such as with wheelchair tennis camp, or an introduction to a variety of sports. Some camps or clinics are specialized for individuals with particular diagnoses; others include anyone with a mental or physical disability. Because of the focused nature of the camp or clinics and the time invested (from several days to several weeks), participants have the chance to socialize and learn specific sport skills. In addition, camp participants often learn techniques and obtain tips from each other on daily living skills such as transferring and catheterization. Affiliation with others is a strong motivating factor in promoting leisure activities.

Ride2Recovery is an example of a cycling group for wounded U.S. veterans and active service members. Founded in 2008, this nonprofit group puts on cycling events around the country to enable military personnel with all sorts of physical and psychological issues to ride together over a period of days. The primary purpose is to help veterans heal and to socialize with others. Riders who have participated in the events have testified to the healing quality of biking as an outlet for stress, a way to become fit and a source of enjoyment from the camaraderie that occurs during the trips. Although only veterans can participate in the ride, volunteers are needed to help with the cycling events in their hometowns and to sponsor riders. Many opportunities are available for nonveterans to be a part of this active group. Other well-orchestrated clinics involving multiple sports and leisure activities have been developed for veterans as well (see Resources 29-1).

Occupational therapists realize the many benefits of directing a camp or being involved with specific sports

events or clinics, which range from raising the awareness of the able-bodied to providing the disabled with opportunities to explore sport. Additional benefits may include training for students and staff who serve as camp or clinic volunteers. Volunteers assist in monitoring participants for heat exhaustion and any untoward effects of exercise (Safety Note 29-1) and assist with coaching. Directing a camp takes time, energy, and funding. Only therapists who are passionate about sport would be willing to expand their duties by being a camp director or

⊕ Safety Note 29-1

Safety Considerations during Active Leisure

Spinal Cord Injury and Autonomic Dysreflexia (T6 and above)

Risk factors

- Being overheated
- Having an obstructed fecal mass
- Having a kink in a catheter tube
- Pain

Symptoms and signs

- Hypertension
- Pounding headache
- Profuse sweating
- Flushing
- Pupil constriction
- Nasal congestion

Occupational therapy assistance

- Obtain medical help: this is a MEDICAL EMERGENCY.
- Remove restrictive binders or clothing.
- Elevate head.
- Check leg bag for obstruction.
- Monitor blood pressure.

Guidelines for monitoring during active leisure pursuits

- Terminate activity if safety is questionable.
- Supervise closely the person with a recent disability.
- Consider extreme environmental conditions.
- Monitor body temperature.
- Monitor sweating and color of skin.
- Encourage fluid intake.
- Observe for signs of fatigue.
- Check for incontinence.
- Encourage skin inspection/recommend pressure relief.
- Evaluate positioning, cushioning, and strapping during activity.
- Consider special training for activity.

offering organized physical activity on a consistent basis. A more efficient method to educate clients about sport opportunities is being aware of clinics for people with disabilities in your city and encouraging participation in these events.

BARRIERS TO LEISURE ENGAGEMENT

A number of factors interfere with ensuring that persons with disabilities ultimately can engage in leisure activities that maintain a satisfactory occupational balance. Some factors stem from contemporary trends in occupational therapy; other interfering factors have to do with client access.

Barriers for Therapists

Occupational therapists often have limited time to work with clients and may feel they lack adequate knowledge about leisure activities and resources, but this is a crucial area for intervention. Asking about leisure interests and desires allows occupational therapists to provide exploratory experiences in a monitored and controlled setting and offer the "just-right challenge" to their clients. Moreover, we can follow up by forging relationships with community and recreational centers to encourage continued participation upon discharge (Procedures for Practice 29-1).

Barriers for Clients

Access to recreational and leisure pursuits may be difficult for persons with disabilities. Personal, environmental, and societal factors may all limit leisure participation. Personal factors may include fatigue, pain, depression, comorbid illness, and medical condition. Activity safety and weather conditions may impact participation as well (Mallinson et al., 2005). Environmental barriers such as poorly designed parking lots and sidewalks without curb cuts may prevent access. A recreational facility may have outdated, inaccessible bathrooms. Transportation to a facility or center may also pose problems, as may the financial requirements for specialized equipment such as wheelchairs designed for specific sports and adapted sports equipment. It may be difficult to find coaches and other personnel who understand the needs of those with disabilities and challenging to find a training partner. Despite these possible barriers, it is vital that people with disabilities have support and encouragement from their family and friends to participate in leisure activities that interest them and are within their capabilities.

Attitudinal barriers in our society are often more disabling than personal and environmental barriers. Individuals with disabilities such as tetraplegia and bilateral upper or lower extremity amputations may not be-

Figure 29-4 Technology to allow independent fishing from a wheelchair. (Photo by Gary Rudolph.)

lieve that they are capable of participating in a variety of activities because of the attitudes of others. Advances in technology and changes in attitudes have allowed people with spinal cord injury and neuromuscular diseases to water ski using a sit ski, people with hand amputations can windsurf using sport-specific prostheses, wheelchair users can rock climb with special equipment, fishermen can fish (Fig. 29-4), and individuals with lower extremity amputations can play tennis (Fig. 29-5). Self-defense classes have been formed for community dwellers with visual impairments (Fig. 29-6). Wheelchairs designed specifically for use on the beach have been developed in addition to numerous models for various sports. With developing technology, opportunities to engage in numerous activities are possible if there is interest and motivation on the part of the therapist and the individual (Fig. 29-7).

In conclusion, human occupation is commonly taken for granted, and its health benefits are not acknowledged

Figure 29-5 Active leisure: wheelchair tennis.

Figure 29-6 Self-defense training with the visually impaired.

Figure 29-7 Independent or group activity: hand-crank three-wheeled bicycle.

(Wilcock, 1998). This is even more pronounced in leisure. Engagement in leisure promotes health and decreases medical costs. Efforts to provide leisure opportunities for adults with disabilities are gradually increasing as we shift from hospital- to community-based treatment. Our renewed interest in community-based intervention supports our efforts to encourage leisure exploration and develop leisure programs for *all* people. Occupational therapists can become more aware of existing leisure opportunities and integrate leisure activities into assessment and treatment. By forming partnerships to develop and promote leisure options in new areas for people with disabilities, we can improve quality of life.

case example

K.J.: Resuming Leisure Activities after Stroke

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information K.J. is a 42-year-old woman who sustained a left cerebrovascular accident (LCVA) resulting in right-sided paresis. She has good return of right upper extremity muscles but lacks coordination. Muscles of right lower extremity are spastic, and K.J. cannot safely ambulate, so she is learning to use a wheelchair. K.J. feels sad and helpless at times, although she is making steady gains in feeding, dressing, and transferring. Previous leisure interests include playing basketball and driving her sports car.	Appreciate the context	"K.J.'s past lifestyle was active, and she valued mobility. I will bring up leisure adaptations when she is receptive. I will want to encourage gains in self-care activities and help her see how this success can transfer over into engaging in leisure pursuits. It will be important for me to listen to K.J.'s concerns and fears. I will provide examples of disabled athletes and information on wheelchair sports. Maybe I'll show a video of wheelchair athletes playing basketball."

Select an intervention approach		"I will address attitudinal barriers regarding belief in self by structuring successful activities of daily living (ADL) sessions. A visit with a wheelchair basketball player may motivate K.J. to work harder and feel better about the rehab process. I will find a car with hand controls because this may also facilitate interest in driving again."
		"I will strengthen K.J.'s upper extremities by having her engage in ADL tasks as well as using light weights and resistive bands. It makes sense to work on gross and fine motor coordination tasks. I will introduce adaptive equipment and sports chairs for wheelchair basketball and discuss driver training programs. I will remediate skills when possible (strength and coordination) and compensate when necessary (wheelchair for mobility and hand controls for driving)."
Reflect on competence		"I will address ADL tasks and equipment, but I may need to refer K.J. to a wheelchair specialist to prescribe a custom chair. Local wheelchair sports camp (offering basketball and other sports) is available in the summer. I will provide contact info and website addresses regarding sports chairs and the rules of wheelchair basketball. I will identify driver training programs in the area and refer her to a driving specialist."

Recommendations

I will involve K.J. in treatment by making tasks relevant and meaningful. K.J. has begun to realize that basic ADL skills are needed to be able to leave the house. Leisure activities of playing basketball and driving a sports car may motivate her to make the most of her time in therapy. I will provide information on wheelchair basketball rules and sports chairs or refer to the Internet for specifics. I will contact an athlete with a disability (preferably a wheelchair basketball player) to demonstrate that K.J. can still be active even though she has had a stroke. This athlete (former patient) may most likely have a modified car or van if he is a wheelchair user. Having someone with a disability who is also an athlete will serve as an excellent role model for K.J., who is unsure about her abilities.

Consider what will occur in therapy, how often, and for how long		"When K.J. can dress and groom independently (with or without devices), transfer safely from a variety of surfaces, and obtain and maneuver the wheelchair efficiently for 30 minutes, she will be able to physically begin playing basketball with a local group of wheelchair players who practice weekly at the community college. I believe that playing basketball will motivate K.J. to gain strength.
Ascertain the patient's endorsement of plan		My therapy sessions will consist of grooming and dressing with adaptive equipment, increasing upper extremity strength by one muscle grade, increasing tolerance to activity, and practicing transfers from all surfaces and planes. I will expose K.J. to driving equipment and sports chairs. I'll conduct daily therapy sessions for 30 minutes for 2–3 weeks. I want to arrange for a wheelchair basketball athlete to visit K.J. (who may also have car controls on a modified vehicle). Because K.J. is anxious to return to past activities, she is looking forward to meeting the wheelchair player and inspecting a car with hand controls. She is beginning to ask me for info on wheelchair basketball rules and specifics about team practices."
		"I want K.J. to understand the importance of doing daily self-care activities to be independent as well as use muscles on a continuous basis. She told me that she feels better about herself now that she can do more and depend less on others."

"I have seen K.J. improve dramatically; she has been less tearful and more motivated to try activities. The visit with the disabled athlete really helped in introducing her to life in a new but satisfying way. She established an easy rapport with him and shared some of her frustrations and fears. K.J. told her family that she is excited about playing basketball again even though she is in a wheelchair."

Summary of Short-Term Goals and Progress	Compare actual to expected performance	"K.J. has met and surpassed all my short-term goals. Although hesitant about using adaptive equipment, she has learned how to use devices well. I think that she will continue to work on perfecting her turning skills in a wheelchair (for tight turns in basketball practices). I have noticed that K.J. has had a brighter affect since the visit with the wheelchair athlete. I think she finally realizes that she can still engage in her prestroke preferred leisure activities. I know that K.J.'s motivation has made a big difference in her therapy outcomes. K.J. enjoyed her active lifestyle before her stroke and thought that it was all over for her after the LCVA. With encouragement and support from the wheelchair athlete and me, she was able to see that life would be slightly different but she could still engage in these favorite activities."
1. Dresses and grooms self independently and uses assistive devices for lower extremity dressing (long-handled shoe horn, sock aid, elastic shoelaces).	Know the person	
2. Upper extremity strength has improved by one grade (from 3/5 to 4/5 on Manual muscle testing).	Appreciate the context	
3. Transfers from a variety of surfaces and planes. Able to perform car transfers and is practicing placing wheelchair in back of driver's seat independently.		
4. Referred to a driving specialist. Appointment to be made when patient is ready.		
5. Wheelchair athlete visited facility and played a one-on-one makeshift game with patient.		

Next Steps	Anticipate present and future patient concerns	"I want to make sure K.J. understands how to manage paralysis as well as signs of stroke. I will review stroke risk factors and how to prevent stroke as well as review info on driver training programs."
1. Prepare patient for discharge by providing specifics on driver training programs (in case identified specialist is not available in the area), sports equipment, and stroke information.		
2. Make sure that patient has all equipment (self-care, customized wheelchair) or knows about what equipment would be most beneficial to obtain (e.g., basketball chair).	Analyze patient's comprehension	"I will ask K.J. to identify ways to minimize stroke. I will have her list strategies she will use at home to take care of daily tasks. Then I'll evaluate her competence in using assistive devices."
3. Encourage patient to contact therapist if any problems or questions arise.	Decide if the patient should continue or discontinue therapy and/ or return in the future	"When K.J. is able to take care of all self-care skills and can use her wheelchair effectively, she is ready for discharge. I will make sure that she has all the necessary resources so that she can obtain info or items if she has not been issued them already."

Clinical Reasoning in Occupational Therapy Practice

Promotion of Leisure Exploration

K.J.'s goal of playing wheelchair basketball after sustaining a stroke may take a while to achieve. What are some preparatory leisure activities she could do before engaging in this sport?

Summary Review Questions

1. How would you define leisure to a patient?
2. What are the benefits of engaging in quiet leisure? Active leisure? Socialization?
3. How might leisure goals be different for someone with a stroke? Spinal cord injury? Lower extremity amputation?
4. Describe specific ways that occupational therapists can integrate leisure into evaluation and treatment.
5. What kinds of barriers limit leisure introduction and exploration? How would you remove those barriers in your own practice?
6. Describe the ways in which leisure activities enhance health and wellness for all people, including individuals with disabilities.
7. Discuss the advantages and disadvantages of the various types of leisure assessments described in this chapter.
8. What leisure activities would you recommend for people with no lower extremity use? No use of one side of the body? Overall general weakness?

Glossary

Horticulture therapy—Gardening as a therapeutic intervention.

Leisure—Freely chosen activity that requires control and commitment. Active leisure involves mental and physical exertion (e.g., wheelchair sports), whereas quiet leisure involves activities, such as reading and crafts, that require less physical effort. Socialization entails contact with others via telecommunication, computer, and/or in person.

Occupational imbalance—Excessive time spent in one area, usually work, at the expense of another, usually leisure. May aggravate health and quality of life.

Recreation—Time that is not spent in work or self-care and may or may not result in observable activity; similar to free time.

Therapeutic recreation—Professional use of recreational activities as primary form of treatment with patients; sometimes called recreational therapy.

Therapeutic recreation specialist—Trained professional who uses recreational activities as a therapeutic intervention with patients.

Optimizing Personal and Social Adaptation

Jo M. Solet

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Integrate the psychosocial perspective in formulating a rehabilitation program.
2. Consider alternative practice models and value their application within the therapeutic relationship.
3. Place patients within life-cycle and family contexts and recognize the implications of this placement for occupations and life roles.
4. Understand the impact of history and course of disability on psychosocial adaptation.
5. Appreciate existential issues raised by illness, injury, and disability; describe ways individuals construct meaning from these experiences.
6. Be alert for psychiatric complications and recognize indications for referral.
Man's origin is dust and his end is dust. He spends his life earning bread. He is a clay vessel, easily broken, like withering grass, a fading flower, a passing shadow, a fugitive cloud, a fleeting breeze, a scattering dust, a vanishing dream.
(*Mazor for Rosh Hashanah and Yom Kippur: A Prayer Book for the Days of Awe,* 1972)

T he immediate change in physical functioning that an individual undergoes as a result of illness or injury is not alone a sufficient predictor of the capacity to benefit from treatment or of the future quality of life. Although the adaptation process may follow a general outline of stages, it is unique for each person and is influenced by the circumstances of onset and course, by age and place in the life cycle, and by the specific personality with characteristic ways of coping. This chapter begins by introducing practice models and treatment structures that address the psychosocial perspective and then guides the reader through life contexts, psychological, and social factors, which must be considered in individualizing occupational therapy (OT) treatment for physical disabilities.

PRACTICE MODELS

Each practice model uses its own theoretical framework to interpret clinical observations, guide treatment planning, and promote recovery. Many occupational therapists use components of more than one of these models; this can lead to rich, empathic, creative treatment, and fruitful participation with the treatment team.

Psychodynamic Model

The psychodynamic practice model, which had its origin in Freud's theories, emphasizes the relationship with the therapist as providing a safe, empathic, and consistent environment in which healing may take place (Rowe & MacIsaac, 1991). It considers patients' internal experiences; conscious and unconscious longings for wholeness, love, and protection; and conflicts about dependency and helplessness. Motivation is conceived as the critical element for successful rehabilitation. The psychodynamic model both values the symbolic nature of activities and mandates that they be selected for intrinsic meaning and relevance for the patient.

Cognitive-Behavioral Model

The cognitive-behavioral practice model focuses therapeutic efforts on the development of patterns of thinking and specific behaviors (Burns, 1990). Therapists who incorporate cognitive-behavioral treatment (CBT) become careful observers and recorders, examining patients' reactions to their experiences and the interactions among their ways of thinking and ways of behaving. These therapists reward successive graded goals shaping thoughts and behaviors that indicate successful adaptation. They point out patterns in client narratives that suggest helplessness or negative projections about the future, helping to substitute more positive thoughts and self-statements. Treatment programs reinforce adherence and good self-care, such as wearing a splint or taking medication, and work to extinguish damaging habits, such as smoking, and socially isolating behaviors, such as aggressive outbursts. CBT treatment components may be designed for individual or group work directed toward specific symptoms including pain, depression, or insomnia (Perlis et al., 2008). Skills for self-regulation, including assertive communication and practicing the relaxation response (RR), may also be components of cognitive-behavioral treatment (Benson & Proctor, 2010).

Relaxation Response

As a component of treatment, the RR bridges conceptual models and is frequently applied in CBT and the Wellness Model (below) (Hamilton, Kitzman, & Guyotte, 2006). The RR is a natural physiological state of deep rest that counteracts stress by lowering heart rate, blood pressure, respiratory rate, and muscle tension. Because the RR and meditative techniques are often sought by patients coping with medical and psychological problems, current evidence related to safety and efficacy continues to receive careful review (Arias et al., 2006; Ospina et al., 2007). Research supports the benefits including decreased emotional distress and improved autonomic and psychoimmune responses (Benson & Proctor, 2010; Kiecolt-Glaser et al., 2010); brain changes related to enhancement of learning and memory, and perspective taking (e.g., empathy, compassion, self-awareness) (Holzel et al., 2011); and even gene expression changes associated with positive physiological outcomes (Dusek et al., 2008).

The RR can be elicited by a number of techniques involving mental focusing through repetition of a word, sound, phrase, prayer, image, or physical activity in the context of passive disregard of ongoing thoughts (Benson, 1993). Techniques include progressive muscle relaxation (PMR), diaphragmatic breathing, and practices such as mindfulness, meditation, Tai Chi, and yoga. As a foundation structure of the RR, focus on the breath is a powerful and ancient tool with a history in various religious and spiritual traditions (see Procedures for Practice 30-1 for basic RR directions). Breathing is a process that is automatic yet also available to personal control and observation through which both physiological state and parallel state of mind may be altered. Nonevaluative attention to in-and-out breaths is undertaken to bring a present-centered mindfulness and compassionate nonattachment to the ebb and flow of inner life. When taught in therapeutic settings, these practices are directed at symptoms such as anxiety, pain, depression, and insomnia. Mindfulness can be practiced in sitting meditation as well as with any occupation: walking, eating, bathing, or stroking a pet.

Procedures for Practice 30-1

Directions for Use in Eliciting the Relaxation Response

- Pick a focus word, short phrase, or prayer that is firmly rooted in your belief system, such as "one," "peace," "The Lord is my shepherd," "Hail Mary, full of grace," or "shalom."
- Sit quietly in a comfortable position.
- Close your eyes.
- Relax your muscles, progressing from your feet to your calves, thighs, abdomen, shoulders, head, and neck.
- Breathe slowly and naturally, and as you do, say your focus word, sound, phrase, or prayer silently to yourself as you exhale.
- Assume a passive attitude. Don't worry about how well you're doing. When other thoughts come to mind, simply say to yourself, "Oh well," and gently return to your repetition.
- Continue for 10–20 minutes.
- Do not stand immediately. Continue sitting quietly for a minute or so, allowing other thoughts to return. Then open your eyes and sit for another minute before rising.
- Practice the technique once or twice daily. Good times to do so are before breakfast and before dinner.

With the development of a mindful focus, proponents believe that daily experience need not be held hostage to regret or fear of the future (Chodron, 1997). Through release from old habits of thought and feeling, mindfulness and other meditative practices are believed to generate novel and creative responses that support psychological resilience. Along with benefits, adverse effects from meditation practices, including psychosis, have also been documented (Arias et al., 2006). In taking patients' occupational history, the culturally aware therapist reviews current and past use of meditation and other spiritual practices, including prayer, yoga, Tai Chi, and Qi Gong. Occupational therapists interested in incorporating RR practices as part of their treatment model seek special training and supervision to adapt programs. For example, Stoller et al. (2012) adapted a yoga program through sensory enhancements to address combat stress in military personnel.

Wellness Model

Research over the past decade confirms that we function as integrated organisms, with changes in one bodily system felt throughout. Separation of the mind from the body is an academic exercise rather than a true reflection of the functioning of the human organism. Mainstream medicine now recognizes important relationships between immune functioning and psychological health first proposed in the early 1980s (Ader, 1981). Psychological states such as depression (Denollet, 1998) and anxiety (Kubzansky et al., 1998) are now routinely assessed as risk factors for heart disease, not just as reactions to it. In addition, the growing preventive perspective in health care has begun to define the behaviors and habits related to sleep (Chien et al., 2010), nutrition (Buning, 1999), and exercise (Ratey & Hagerman, 2009) that, through multiple interconnected channels, are likely to extend life and lead to greater physical and psychological well-being.

Health behaviors may be difficult to address, and psychological well-being may be difficult to achieve in the face of the stresses such as pain and limited mobility, compromised social integration, and altered sleep and appetite. The occupational therapist works with other members of the clinical team to ensure that treatment addresses a foundation of health-promoting behaviors to support maintenance of function and reserve capacity of organ systems in those with chronic disabling conditions.

Model of Human Occupation

Although the cognitive-behavioral and psychodynamic models are also applied by psychologists, social workers, and psychiatrists, the Model of Human Occupation (Kielhofner, 1992) evolved in the context of OT. This model focuses on engagement in the experience of living. The client is recognized as "an occupational being for whom access and participation in meaningful and productive activities is central to health and well-being" (American Occupational Therapy Association [AOTA], 2002, p. 613). Human activities are defined as multidimensional: physical, social, spiritual, and symbolic, and as embedded within each individual's specific psychological, and cultural contexts (AOTA, 2008). Evaluation in this model considers strengths and difficulties in occupational behaviors that are necessary to the fulfillment of life roles such as worker, parent, or friend. Treatment seeks to develop, remediate, or enhance performance and support occupational balance (Anaby, 2010). Success in occupational performance is inherently organizing to the personality and is importantly related to feelings of mastery, competence, group acceptance, and sense of identity (AOTA, 1995a, 1995b).

PRACTICE STRUCTURES

Practice structures associated with service delivery influence efforts to optimize patient personal and social adaptation. Occupational therapists work with patients individually and in groups. Group participation is often an adjunct to or follow-up for individual treatment.

Individual Treatment

Individual treatment is framed by the therapeutic relationship, the alliance between a patient and therapist, which begins during the evaluation period (see Chapter 14 for an in-depth discussion of therapeutic rapport). As the relationship develops, the occupational therapist learns not only about the physical capacities of the patient, such as strength and range of motion, but also about the type and degree of explanation the patient will find helpful during the course of treatment.

Patients who retain the capacity may wish to tell their story, describing to the occupational therapist how the illness or injury came to pass, their reactions to it, their losses, and their expectations of recovery. Listening attentively to patients' stories, even when their histories are available in some form in the medical record, develops trust and tells patients that they are unique and their feelings and experiences are valued. Listening also supplies important information about interaction and communication ability, mood states such as depression or anxiety, ways of coping, and family and cultural contexts. All of these are critical to formulating social and psychological goals as part of intervention planning.

Group Treatment

Group treatment supplies a practice environment for patients' social participation, a therapeutic envelope or safe holding environment that is broader than that of individual treatment. Groups have a developmental progression over time depending on the chosen activities and capacities of participants: from parallel activity, through brief interactions, to mature camaraderie and supportive cooperation (Donohue, Hanif, & Berns, 2011). Group treatment interrupts isolation and provides a context within which to identify and solve common problems. Groups may be organized to address goals related to specific disabilities, to promote mastery of skills, to practice leisure or creative activities, or to facilitate transitions. Multiple family groups may be organized to help members socialize and adapt to caregiving roles (Rodgers et al., 2007). Although the primary focus of any specific group may not be to address psychological or social needs, treatment components influence participants' total well-being and provide a shared space for creating dignity, responsibility, meaning, and pleasure (Ziegler, 1999).

As groups evolve beyond parallel participation into interaction among members, participants support and learn from each other and begin to value themselves more highly. A group can also serve as a magnifying glass in which difficult behavior can be brought under the observation of others. When supportive confrontation is used to address and modify this behavior, it improves an individual's opportunities outside the treatment setting. When group discussions deepen, they provide for disclosure of grief and fears, for voicing existential concerns, for organizing personal

Procedures for Practice 30-2

Planning Group Treatment

Choosing Goals for Group Participation

- Practicing social behaviors
- Following rules and recognizing group needs
- Identifying and solving common problems
- Learning specific skills and activities
- Accepting supportive confrontation and modifying behavior
- Disclosing feelings, existential concerns, and shared hopes
- Enhancing self-esteem through supporting others

Considerations for Choosing Group Members

- Cognitive and social capacities
- Readiness for broader interaction
- Congruence with other members
- Attention and memory
- Psychosis and dangerousness
- Communication ability
- Cultural background
- Energy limits

narratives, and for engendering shared hopes (Alonso & Swiller, 1993). Occupational therapists include these social and psychological goals in all group planning, treatment, and documentation (Procedures for Practice 30-2).

THE ADAPTATION PROCESS

Substantial individual variations in psychological and social adaptation to disability are related to many factors including the onset, course, and severity of the disability; the patient's age and place in the life cycle; and individual differences in personality, ways of coping, and attributing meaning to experience. In addition, access to quality care, accessible housing, barrier-free public transportation, and consistent social and community connection support occupational participation and the adaptation process (Crawford et al., 2008; Jenkins, 2011). Some illnesses and disabilities that limit occupational participation are "visible" to the layman and may affect the way individuals are treated in the social and vocational contexts. Other "invisible" disabilities require patients to make choices about disclosure and the need to seek special accommodations. As part of therapeutic support for adaptation, occupational therapists address patients' experiences in social and vocational arenas by engaging with them about disability disclosure issues related to employment barriers, adaptive technology, and housing (Griffin, 2011).

Stage Theories

Viewing adaptation to disability as a natural course of stages, such as denial, resistance, affirmation and integration or shock, denial, anger, depression, and acceptance (Miner, 1999), can be a useful way to conceptualize the psychological reorganization. In reality, these stages may flow together and even be reexperienced as new challenges arise (Dewar & Lee, 2000). Conflicts and unmet needs in love and work, unresolved before illness or injury, may assume greater proportions. Clinicians may unconsciously protect themselves from recognizing the realities of living with a disability by assuming that all patients are passing through a natural series of stages that will lead to a satisfying outcome. Adaptation to mild disability may be substantial by 3 years. However, even at 4 years, the process is likely to be less complete following severe disability, as measured by satisfaction with income, social life, and leisure activities (Powdthavee, 2009).

The four phases from acute injury through rehabilitation described by Morse and O'Brien (1995) constitute a template that may help therapists to recognize changing psychological states and anticipate the needs of their patients. The empirical study of traumatic injury and hospitalization upon which the stages are based demonstrates the special challenges of traumatic onset and offers illustrations of each stage using the language of patients' own recollections.

The first phase, "vigilance: becoming engulfed," encompasses the overwhelming physiological insult in which extraordinary cognitive efforts and heightened senses are recruited to preserve life. During this period immediately following traumatic injury, some patients in the study recalled detachment, a sense of being both observer and participant, as they began to direct the helpers who had arrived to care for them.

The second phase, "disruption: taking time out," begins when the individual relinquishes responsibility to caregivers or becomes unconscious. Patients remembered this part of their experience as a fog in which they were lost between nightmares and intolerable wakefulness. Patients in critical condition could not distinguish reality or focus beyond themselves. They were disoriented, heavily sedated, and not in control of their reactions. Patients at this stage sometimes perceived their caregivers as dangerous and the environment as hostile. Recognizing that during this stage many patients are afraid to be alone, the occupational therapist in the acute setting may facilitate the continuous presence of friends and family members, enlisting their help in orienting the patient.

The third phase, "enduring the self: confronting and regrouping," starts as the patient becomes more aware of his or her surroundings and begins to recognize the extent of the injuries. This is a time of focus on the present in which the conscious decision to carry on and rejoin the world must be made, even as growing awareness intensifies the psychological pain. Patients in the study described fear, panic over complete dependence, dread of painful treatments, and desperate efforts at control. During this stage, patients expressed shock at the loss of their former selves and began to anchor to staff and others for support and assistance. Some expressed an idealized view of their past selves as competent and attractive and their lives before the disablement as fully satisfying. Often, they believed full recovery would occur in weeks or months, even with severe spinal cord injuries; the smallest gains were very important.

This is a time when the sensitivity of caregivers is critical for supporting hope. The therapist avoids making predictions and promises about the expected degree of recovery, because these may later prove unattainable, compromising the therapeutic relationship and leaving the patient feeling cheated, angry, resentful, and depressed (Davidhizer, 1997). Although hopes are often initially focused on full recovery, such as "walking again" after spinal cord injury, over time with successful adaptation, hopes are likely to evolve toward the development of life quality and satisfaction (Dorset, 2010). An early intervention for certain patients during this stage is training in diaphragmatic breathing to induce the RR. As described earlier, breathing may provide the first avenue for perceived self-control.

The last stage, "striving to regain the self: merging the old and new reality," is the period of physical and psychological challenge in which active rehabilitation takes place. Goals include making sense of the experience, getting to know the altered body, and accepting the consequences, including the possibility of continued dependency. This is the stage during which patients may begin to revise and reformulate expectations. The OT treatment plan integrates these psychological demands and addresses them in concert with activities of daily living, strengthening, endurance, mobility, and prevocational training. As preparation for the social situations that may be encountered after discharge from the protective rehabilitation environment, treatment anticipates and addresses fears of inadequacy and of rejection by others (Gardner, 1999). Participation in group treatment, including role-playing specific situations, such as facing direct questions about the disability or about altered appearance, may be a component of this social preparation.

Onset and Course

The circumstances of onset and the course of the specific disability are important factors influencing the adaptation process.

Early Onset

When an individual is born with a disability such as spina bifida or has an injury in early childhood, the sense of self

develops continuously with the disability, typically within the framework of the family and often with the support of therapy mandated through school programs. The challenge for the individual born with a disability or disabled in early childhood is to grow into each life stage encountering new developmental expectations—physical, psychological, and social. A disability that does not have major effects in childhood may later become significant as cognitive, emotional, and behavioral demands change and expectations for independence increase (Simkins, 1999). A significant proportion of individuals with early disabilities later develop new medical, functional, and support needs as they reach their forties and fifties (Kemp, 2005). Through a series of interviews with adults disabled as children, King et al. (1993) identified three pathways—belonging, doing, and understanding—through which challenges were met at these life "turning points." Successful adaptation came through social support, described as feeling "believed in"; through determination and the conviction that challenges could be met; and through realization, by changing beliefs and expectations.

Degenerative Illness

When disability has a slow onset and course, as is the case with degenerative illnesses such as rheumatoid arthritis and multiple sclerosis, increasing disability is expected. Degenerative illnesses are not fully predictable; the course may be slow or rapid, complicating efforts to retain control over the life course. Each loss can feel like a reminder, a new insult. In multiple sclerosis, for example, there may be plateaus or even periods when symptoms remit but later recur (Hwang et al., 2011). Postpoliomyelitis syndrome occurs in a different pattern. Seventy percent of individuals who had a primary polio infection years before develop new symptoms, such as fatigue, pain, and atrophy, that require them to revisit struggles from their past (Thoren-Jonsson, 2001). Some with degenerative illnesses may stretch to the limits of their physical capacity in an effort to maintain occupations intrinsic to their life roles and to remain connected to valued peer groups. Ideally, as symptoms progress, processes of realization and reorganization bring with them adaptation and an acceptable compromise including altered patterns and balance of daily occupations (Jonsson, Moller, & Grimby, 1998). Maintenance of a hopeful attitude is more difficult when stabilization or improvement in quality of life cannot be anticipated (Dorset, 2010). The challenges of degenerative illness are to adjust self-concept, continually adapt to reorganized life roles, maintain internal resources, and evolve concrete supports in the face of impending decline (Boeije et al., 2002).

Traumatic Injury and Illness of Rapid Onset

Traumatic injuries, such as spinal cord injury, and disease processes with extremely rapid onset, such as Guillain-Barré syndrome, do not allow for psychological preparation (Ville et al., 2001). The dramatic nature of the onset may quickly exhaust the reserves of friends and family. Affected individuals may undergo not only an immediate change in ability to function but also a discontinuity in time and sense of self, a loss of personal identity, and a shift in confidence about the world as safe and just (Morse & O'Brien, 1995). The individual is also at risk for development of post-traumatic stress disorder (PTSD), characterized by hyperarousal and reexperience of the trauma known as flashbacks (Champagne, Koomar, & Olsen, 2010).

Late Effects of Traumatic Injury

Decisions made earlier in life can have serious consequences for later abilities. Evidence of the long-term effects of repetitive head trauma leading to chronic traumatic encephalopathy (CTE) has now been conclusively linked to participation in contact sports such as football, boxing, wrestling, and soccer (Stern et al., 2011). Efforts are underway to document the mechanisms and relate function to extent of the damage. This is needed to better inform policy for the protection of millions of school and professional athletes. Military personnel are also at risk from blast effects and from accumulated concussive injuries, with full consequences potentially manifesting years after service. Individuals at risk or already showing effects are challenged to reorganize their plans around uncertainty and the possibility of progressive decline. Cognitive, mood, and behavioral symptoms such as memory changes, depression, emotional instability, and poor impulse control may compromise coping strategies and undermine important supporting relationships (Stern et al., 2011). An added burden for some affected individuals is the recognition that their progressive disability may have been preventable. Attention to the neurodegenerative effects of repetitive head trauma is decades overdue.

Disability and the Life Cycle

The developmental tasks of each period of life are biologically, socially, and culturally determined and build upon those that have preceded them (Franz & White, 1985). Therefore, the point in a person's life at which he or she becomes disabled, together with the trajectory and severity of the disability, helps to determine what will be entailed in the long-term process of adaptation. The occupational therapist holds in mind the developmental demands of a patient's place in the life cycle and addresses ways in which these demands may be met even within the context of disability.

Adolescence

Currently, 90% of those born in the United States with a disability live to at least age 20 years (Schultz & Liptak, 1998). Along with the usual challenges of young adulthood,

Figure 30-1 Running partners. (Black and white photo by Paul Solet, Los Angeles, CA; see paulsolet.com.)

including transition from school to work and from parents and family to the broader community, those disabled at birth or in childhood must negotiate the change from child to adult health care. This can include losing long-term supportive relationships and taking increased responsibility for care coordination and decision making (Schultz & Liptak, 1998). When adolescents or young adults who have already acquired some independence from their parents become disabled, they may find being thrown back into childhood dependence especially painful. Psychological distress in adult rehabilitation inpatients has been reported to be greatest among these younger patients (Laatsch & Shahani, 1996).

The emphasis on peer acceptance, athletic ability, physical appearance, and emerging sexuality at this time of life puts the disabled young adult at special risk for rejection and social isolation; development of social competence is an especially important contributor to successful adaptation (King et al., 1993) (Fig. 30-1). In addition, as they reach the age that society presumes coincides with independence, young adults may no longer qualify for the instruction and therapy available through many public schools and mandated by law when they were younger. Research confirms the need for community-based transition services to support adolescents with disabilities in "building bridges" to the adult world (Stewart et al., 2001).

Adulthood

The developmental tasks of adulthood may include confirming career choice, finding a partner, and parenting children. When an adult at this point in the life cycle becomes disabled, plans and conceptions about the future, which may already have been the focus of substantial effort, require reorganizing. Adapting to disability occurring at this stage may require altering vocational course, finding different leisure activities,

redesigning an intimate partnership, and rebalancing parenting roles, just when some sense of competence and direction has been won (Rena, Moshe, & Abraham, 1996).

Midlife

A disability that strikes in midlife may find the individual at the peak of his or her career mastery and earning capacity, sometimes with adolescent children or aging parents as dependents. Although a history of successful coping with multiple life roles may already exist, this may be a difficult time to accommodate change and reorganize responsibilities (Quigly, 1995). Available resources may be limited, especially when the disabled person has been serving as the financial head of the household. Historically, disabled workers age 18–60 years have been shown to have substantially lower adjusted family incomes than others in the same age brackets and to be twice as likely to live in poverty (Social Security Administration, n.d.). A person disabled at midlife may feel prematurely aged, deprived of the anticipated leisure activity of healthy retirement and the hard-earned relief that follows discharge of career and parenting duties. In addition, marriage or intimate partnership may be at risk, because some nondisabled partners choose to avoid additional demands or find that the now-disabled partner seems no longer to be the same person they married.

Later Life

The rising wave of aging "baby boomers" will provide a special challenge to health care resources in the next decades. Disability in later life, even at a time when health decline may be anticipated, threatens the individual's ability to participate in the community in which he or she may have a long history and feel an important identification. Isolation is common. The elderly person may be realistically worried about losing his or her home or may already be institutionalized. He or she may be concerned about being a financial or care burden to an aging partner or to children who are stressed by their own responsibilities. Many caregivers of individuals older than 65 years are themselves older and in fair to poor health. Anticipated generative roles such as grandparent or mentor, with the opportunity to offer wisdom and nurturance, may be short-circuited. An elderly disabled person may already have lost his or her social cohort and main supporting relationships. Interests and leisure activities developed over a lifetime may have to be abandoned and efforts made to find other satisfactions (Hasselkus, 1991). Furthermore, the devaluation of the elderly in our society, commonly combined with limited financial resources, can compromise care and undermine motivation (Kemp, 1993). The experience of overwhelming loss without hope for the future can lead to despair. Just as when working with younger patients, the occupational therapist models a problem-solving mindset with realistic expectations, reconciling capacities

and marshalling patient strengths toward a sense of ful-fillment (Bontje et al., 2004). When remaining time before death is limited, some elderly people feel an urgent need to undertake a life review, drawing together the strands of meaning from their past. The occupational therapist recognizes the privilege of participating in this life-review process (Frank, 1996).

Individual Differences

Patients come to treatment with formed personalities and ways of interacting with the world that may or may not have been healthy or effective even before the injury or illness. Patients may regress during hospitalization when deprived of occupations, relationships, and areas of con-trol that supported their personal and cultural identities. Some must deal with lost bowel or bladder function or inability to walk, capacities that they developed as ba-bies. Others may have cognitive or memory changes that diminish their ability to make plans or follow directions. Those hospitalized for medical problems are known to suffer more psychiatric illness than their healthy peers, especially depression (Joseph, 2005). Some patients seem easy to treat; others are recalcitrant, uncooperative, or resistant. Some become increasingly demanding, ask for special treatment, break rules, and exhaust all efforts (Main, 1957). Some appeal to the therapist's wishes to res-cue them; others, in their failure to improve, stir feelings of disappointment, shame, and helplessness in the ther-apist (Groves, 1978; Kahana & Bibring, 1964). It is some comfort for the new occupational therapist to recognize that these feelings are all part of the normal experience of being a clinician. Collegial support and knowledgeable su-pervision can help with the treatment of difficult patients and the management of the therapist's own feelings.

Personality

Individual differences in personality, along with varia-tions in cultural context and personal history, contribute to the uniqueness of responses to illness and injury. It is often said about head injury: "It is not just the injury, but the head that matters." Serious stresses may intensify nor-mal fears, longings, and relationship demands. Ongoing pain, with the attendant loss of sleep and degraded sense of mastery, can further alter functioning. Psychiatric ill-ness and character problems can be exacerbated by threats to physical health and the integrity of the body (Zegans, 1991). The occupational therapist treats each individual as unique and addresses distinctions among an array of personality styles (Kahana & Bibring, 1964) and ways of coping (Solet, 1991).

Personality characteristics that have driven an individual's career choices and have helped define rela-tionships may be a mismatch for the requirements of

hospitalization. Patients who are orderly, punctual, and conscientious may find that perceived loss of control dis-torts their self-esteem. They may react by becoming de-manding, inflexible, and obstinate; if they become openly angry, they may feel ashamed (Kahana & Bibring, 1964). A clinical approach that is congenial, efficient, predict-able, and routine and that includes explanations and appropriate inclusion in decision making is most reas-suring for these individuals. The occupational therapist takes special care in pacing and grading challenges to provide for and recognize periods of control and success.

Patients who have a history of loss, helplessness, abuse, or abandonment may react to illness or injury with fears that no one will take care of them. They may make in-tense, urgent demands and seem overly dependent, angry if disappointed, occasionally impulsive, and insatiable in their need for reassurance. Some, feeling unlovable, may expect abandonment and may withdraw rather than cling (Kahana & Bibring, 1964). A successful clinical approach for these individuals includes readiness to give care and to show concern, along with setting limits that are consistent and not punitive. Good coordination between caregivers is especially important for these patients, who sometimes compare team members or complain about one team member to another.

Some individuals act guarded or suspicious when hospitalized (Kahana & Bibring, 1964). These charac-teristics may be an intensified part of their usual per-sonality but may also arise from the disorientation and lost sense of continuity that can accompany illness or injury. Neurological and sensory changes can make rela-tively ordinary events difficult for patients to interpret; a right-hemisphere lesion or even the loss of eyeglasses or a hearing aid may have important ramifications. The oc-cupational therapist is alert to the variety of conditions and diagnoses that may relate to such behavior. Wary, sus-picious patients may need continual orienting and often benefit from the reassurance and company of friends or family. The occupational therapist uses language patients can understand to acknowledge their worries, answer questions, and address complaints without arguing or re-inforcing false observations. Especially if suspiciousness evolves or becomes more elaborate, the occupational ther-apist seeks neurological or psychiatric consultation.

Patients may react to their helpless state by asserting their importance, being smug or grandiose, or demanding that only the most esteemed clinicians be involved in their care. When they are deprived of the surroundings, belong-ings, and roles from which they derive identity, dignity, and status, patients need confirmation that these things are recognized. The occupational therapist uses history taking as a time to begin offering this recognition and acknowledgment. Repeatedly feeling forced to confront their impairments can provoke some patients to make compensatory claims of superiority. The therapist resists

the urge to put these difficult patients in their place because such expressions of entitlement are often a sign of deep vulnerability (Groves, 1978). The occupational therapist is compassionate and points out areas of strength and strategies for ongoing effort (Keith, 1999).

Some patients seem to reject caregivers' efforts to reduce their suffering. They may appear self-sacrificing, have a history of bad luck, or even seem to revel in their misery (Kahana & Bibring, 1964). When patients do not seem to wish to recover, their symptoms may be serving a hidden purpose, such as penance or atonement (Solet, 1991). The occupational therapist may have to refer a patient who appears excessively guilt ridden for psychotherapy. Alternatively, illness or injury sometimes returns isolated or lonely people to a caring social environment from which they do not wish to be separated by recovery. Treatment planning should recognize needs for social stimulation and companionship. In collaboration with the patient, the occupational therapist organizes in advance for appropriate social contact after discharge.

Ways of Coping

Coping can be defined broadly as the cognitive, emotional, and behavioral efforts individuals make to manage external and internal challenges that tax their ordinary resources. Coping includes what people think, feel, and do in response to stress. Ways of coping can be understood as organized between three sets of poles: seeking versus withdrawing from social connections, seeking versus avoiding information and control, and expressing or repressing emotional reactions. Coping efforts contribute to health because they help define capacity for perceiving and reporting symptoms, for decision making, for complying with treatment demands, and for accepting comforting and support, all of which affect physiological processes and the sense of well-being (Stone & Porter, 1995).

Although individuals may have characteristic ways of coping that align with their personalities, the demands of any particular situation, including the length of time the challenge has lasted, are also important in determining ways of coping. For example, the period before surgery that provides the opportunity for active coping by seeking information and making decisions is very different from the postsurgical period, in which little control can be exercised and detachment or distraction may be most useful. In parallel fashion, coping with an acute health crisis may draw on different coping capacities from a patient and family than those required by an ongoing disability. As coping requirements change or awareness increases, the patient and family may reappraise their situation, recognizing new possibilities and drawing on additional resources.

In the clinical setting, ways of coping are assessed by self-report questionnaires, clinical observation checklists, and interviewing (Lazarus & Folkman, 1984; Solet, 1991).

As part of evaluation, the occupational therapist asks the patient and family members about prior challenges or crises and the coping efforts that were made. Treatment then draws on successful coping, such as securing arrangements for continued religious participation during hospitalization when this has proven to be an important source of strength in the past (Larson & Milano, 1995). Treatment may include active teaching to enlarge the patient's universe of coping alternatives. Examples include keeping a journal to encourage emotional expression (Pennebaker, 1995); participating in a specialized group to enhance social connection (Weber, 1993); gaining companionship, comfort, or direct help from a pet or companion animal assistant (Gal, 1999); practicing the RR to decrease perceived pain and anxiety (Benson & Proctor, 2010); and learning assertive communication to feel more confident about asking questions, identifying goals, and collaborating in treatment decisions. No particular way of coping is in itself good or bad; it must suit the individual in his or her specific circumstances. For example, coping by wishful thinking, denial, and withdrawal may serve important protective purposes early after an injury, when recognition of the extent of losses could overwhelm the individual. Because successful adaptation can involve cycles of approach and avoidance, occupational therapists are cautious about fracturing patients' protective ways of coping; they are aware of possible reactions including anxiety, shame, and resentment. An avoidant coping strategy when it lasts over an extended period can prevent full participation in treatment and limit needed emotional expression, knowledge acquisition, and social reintegration. Lasting avoidance, denial, or withdrawal may indicate overwhelming fears, guilt, or self-loathing or signal cognitive impairments and is cause for seeking psychiatric or neurological consultation.

THE SEARCH FOR MEANING

Occupational therapists are confronted daily with illness and injury. We grapple with ways to continually affirm our profession and to make sense of the suffering we witness (Peloquin, 2002). Our patients, facing these same questions of meaning, look to us not just for help in physical recovery but for our vision to guide them in interpreting their experiences. Their confrontation with the fragile nature of life may bring their deepest longings to the surface; they wish for vanished loved ones, protection, belonging, vigor, significance, and relief (Brendel et al., 2001).

Existential Questions

What is really important for a life to be worth living? What is it others will say about me when I die? What will my life say? Those are the kinds of questions my brain was filled with after the accident. It's no wonder I couldn't focus on details when the questions of life were asking to be answered. (Lowenstein, 1999)

Our patients ask us to recognize and acknowledge these questions and longings. They offer us the privilege of helping them to reclaim personal continuity and to create meaningful life narratives, which integrate their experiences of illness or injury (Charon, 2005, 2006). They challenge us to seek and reinforce their motivation to heal and to nurture their well-being at critical turning points and in the face of what for some will be lasting physical compromise (Pande & Tewari, 2011). They need us to join with them in celebrating the presence of interior life, personal connection, and the mystery of existence, despite ambiguity, painful loss, and the final certainty of death (Fig. 30-2).

Attributions

Meaning and belief systems are fundamentally woven into the human mind and society. The way we make sense of experience not only describes but actually affects our reality (Kleinman, 1988; Peloquin, 2002). Many people with an illness, injury, or traumatic life event eventually ask "Why me?" and try to make an attribution about or create an explanation for their experience. Clinical research has demonstrated the range and nature of these attributions (Solet, 1991) (Table 30-1).

Retribution

Some individuals see their illness or injury as a punishment, penance, or retribution. As children, we are taught that when we break rules, we will be punished; thus, it may be natural on some deep level to believe that

Figure 30-2 The self in danger. (Pen and ink by Margaret Rusciano Tolksdorf, Pelham, NY; see virtualeasel.com.)

Table 30-1 **Patient Attributions**

Type of Attribution	Description of Individual and Situation	Quotation Showing Explanation for Illness or Injury
Retribution	Salesman drinking and driving, now a paraplegic following an accident	"I don't believe God could be persuaded to forgive me for killing a child in the accident."
Faith	Computer expert, mother, hit by an electronic garage door when dropping off her car for repair	"I have learned to live one level higher. Life requires a leap of faith when you no longer understand or validate in the same way. The intuitive comes to the forefront; before it stood behind."
Personal responsibility	Poet, mother, rode as a passenger on an icy day in a car she knew to be in poor repair	"I never thought about what I was doing then, but because I'm responsible for my injury, I think about that choice all the time."
Victimization	College student, former swimming champ, attacked when skinny dipping by hoods offended by his exposure in front of their girlfriends	"I am afraid the possibilities for my future are diminished. It is so hard to see friends and younger sibs going through school, finishing, moving on with their lives. I am NOT an evil guy; what is this for? When this happened, I was sure I had died and gone to purgatory."
Acceptance	Biochemist hit by a bus crossing the street	"Is there any reason the owl eats the bunny and not the other way around? Injury and death are part of all nature. I am different now: I have lost my arrogance."
Chance	Engaged woman following an accident that disabled her and killed her fiancé	"People like to take credit for the good things and blame others for the bad things, but really, an awful lot happens by chance. The important thing is to be ready for the good things—and I am ready."

a painful event indicates badness or unworthiness deserving of punishment. In actuality, no realistic connection may be present between patients' behavior and their injuries, or they may be accurate in describing a connection, such as a history of drunk driving or unsafe sexual practices. In either case, attributions of retribution can render individuals immobilized by guilt and shame, unable to seek information or emotional support or to participate actively in their own recovery (Solet, 1991). They may require support to forgive themselves; some also need to focus on altering their dangerous behaviors. The opportunity to be heard and the reality of being accepted by the occupational therapist can help them begin to value themselves, feel worthy of treatment, and invest in the future.

Victimization

Again, either through a realistic analysis or based on deep feelings alone, some patients see themselves as victims. Especially when facts support the construction, such as after an assault, or serious medical error, where injury seems to have been personally directed or avoidable through reasonable diligence, the occupational therapist validates the attribution and acknowledges the loss of trust that follows from such an experience. The risk for patients who make attributions of victimization is that they may take on the role of victim more broadly as a lasting self-characterization. They may be unable, because of fear, anger, or sense of helplessness, to see the world as a safe place safe to rejoin. Some may react by withdrawing; others may misdirect their anger, potentially alienating caregivers. The occupational therapist helps by showing the realistic boundaries of these beliefs, by being a reliable and trustworthy caregiver, and by offering activities that help generate tolerance.

Chance

Chance or luck may sometimes be invoked by patients to explain illness or injury. Such an arbitrary universe as these patients perceive may be seen as dangerous and out of control, a form of impersonal victimization. Alternatively, an arbitrary universe may be benign and open to individual willingness to accept not just loss, but opportunity. The occupational therapist encourages patients who endorse chance to see hopeful possibilities.

Faith

Many patients demonstrate faith that their experience of illness or injury will, in the end, have meaning and purpose. These attributions based on faith need not exist only within the context of formal religion to engender optimism and encourage adaptation (Benson, 1995). Some hold a deep conviction that there is a plan for the universe in which good will ultimately prevail, a plan beyond ordinary human understanding (Rankin, 1985). Attributions of faith may be especially poignant for those who are isolated and have few

relationships because of their disability, allowing them to feel deeply valued beyond their difficult individual circumstances (Solet, 1991). Recent research points to the healing nature of deep self-disclosure such as may take place in prayer (Pennebaker, 1995). Occupational therapists are open to hearing about patients' spiritual lives and practices as elements of culture and daily life that can support healing.

Narratives and Metaphors

Patients want to tell their stories, and they need to be heard. The process of constructing and sharing a narrative of illness or injury organizes experience, shapes continuing perceptions, and breaks isolation. Through narrative, patients connect the present to the past, forming continuity in their lives and identities (Charon, 2005, 2006).

Increasingly, patients are turning to the Internet, especially to disease- or disability-specific sites to exchange narratives of their experiences and to offer support and treatment information. Analyses of some virtual communities has shown the information offered can be accurate and sophisticated, with patients helping each other and family members to become more aware of treatment possibilities and more ready to be active partners in decision making (Hoch & Ferguson, 2005). Occupational therapists may help patients identify virtual communities connected to reputable sources and may serve as translators and interpreters when relevant materials are complicated or raise questions about care and prognosis.

Occupational therapists use specific structures to collaborate with patients in interpreting their lives, including life charts, assisted autobiographies, and occupational storytelling (Frank, 1996). Through attentive listening, occupational therapists not only validate patients' experiences but also enhance their own clinical reasoning, tailoring empathic language and treatment activities to match patients' individual needs and motivations (Kautzman, 1992).

A common characteristic of these narratives is the use of certain metaphors that connect individuals' experiences to universal themes of culture and help to place their suffering in meaningful contexts. Hawkins (1993) described five metaphors that frequently serve as frames for interpreting illness or injury; each can be understood as coordinating with role expectations for the therapist and with specific risks for patient adaptation (Solet, 1991).

Rebirth

The metaphor of rebirth is a central religious and mythological theme. Through it, illness, injury, and the closeness of death are seen as transformative and regenerative (Hawkins, 1993). It is common for patients to reevaluate their lives around their illness or injury and to describe a profound altering of values and priorities. The old self dies, and a new and different self is born through suffering. The change brought about through this confrontation can be experienced like a religious conversion; wisdom and

spiritual renewal can become the gift and compensation for suffering. Part of the role of the occupational therapist is to bear witness to these changes. Sometimes the illness is equated with a life of sinfulness: drugs, unsafe sex, smoking, bad diet, and aggressive treatment of others. The patient may wish the therapist to grant absolution and confirm worthiness for care. The risk to patients using this metaphor is its association with passivity and attributions of deserved punishment, rendering them unable to mobilize for the rigors of treatment (Solet, 1991).

Battle

The metaphor of battle is very common and is the most congruent with the Western system of medical care (Hawkins, 1993). It is frequently used by clinicians and even politicians. We hear often of "the war on cancer" and "the war on drugs." In this metaphor, the patient becomes the hero doing battle with a monstrous foe; the therapist is the ally in "fighting disease." The illness or disease is seen as exogenous, from the outside, and a crusade is launched to attack it. This metaphor combines aggression with social optimism and dignifies the active, courageous stance known colloquially as "fighting spirit" (Walker, 1999). Although some patients may relate easily to this aggressive position; others, by personality or beliefs, find the metaphor disturbing. The battle metaphor of attack may not be fully suitable for some illnesses. Cancer cells are, in fact, not an external threat, like plague or tuberculosis, but parts of the self turned unruly (Mukherjee, 2010). Pain can also be difficult to conceptualize as an invading adversary with which to do battle, because it may be experienced as coming from within by the patient. In treating rheumatoid arthritis and other autoimmune diseases, the goal is quite the contrary: to help the patient's body to stop fighting itself.

Athlete

Somewhat related to the battle metaphor is that of the athlete. The patient deals with illness as a game or sport in which the central issues are courage, stamina, and endurance (Hawkins, 1993). The therapist is the coach; the patient is in training; new skills are learned through practice. This is particularly effective for individuals who have a history of sports participation or are sports fans. The risk to patients with this metaphor is in its implications regarding performance. There is an audience in sports; there are rules and standards that must be followed, and trespass may lead to shame, as if the game were lost. The requirement to be courageous and strong throughout the ordeal so as not to lose or disappoint may prevent real communion with others over the reality of suffering and the inevitability of death. It may be helpful to emphasize that patients, caregivers, and family are all part of the team.

Journey

Illness as journey is a common metaphor found in narratives in which the patient travels to the kingdom of the sick, returning with the gift of wisdom. Susan Sontag (1988), writing about cancer, described the disease as granting "a more onerous citizenship" (p. 3). Within this metaphor, the therapist serves as a guide, having accompanied others in this same land. The journey of illness or injury may be a rite of passage involving degradation, humiliation, and depersonalization (Hawkins, 1993). This metaphor fits especially well with the loss of vision or with traumatic brain injury and the period of rehabilitation. The individual leaves the world of ordinary sensations and consciousness and finds that expectations must be redefined; roles and relationships are changed, and activities that were once taken for granted must be relearned or abandoned.

One risk to patients with the journey metaphor is that it can lead to a perception of exile as injury, illness, and disability can be isolating, sometimes permanently. In a very real sense, withdrawal from society may result when the individual cannot cope because of alterations in appearance, personality, mastery, or ability to communicate. Lack of accessibility and actual physical barriers may prevent return to the community (Jenkins, 2011). Historically, exile has been forced when behavior or appearances ranged far from society's accepted norms or when the spread of infectious diseases threatened others, as with acquired immune deficiency syndrome (AIDS) or leprosy. Group participation with other "travelers" may help limit isolation.

Nature

In contrast to the four metaphors described earlier, the New Age metaphor places faith in the healing powers of nature, especially the efficacy of positive emotions. This metaphor may be construed as a reaction to aspects of modern medical care, which has been faulted for defining the patient as the passive focus of technology, subject to external treatment forces, rather than as a vessel filled with self-healing resources. The therapist's role here is as caring partner. The disease or injury may be described as presenting an opportunity to alter values or to recognize and integrate hidden powers of the self. The risk to patients is the sense of bafflement, failure, and shame they may feel if conscientious efforts are not rewarded with health. This construction emphasizes the requirement to be "positive." Individuals may construe normal feelings of grief, fear, or anger as hindering their own recovery. They may be unable to accept ownership of authentic feelings. This metaphor works best when the occupational therapist demonstrates belief in the goodness of the full spectrum of human feelings and in the whole cycle of nature, which includes not only spring but also winter.

Pathography

Occupational therapists may prepare themselves to respond with empathy to their patients' narratives by exploring published accounts of illness or injury known as pathographies (see Resources 30-1). Authors have many

motivations, including trying to find meaning in their own experiences, consolidating changed identities, breaking isolation, validating others, offering hope or counsel, exposing inhumane care, and giving specific information about treatment alternatives. Some pathographies are inspiring tales of recovery or of transcendence over pain or disability, even over imminent death. Some are offered by family members as a testimonial to a loved one or a journal of the shared ordeal; others aim to elevate natural healing capacities and transform our health care system. Numerous popular films also depict disabled characters, their struggles and ways of coping (see Resources 30-1). Such films, even when their stories are fictional, help us understand views of illness and disability in our culture. For some patients or their families, the occupational therapist selects readings or films as an educational component of treatment. For patients who are able, journaling, writing, or visual arts are therapeutic, support hope, and document improvement; this is one of the founding principles of our field.

THE HEALING CONTEXT

Although health care policy makers assume families will provide a healing context for their disabled members, very little formal structure is in place to support their efforts (Levine, 1999). As the population ages and advances in medical technology extend lives, the burden on family members continues to grow. Idealizing or romanticizing the position of disabled individuals and their families

avoids confronting the real deprivations many suffer and camouflages important ethical questions regarding responsibility for the allocation of societal resources (Saetersdal, 1997).

Family Caregiving

In the United States, 52 million unpaid informal caregivers provide care to individuals age 18 years and older who cannot perform necessary activities on their own; the overwhelming majority of these caregivers are family members (Coughlin, 2010; Institute of Medicine, 2008). Caring for a spouse continues to be the most commonly reported caregiving situation for those older than 75 years (Wagner & Takagi, 2010). The proportion of individuals older than 65 years in the United States is growing and will in 2030 be more than double what it was at the turn of this century. The level of stress on partners and family members suggests some carry a degree of responsibility that can damage their own health and well-being.

Loss of disabled persons' income often places families in financial jeopardy. Although government expenditures on health care for the disabled have risen rapidly, spending on education, training, and employment has been declining (Taylor, 2011). Analysis of census supplementary survey data showed that for men and women at least 55 years of age, the presence of long-lasting conditions that substantially limit one or more basic physical activity is inversely related to social class (Minkler, Fuller-Thompson, & Guralnik, 2006).

Family Reorganization and Identity

Families with a newly disabled member or one who is losing functional capacity through the common pattern of accelerated aging, experience grief and changes in routines, roles, and expectations, often compounded by expanded financial burdens (Lynch, Kaplan, & Shema, 1997). These additional stresses may exacerbate preexisting marital discord or substance abuse. Family reorganization requires learning and concrete problem solving, as well as transformation within the family unit, parallel to that of the disabled person. Partners and families struggle to forge new identities among themselves and for integration within their communities.

Engaging with Family Members

The occupational therapist, often working in concert with a nurse or social worker, may be the major preparatory interface with the formal health care system for a family planning to receive a disabled member at home. To initiate collaboration with the family, the occupational therapist assesses readiness and does not force premature instruction that could frighten, anger, or alienate the family (Levine, 1999). In all contacts with the family, the occupational therapist remains aware and respectful of the rights (see the discussion in Chapter 2 regarding the Health Insurance Portability and Accountability Act [HIPAA]) and wishes of the patient with regard to privacy and confidentiality (Procedures for Practice 30-3).

Important differences between what occupational therapists and family members value as treatment and support have been documented. Hasselkus (1991, 1994) found that occupational therapists focused treatment planning on disabled individuals' level of independence. Family members, however, were more likely to express concern that their returning member will be safely cared for with a sense of maintained identity. Ongoing life satisfaction and dignity, rather than level of self-care, are becoming recognized as the most valuable measures of rehabilitation success and may be most congruent with patient and family hopes and expectations (Dorset, 2010; Wadensten & Ahlstrom, 2009).

If the patient is to be discharged home, the occupational therapist ideally accompanies the patient on a predischarge visit to assess home safety, to plan for installation of assistive devices, and to organize the sleep environment. This is a good time to facilitate social participation by helping the patient (and family) become aware of community resources and barrier-free opportunities. Community connection is especially important to those living independently with a disability. The occupational therapist also offers information to the patient and family related to specific support and advocacy groups through which they may share problem solving, feel a sense of camaraderie, and be empowered if they choose to work to improve the system for themselves and others.

Procedures for Practice 30-3

Engaging with Family Members

Goals of Interaction with Patients' Families

- Seeking information about family medical and social history
- Offering specific information about disability and treatment
- Collaborating and fostering inclusion in decision making
- Validating feelings
- Acknowledging experiences
- Fostering hope and successful coping
- Guiding reconnection with patient
- Instructing in issues of patient care and safety, including home visits and use of assistive devices
- Facilitating use of community resources, including barrier-free opportunities and support groups

Considering the Family Context

Try to answer the following questions when assessing a patient's family context:

- Where is the patient in the life cycle, and what have been the patient's roles and responsibilities?
- How have the roles, responsibilities, and expectations of family members now been altered?
- Is there lost income and/or added medical and caregiving expense?
- What family problems may be exacerbated by this crisis?
- How has the family coped with crises in the past?
- How will the likely course of the disability affect the family?
- How is the family making sense of the experience? Do they have a specific cultural perspective or religious beliefs?
- To what communities do they belong that may be a source of help or strength?
- Do they need referral for family counseling?

Some patients are discharged to separate quarters or to institutional settings. Discharge of a family member to a long-term care facility can involve wrenching decisions, especially in families in which traditional culture and values include loyalty and strong bonds among members (Banks, 2003). This is true even when it seems clear to the clinical community that taking the individual home would seriously overtake the resources of the family. The occupational therapist acknowledges these feelings and helps organize ways to maintain family relationships when the disabled member will not be returning home.

In certain cases, family stress may be extreme, communication difficult, and reactions overwhelming. Family

members may disagree over what care is appropriate for individuals who are not legally competent to make decisions about their own care. In nontraditional family constructions and partnerships, additional stresses may result from lack of legal recognition of couple and parenting commitments with the associated rights to direct and oversee care and to qualify for certain health insurance coverage. In the United States, many states grant marriage licenses to same-sex couples; same-sex marriage is legally recognized throughout Canada. The occupational therapist makes sure to be aware of whom the patient considers "family."

Although most people fail to prepare legally for sudden illness or disability, when decline can be anticipated, as with degenerative illness, individual wishes about palliative care can be discussed, powers of attorney can be organized, and health care proxies completed. When an illness has been shown to have possible genetic links, additional questions arise, including whether other family members should undertake testing and what the implications might be for pregnancy. Specially trained genetic counselors can clarify the ethics and science, supporting informed decision making (Patenaude, 2005). The occupational therapist is alert to the possible necessity of specialized referrals.

Procedures for Practice 30-4

Addressing Substance Abuse

- Take an occupational history. Was the patient functioning in work or school? Was the patient maintaining relationships?
- Are any family members likely to be helpful in describing the patient's history?
- Is there any evidence that substance abuse was a primary cause of the condition?
- Might the condition have provoked substance abuse?
- Are there predisposing factors such as depression, trauma, family history, or membership in a marginalized group?
- Does evidence support need for referral?

Treatment Goals for Substance Abuse

- Improve health habits and self-care
- Develop skills in self-regulation and impulse control
- Experience group participation, learn to communicate needs, learn to give and receive support
- Prepare for constructive vocational role
- Value a clean and sober identity
- Connect with community resources such as Alcoholics Anonymous to maintain sobriety

Partnership and Sexuality

The unique role of occupational therapists in addressing both activity and meaning places them in an ideal position to include sexual well-being among treatment goals. Sexual well-being correlates with adjustment and satisfaction in other areas of life and is an important component of the partnership bond (Woods, 1984). As one of the activities of daily living, sexual activity merits an accepting, problem-solving focus.

To acknowledge and accept the sexual identity of their patients, occupational therapists become aware of their own beliefs and values and suspend judgment when these values differ from those of their patients. Even when the primary sexual counseling is done by another team member, occupational therapists are prepared to recognize intimate needs within different stages of the life cycle and sexual orientation and to initiate discussion of sexual activity, including birth control and safe practices, while maintaining clinically appropriate boundaries. Embarrassment or a sense of undesirability may prevent patients from raising sexual concerns themselves. The occupational therapist acquires sufficient medical and psychological background to anticipate patients' needs and questions. Desire, sexual responsiveness, sensory channels, and mobility may be altered by disability (Basson, 1998; Hulter & Lundberg, 1995). The occupational therapist explicitly helps the disabled person by encouraging him or her to reconceptualize sexuality and sexual activity more broadly and to explore new possibilities for sexual expression. When the disabled individual has a consistent sexual partner, the therapist may offer the opportunity to include him or her in teaching or treatment sessions. A satisfying sexual relationship is learned; it is based on more than simple instinct or appetite and does not have to be unplanned or spontaneous to be fulfilling (Woods, 1984). The disabled person and his or her sexual partner may learn to adapt to periods of fatigue, continence timing, or requirements for special positioning.

Fears may contribute to the disabled person's hesitancy about sexual activity. Fear of rejection may be based on altered appearance or on perceptions of the social acceptance of the needs and desires of disabled people. Patients with certain diagnoses may have been warned about the danger of overexertion and may harbor fears about heart attacks or strokes. Some patients fear being injured by sexual activity or anticipate increases in their pain. Here a physician knowledgeable in sexual medicine can be a critical resource. Informed and sensitive medical management, sometimes including medications, can help disabled individuals claim their sexual selves.

In some settings, disabled individuals are vulnerable to sexual exploitation or abuse, especially when cognitive

or verbal limitations prevent them from reporting their experiences or serving as reliable witnesses in a court of law. Occupational therapists who work with such patients are aware and alert to these possibilities and meet legal and ethical requirements for reporting concerns.

COMPLICATING FACTORS

Disruption and reintegration are natural to the life course; the capacity to adapt to disruption with new integration is described as resilience (Flach, 2004). The occupational therapist recognizes that positive change and reorganization may also be part of the portrait of illness and disability (Schroevers, Kraaij, & Garnefski, 2011). However, a trajectory of resilient adaptation can be compromised, especially when multiple serious stressors come together or when loss is a result of victimization (Quale & Schanke, 2010). Substance abuse, pain, depression, PTSD, and disrupted sleep are among complications of illness and injury that hinder adaptation and mandate specific treatment.

Substance Abuse

Social isolation, losses producing painful feeling states, and traumatic experiences related to injury confer special vulnerability putting disabled individuals at higher than normal risk for substance abuse (Moore & Li, 1994). Alcohol and drug use have been implicated not just as reactions to but also as causative agents in disability, most notably in relation to auto accidents. Evidence points to alcohol playing a role in a significant number of spinal cord injuries (Heinemann, Mamott, & Schnoll, 1990). Beyond health complications such as malnutrition and liver disease, which may affect all abusers, disabled abusers may be at increased risk for adverse drug interactions, falls caused by balance or mobility impairments, and sores and gastrointestinal bleeding that can go undetected because of sensory losses (Yarkony, 1993).

In studying users' history of drug choice, Khantzian (1990), who posited a self-medication theory of substance abuse, found that individuals experiment with various classes of drugs and settle on those that offer a specific needed relief. For example, individuals used stimulants to relieve depression and hyperactivity, opioids to mute psychologically disorganizing feelings such as rage and aggression, and alcohol to break emotional constriction and allow for release or social connection. Primary causes for substance abuse, he concluded, are difficulties in managing feelings, low self-esteem, lack of supporting relationships, and poor self-care, which are particularly common among individuals with abusive or traumatic histories or living in under-resourced circumstances. Use of drugs and alcohol is associated with depression and anxiety after traumatic head injury (Anson

& Ponsford, 2006). Meyer (1999) studied not only the neurobiology of addiction but its sociology as well. He concluded that for some individuals, drug use becomes a main source of activity and occupation, especially when no compelling or achievable alternative future can be perceived or undertaken. As members of the treatment team, occupational therapists are alert to the possibility of substance abuse (see discussion in Chapter 3), prepared to make appropriate referrals, and able to participate in humane, respectful care (Procedures for Practice 30-4). Well-designed substance abuse treatment addresses appropriate stages of recovery; is sensitive to ethnic, cultural, and linguistic differences; and is responsive to patients' particular needs (Cambridge Health Alliance, 1995). Community-based 12-step programs such as Alcoholics Anonymous offer a philosophy for living a fulfilling life and provide an opportunity not only to receive sponsorship support but to provide service to others as well. Suggested treatment goals for substance abuse are listed in Procedures for Practice 30-2.

Pain

Although not a diagnosis in itself, pain accompanies many illnesses, injuries, and disabilities including spinal cord injury, acquired amputation, cerebral palsy, multiple sclerosis, postpolio syndrome, and many developmental disabilities (Ehde et al., 2003; Engel, 2011). The experience of pain is directly related to well-being and is an impediment to resilience. More than a simple sensation, pain is a perception that emerges at the intersection of body, mind, and culture. Pain is an ineffable private experience that each individual must learn to interpret, but it is also a universal phenomenon with broad influence on society at large, in terms of lost workdays and use of health care resources. According to a 2011 Institute of Medicine report, 116 million Americans suffer from chronic pain, with many partially or fully disabled; arthritis, headaches, and back pain are among the largest contributors.

The Personal Experience of Pain

The daily reality of the individual in pain often includes sleeping difficulties, problems concentrating, and decreased mobility, all of which may limit occupational performance. Altered moods, especially agitation or lethargy with depression, are common among those who experience pain over an extended period, especially after multiple treatments without relief. Grief over lost mastery and diminished life roles with feelings of rage, helplessness, victimization, and defectiveness can lead to social withdrawal. Prompt and preemptive treatment of pain is a strong priority, ideally before roles, relationships, and even identity become irretrievably eroded (Harris, Morley, & Barton, 2003).

Pain Treatment

A full pain treatment program includes educational, physical, psychological, and pharmacological components and is administered through a team of clinicians that includes an occupational therapist (Robinson, Kennedy, & Harmon, 2011). Group and individual treatments are often combined. Education that presents a mind–body pain model gives recognition to both the stress and distress that accompany pain, breaks down the mysteries of the pain experience, and supports the efficacy of several avenues of treatment (Caudill, 1995; Solet, 1995). Recognition and validation are crucial elements because patients with pain may feel that no one understands the extent of their suffering (Main & Spanswick, 1991).

The mind–body model encourages patients to view their pain not as a simple response to tissue damage but as a complex experience that can be affected by many factors, such as positioning for activities, sufficient sleep, and emotional reactions (Jenkins, 2011). Diary keeping (self-monitoring) provides information about which specific factors affect an individual's pain experience; this is vital for collaboration in treatment planning. Diary keeping also documents evidence of improvement, which bolsters motivation and supports treatment adherence.

The various components of a pain treatment program can include instruction in pacing and body mechanics, stretching, strengthening, low-impact aerobic exercise, massage, acupuncture, as well as RR training, biofeedback, CBT affect management (control of emotional reactions), and practice in assertive communication (Rochman & Kennedy-Spain, 2007). Each of these treatment components properly chosen and applied may help patients manage their pain, even when complete relief is out of reach (Persson, Andersson, & Eklund, 2011).

Depression

Theoretical debate and research over the etiology of depression continues, with exploration including reactions to loss, neurobiological mechanisms, and genetic predispositions. These explanations need not be mutually exclusive because the brain is the substrate for interpretation of personal experience. Clinicians sometimes mistakenly assume that depression is simply a stage or normal reaction to a disabling illness or injury and that it will remit if left untreated. With periods of hospitalization so short in the current health-care environment, those with lasting depression are in danger of being lost to follow-up.

Among medically ill older adults, major depression is experienced by an estimated 20%, and minor depression is experienced by an additional 20%–30% (Koenig & George, 1998). Personal or family histories of depression constitute special risk factors following the onset of illness or injury. In some cases, depression is part of a larger picture that includes swings in energy level and emotions, called bipolar disorder or manic depression. Depression, whatever the cause or pattern, can undermine all areas of functioning and, when severe, is life-threatening. The presence of depression mandates referral for assessment, including for risk of suicide. As many as 15% of those who suffer from depression or bipolar disorder commit suicide each year. Suicide is the ninth leading cause of death in the United States (Nemeroff, 1998).

Diagnosis and Treatment of Depression

Coping styles characterized by avoidance, wishful thinking, self-blame, and use of drugs and alcohol are associated with higher levels of depression, anxiety, and poorer psychosocial functioning (Anson & Ponsford, 2006). Patients whose motivation to participate in treatment is sapped by significant or unrelenting depression not only lose a critical opportunity to reorganize life skills and identity in a protected setting but also fare poorly if depression remains untreated after discharge. Depression is a confirmed risk factor for future heart disease (Denollet, 1998) and increases the risk of dying after a heart attack or stroke (Nemeroff, 1998).

Making a diagnosis of depression in cases of ill, injured, or disabled patients can be complicated; symptoms customarily associated with depression, such as sleep or appetite changes, can be directly related to the primary conditions for which some disabled patients are seeking care. In addition, brain damage also alters neurobiology.

Because occupational therapists often have a close and continuous relationship with their patients, careful observation and documentation of behaviors, feelings, and ways of thinking contribute important information to diagnosis. The occupational therapist looks not only for somatic or bodily symptoms but also for cognitive and emotional signs of depression. These include indecisiveness, inability to concentrate, diminished interest or loss of pleasure in formerly enjoyable activities, feelings of worthlessness or excessive guilt, and recurrent thoughts of death or suicide (Nemeroff, 1998).

Patients with bipolar disorder commonly receive diagnostic attention during a depressive phase; the full scope of their illness is at first not always clear. Because the implications for treatment are different, especially for medications, it is important when considering depression also to look for any personal or family history of mania. Symptoms include very high energy, sleeplessness, pressured speech, grandiose thinking, unbridled spending, and even delusions (Ghaemi & Sachs, 1999). Patients' lack of insight into and inability to report their own psychological state during manic periods is the rule.

The occupational therapist documents concerns about depression or mania in the medical record, including supporting observations, and brings this information

Indications for Psychiatric Referral

- Inability or unwillingness to comply with treatment
- Substance abuse
- Uncontrolled pain
- Traumatic flashbacks or dissociation
- Depression with suicidal tendency
- Mania
- Hostility, agitation
- Paranoia, unwarranted fears
- Hearing voices, delusions
- Social isolation or withdrawal
- Extended denial
- Unresolved religious or existential crisis
- Overwhelming guilt
- Family upheaval

to the attention of the treating physician or team to facilitate referral for psychiatric evaluation (Safety Note 30-1). Assessment for antidepressant and/or mood-stabilizing medications and psychotherapy is a high priority. Components of OT treatment for depression include restoring self-care and appetites, improving feelings of mastery through meaningful goal-directed activities, reframing self-defeating cognitions, and encouraging social integration.

Post-Traumatic Stress Disorder

Individuals injured or disabled through war, natural disaster, accident, abuse, or violent crime are at special risk for the symptom complex called post-traumatic stress disorder. Symptoms can include hyperarousal (vigilance), nervousness, fearfulness, nightmares, flashbacks (spontaneous reexperiencing), ruminations, emotional numbing, and mental absence or dissociation (Champagne, Koomar, & Olsen, 2010). For some patients, the resulting disability may constitute life-long physical evidence of the traumatic experience, even serving as a proprioceptive cue or trigger for PTSD symptoms and continuing stress reactions.

Individuals showing symptoms of PTSD require immediate referral to be evaluated for specialized psychotherapy and possible medication. Coordination between caregivers is critical to a positive outcome for these patients, who need a safe, predictable environment in which they can make sense of their experiences. Occupational therapists help individuals with PTSD to organize daily life structure and to enhance their ability to feel safe while participating in meaningful roles and activities (Champagne, Koomar, & Olsen, 2010). Listening to their

narratives can be disturbing, so strong team support and supervision become important for all involved caregivers, including occupational therapists.

Limited Sleep

The ordeal of injury or illness can be exhausting in itself, fraught with layers of uncertainty and challenges to managing care in our often-difficult health-care system. Beyond this, patients may be not be getting sufficient quality sleep. There are multiple routes through which sleep affects adaptation and the ability to benefit from treatment. Deficient sleep affects attention, memory consolidation, and even tolerance of frustration. Because occupational therapists typically meet with patients several times a week and have the opportunity to evaluate sleep environments, they are in a good position to screen for sleep problems.

A complex, dynamic state, critical to growth and development, sleep changes through the life cycle, typically becoming shorter and lighter with aging (Ohayon & Vecchierini, 2005). The Occupational Therapy Practice Framework (AOTA, 2008) recognizes sleep as an occupation. Along with nutrition, exercise, and social connection, sleep is one of the pillars of health and well-being.

Two processes interact to determine our drive for sleep: the homeostatic drive increases with accumulated time awake, and the circadian biological clock organizes a physiological cycle of body temperature and hormone release, regulating the variability of sleepiness and wakefulness throughout the night and day. Sleep is characterized by patterns of changing brain waves that present in cycles of about 90 minutes each, throughout the night. Within these cycles, different stages of sleep are identified by the frequency and amplitude of the brain waves. The stages of sleep fall into two categories, non-rapid eye movement (NREM or non-REM) sleep, which indicates progressively deeper stages and predominates in the earlier cycles of the night in adults, and rapid eye movement (REM) sleep, in which most dreaming occurs and which predominates closer to morning (Kryger, Roth, & Dement, 2011). Clinical research in sleep medicine includes exploration of the roles of NREM and REM sleep stages in contributing to specific functions, including emotional regulation, cognition, learning, and memory consolidation.

Even healthy adults, when deprived of sleep, will show deterioration in performance (Cohen et al., 2010). Adequate sleep is necessary for restoration of mind and body and for successful occupational balance (Anaby, 2010). Disordered sleep is a major public health concern affecting both genders, all races, and all socioeconomic levels (Hale, 2005). Research and clinical evidence confirm the impact of lack of sleep on safety, learning and memory, cognitive performance (Durmer & Dinges, 2005; Poe, Walsh, & Bjorness, 2010), and even immune function (Irwin et al., 2008).

Insufficient sleep is negatively associated with psychological well-being: lowered mood, irritability, aggressiveness, and psychosocial difficulties (Haack & Mullington, 2005). The range of health effects that may result from insufficient or disordered sleep includes elevated stress hormones and inflammatory markers, impaired glucose tolerance, diabetes (Zizi et al., 2011), obesity (Flier & Elmquist, 2004; Patel & Hu, 2008), hypertension (O'Connor, Caffo, & Newman, 2009; Redline, 2009), and cardiovascular disease and stroke (Buxton et al., 2012). However, assessment of sleep is still not routine in primary care (Sorscher, 2008). Insufficient or disordered sleep may be implicated as a causal factor or resulting complications for many patients treated by occupational therapists (Stroe et al., 2010; Zee & Turek, 2006).

In addition, pain, depression, substance abuse, and PTSD may have negative reciprocal interactions with sleep; they disturb sleep, and then disturbed sleep can make them worse. Conditions that may compromise sleep include acute and chronic pain (Hamilton, Karlson, & Catley, 2007; Roehrs et al., 2006), head injury (Parcell et al., 2008), spinal cord injury (Epstein & Brown, 2010), Parkinson's disease (Sixel-Doring et al., 2011), multiple sclerosis (Braley & Chervin, 2010), stroke (Coelho et al., 2010; Johnson & Johnson, 2010; Watson, 2010), rheumatoid arthritis (Luyster et al., 2011), chronic fatigue syndrome (Burton et al., 2010), Alzheimer's disease (Hwang et al., 2011), and heart disease (Chandola et al., 2010), as well as disorders of breathing, anxiety disorders including PTSD, and major mental illness.

Because excessive sleepiness has been repeatedly implicated in auto, truck, and major industrial accidents (Drake et al., 2010), when injury is known to be accident related, a red flag for sleep screening should be raised. No prior sleep assessment is currently required federally or shared by individual states to secure a commercial driver's license.

Assessing Sleep

Questionnaires and self-reports can be useful for screening or initial assessment of some patients. However, some sleep problems, even when severe, can be outside patient awareness; some patients may report unexplained excessive daytime sleepiness. Especially when greater than expected impairments in occupational and social functioning are seen during evaluations, sleep problems may be implicated. Although diagnosis of deficient sleep is outside the professional expertise of occupational therapists, they may provide initial screening through questionnaires such as the Epworth Sleepiness Scale (Johns, 1991) and may document partner or family reports leading to referral. Full sleep assessment includes a polysomnogram, composed of electroencephalogram, electrooculogram for eye motion, and electromyogram for muscle activity. The "sleep study" is used to differentiate the stages of sleep; to indicate time to fall asleep, called "sleep latency"; proportion of time in bed actually spent sleeping, called "sleep efficiency"; and to indicate how often arousals from sleep occur and for how long (Kryger, Roth, & Dement, 2011).

Sleep Disorders and Treatments

Although sleep difficulties are secondary to many illnesses and injuries, they may also occur as primary disorders. A summary of some common barriers to sleep with related OT treatment contributions follows.

Sleep Environments. Hospitals and long-term care facilities too often fail to provide adequate sleep environments (Buxton et al., 2012); hospital noise levels have been rising for decades (Busch-Vishniac, 2005), compromising healing and adaptation. Night noise is among the most common complaints on patient quality-of-care surveys. Critical care units are particularly difficult for patient sleep, in part because of monitor alarms, a large proportion of which may not be clinically relevant (Solet & Barach, 2012). Multistep programs have been designed and tested to improve night noise and light exposure, timing of medications, and night care routines. The Somerville Protocol is an evidence-based night care program that can be implemented by staff to improve quality of care and better preserve patient sleep (Bartick et al., 2010).

Sleep Hygiene. Sleep hygiene is characterized as a sleep-friendly environment together with specific behaviors. For patients who will be discharged home, the home visit checklist should include examination of sleep quarters that should be rendered *quiet*, *dark*, *cool*, *comfortable*, *clean*, and *safe*. Because light counteracts the hormone melatonin that initiates sleep, "black-out" window shades or eye masks can be used to block ambient light. Light sources within the room such as bright digital clocks should be dimmed or removed, and lighted screens on TVs and computers should ideally be kept out of bedrooms or at least shut down at night. Because body temperature drops as part of initiating sleep, a cool bedroom (mid to high 60s) should be maintained as most conducive to sleep. Cords, equipment, and obstructing furniture should be removed to prevent falls during night awakenings. Commitments from partners, roommates, or family members should be solicited to ensure sufficient nighttime quiet, to keep pets under control, and to facilitate a consistent sleep schedule. For those with very limited resources, availability of a safe place for sleep should be understood as an occupational justice issue, because it is a determinant of health (Blakeney & Marshall, 2009).

Along with a sleep-friendly environment, specific behaviors support health. These include exposure to sunlight, especially in the morning, to increase alertness and reinforce normal circadian rhythms; sufficient time in bed; and a relatively consistent natural sleep-wake schedule.

Definition 30-1

Sleep Disorders

Insomnia refers to repeated difficulty with sleep initiation, duration, consolidation, or quality that occurs despite adequate time and opportunity for sleep, resulting in some form of daytime impairment. Insomnia with short sleep duration is associated with increased mortality (Vgontzas et al., 2010). Occupational therapy interventions include: relaxation response, cognitive behavioral therapy (especially addressing sleep-related anxieties) (Haynes, 2009), exercise (Passos et al., 2010), modifying sleep environments, and limiting caffeine and alcohol (Roehrs & Roth, 2011).

Obstructive sleep apnea (OSA) is caused by partial or complete blockage of airway passages during sleep. Snoring is a common sign. Repeated awakenings, typically not remembered, driven by decreased oxygen saturation affecting the brain, occur dozens or even hundreds of times a night. These can lead to excessive daytime sleepiness and cognitive impairments, as well as diabetes, cardiovascular disease, stroke, and even increased cancer risk. Treatments include continuous positive airway pressure (CPAP), a system that pushes air through the nose via a face mask (Tomfour et al., 2011), sleep positioning to side-lying, dental devices, corrective surgery (Verse & Hormann, 2011), and weight loss (Vasquez et al., 2008). The occupational therapist may be enlisted to help with treatment adherence and weight loss programs.

REM Sleep Behavior Disorder (RBD) results when the normal muscle paralysis or atonia that occurs during rapid eye movement (REM) sleep fails, and the affected individual moves as if acting out a dream. Most common in men older than 50 years, there is research documentation that RBD may be a precursor to dementias or Parkinson's disease (Sixel-Doring et al., 2011).

Restless Leg Syndrome (RLS) is a sleep disorder in which there is an urge to move the legs in order to stop unpleasant leg sensations that may be described as "crawling" or "tingling" especially during the evening. During sleep, involuntary leg movements occur and can lead to repeated arousals that are not remembered (Bayard, Avonda, & Wadzinski, 2008; Kushida, 2007). Risk factors include peripheral neuropathy, chronic kidney disease, iron deficiency, Parkinson's disease, and medication side effects. There is also higher prevalence among clients with a history of stroke (Coelho et al., 2010) and fibromyalgia (Viola-Saltzman et al., 2010). The occupational therapist may provide recommendations for exercise, stretching, massage, and warm baths to bring symptomatic relief.

The occupational therapist addresses issues of inconsistent or limited sleep time as a result of poor lifestyle choices, management of multiple roles and responsibilities, or difficult shift-work requirements. Better choices, prophylactic napping, limitations on alcohol and caffeine, and contracts with family members with regard to sleep needs and timing are options for improving sleep hygiene. Many patients will be cared for at home by family members; education for caregivers about their own sleep needs and optimal sleep environments can be valuable. When well rested, caregivers are more able to offer attentive and compassionate care.

case example

Mr. D.: Adaptation after Stroke

I felt a cleaving in my mind
As if my brain had split;
I tried to match it, seam by seam,
But could not make them fit.

The thought behind I strove to join
Unto the thought before,
But sequence ravelled out of reach
Like balls upon a floor.

Emily Dickinson (1830–1886)

This case study follows the structure introduced in this chapter for integrating psychosocial components in treatment planning as well as the dynamic interactional approach described by Toglia (2005). The internal dialogue in the Case Example emphasizes these aspects as related to stroke recovery. The patient described, Mr. D., was in active inpatient rehabilitation for 3 months, followed by periodic home visits for outpatient treatment. Medical complications contributed to his unusually long length of stay. During the period following his stroke and after a second stroke until his death, he continued to correspond with this author, his occupational therapist. He expressed the wish that his experiences be used to help others. He often quoted the Emily Dickinson poem above. The accompanying series of drawings demonstrate his growing awareness during his inpatient stay (Fig. 30-3).

"A Man"

Figure 30-3 Six serial self-portraits drawn by Mr. D. during months 3, 4, and 5 after right-hemisphere stroke.

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information Mr. D. was a 53-year-old right-handed white man who suffered a severe right thalamic hemorrhage with rapid onset and steady improvement. His presenting problems at inpatient occupational therapy assessment included left hemiparesis; left homonymous hemianopsia; left neglect and anosognosia; disorientation to time and place; deficits in perception, attention, memory, and visuospatial processing; and complete dependence in activities of daily living. Mr. D. retained superior verbal ability, had an advanced education, strong family support, and adequate health insurance. He was a husband, father, and former university dean and public administrator and was his family's primary breadwinner.	Appreciate the context Understand premorbid circumstances and characteristics	"Mr. D. was obviously in the prime of his career at the time of his stroke; it must have come as such a shock to him and his family. His vocational background suggests that he is used to being highly respected and in charge. He has been directing others, not accepting direction. I imagine that it will be particularly difficult for him to adjust to a dependent role of any duration. I will want to think of as many ways that he can be in control as possible and support his family in recognizing his needs in this regard." "With high school–aged children and a spouse who has not been working outside the home, financial pressures may add to the stress. I wonder if his wife may need to seek employment and may not be available as a caregiver for him when he returns home." "Mr. D.'s denial of the severity of his disability is a major obstacle to recognizing the need for and committing to occupational therapy treatment."
	Select an intervention approach	"I know it will be important that I show respect for his history of life roles by prioritizing occupational therapy goals related to intellectual and social skills and beginning with activities that emphasize **compensation** through his most preserved areas of function. This strategy should help increase his motivation and sense of personal continuity." "Mr. D.'s preserved verbal strengths will help in building our therapeutic alliance."
Recommendations Related to Personal and Social Adaptation The following goals were set for inpatient treatment (5 days/week for 3 months) and outpatient follow-up: (1) foster therapeutic alliance; (2) identify/enlist motivating strategies; (3) consider past occupational roles and future adaptation; (4) encourage partnership in setting priorities for goals; (5) develop sense of mastery and control through specific skill development and relearning—reading, self-care, and mobility; and (6) guide the search for meaning.	Consider the patient's appraisal of performance Consider what will occur in therapy, how often, and for how long Solicit the patient's mod-ifications and endorsement of plan	"Trust will be critical in countering neurologically based denial. I must help him to believe there are good reasons for what I am asking of him. As his denial begins to break, the increased awareness of his losses will be painful; questions of meaning are likely to arise. I will try to help him find his own best way of making sense of his experiences. I will have to examine my own feelings about what has happened to him, a robust and gifted man at the height of his career." "I think that it is important to integrate safety and self-care goals into treatment if he is to return home without requiring a full-time aide. Continued dialogue will be needed to negotiate for attention to these goals and to address issues of physical dependency, which at present do not appear relevant to him."
Interventions Related to Personal and Social Adaptation • Improve orientation to time and place. • Solicit narrative of his experiences related to the stroke. • Compensate for left visual field deficits and denial using cues from occupational therapist. • Improve awareness/positioning and range of motion in left upper and lower extremities.	Assess the patient's comprehension and processing strategies	"I need to continually orient Mr. D. to his surroundings and circumstances and, later, to the occupational therapy role. Other staff and team members can be enlisted to help so that Mr. D. is getting a consistent message. Staff and team should be made aware of the effects of his neurological deficits on his reasoning and tendency to confabulate."

- Maneuver the wheelchair for short distances.
- Practice supervised self-care.
- Attempt reading and writing.
- Address existential questions.
- Open lines of communication with family.

Organize cues, structure	"Sometimes he sounds almost psychotic, but I appreciate that actually he is trying to make narrative sense of what he experiences through a limited field of vision and with a damaged perceptual framework normally supported by the right hemisphere."
Compare actual to expected performance	
Know the person	"With his denial breaking, I believe that it is crucial to avoid flooding Mr. D. with failures in these areas. Time must be allocated in occupational therapy to enjoy relative successes before new demands are added. With growing awareness of losses, periods of despair or depression may emerge."
	"I can see our alliance is deepened when I identify and name his feelings and reflect back what I have heard. Mr. D.'s drawings convey a great deal about his changing body image and sense of self."
	"His stories help me understand and guide the developing ways in which he is trying to make sense of what has happened to him."
Appreciate the context and cognitive strategies in use	"I need to keep in mind how much Mr. D.'s life has changed. He was accustomed to giving orders, delegating authority, and having his decisions respected. How can I help him find some sense of mastery outside those roles that have been so much of his identity? What are his family members expecting? What additional relationships, institutional, and community supports are in place that can help Mr. D.'s world work for him when he is discharged? Friends? Church?"

Next Steps

As an outpatient, Mr. D. worked toward being able to (1) compensate for neglect and visual field deficits in the context of reading and writing tasks, (2) initiate social interaction including telephone management skills, (3) monitor moods, (4) walk short distances with an assistive device, (5) carry out exercises to maintain left arm range of motion, (6) continue drawings and narrative, (7) explore vocational requirements and expectations, and (8) participate in a home visit for assessment of safety and equipment.

Anticipate present and future patient concerns	"As Mr. D. continues to adjust to what has happened to him, I anticipate that he will have concerns with his level of dependency. He was the breadwinner; he is not likely to return to a high-paying position. He took care of his wife and family. Will they now have to take care of him? There is a risk of repeat stroke; ongoing medical management is critical. Does he have fears about this? What fears and questions might his family have?"
Recognize that which has brought meaning and purpose to his life in the past	
Assess patient's comprehension and changing awareness of deficits and the related implications for adaptation.	"So far, no signs of a plateau in improvement have been seen. Mr. D. wants to continue occupational therapy after discharge, and I agree that he should. Coming home will be hard. He has been in a supportive environment with much interaction where his safety has been assured. His family has been attentive, but they have not had primary responsibility for his care. Outpatient therapy will maintain alliance during this critical transition and continue building competence. Family expectations must be explored; they will require transitional support as he returns home."
Engage family and other caregivers to recognize needed resources for safety, daily structure, cueing, and social support	
Plan for discharge and outpatient follow-up	

Clinical Reasoning in Occupational Therapy Practice

Cognitions Associated with Pain

Chronic pain is commonly associated with certain elements of self-narrative. As part of effective pain treatment, the individual must learn to become aware of and change thoughts or cognitions that are undermining function and self-esteem (Gallagher, 1997). The statements that follow might be uncovered through monitoring or in dialogue. Using Helplessness and Dependency as examples, write positive alternative statements for the examples of Rumination and Retribution, Punishment in the spaces provided below.

Helplessness: The pain prevents me from doing all the things I want to do. The pain makes me bad at everything I used to be good at. Why try?

Alternatives: When I pace myself, I get things accomplished. It is harder to do some things, but I can still do many things well.

Dependency: I can't be expected to do anything when I feel like this. Others should take over for me.

Alternative: Some things are harder to accomplish, but I can still do them. I will ask for help when I truly need it.

Rumination: I think about the pain every minute to be sure it is not getting worse.

Alternative _____
_____
_____

Retribution, Punishment: I must have done something to deserve this.

Alternative _____
_____
_____

Clinical Reasoning in Occupational Therapy Practice

Mr. D. Sleeps Poorly

The wife of Mr. D. reports that he was "never a good sleeper" and now continues to snore loudly at night. Could a sleep disorder have contributed to his stroke risk? How might poor sleep compromise Mr. D.'s adaptation and ability to benefit from therapy? How might the occupational therapist respond to this new information?

Summary Review Questions

1. Write a letter from the rehabilitation hospital to a close friend or family member describing your feelings and efforts to cope following a disabling accident.

2. Generate five short hypotheses through which to understand why a patient might seem unmotivated in treatment. Considering your hypotheses, what components would you expect interventions for pain and depression to have in common. Why?

3. Present briefly the four stages from injury to rehabilitation as described by Morse and O'Brien (1995). In what ways are stage theories helpful? What wrong assumptions can they produce?

4. What stresses might disabled patients' families or partners experience? What are three ways occupational therapists ease those stresses?

5. Explore an Internet site serving a virtual community of ill or disabled individuals. Give examples of support and information that you find being exchanged. What criteria would you use to evaluate this connection and information for participants? In what ways might the interchange be like group treatment? In what ways might it be different?

6. Respond to this patient's question: "Why go on living with a severe disability?" What feelings or reactions in yourself over such a question would lead you to seek extra support or supervision?

7. List four indications that would cause you to seek psychiatric consultation or referral for the patient in Question 6.

8. Describe three ways in which disordered sleep might compromise patient adaptation. List the parallel

occupational therapy interventions that could support improved patient sleep.
9. View one or more of the films that portray a disabled person. What strategies for coping are depicted in the film(s)? What is demonstrated about the close relationships and occupations of disabled individuals? How might the film(s) influence the audience's understanding of living with a disability?
10. Examine a pathography by a patient or a patient's family member. In what ways are the experiences portrayed useful to you? Might they be helpful to patients?

Glossary

Adaptation—Alteration or adjustment by which an individual or species improves its condition in relation to its situation or environment.

Attribution—The process by which an individual assigns causality.

Cognitive-behavioral therapy (CBT)—A systematic form of talk therapy that emphasizes the impact of thoughts on emotions and behaviors.

Coping—Cognitive, emotional, and behavioral efforts individuals undertake to manage external and internal challenges that tax their ordinary resources.

Existential—Description of a perspective that emphasizes the human condition, including the recognition of mortality and the felt necessity to create meaning.

Mindfulness—Maintaining a calm and nonjudgmental awareness of consciousness in the present moment.

Obstructive sleep apnea (OSA)—Partial or complete blockage of airway passages during sleep leading to repeated awakenings driven by decreased oxygen saturation.

Post-traumatic stress disorder (PTSD)—Lasting psychological response to witnessing or experiencing traumatic events, especially when helpless to prevent them.

Relaxation response (RR)—A physiological state characterized by slowed brain waves, lowered heart and respiratory rates, and lowered blood pressure that is believed to enhance health and well-being.

Resilience—The psychological capacity to respond to disruption with a new integration.

Optimizing Access to Home, Community, and Work Environments

Dory Sabata

Learning Objectives

After studying this chapter, the reader will be able to do the following:

1. Understand key historical events and policies that influence accessibility of home, work, and communities.
2. Explore occupation-based interventions to maximize access to participation at home, in the workplace, and in communities.
3. Recognize examples of products, design features, and other contextual factors that interact with each unique client's ability to perform occupations.
4. Summarize current evidence that considers how to reduce environmental demands and facilitate access to home, work-place, and community.
5. Identify occupational outcomes when creating a fit between environmental demands and the individual's capacities.

Τhe focus of this chapter is on optimizing accessibility as an avenue for improving occupational performance for adults with physical dysfunction. The physical environment and technology are primary factors to consider relative to accessibility. Two overarching approaches are described in this chapter to address the barriers and strategies for optimizing access to home, work, and community: (1) changing policy and (2) changing the physical environment through environmental modifications and technology. Research demonstrating efficacy for these types of interventions will also be described in terms of client outcomes.

HISTORICAL PERSPECTIVES AND POLICIES AFFECTING ACCESS

Political advocacy and legislation influence current occupational therapy practices for optimizing environmental access worldwide. This section summarizes key public policies and legislation that supports increased access to home, community, and workplace in the United States and other nations. In the last 20 years, many countries have expanded their public policies promoting accessible design standards in the home and community. International policy changes were evident in the early 1990s with the United Nations General Assembly approval of Standard Rules on the Equalization of Opportunities for Persons with Disabilities (1993).

Legislative Movement toward Accessibility

A number of key legislative initiatives in the United States paved the way for increasing access for people with disabilities to community, job, and residential environments (Procedures for Practice 31-1). The following historical review highlights the impact of advocacy efforts over the past 50 years.

In 1954, the Hill-Burton Act, Pub. L. No. 83-565 addressed construction and design in federally funded hospitals. The Architectural Barriers Act of 1968, Pub. L. No. 90-480 (1968) created the United States Architectural and Transportation Barriers Compliance Board (ATBCB), which was authorized to study architectural design and develop standards for the construction of accessible buildings. Their findings are reported in the Minimum Guidelines for Accessible Design (MGRAD) (ATBCB, 1982). The Rehabilitation Act of 1973, Pub. L. No. 93-112 (1973) expanded the powers of the ATBCB or Access Board, which was then authorized to enforce federal accessibility requirements in federally funded buildings, federally funded programs, subsidized and public housing, and transportation facilities. These standards, called the Uniform Federal Accessibility Standards (UFAS), are based on MGRAD and guidelines of the American National Standards Institute (ANSI). Services to increase quality of life for people with disabilities were

established in accordance with the Comprehensive Rehabilitation Services Amendment of the Rehabilitation Act of 1973. Activists led the movement for independent living and civil rights among people with disabilities (Ainsworth, de Jonge, & Sanford, 2011).

Grassroots advocacy for civil rights have led to federal policy changes affecting access for people with disabilities in the United States. Additionally, state governments in Australia and New Zealand have adopted policies addressing civil rights of people with disabilities. However, other countries, including Canada and the United Kingdom, have not shared a civil rights perspective in affecting policies at a state or federal level. In Canada, various principalities have adopted their own standards and principles for public accessibility for people with disabilities, but the standards and principles lack consistency. In the United Kingdom, social policies have also begun to address accessibility for people with disabilities (Ainsworth, de Jonge, & Sanford, 2011).

Housing Accessibility Policies

This section discusses public policies affecting accessibility in Japan, Australia, European Countries, Canada, and the US. Japan is perhaps on the leading edge of accessibility in private housing implementing universal design

---

Procedures for Practice 31-1

U.S. Guidelines, Standards, and Regulations of Accessible Design

Occupational therapists who work with contractors and designers familiarize themselves with the following standards, guidelines, and legislation that affect accessibility and the physical environment.

- Americans with Disabilities Act of 1990 (ADA), Amended 2008
  - Americans with Disabilities Act Accessibility Guidelines (ADAAG)
  - Americans with Disabilities Act Accessibility Standards
  - Olmstead Decision of 1999
- American National Standards Institute (ANSI)
  - Minimum Guidelines for Accessible Design (MGRAD)
- Architectural Barriers Act of 1968 (Public Law 90-480)
  - Architectural and Transportation Barriers Compliance Board (ATBCB)
- Fair Housing Amendments Act of 1988 (FHAA)
  - Fair Housing Act Accessibility Guidelines (FHAAG)
- Hill-Burton Act (Public Law 83-565)
- Rehabilitation Act of 1973 (Public Law 93-112)
  - Section 504 of the Rehabilitation Act
- Uniform Federal Accessibility Standards (UFAS)

in new construction. Denmark requires minimum standards for wheelchair accessibility in single family homes. Norway, Sweden, and select parts of Australia have basic accessibility regulations for multifamily homes as well (Ainsworth, de Jonge, & Sanford, 2011).

Although the United States may be considered a leader in federal policies for public accessibility, it falls short in terms of policies for private housing accessibility. At present, housing is rarely built to adapt over time to owners' changing needs. The only housing policies in the United States pertain to public housing.

The Fair Housing Amendments Act (FHAA) of 1988 established the Fair Housing Act Accessibility Guidelines (FHAAG) for multifamily housing of four units or more and civil rights housing protection for people with disabilities. The FHAA mandates accessibility compliance and civil rights protection in private housing. People with disabilities are provided equal access to housing and a mechanism for filing complaints when their civil rights are violated. According to this law, the resident cannot be denied the opportunity to modify the rented home to meet individual needs for accessibility. The cost of the modification, however, is the responsibility of the renter. The landlord may require that the work be done by an approved professional, and an escrow account may be established in which the tenant must place funds for returning the residence to its original state.

Additional advocacy efforts have slowly begun to affect practices in housing construction at local levels. Eleanor Smith of Concrete Change coined the concept of visitability and suggests that all home environments be designed so that people can visit one another. Visitability considers three basic features of homes that make them accessible to visitors who use wheelchairs: a no-step entrance, wide doorways (32 inches), and access to a first floor bathroom. In some communities, builders now offer these features as an option in new home construction. All of these efforts laid the groundwork for current practices for optimizing physical accessibility of homes.

Contemporary Policies Affecting Public Accessibility for People with Disabilities

In 1990, with Congressional approval, the Americans with Disabilities Act (ADA) was enacted to protect the civil rights of Americas with disabilities by extension of equal rights protection established by the Civil Rights Act of 1964. Part of the ADA stipulated that state and local accessibility regulations must be considered in the design or modification of public spaces including businesses, schools, parks, and other recreational facilities, state and local government buildings, and public transportation. The ATBCB used both the Uniform Federal Accessibility Standards (UFAS) and FHAAG standards to create the Americans with Disabilities Act Accessibility Guidelines

(ADAAG) in 2004. Even with the implementation of this policy and associated practices, challenges to accessing home, work, and community persist.

A group of people with disabilities advocated for access to the community and challenged current practices under the ADA. That led to a pivotal U.S. Supreme Court decision: the Olmstead Decision (1999), which upheld the rights of persons with disabilities under the ADA and led to increased opportunities for people with disabilities to live in the community and receive services.

ADAAG was developed to offer some specifications for designing more accessible public spaces. However, ADAAG was based primarily on the needs of younger adults with disabilities and was not designed to meet the needs of older adults (Sanford, 2001). ADAAG was replaced in 2010 with Accessibility Standards that consider some of the needs of older adults and serve as a starting point to improving access to public places for employment and community activities in the United States. The U.S. Accessibility Standards have applied since March 15, 2012 (see Table 31-1).

Grab-bar configuration is one notable change from the former guidelines to the current standards. The Accessibility Standards considered that older people often need to use grab bars in public toilets. Previously, the Accessibility Guidelines indicated that toilets have two horizontal grab bars on a side wall and one on the wall behind the commode. These bars were intended to support an upper body transfer for someone with lower extremity amputations. However, the current standards now take into account that many older people need support for a standing transfer. Therefore, an option for grab bars on either side was included as a current alternative to the bar behind the toilet.

The Accessibility for Ontarians with Disabilities Act (AODA) in Canada (AODA, 2012) is similar to the ADA. Both policies have corresponding design specifications for each locality. Table 31-1 compares some of the accessible features in the United States and Ontario, Canada laws. Moreover, the Ontario Government has a greater goal to create a barrier-free community by 2025. A series of standards are currently under development to improve accessibility in Ontario. Policy changes can occur at the local level through grassroots efforts or can take years to decades to change at a federal level. Therefore, occupational therapists typically make more of a difference by changing the physical environment whether for a population or for an individual. The next section will explore the process by which occupational therapists plan and implement interventions to the physical environment to optimize access.

CHANGES TO THE PHYSICAL ENVIRONMENT

To develop an intervention plan that optimizes access, occupational therapy practitioners need to consider policies and laws affecting accessibility (described

Table 31-1	Select Accessibility Standards in the United States and Ontario	
Public Space Measurement	**U.S. Accessible Design Standard**	**Ontario Accessible Design Standard**
Accessible entrance	At least one	50%, at least one
Minimum clear width of an accessible route	Clear opening 32 inches (815 mm)	900 cm (35 inches)
Thresholds	1/2 inch maximum, 3/4 inch maximum on existing doors, beveled maximum slope 1:2	13 mm (0.5 inches) maximum, beveled maximum slope 1:2
Unobstructed reach range for placing controls	Adults: high forward reach 48 inches (1220 mm) maximum and the low forward reach 15 inches (380 mm) minimum above	For adults, controls not mounted above 1200 mm (47 inches) or below 400 mm (16 inches)
Stairs	Rise: 4–7 inches (100–180 mm) high, run: 11 inches (280 mm) deep minimum	Rise 125–175 mm (5–7 inches); run 280–355 mm (11–14 inches)
Ramp	Ramps cannot be higher (rise more) than 30 inches (760 mm) from the ground; ramps can be steeper for historic buildings than the minimum 1:12 rise to run (length); less steep ramps (1:18 run to rise) are recommended where space permits; standards include considerations for cross slope, edge rails, handrails.	Clear width 1100 mm (43 inches), slope no steeper than 1:15; considerations for cross slope, edge rails, handrails

Comparison of select accessibility standards under the Americans with Disabilities Act (ADA), amended 2008, and Integrated Accessibility Regulation under the Accessibility for Ontarians with Disabilities Act (AODA) of 2008.

earlier), theoretical underpinnings of how the environment affects occupation, and assessment tools and approaches described in Chapter 10. That information contributes to activity analysis and professional reasoning which results in an intervention plan. As we analyze an activity, we consider the context in which the activity occurs. This includes the space and object demands, as well as social and cultural expectations (American Occupational Therapy Association [AOTA], 2008).

Role of Occupational Therapy in Environmental Modifications

Occupational therapists analyze the physical environment as it relates to human performance, determine specific functional and environmental demands, and negotiate intervention options in collaboration with the client and support network. Strategies for reducing environmental demands in relation to specific performance skills are outlined in Procedures for Practice 31-2.

The generalist practitioner understands that the environment can be changed to decrease demands or to maximize abilities to facilitate performance. Specialists in accessibility and environmental modifications also understand the range of possible interventions and are conversant in the language needed to communicate effectively with building professionals in addition to their clients. Other specialist competencies have been identified by the AOTA for the Specialty Certification in Environmental Modifications (AOTA, 2009).

Occupational therapy practitioners who are generalists or specialists both have skills to optimize accessibility. Occupational therapists evaluate the occupational functioning of their clients in the physical context and make recommendations for changes to the environment to optimize accessibility. A client-centered approach to service delivery empowers the client to advocate for his or her own needs with knowledge and a wide array of resources (see Resources 31-1).

Intervention Strategies to Optimize Accessibility

Through activity analysis, occupational therapists can identify the barriers in the physical environment that may contribute to further disabling a person with functional limitations (see Procedures for Practice 31-2). Four intervention strategies will be introduced that optimize access and promote participation in the home, workplace, or community.

1. Inclusive and universal design
2. Environmental modifications
3. Assistive technology
4. Task simplification strategies

Inclusive and Universal Design

Occupational therapists understand the needs of people with a variety of health conditions; occupational therapists can contribute to increasing accessibility of spaces

Procedures for Practice 31-2

Selected Limitations in Performance Skills and Sample Environmental Interventions to Reduce Activity Demands

Performance Skills					Environmental Intervention to Reduce Activity Demands
Visual	**Hearing**	**Motor**	**Attention**	**Communication**

and products that are used by many people. **Inclusive design** of objects and spaces takes into account the needs of people with disabilities, whereas universal design considers all possible users of the space or object. These two related design approaches address the extremes rather than simply the means or average features of a population. Because of these approaches, a broader range of people can better access products and spaces.

Products that are designed for use by everyone should use universal design principles (see Procedures for Practice 31-3). One example is the use of an automatic opening door. Automatic doors decrease the need for strength, motor skills, and cognitive skills. In addition to being useful to people with these types of functional limitations, automatic doors can be helpful to any worker who is carrying packages through the doorway. A no-step entrance and a curbless shower are examples of universal design features in the home.

Use of various readily available applications for computers for a variety of input and output such as voice recognition, screen reading, and other augmentative communication features are examples of inclusive design in the workplace (Definition 31-1). Schools and other community environments where learning occurs also need to consider the design of learning materials and whether or not they are accessible to a wide range of users.

The original principle of universal design considered products and spaces. Later, a set of universal design learning principles (CAST, 2011) were developed with the intent of increasing access to education (see Procedures for Practice 31-4).

Procedures for Practice 31-3

Principles of Universal Design

When designing a space or product to be used by all potential users, consider the following principles.

Equitable Use: The design is useful and marketable to people with diverse abilities.

Guidelines

- Provide the same means of use for all users: identical whenever possible; equivalent when not.
- Avoid segregating or stigmatizing any users.
- Provisions for privacy, security, and safety should be equally available to all users.
- Make the design appealing to all users.

Flexible in Use: The design accommodates a wide range of individual preferences and abilities.

Guidelines

- Provide choice in methods of use.
- Accommodate right- or left-handed access and use.
- Facilitate the user's accuracy and precision.
- Provide adaptability to the user's pace.

Simple and Intuitive: Use of the design is easy to understand, regardless of the user's experience, knowledge, language skills, or current concentration level.

Guidelines

- Eliminate unnecessary complexity.
- Be consistent with user expectations and intuition.
- Accommodate a wide range of literacy and language skills.
- Arrange information consistent with its importance.
- Provide effective prompting and feedback during and after task completion.

Perceptible Information: The design communicates necessary information effectively to the user, regardless of ambient conditions or the user's sensory abilities.

Guidelines

- Use different modes (pictorial, verbal, and tactile) for redundant presentation of essential information.
- Provide adequate contrast between essential information and its surroundings.

- Maximize "legibility" of essential information.
- Differentiate elements in ways that can be described (i.e., make it easy to give instructions or directions).
- Provide compatibility with a variety of techniques or devices used by people with sensory limitations.

Tolerance for Error: The design minimizes hazards and the adverse consequences of accidental or unintended actions.

Guidelines

- Arrange elements to minimize hazards and errors: the most used elements should be most accessible; hazardous elements should be eliminated, isolated, or shielded.
- Provide warnings of hazards and errors.
- Provide fail-safe features.
- Discourage unconscious action in tasks that require vigilance.

Low Physical Effort: The design can be used efficiently and comfortably and with a minimum of fatigue.

Guidelines

- Allow user to maintain a neutral body position.
- Use reasonable operating forces.
- Minimize repetitive actions.
- Minimize sustained physical effort.

Size and Space for Approach and Use: Appropriate size and space is provided for approach, reach, manipulation, and use regardless of user's body size, posture, or mobility.

Guidelines

- Provide a clear line of sight to important elements for any seated or standing user.
- Make reach to all components comfortable for any seated or standing user.
- Accommodate variations in hand and grip size.
- Provide adequate space for the use of assistive devices or personal assistance.

Definition 31-1

Assistive Technology for Communication

- Augmentative and alternative communication
- Speech recognition
- Voice recognition
- Personal e-communication system
- Closed captioning
- Open captioning

Environmental Modifications

Most existing environments have not been built with universal design features in mind, and therefore, environmental modifications are needed to increase accessibility. Environmental modifications are changes made to the current physical environment. Occupational therapy practitioners collaborate with the client and with other team members (such as design, construction, and other building professionals) to develop a plan for reducing environmental barriers.

Procedures for Practice 31-4

Universal Design Learning Principles

Principle I. Provide Multiple Means of Representation

Guideline 1: Provide options for perception
Guideline 2: Provide options for language, mathematical expressions, and symbols
Guideline 3: Provide options for comprehension

Principle II. Provide Multiple Means of Action and Expression

Guideline 4: Provide options for physical action
Guideline 5: Provide options for expression and communication
Guideline 6: Provide options for executive functions

Principle III. Provide Multiple Means of Engagement

Guideline 7: Provide options for recruiting interest
Guideline 8: Provide options for sustaining effort and persistence
Guideline 9: Provide options for self-regulation

CAST. (2011). *Universal design for learning guidelines* (version 2.0). Wakefield, MA: Author.

Home Modifications. Modifications can be made to any physical environment. Individuals have more control over changes to their own homes, and they often spend a great deal of time in their homes. Therefore, when changing the physical environment, the home is most likely to be addressed. Evidence suggests that home environment interventions are most effective when they consider the needs of the individual client (Stark et al., 2009; Velligan et al., 2009).

A home bathroom in the United States is not typically built to accommodate someone who uses a wheelchair. Therefore, a bathroom in the home may need to be remodeled or modified to provide the resident access to the bathroom. One modification might be replacing a bathtub with a curbless shower to facilitate bathing in a wheelchair or adding grab bars near a toilet (Figs. 31-1 and 31-2).

Even the bathroom entrance may not be designed for a wheelchair. The Accessibility Standards outline the turning radius needed for a standard wheelchair to be able to enter and exit a room, such as a bathroom (Fig. 31-3). This standard only applies to public spaces but is often used as a guide for remodelers designing bathroom modifications for a wheelchair user.

A systematic review suggests that home modifications contribute to fall risk reduction and lessen the effects of functional decline. Outcomes were particularly strong when home modifications addressing the environment

Figure 31-1 The photo on the left is a typical bathroom with sink, toilet, and shower. A grab bar and a tub transfer bench are in the shower to assist with transfers. The wall-hung sink without a cabinet is accessible to roll under. The pipe is insulated to prevent leg burns. The transfer bench prohibits the shower curtain from fully closing and water gets on the floor. The lighting is poor and the space is cluttered. The photo on the right has been modified and has a curbless shower with a handheld shower head. The rolling bath seat allows for transfer prior to reaching the shower. The cutout in the seat allows for washing without having to stand. The lighting is improved with access to natural lighting as well as ambient lighting. Clutter has been removed. (Photos courtesy of Lifewise Renovations, Prairie Village, KS.)
Figure 31-2 This illustration provides information about the placement of a side-wall grab bar near a public toilet according to the ADA Standards for Accessible Design. The grab bar in this position needs to be at least 42 inches (1065 mm) and must be placed no more than 12 inches (305 mm) away from the rear wall. (This figure is in the public domain and is not copyrighted.)

were combined with other interventions addressing the person's capacities. For instance, physical activity such as strength training combined with environmental modifications has greater impact on reducing fall risk (Chase et al., 2012). See Safety Note 31-1 for other fall-prevention considerations.

Safety Note 31-1

Safety Considerations to Reduce Fall Risk

Falls can cause injury and even fatality. A multifactorial approach can help reduce the risk of falls among people at greatest risk of falls and fall-related injuries. However, all of us are susceptible to falls. Some strategies can contribute to safety and minimize environmental fall risk factors.

- Exercise regularly. Engage in balance and mobility activities such as walking or Tai Chi.
- Manage medications, particularly if taking multiple medications.
- Discuss fall risk factors and assessment with your medical provider.
- Reduce clutter in your path.
- Have adequate, low-glare lighting for work.
- Use readily available mobility supports (grocery cart, handrails, seating to rest).
- Get sufficient sleep.
- Reduce cognitive demands or limit multitasking while moving around.
- Select useful and fitting mobility devices (cane, walker, and wheelchair) when needed.

Modifications to Public Spaces. Changes to the workplace or community settings are more challenging for an individual to change. At work, one can make changes to one's own workstation more than one is able to change the larger workplace. Evidence suggests that people are more likely
Figure 31-3 This diagram indicates the dimensions required according to ADA Standards for Accessible Design for the turning radius of a standard wheelchair in entering and exiting a doorway, including a bathroom stall. (This figure is in the public domain and is not copyrighted.)

to have accommodations at their workstation to optimize their access at work than in the general workplace (Sabata et al., 2008). In broader community environments, any modifications or accessibility features are typically the result of advocacy for a population and changes in policies but are even less likely to have changes to the physical environment to meet specific individual needs.

Assistive Technology

The Assistive Technology Act of 1998 defines assistive technology as "any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities." Assistive technology can be added to the physical environment (p. 6). Some examples of assistive technology in the bathroom can range from a long-handled sponge for bathing to digital motion sensors to detect a fall.

Task Simplification Strategies

Design features, modifications, and assistive technology are used to decrease environmental demands and to reduce barriers. Task simplification minimizes the steps or demands of the procedure for completing a task (Procedures for Practice 31-5). Occupational therapists provide

Procedures for Practice 31-5

Therapeutic Intervention to Promote Safety and Independence: Principles of Task Simplification

- Use both hands to work with symmetrical motions when possible.
- Organize work supplies within reach.
- Slide heavy objects rather than lifting and carrying. For example, slide pots from sink to range. Use a wheeled cart.
- Stabilize tools to work surface, so both hands are free to work.
- Let gravity work for you (e.g., refuse chute, gravity-fed bins, or a pan below the level of a cutting board).
- Create efficient, visible storage (e.g., wall mount with hooks, magnetic racks for knife and utensil storage, and vertical storage racks).
- Place controls and switches within reach, or automate.
- Consider body mechanics, seating, and surface height in design of individual workstations.
- Provide sufficient lighting and ventilation.
- Create pleasant working conditions to minimize stress and strain

training to clients who need to learn how to do a task in a different way.

One way in which a task can be simplified is by teaching a client to perform a task from a different position, such as seated rather than standing. Sitting to complete an activity can reduce physical demands and free up the person to focus on other skills needed to complete an activity. For instance, people typically shower while standing. For someone fearful of falling, sitting during a shower still engages the person in self-care. The addition of a shower chair along with learning to bathe from a seated position provides the person with access to activities of daily living (ADL) at home.

Another way to simplify the demands of tasks is to plan for high- and low-energy activities. Moving around the community can use more energy than moving around one's home. A person who fatigues easily may need to plan for manageable community outings followed by periods of restful activities. Also, by recognizing their peak energy times (whether morning or afternoon), clients can plan and prioritize their schedules to best meet their needs.

Individuals may be able to make changes to decrease activity demands. However, some activities may require a community effort to make a community environment more accessible. For example, places of worship may need to consider inclusive designs to optimize participation in spiritual or religious practices, particularly as part of a church community. In one study, researchers found that spiritual leaders were often willing to make changes but needed to be made aware of strategies to create a more inclusive environment (Griffin et al., 2012).

Occupation-Based Interventions to Optimize Access

Contractors, designers, policy advocates, and other health providers may all be concerned about accessibility. However, occupational therapy specifically addresses the occupations of a person's life within the context of where those occupations are performed. Many leisure activities, instrumental activities of daily living (IADL), and some ADL are performed in community spaces. At work, occupational therapy is often focused on access to the work site and accommodations to complete the job tasks. Additionally, other activities such as socializing with coworkers, lunchtime, and accessing the restrooms need to be considered.

In these public spaces, government regulations can affect current accessibility features (see Procedures for Practice 31-1). Public spaces allow for less individualization and instead attempt to meet the needs of a broad population. However, these mandates often fall short of universal design. Advocacy may be needed to improve current standards for access to public spaces for a heterogeneous population.

In the home, interventions can be more tailored to individual needs. In this setting, people engage in ADL such as bathing, dressing, eating, and moving around their home. Cooking, cleaning, and caring for others are IADL commonly performed at home. Interventions directed at the environment may be just as important as those that address a person's abilities. The American Occupational Therapy Association has developed practice guidelines on home modifications (Siebert, 2005). The original version is currently under revision to better identify and demonstrate current evidence-based practices in home modifications.

Occupational therapy recognizes that each individual has varying skills, each home has unique features, and the occupations of daily life may be performed differently by different people. Therefore, interventions addressing the environment must also consider how an occupation is performed and what skills the person has to be able to perform each activity.

Home and Community Mobility

When moving around the house or walking around the community, steps can pose a challenge to some. Steps require a person to manage a change in balance and in elevation. For people who are ambulatory but unsteady, a solution may be adding secure handrails to support the body. Handrails can be a low-cost modification initially used to support older people as they are trying to use the steps. People who use mobility devices (e.g., walkers and wheelchairs) may need more extensive modifications to the environment such as a ramp or lift.

Ramps are one option to creating a no-step entrance. The slope of a ramp must address the trade-off between human endurance and strength. A steeper ramp can be a shorter distance, while a less steep ramp will be longer. Figure 31-4 demonstrates the rise to run ratio or ramp slope as indicated in the Accessibility Standards. Although these standards are not applied to personal homes, many builders use these standards as their guide for residential ramps as well.

When the entrance to a home is very steep or the yard space required to build a ramp is insufficient, lifts may be another alternative. An often aesthetically pleasing option is to use soil and ground covering to create a gradual sloping feature called an earth berm.

Additionally, policies designed to create equal access for people with disabilities can result in design that promotes movement in and around the workplace. For example, heavy doors can be challenging to open. The U.S. Accessibility Standards indicate that doors should open with 5 pounds or less of pressure or with electronic controls. This standard applies to public spaces such as workplaces.

An increasingly obese population adds to the need for more accessible home and public environments. Now employers are taking steps to modify physical demands in the workplace in order to promote more healthy movement while at work. For instance, some employers have used the workplace environment to promote healthy lifestyle choices and have had some success in influencing healthy behaviors (Brehm et al., 2011; DeJoy et al., 2011).

Toileting, Bathing, and Grooming

Toileting, bathing, and grooming are typically performed in the bathroom. When bathrooms are not accessible, people may perform these activities in other locations. For instance, some people use a bedside commode in a bedroom or living room instead of the toilet in the bathroom. People who cannot access their second-floor bathroom may sponge bathe in the kitchen sink or consider remodeling to create a first floor bath.

The physical environment can be designed to meet individual needs and optimize access to toileting, bathing, and grooming. The features in the context and environment must be considered in relation to the person's performance skills and the **activity demands** (AOTA, 2008). Squatting down to sit on the toilet and standing up when finished require leg strength and range of motion. However, the demands can be reduced by raising the height of the toilet to better fit one's body to reduce the amount of squatting needed to get on and off the toilet. Other people need upper body support to balance or push up when shifting from sit to stand, so grab bars may be installed. The interventions in the environment need to consider both the person and the
Figure 31-4 The solid line depicts a ramp slope of 1:12 (rise:run). This ramp is steeper and shorter. The dotted line depicts a longer less steep slope of 1:20 (rise:run).

activity demands. Figure 31-1 shows some features that offer different options for creating a more accessible bathroom.

Workplace restrooms and break rooms at work often are subject to accessibility standards. Toileting is not part of a job task but is still a necessary occupation at work. Therefore, occupational therapists need to understand how to optimize access to bathrooms for clients in the workplace.

As is clear from the previous discussion, occupational therapists can help clients optimize access to home and work in many ways. The interactions of the person's abilities and the environment are key in determining which interventions will best facilitate occupational performance. Specific environmental modifications can help to minimize activity demands for specific performance skills.

FROM PLAN TO IMPLEMENTATION: ENVIRONMENTAL INTERVENTIONS

Occupational therapy practitioners work with clients to make them aware of the ways in which environmental interventions can decrease activity demands. Clients can often identify the occupational areas that are difficult for them, but they may not realize that the environment presents barriers to their occupational functioning. Occupational therapy practitioners identify the demands and barriers presented in the environment and help clients address these accessibility issues in treatment plans.

The goal of environmental interventions is to optimize accessibility to facilitate performance in occupations. Some common challenges to environmental interventions include the client's awareness of resources, funding availability, and interdisciplinary communication.

Awareness of Resources

Occupational therapy practitioners can help families identify needed home modifications and access services. Home modifications are often pieced together through a variety of service providers. In the United States, Area Agencies on Aging and Centers for Independent Living are federally supported social service organizations that vary by location as to whether they offer home modification services. Rebuilding Together is a national nonprofit provider of home modifications and home repair with local chapters across the United States. The variability across geographic locations can be challenging in finding service providers who assist with creating accessible home environments.

Vocational rehabilitation services often assist with workplace accommodations for people with disabilities. Some workplaces have ergonomic consultants or departments that help create workplace environments that reduce the risk of injuries while optimizing work productivity. The needs of aging workers is a new challenge for many workplaces to begin to address.

Accessibility of public spaces is regulated by the ADA. Many buildings and spaces, however, were built prior to 1990 (when the ADA took effect). Older buildings continue to contain many accessibility barriers. New construction in the United States is subject to meeting the ADA Accessibility Standards. Occupational therapists can serve not only as consultants to projects aimed at increasing community accessibility but also as advocates raising awareness of the barriers to community participation.

Community coalitions, local building codes, and local services available can all affect community accessibility. Interested individuals and organizations may form local coalitions to promote changes in building codes or to better coordinate the delivery of services. Since the information age, virtual communities also exist through the internet. Occupational therapy practitioners can assist with gaining access to electronic and information technology for people with disabilities. This can be achieved by understanding the various formats, software programs, and interfaces with the technology needed by people with disabilities.

Funding Issues

One of the major barriers to home, workplace, and community access is finding funding for the changes. Universal design is a relatively recent concept and is not yet a standard practice in the design of new building and construction of homes, workplaces, and communities. New construction with accessibility features costs less than retrofitting existing structures.

Funding must be pieced together from a variety of sources. Individuals pay out of pocket. Employers may assist with funding workplace accommodations. Some insurance companies may pay for home and/or workplace accommodations. Community organizations with grant funds may pay for services that improve community accessibility and home accessibility. Funding options vary greatly by location, organization, and reason for the intervention.

Communication and the Interprofessional Team

As in other areas of practice, occupational therapy practitioners work in collaboration with other professionals who have different perspectives and terminology. Building professionals, such as contractors, designers, architects, and building code officials, are not part of a typical health care team but can be part of the team providing environmental interventions to promote accessibility. Interprofessional teams need to develop a method of communication that promotes collaborative problem solving.

| Evidence Table 31-1 | Best Evidence for Occupational Therapy Practice Regarding Home Modification Interventions |

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Assistive technology (AT) and environmental interventions (EIs)	Occupational therapy (OT) visit with recommendations, implementation of AT and EI	Frail elderly adults in New York (N = 104; treatment, n = 52; controls, n = 52).	For treatment group, mean AT devices received, n = 15; mean EI, n = 1.44; mean visits from OT, n = 8.9; and mean visits from technician, n = 2.4. Those in control received usual care (e.g., nursing visits).	Randomized, controlled study; Level: IA2a	Significant difference in number of AT devices received Significant difference in number of EIs received Cost-effective alternative to long-term care	AT devices: t = 6.57, p < 0.001, r = 0.297 EIs received: t = 4.1, p < 0.001 r = 0.14 Lower mean total costs for those in treatment group ($14,173) compared to controls ($31,610); effect size, d = 0.56	Mann et al. (1999)
Home intervention to reduce functional difficulties	OT and physical therapy (PT) home visits including home modifications, education about cognitive and behavioral strategies, balance-related exercises	Community-dwelling older adults who had difficulty performing daily activities (N = 319; controls, n = 159; intervention, n = 160)	Intervention group: five 90-minute OT visits plus one 20-minute phone follow-up and one 90-minute PT visit Control group did not receive any intervention (received safety book after posttest)	Randomized, controlled block design; Level: IA1b	Significantly less difficulty with bathing and toileting compared with control group	Intervention participants had less difficulty with instrumental activities of daily living (IADL) than controls p = 0.04, confidence interval (CI) = −0.28–0.00; similar with ADL (P = 0.03, 95% CI = −0.24 to −0.01)	Gitlin et al. (2006)
Comparison of environmental assessment and modification provided by an occupational therapist versus an unqualified trained assessor	Westmead Home Safety Assessment and strategies to address hazards	Community-dwelling adults age 70 years and older with a recent history of falls (controls, n = 78; OT assessor, n = 87; trained assessor, n = 73)	1.5–2-hour home assessment and two follow-up phone calls	Randomized controlled trial Level: IA1a	Participants in the OT group had significantly fewer falls at 12-month follow-up; no change in fall rate for those in trained assessor group (controls)	OT group: Incident rate ratio (IRR) = 0.54; CI = 0.36–0.83, p = 0.005 Trained assessor group: IRR = 0.78 CI = 0.51–1.12, p = 0.34	Pighills et al. (2011)

Occupational therapy recommendations that address client's occupational functioning are made in collaboration with the contractor who understands structural and construction issues. As with any type of team, all members need to have a similar understanding of the goal to effectively achieve the desired outcome.

EFFICACY AND OUTCOMES

The ultimate goal of optimizing accessibility is to maximize occupational functioning and social participation. People with disabilities, older adults, caregivers, personal assistants, and potentially anyone who is part of a particular environment can all benefit from the outcomes of environmental interventions.

As a person ages, changes with aging may be modulated by reducing participation in activities rather than in changing the environment. Unknowingly, by limiting activities, the older person may contribute to further declines in physical functioning. However, researchers have demonstrated that home modifications and assistive technology can actually reduce the risk of functional decline among people as they age (Gitlin et al., 2009; Gitlin et al., 2006; Wilson et al., 2009). A growing body of evidence (see Evidence Table 31-1) supports the notion that home environment interventions can optimize access. Even as a person ages, the environment can play a significant role in the person's access to ongoing participation (Petersson et al., 2009; Yen et al., 2012).

Individualized interventions, often in the home, help meet the specific needs of a person. Ongoing public policies that promote accessibility and inclusive design help to make community spaces and activities available to a wide range of people. Advocacy efforts along with individualized interventions are both needed to continue to improve the access to home, work, and community.

case example

Mrs. P.: Implementing Environmental Interventions to Optimize Occupational Performance

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information	Appreciate the context	(See related assessment chapter, Chapter 10, for description of the assessment process and patient's background.)
Mrs. P. is an 85-year-old woman who sustained a right-sided cerebrovascular accident 2 months ago resulting in left-sided hemiparesis. She was recently discharged from the rehabilitation center to an apartment that she has shared with her husband for more than 30 years. Mr. P. would like to hire an attendant a few hours a day to assist with Mrs. P.'s personal care and to help with the housekeeping, but financial constraints do not allow for this. Both Mr. P. and their daughter carry out most of the household tasks and have reported becoming increasingly frustrated and fatigued. They both say that they do not believe that they can leave Mrs. P. alone because of their concerns about her safety and independence. Prior to her stroke, Mrs. P. prided herself on her ability to care for her husband and her home. Mrs. P. has been referred to the community occupational therapist to address concerns about her independence and safety in her home environment.		"Mrs. P. is returning home where she lives with her husband. She needs assistance with personal care and housekeeping. Her husband wants help but cannot financially afford to hire an assistant for his wife. Their daughter lives nearby and helps when she can."
	Select an intervention approach	"I anticipate that Mrs. P. will be able to safely engage in some self-care and housekeeping activities. I may be able to help her delay further decline or even delay institutionalization by implementing environmental interventions and helping her acquire assistive technology that promotes accessibility and optimizes her occupational performance."
		"I will focus on environmental modifications and assistive technology and determine how to decrease demands in the home environment to increase occupational performance."

	Reflect on competence	"I have worked with several clients with unilateral hemiparesis resulting from a stroke who were discharged home. I am knowledgeable about various tools and databases (such as AbleData) and am confident that I will be able to offer some options of products that may be useful to the needs of my client. I will work with another therapist who is knowledgeable in other techniques for stroke recovery that focus more on remediation such as constraint-induced movement therapy. I will also make referrals to social work for assistance with finding funding sources and locating caregiver support for the family members."

Recommendations

The occupational therapist recommended three to five visits to negotiate environmental modifications and assistive technology. In collaboration with Mrs. P., her husband, and her daughter, the occupational therapist established the following long-term treatment goals: (1) following bathroom modifications, Mrs. P. will safely complete bathing activities with minimal supervision and prompting; (2) after instruction on task modification, Mrs. P. will engage in light housekeeping tasks with minimal assistance from family; (3) Mrs. P. will complete dressing and grooming tasks with the use of assistive devices and verbal prompting; and (4) Mrs. P. will participate in activities at a senior center two or three times a week.

	Consider the patient's appraisal of performance	"Mrs. P. lacks awareness of safety risks. I suspect that she may have attention deficits or executive function disorder, and further assessment is needed. This might explain why she does not demonstrate any memory deficit but does seem to have difficulty with initiation and sequencing. She is aware of changes in her abilities to perform meaningful activities."
	Consider what will occur in therapy, how often, and for how long	"Mrs. P. will have home modifications made to her bathroom including replacing the tub with a shower, placing nonskid strips on the shower floor, and installing grab bars. Here is how I plan to approach Mrs. P.'s other needs: provide Mrs. P. and her family members with training on safety issues and how to protect and care for her paralyzed side, which is likely to be neglected; use task modification strategies to engage Mrs. P. in meaningful housekeeping tasks; provide visual and verbal cues to encourage visual scanning to the affected side and to avoid injury; and provide assistive devices to assist with dressing, grooming, and meal preparation activities."
	Ascertain the patient's endorsement of plan	"Mrs. P. is motivated to engage in housekeeping tasks, which are important to her. She is agreeable to the plan and understands that her family will feel more secure if she follows through with the recommended safety features."

Summary of Short-Term Goals and Progress

1. Mrs. P. will complete dressing and grooming tasks daily with the use of assistive devices.
2. Mrs. P. will complete at least two instrumental activities of daily living (IADL) with task modification strategies, assistive devices, and setup from family.

The occupational therapist introduced task modification strategies and assistive devices that facilitate access to participation in self-care and household activities. The therapist recognized that Mrs. P. was motivated to contribute to her family and her household.

The occupational therapist recognized that Mrs. P. liked gadgets and that she was open to trying assistive devices that reduced physical barriers. The therapist assisted Mrs. P. and her family in selecting several assistive devices to increase activities of daily living (ADL) and IADL performance and then trained Mrs. P. to use them. Mrs. P.'s family reported that Mrs. P. was less dependent on them for self-care activities.

	Assess the patient's comprehension	"I could see that Mrs. P. became frustrated with learning to use a button hook for dressing. We discussed other alternatives, and eventually, she preferred to have Velcro® fasteners on her clothes to replace buttons."
	Compare actual to expected performance	"Mrs. P. was able to use a spiked cutting board while seated at the kitchen table. Her family assisted with setup, but otherwise, she was able to complete most meal preparation."
	Know the person	
	Appreciate the context	"I anticipated that Mrs. P. would improve her participation in activities with the strategies and devices. She was highly motivated. We did have to try some different strategies to get the expected outcome. An additional outcome was that her family caregivers felt less burdened."

Next Steps

Revised short-term goals (1 month):

Following bathroom modifications and training with assistive devices, Mrs. P. will complete bathing with minimal supervision two times per week.

Decide whether the patient should continue or discontinue therapy and/or return in the future

"Mrs. P. does not want to be dependent on her husband to assist her with bathing. She is waiting for assistance from Rebuilding Together to provide a roll-in shower in place of her tub."

"I am concerned about Mrs. P.'s visual left neglect. She does not seem to be aware of the deficit, and she is resistant to strategies for visual scanning to the left. Also, she has fallen a couple times in the past month. Her visual and sensory perception is impaired, and she has difficulty when getting up from a chair. I wonder if she is experiencing orthostatic hypotension, which is contributing to her fall risk. I have referred her to a physical therapist. Following her bathroom modifications, I will visit her again and provide training."

Clinical Reasoning in Occupational Therapy Practice

Mr. P.: Determining Environmental Interventions to Optimize Access to Community

Mr. P. had a rough night and did not get much sleep. He got up early to take his wife to a doctor appointment. He took a shower, and on his way out he fell on the tile floor. He was very sore and developed bruising but did not have any serious injury or breaks. However, since then he has become fearful of falling again. Although he used to bathe nearly every day, now he is bathing once a week. He meets up with his friends or leaves the house only on days that he bathes. This has significantly changed his outings in the community. He has a combination shower/tub and has to enter the tub to take a shower. The bathroom lighting is over the sink. The shower is poorly lit, once the shower curtain is pulled.

What factors in the environment might have contributed to the fall? What environmental interventions might support his bathing and therefore support his participation in activities with his friends?

Summary Review Questions

1. What historical events and policies affect current practices and trends in accessibility of homes, workplaces, and communities? Why is knowledge of these important to the occupational therapy practitioner who consults on accessibility?
2. What are some examples of how each of the four intervention strategies presented could be applied in the home, workplace, or community?
3. What are some of the design and product solutions that help to reduce activity demands at home, at work, or in the community?
4. How do the types of occupations performed at home, in the workplace, and in the community affect the types of environmental interventions selected?
5. What resources are available to occupational therapists and families to help them implement environmental modification interventions?
6. What does evidence suggest are some of the key benefits to clients who use environmental interventions?

Glossary

Activity demands—The objects, space, skills, and abilities required to complete a series of tasks.

Context—The social, physical, cultural, and temporal factors external to a person.

Environmental demands—External factors that interact with a person's capacity.

Environmental modifications—Changes to the physical environment, with the intent of improving safety and occupational performance.

Inclusive design—Design that takes into account the needs of people with disabilities.

Performance skills—The actions of a person based on abilities.

Physical environment—Features of a person's surroundings that are built or exist in nature.

Space and object demands—The room required and tools needed for a specific occupation.

Universal design—Concept that products and spaces are designed to meet the needs of all possible users.

Visitability—Concept that homes can be accessible for a person in a wheelchair to visit.

Preventing Occupational Dysfunction Secondary to Aging

Glenn D. Goodman and Bette R. Bonder

Learning Objectives

After studying this chapter, the reader will be able to:

1. Describe normal age-related changes as they relate to areas of occupation, performance skills, performance patterns, and client factors (body functions and body structures).
2. Discuss activity patterns of older adults as related to activities of daily living, instrumental activities of daily living, education, work, play, leisure, and social participation.
3. Describe considerations in assessing the function of older adults.
4. Discuss occupational therapy interventions that facilitate function in older adults.
5. Describe the factors that make intervention following illness or injury for older adults different from that of younger adults.

Sense of self-efficacy and self-esteem

Satisfaction with life roles
• Self-maintenance
• Self-advancement
• Self-enhancement

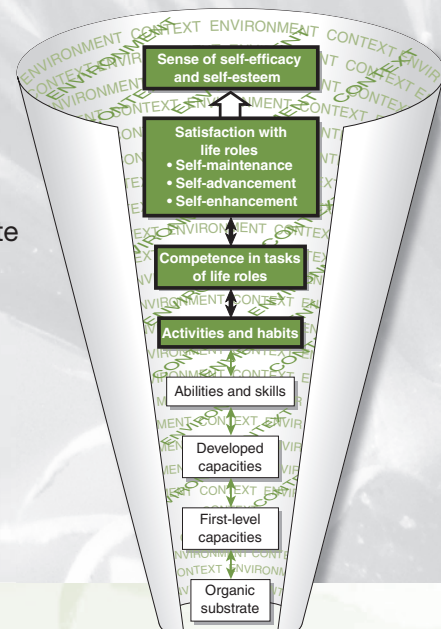
Competence in tasks of life roles

Activities and habits

Abilities and skills

Developed capacities

First-level capacities

Organic substrate


The older population (persons 65 years or older) was 39.6 million in 2009 (Administration on Aging, 2013). They represented 12.9% of the U.S. population, about one in every eight Americans. By 2030, there will be about 72.1 million older persons, more than twice the number in 2000. People age 65 years and older represented 12.4% of the population in the year 2000 but are expected to grow to be 19% of the population by 2030 (Administration on Aging, 2013).

Minority populations are projected to have increased from 5.7 million in 2000 (16.3% of the elderly population) to 8.0 million in 2010 (20.1% of the elderly) and then to 12.9 million in 2020 (23.6% of the elderly). Between 2010 and 2030, the white population of those age 65 years and older is projected to increase by 59% compared with 160% for older minorities, including Hispanics (202%), African Americans (114%), American Indians, Eskimos and Aleuts (145%), and Asians and Pacific Islanders (145%) (Administration on Aging, 2011). As the older population increases, more services will be required for the treatment and management of chronic and acute health conditions. Providing health care services for Americans of all ages will be a major challenge in the 21st century (Administration on Aging, 2011).

These figures have considerable import for health care providers, particularly occupational therapists. Enhancing functional performance of older adults can have economic, social, and personal benefits for these individuals, their families, and society as a whole.

The emphasis in this chapter is on the normal aging process. Older adults are, of course, subject to all of the illnesses and injuries that affect younger people, as well as some that are far more likely to occur in older individuals, such as cerebrovascular accidents, dementing illnesses, and cancer. Other chapters in this volume address mechanisms by which therapists can provide effective intervention for these conditions. When illness or injury occurs, however, the therapist must put the consequences in the context of the individual's life stage, which makes understanding normal aging essential. Special considerations in intervening with older adults are also discussed in this chapter.

NORMAL AGING

Many theories are applied in the study of successful aging. Theories related to aging include biological (genetic/cellular, evolutionary), neuropsychological, psychological (life span/developmental, selective optimization with compensation, cognitive and personality theories), and sociological theories (life course, social exchange, and critical perspectives of aging (Bengston & Bonder, 2009).

Changes that accompany normal aging occur in every sphere. At an individual level, normal aging affects the organic substrate, first-level capacities, developed capacities, abilities and skills, activities and habits, competence and satisfaction of life roles, and self-efficacy/self-esteem. It is essential to remember, however, the wide variation among individuals. Many individuals at age 80 years have a vigorous stride and engage in activities that would exhaust many a younger person.

Age-related changes occur to varying degrees among older adults, with varying effects on performance. The existence of a physical change does not necessarily lead to a commensurate decrement in function. Many studies identify multiple factors related to successful aging. Some of these factors include genetics (Glatt et al., 2007), level of education (Depp & Jeste, 2006), marital status, family status (e.g., families with and without children), working for pay, volunteering, practicing healthy behaviors, having adequate social supports, and maintaining strong religious beliefs (Pruchno et al., 2010).

ORGANIC SUBSTRATE AND FIRST LEVEL CAPACITIES

This section summarizes age-related changes in the sensory, neuromuscular, cardiovascular, and cognitive systems. These organic substrate and first-level capacities are client factors and performance skills as described in the Occupational Therapy Practice Framework (American Occupational Therapy Association [AOTA], 2008).

Sensory Changes

Some sensory changes normally occur with aging; others result from disease processes common among older adults (Hooper & Dal Bello-Haas, 2009). One role of the occupational therapist is to evaluate the level of dysfunction caused by changes in sensation and in the process skills that allow individuals to interpret sensory input. Therapists then can determine strategies to compensate for problems that interfere with abilities, activities, tasks, and engaging in life roles.

Changes typically occur in all sensory spheres, including vision, hearing, gustation, olfaction, touch, and vestibular sensation. Changes in multiple sensory channels require careful intervention to optimize function. Furthermore, decrements may occur at the level of reception, interpretation, or integration, that is, either peripherally or centrally in the nervous system (Bottomly & Lewis, 2007). Sensory loss can severely impair the older person's ability to communicate; the psychosocial consequences can be devastating (Brennan & Bally, 2007).

Vision

Of older adults, 18% experience deficits in vision. Among people age 85 years and older, 28% reported trouble seeing (Federal Interagency Forum on Aging-Related Statistics, 2010).

Primary age-related changes in visual function include loss of subcutaneous fat around the eye; decreased tissue elasticity and tone; decreased strength of eye muscles; decreased corneal transparency; degeneration of sclera, pupil, and iris; increase in density and rigidity of the lens; disease processes such as diabetes; and slowing of central nervous system processing (Hooper & Dal Bello-Haas, 2009).

Deterioration of near vision, called presbyopia, begins to affect most people when they are about age 40 years (American Optometric Association, n.d.). The lens loses its elasticity and becomes less able to focus because of weakness in the ciliary body (Lewis, 2003). Presbyopia is easily accommodated through the use of a well-known assistive device: eyeglasses.

Another common change is development of degenerative opacities (cataracts) of the lenses, which lead to decreased sensitivity to colors, increased sensitivity to glare, and diminished acuity (Hooper & Dal Bello-Haas, 2009). Additionally, musculature that controls eye movement tends to lose strength and tone (Tideiksaar, 2009). Tear secretion may be reduced, and degenerative changes may occur in the sclera, pupil, and iris (Bottomly & Lewis, 2007). Such changes can result in excessive dryness, loss of light/dark accommodation, and poor night vision. Finally, decreased color vision and changes in the vitreous body that affect retinal function occur with aging (Bottomly & Lewis, 2007).

The effects of diseases like diabetic retinopathy and retinitis pigmentosa, both of which may lead to total blindness, are most pronounced in the elderly population because both are progressive and degenerative (Hooper & Dal Bello-Haas, 2009). Macular degeneration, a disorder causing loss of central vision as the macula deteriorates, is most common among older individuals. Most older individuals with macular degeneration retain sufficient peripheral vision to assist in mobility but not enough for activities such as reading or watching television (Perski, n.d.).

Hearing

In 2008, 42% of older men and 30% of older women reported trouble hearing (Federal Interagency Forum on Aging-Related Statistics, 2010). The percentage was higher for people age 85 years and older (60%) than for people age 65–74 years (28%). Conductive hearing loss may be the result of problems in the external or middle ear, such as wax buildup, eustachian tube blockage, or stiffness of the ossicles and membranes (Lewis, 2003). Age-related sensorineural hearing loss, known as presbycusis, results from dysfunction of the sensory hair cells of the cochlea, neural connections from the cochlea to the cerebral cortex and brainstem, or vascular changes in the auditory system (Lewis, 2003). Tinnitus, a buzzing or ringing sensation, is experienced by 2–3 million Americans and increases with age (Hooper & Dal Bello-Haas, 2009). Functional consequences of these changes include difficulty hearing high-frequency sounds and speech, problems filtering background noise during conversation, an increase in auditory reaction time, and challenges to balance caused by inner ear changes (Hooper & Dal Bello-Haas, 2009).

Taste and Smell

Thresholds for taste and smell increase with age (Hooper & Dal Bello-Haas, 2009). The inability to detect aromas may cause food to seem tasteless, possibly resulting in secondary nutritional disorders. Individuals may not be able to detect harmful odors such as natural gas, spoiled food, or smoke (Hooper & Dal Bello-Haas, 2009). Smoking or environmental exposures may exacerbate age-related changes in taste and olfaction (Bottomly & Lewis, 2007).

Tactile Changes

Changes in the number and sensitivity of touch and pressure receptors have been reported (Hooper & Dal Bello-Haas, 2009). A decreased response to tactile stimuli, higher touch thresholds, and a decrease in the ability to detect touch and pressure can result but are highly variable. Tactile sensation can be preserved and improved with therapeutic interventions (Hooper & Dal Bello-Haas, 2009). Some literature suggests there are structural and biochemical changes in nerve fibers that occur in older adults related to perception of pain and temperature (Caprio & Williams, 2007).

Proprioceptive and Kinesthetic Changes

Documentation of changes in proprioception or kinesthesia that are purely related to aging is scant. Changes in proprioception secondary to loss of vision, peripheral vascular disease, arthritis, cardiovascular disorders, stroke, disorders of the inner ear, and diabetes have been reported (Bottomly & Lewis, 2007).

Vestibular Function

Vestibular changes are particularly significant because of the importance of falls as a health risk for older adults. Approximately 33% of older adults fall each year, and 15% of these individuals experience serious health consequences, such as broken hips and traumatic brain injury. Falls are the leading cause of death caused by accidents in persons age 65 years or older (Tideiksaar, 2009).

Vestibular righting response diminishes with age, which can lead to problems in maintaining balance. Age-related changes in static balance, dynamic balance, and gait appear to increase the probability of falls (Bottomly & Lewis, 2007; Tideiksaar, 2009).

Central Nervous System

With age, the cerebrum atrophies (Bottomly & Lewis, 2007), and cerebrospinal fluid space increases. Neurons are lost or atrophy, particularly in the precentral gyrus, postcentral gyrus, superior temporal gyrus, and Purkinje cells of the cerebellum (Bottomly & Lewis, 2007). The number of synapses decreases, and neurotransmitter systems change (Dal Bello-Haas, 2009). In addition, plaques, fibrillary tangles, and other cellular abnormalities have been found in the brains of functionally normal older adults (Lewis, 2003). Responses to stimuli as measured by electroencephalogram also slow down.

Peripheral Nervous System

Among the changes in the peripheral nervous system seen in aging are loss of neurons and both myelinated and unmyelinated nerve fibers, decrease in myelin, axonal atrophy, and slowed nerve conduction velocity (Dal Bello-Haas, 2009). Variation among individuals makes functional and structural generalizations problematic.

Musculoskeletal System

The normal change in the musculoskeletal system can have consequences for mobility and function. The following sections describe the normal aging process as it affects muscles and bone, as well as the impact of various diseases on the musculoskeletal system.

Muscles

Changes in muscles that are attributed to aging include a decline in the number and size of muscle fibers, decreased muscle mass, an increase in fatty and connective tissue, decreased metabolism of protein, increased muscle fatigue, and a reduction in the number of motor neurons (Dal Bello-Haas, 2009), resulting in loss of muscle strength, decreased endurance, and slower walking and rising times.

Joints

Joint function declines steadily after age 20 years. Ligaments and tendons become less resilient and more prone to injury (Bottomly & Lewis, 2007). The quantity and viscosity of synovial fluid decrease with aging. Cartilage becomes opaque, with an increase in cracks and fraying (Bottomly & Lewis, 2007), which can be reduced with preventive intervention or may require corrective surgery. The effects of weight bearing and stress on joints and the effects of diseases, such as the various kinds of arthritis, make the rate and nature of cartilage deterioration highly variable.

Bones

Bone loss of up to 1% a year occurs until age 50 years for men and women (Dal Bello-Haas, 2009). Women older than age 50 years have a rate of bone loss double that of men. By age 65 years, at least 50% of women have developed some form of osteoporosis. The rate of degeneration slows by age 70 years (Lewis, 2003). The rate of bone loss continues to increase similarly in men and women after age 80 years (Dal Bello-Haas, 2009).

Effect of Disease on the Musculoskeletal System

Arthritis, osteoporosis, connective tissue diseases, orthopedic injuries from falls and trauma, and repetitive motion disorders are most prevalent in elderly individuals (Tideiksaar, 2009). Almost 50% of men and women have some form of arthritis by age 65 years (Federal Interagency Forum on Aging-Related Statistics, 2010). Approximately 332,000 hip fractures occur annually in the United States, primarily in individuals age 65 years and older. Almost 25% of older adults who fracture a hip die within 1 year (Tideiskaar, 2009).

Cardiovascular Changes

The cardiovascular system loses efficiency with age, which is the result of changes in the frequency and regularity of the conduction system; a reduction in pacemaker cells (Bottomly & Lewis, 2007); alterations in blood pressure (Federal Interagency Forum on Aging-Related Statistics, 2010); changes in the elasticity, length, and thickness of the arteries (Bottomly & Lewis, 2007); a decrease in heart rate and stroke volume; and a general thickening of specific heart tissues, such as the atria and valves (Bottomly & Lewis, 2007).

Elastic tissues decrease and fibrous tissues increase, affecting the medium and small airways constructed of smooth muscle. The joints of the chest wall stiffen, the muscles of the diaphragm flatten, and the chest wall becomes more barrel shaped and less compliant (Dean & De Andrade, 2009). Approximately 50% of individuals older than age 65 years have hypertension (Federal Interagency Forum on Aging-Related Statistics, 2010). However, conditioning training can elicit the same physiological benefits to older adults as in younger people (Dean & De Andrade, 2009).

Cognitive Changes

Age-related changes occur in some aspects of intelligence, problem solving, abstract reasoning, memory, memory processing, and attention. Changes are most noticeable after age 70 years, although gradual decline occurs when individuals reach the age of 30 years (Anstey & Low, 2004). As measured by the Wechsler Adult Intelligence Scale, the intelligence quotient decreases with advancing age, largely the result of decreases in the performance rather than verbal subscales

(Miller et al., 2009). Performance subscales may depend on fluid intelligence (the ability to use new information), whereas verbal subscales may use crystallized intelligence (recall of stored memories) (Anstey & Low, 2004). In particular, flexibility in reasoning tasks seems to decline (Miller et al., 2009), although older adults show wide individual variation in these cognitive capacities. Some kinds of problem-solving skills also seem to become less efficient (Anstey & Low, 2004), although older adults show actual improvement in solving interpersonal or emotionally salient problems (Blanchard-Fields, Mienaltowski, & Seay, 2007).

In general, well older adults do not have problems with processing and short-term storage of information, although some have difficulty encoding large amounts of information at once (Anstey & Low, 2004). Decrements in long-term memory and encoding are noticeable (Anstey & Low, 2004). Older adults have more trouble recalling information than do younger ones. An older person may remember the face and personality of an acquaintance but have difficulty retrieving the name. This difficulty is much less pronounced when the information has practical significance. Everyday or practical memory may be of considerable salience for elders (Riley, 2009).

When cognitive changes begin to interfere with function, the decline is labeled mild cognitive impairment (MCI) (National Library of Medicine, 2007). MCI is characterized by changes in memory. Unlike dementia, other cognitive functions are relatively spared. There is ongoing research to understand whether MCI is a precursor to Alzheimer's disease (AD). It is estimated that roughly 25% of individuals with MCI develop AD within a year (Petersen et al., 1999). For some individuals, memory training has helped minimize associated functional decrements (Riley, 2009). One challenge in examining cognitive change in older adults is the clear association between sensory decline and cognition (Valentin et al., 2005), because visual or hearing deficits may reduce the individual's ability to respond accurately to questions or to follow instructions.

A Special Note about Dementia

Dementing illnesses are common among older adults. Dementia, which is characterized by forgetfulness, difficulty finding words, and other cognitive loss, is not a normal condition of aging. Rather, it is a symptom of any of several disease processes (Riley, 2009). Some, such as depression, sensory deprivation, malnutrition, and drug toxicity, are reversible; others are not. AD, the most common form of dementia, is a progressive disorder that eventually leads to total disability and death. In its later stages, AD causes motor impairment as well as personality change, and individuals with AD will have difficulty participating in prevention or rehabilitation for other conditions. Of particular concern are catastrophic reactions, severe emotional

Procedures for Practice 32-1

Strategies for Working with Individuals with Dementia

- Place items used frequently in visible locations.
- Use simple, one-step instructions.
- Maintain habitual activities as much as possible; simplify as needed.
- Obtain a bracelet identifying the person as memory impaired in case of wandering.
- Encourage physical activity during the day to improve nighttime sleep.
- Provide activities that stimulate memory (e.g., baking or music that the person used to enjoy).
- Include activities that enrich life; access procedural memory to support participation.
- Avoid excessively crowded or unfamiliar surroundings that might lead to catastrophic reactions.
- Contact the local Alzheimer's Association for resource lists and support groups.

outbursts that typify the middle stages of AD associated with confusing or overwhelming situations.

It is beyond the scope of this chapter to deal with the methods for intervening with individuals with dementing disorders. A few suggested intervention strategies are included in Procedures for Practice 32-1 and in Chapter 24 of this book. Health care professionals should be familiar with the early symptoms of cognitive disorder, such as difficulty finding words, forgetfulness about everyday events, and a lack of recollection of familiar individuals. When noted, these symptoms should be carefully evaluated by a geriatrician, a physician trained to work with older individuals. Reversible causes may be treated relatively easily. If the individual has an irreversible dementing illness, a variety of management strategies can help caregivers to cope with resulting problems. This enhances quality of life for both the ill person and the caregivers.

DEVELOPED CAPACITIES: CHANGES IN VOLUNTARY RESPONSES

Changes in organic substrates and first-level capacities may impair such voluntary responses as rising from a chair and gait speed. Weakness in ankle dorsiflexion and knee extension has been correlated with falls in older individuals (Tideiksaar, 2009).

Loss of dexterity and coordination are common with aging (Dal Bello-Haas, 2009). Scores on dexterity tests (Jebsen et al., 1969; Mathiowetz et al., 1985a, 1985b) decline with age.

ABILITIES AND SKILLS: PHYSICAL CAPACITY

The following changes in physical capacity typify skills and abilities that are affected by normal aging: postural alignment, sway, and instability with postural changes (Tideiksaar, 2009), gross motor coordination (Bottomly & Lewis, 2007), fine motor coordination and dexterity, strength and endurance (Bottomly & Lewis, 2007), walking speed, step length, and step height (Bottomly & Lewis, 2007; Tideiksaar, 2009), and reaction time (Bottomly & Lewis, 2007).

ACTIVITIES, HABITS, AND ROLES

Elders have greater personal choice in determining their tasks and life roles than do younger individuals. Although some individuals must continue to work to support themselves, particularly in challenging economic times, many have the option of retiring from paid employment. Those who have children typically have finished rearing them. Because living in certain school districts is no longer an issue, some elders opt to sell their home and move to an apartment or to new community. For others, aging in place is a significant issue (Rantz et al., 2011). Occupational therapists can assist in this by evaluating for safety in the home environment, recommending modifications that improve access, and assisting with community mobility to facilitate both daily living needs and access to meaningful tasks and life roles.

As with physiological changes, activity patterns are highly individual (Gauthier & Smeeding, 2003). Some older adults engage in many activities; others focus on one or two. Changes in habits include different time use; more time is spent in leisure and less in paid employment. There are gender and cultural differences in activities such as housework and social activities (Gauthier & Smeeding, 2003). The development of useful, dominating, or impoverished habits (AOTA, 2008) can impact an older adult's health and longevity.

Most older adults accommodate to age-related changes well by modifying routines or finding and accepting assistance. This is especially true when the activity is one for which it is socially acceptable to receive help. Help with driving, cooking, or managing finances is often acceptable. Some older adults are determined to do for themselves, whereas others are accepting, even relieved, when they can rely on others to take care of them.

Self-Care

Independence in self-care is a significant issue for older adults. In 2007, 42% of individuals older than age 65 years reported difficulty with activities of daily living (ADL) and instrumental activities of daily living (IADL). Of institutionalized older Americans, 83% report difficulties in ADL (Administration on Aging, 2011). Heavy housework, such as mopping floors and washing windows, is difficult for many individuals and may be hired out or done by family members. In addition, most elders spend more time on self-care activities than they did when younger (Christiansen, Haertl, & Robinson, 2009). Issues of time can be significant when self-care consumes such a large proportion of the day that other desired activities cannot be pursued.

Substantial disability in self-care is most likely to be perceived when there is a sudden change because of illness or change in social circumstances rather than the gradual ones that affect most well elders. If the change is loss related, emotional reactions that typically accompany loss must be addressed. Changes perceived as positive, however, such as a move to a long-desired retirement location, can also cause unanticipated emotional difficulties.

Urinary Incontinence

Urinary incontinence affects more than 25 million Americans. Of homebound older adults, 53% are incontinent (National Association for Continence, 2008). The inability to bathe and urinary and bowel incontinence are issues that can influence life-altering decisions for elders. Those who are unable to bathe or who are incontinent are most likely to be placed in institutional settings, which is an event that most elders wish to avoid. Interventions for urinary/bowel incontinence include surgery, medications, and behavioral treatment. Occupational therapists provide behavioral interventions that may include regular scheduling of toileting, pelvic muscle reeducation (Kegel exercises), biofeedback, bladder training, urge inhibition, bowel management, and dietary and fluid modifications (Dumoulin, Korner-Bitensky, & Tannenbaum, 2007).

Work

Emerging patterns in work and retirement reflect increasing diversity in the older population (Sterns, Lax, & Chang, 2009). Many older adults are making choices that differ from those of previous generations. Although there is a trend toward earlier retirement compared with previous generations, there is also a trend toward continued paid employment, albeit in new work circumstances (Bambrick & Bonder, 2005). Elders describe multiple reasons for wanting to continue to work, including issues of independence, sense of self-worth, and a wish to continue to contribute to society. Elders remain capable of work far beyond the traditional retirement age of 65 years (Sterns, Lax, & Chang, 2009). The work force is changing rapidly, with an increase in the number of female workers and an increase in the percentage of workers age 55 years and older being major trends (Sterns, Lax, & Chang, 2009).

Historical discrimination against older workers is being addressed through policy initiatives such as the Age Discrimination in Employment Act and the Americans with Disabilities Act (Sterns, Lax, & Chang, 2009). Changing demographics require fundamental reconsideration of policies designed to either encourage or discourage elders' choices about paid employment.

Older workers require slightly more time to learn new skills. They respond best to learning that is based on practical examples. They also complete less work than younger workers but with an equivalent error rate. Given appropriate accommodations, however, older workers can continue to be productive and valuable workers far into later life. Age has not been found to be related to work performance, and other characteristics such as personality, essential job functions, and motivation are more important in matching an individual to any given work situation (Sterns, Lax, & Chang, 2009) (Fig. 32-1). Many older workers continue in jobs requiring high levels of physical function.

Retirement

Substantial evidence exists that voluntary retirement is not viewed as a negative event (Bambrick & Bonder, 2005). When retirement is involuntary, however, either as a result of a personal situation such as failing health or external events such as layoffs, individuals are likely to be dissatisfied with retirement (Sterns, Lax, & Chang, 2009). Retirement often does not mean the cessation of productive activity (Bambrick & Bonder, 2005). Individuals who engage in volunteer work, child care, or other forms of unpaid service report that these have value both to them and to others. Bambrick and Bonder (2005) found that older adults value this kind of work for contributing to self-concept, giving back to the community, and staying engaged. Key elements in addressing adjustment to retirement include time use, meaningful occupations, self-worth, and health maintenance or wellness.

Leisure

Leisure provides a sense of identity and life satisfaction for individuals who are no longer working and appears to delay onset of some disabling conditions. Furthermore, it offers opportunities for expression of important personal meanings. For older adults, the line between leisure and work may be indistinct, with activities providing both a sense of usefulness to others and satisfaction of personal need for engagement and challenge (Bambrick & Bonder, 2005) (Fig. 32-2). Older adults can derive great satisfaction from meaningful leisure activities.

Bundy and Clemson (2009) identify three elements that contribute to the leisure experience of older adults: control, motivation, and freedom from constraints of real life. Occupational therapists should identify the amount of involvement, flow, and commitment (engagement) in activities and help older adults to identify these activities, manage them, adapt them, and enjoy them. Other important concepts to consider when addressing leisure with older adults include personal characteristics or preferences (e.g., social participation versus isolation), self-perception ("If I can't golf the regular way, golfing is meaningless to me"), physical, cognitive, and social skills, and context and environment.

Driving

According to the Insurance Institute for Highway Safety (2011), in 2009, 61% of the deaths in crashes involving drivers age 70 years and older were the older drivers themselves, and 16% were their passengers. In contrast, in

Figure 32-1 The gentleman pictured is still on the job, despite the physical demands of his work in delivering supplies around his organization.

Figure 32-2 Even elders with substantial impairments derive great satisfaction from meaningful leisure activities.

crashes involving at least one driver younger than 30 years of age, 42% of the deaths were the drivers younger than age 30 years; 24% were their passengers. However, since 1997, deaths of older passenger vehicle occupants have declined 33%, whereas deaths of older pedestrians have declined 38% (Insurance Institute for Highway Safety, 2011).

AOTA is an excellent resource for materials related to driving safety for all persons with special assistance for working with older drivers (http://www.aota.org/Older-Driver.aspx). One example of an AOTA collaborative program with AAA and AARP is Car Fit (http://www.car-fit.org/). This educational program helps older drivers assess the fit of their personal vehicles. Model driving evaluation and rehabilitation programs for the older driver include measuring driver potential before on-road evaluation; measuring and improving driver performance with on-road testing and intervention; proper documentation of fitness to drive; environmental and ergonomic factors impacting drivers, passengers, and pedestrians; and communication with all of the stakeholders in making a decision about the safe performance of an older driver (Ekelman et al., 2009; Pellerito, 2006).

Sexuality

Miracle and Miracle (2009) identify three myths about sex and older adults.

- Older adults do not have sex.
- New drugs have greatly enhanced sex lives of older adults.
- People find each other less physically attractive over time.

The opportunity to develop and maintain intimacy in later life is challenging. Factors that affect this include a disproportionate number of females because they live longer than males; older adults living in institutions where opportunities may be limited by policies and environmental factors, declining health; increased incidence of diseases that affect physical and psychological function; and impoverished habits such as smoking and alcohol (Miracle & Miracle, 2009). Occupational therapists should recognize this as a valued activity for some older adults and provide interventions to support sexual activity as appropriate.

Sexuality is frequently ignored in studies examining quality of life. One study reported a strong relationship between the amount of sexual activity and measures of intimacy and satisfaction with personal relationships (Robinson & Molzahn, 2007). One major concern that is frequently cited is the unwillingness of health care providers to address sexuality with clients old or young (Miracle & Miracle, 2009; Robinson & Molzahn, 2007). Barriers and factors that are important to address regarding sexuality in older adults include the loss of a life partner and the ability or interest to "date" again; knowledge and understanding of sexuality; family values and contexts; acquisition of privacy; patient safety; physiological issues; effects of disease;

medications; pain with intercourse; cognitive, physical, psychological, and social skills; and the effects of alcohol and smoking (Miracle & Miracle, 2009).

Satisfaction of Emerging Personal Needs and Meanings

Researchers and practitioners have made increasing attempts to understand the occupations of older adults (Bambrick & Bonder, 2005; Nilsson et al., 2007; Windsor, 2009). In particular, researchers are interested in knowing what is important to elders and how their occupations contribute to quality of life.

Physical health is not, in and of itself, sufficient to ensure good quality of life (Lent, 2004). Occupational therapy reflects a belief that individuals are most satisfied with their lives when they engage in a variety of occupations that balance self-care, work, and leisure (AOTA, 2008). Research suggests that this is true for older adults as well as younger individuals (Nilsson et al., 2007; Rowe & Kahn, 1998; Windsor, 2009).

Elimination or Alteration of Roles

Elders can make choices about adding roles, but far less choice is involved in loss of social roles. Death of a spouse or loss of physical capacity dramatically shifts occupational tasks. As an example, one woman who had made her living as a weaver found that she could no longer sit at a floor loom. She chose to weave at a small table loom (Bonder, 2009b). The salient issue seems to be finding outlets for expression of personal meaning (Menec, 2003; Morrow-Howell et al., 2003).

Additional Roles

Elders not only lose or choose to end previous roles; they also add roles. An elder who stops paid employment becomes a retiree and may become a volunteer. A parent whose children are grown may become a grandparent. In some instances, even roles that are not chosen may be satisfying. For example, some elders become not only grandparents but surrogate parents for their grandchildren. As many as 10% of elders are custodial grandparents (Hayslip & Kaminski, 2005). Although this may be perceived by some as a burden, many grandparents express great satisfaction with this role.

COMPETENCE AND SELF-ESTEEM: PSYCHOSOCIAL

Psychosocial status may be the most significant predictor of occupational function. Motivated, enthusiastic individuals tend to fare well, often despite what appear

to be substantial physical limitations (Chappell, 2008). Practitioners must attend to situations in which the individual, following an injury or illness, becomes depressed, loses motivation, and becomes increasingly disabled.

Self-esteem drops sharply in later life (Robins & Trzesniewski, 2005). Protective factors include strong coping skills (Moyle et al., 2010). In particular, keeping active, maintaining relationships and community connections, and spirituality contribute to a sense of well-being in later life.

Changes in psychosocial status must be separated into those that are psychological and those that are social. For a well older adult, the former relate to developmental tasks of later life. The latter relate to external factors, including major life changes such as retirement and the loss of social contacts through residential relocation, retirement, or death of peers.

A number of theorists have attempted to identify the normal psychological processes that accompany aging. Among the theories are disengagement, activity, continuity, and life span models. The principal characteristics of these theories are noted in Table 32-1. Although each theory has appeal, each also has limitations in explaining the psychological functioning of older individuals.

It is well established that older individuals have significant losses of social contacts (Bonder, 2009a). There is,

Table 32-1 **Summary of Theories Related to Occupational Therapy for Older Adults**

Theories/Category	Constructs
Genetic theories/biological (Slagboom et al., 2010)	1. Particular genes can predict longevity or susceptibility to disease. 2. Mutation of genes could extend longevity. 3. Familial studies may identify longevity genes in families where there is a history of long life.
Activity theory/psychological (Havighurst, 1963; Longino & Kart, 1982)	1. Elderly strive to maintain activity. 2. High levels of activity correlate with well-being.
Continuity theory/psychological (Atchley, 1989)	1. Elderly attempt to continue activities that were always important to them. 2. Elderly perceive activities as continuous. 3. Elderly adapt activity to compensate for change. 4. Successful aging is characterized by degree of continuity achieved.
Life span theories/psychological (Erikson, 1963; Levinson, 1986; Neugarten, 1975)	1. Old age is continuation of the developmental process, representing a new developmental stage. 2. Tasks specific to the stage can be identified. 3. Successful aging results from accomplishing tasks.
Selective optimization with compensation/psychological (Baltes & Baltes, 1990).	Elders cope with changing function by: 1. selecting activites they can maintain 2. optimizing those they choose to continue 3. compensating for those they give up
Neurodegenerative change theories/ Neuropsychological (Woodruff-Pak & Papka, 1999)	1. Age-linked neuropathological changes occur in some diseases (Alzheimer's and Parkinson's) that produce changes in cognitive function. 2. No one theory adequately explains these observed phenomena. 3. Activities such as cognitive exercises and diet changes may stave off or reverse these changes.
Social constructionist theory/ sociological (Bengston, Burgess, & Parrott, 1997)	1. Individual processes of aging are influenced by social definitions and structures. 2. Each individual constructs meanings from his or her own experiences. 3. Qualitative research is emphasized.
Person-environment-occupation/ occupational therapy (Christiansen & Baum, 1997)	1. Successful occupational engagement results from an interaction of the person, the environment, and the occupation. 2. Intervention can occur in any of these three elements to enhance performance.

Adapted from Bengston, V. L., & Bonder, B. (2009). Theories of aging: A multidisciplinary review of occupational and physical therapists. In B. R. Bonder & V. Dal Bello-Haas (Eds.), *Functional performance in older adults* (3rd ed., pp. 28–44). Philadelphia: F. A. Davis.

however, great variability in how individuals cope with such losses. For example, loss of a spouse is devastating for most older individuals (McGarry & Schoeni, 2005). Some individuals compensate within a year or so, whereas others never recover. Higher socioeconomic status and social and spiritual resources seem to predict better long-term adjustment to loss of a spouse. Some elders are open to and actively seek new social relationships, whereas others become increasingly isolated. Because social relationships are so closely linked to well-being in later life (Park, 2009), therapy can be beneficial if it focuses on supporting strategies to build social networks.

IMPEDIMENTS TO OCCUPATIONAL FUNCTION

We review two categories of barriers to occupational function: disease and environmental factors.

Impact of Disease

Almost all older adults eventually fall ill or have an injury that may call for secondary or tertiary preventive interventions, that is, minimizing consequences early in treatment or enhancing rehabilitation once severe disability has occurred. The following special characteristics of older adults must be considered in planning intervention.

Differential Severity of Condition

Some conditions that are relatively innocuous in younger individuals, influenza, for example, can have severe consequences for older individuals (Dal Bello-Haas, 2009). On the other hand, cancers that may be terminal in younger adults are often quite slow growing in older individuals.

Multiple Health Problems

Otherwise well older adults are likely to have two or three chronic health problems (Administration on Aging, 2013); for example, rheumatoid arthritis and osteoporosis, each of which may require a different intervention. Although moderately strenuous weight-bearing exercise may be the treatment of choice to prevent bone loss, such activity may exacerbate the arthritis.

Duration of Recuperation

Older adults generally recuperate more slowly than younger ones, even if the eventual outcome is every bit as good. Treatment often ends too soon for older individuals.

Consequences of Dysfunction

Most elders prefer to live independently or "age in place" (Bonder, 2009a). It is their wish to remain in the living situation to which they have grown accustomed. Illness and dysfunction, however, can lead to a decision to institutionalize. Functional abilities are central to such decisions. In particular, bathing and toileting abilities influence family decisions. For this reason, occupational therapists often find that elders want to emphasize these abilities in treatment.

Environmental Factors

As with all clients, environmental factors, both physical and social, can have a profound influence on function. Issues described in Chapters 3 and 10 of this text should be carefully considered during interaction with elderly clients, because changes to the personal, social, cultural, and environmental context can greatly facilitate personal abilities.

Depression and Other Mental Health Concerns

As is true for all age groups, older adults may experience a number of significant psychiatric disorders. Dementia, which was discussed above, is listed in the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association [APA], 2000) and is one of the few psychiatric disorders that affects primarily older adults. The most common disorders among older adults are anxiety disorders and depression (Meeks et al., 2009).

Depression may be a continuation of a lifelong mood disorder. However, depression can also be linked to physical illnesses such as heart disease (Ai, Rollman, & Berger, 2010; Mast, 2010), stroke, or hip fracture (Meeks et al., 2009). Depression also presents somewhat differently in older adults as compared with younger individuals. Older adults are likely to have more somatic complaints, social withdrawal, and lethargy, often without reported depressed mood. In addition, depression in older adults may present as dementia (Meeks et al., 2009). Depressive dementia is characterized by poverty of response and apathy and is reversible if the depression is successfully treated.

Older adults, especially older men, have high rates of suicide as compared with younger populations (Szanto et al., 2002). Clinicians should be alert to signs of suicidal ideation and should ensure that appropriate intervention is provided when risk is suspected.

Depression is one of the more treatable psychiatric disorders. Among the potentially effective interventions are specific kinds of reminiscence focused on life review and on building relationships (Cappeliez, O'Rourke, & Chaudhury, 2005). Another strategy that has beneficial impact, not only for treating depression but also for supporting mental health well-being more generally, is intervention to enhance resilience (Moyle et al., 2010).

Elder Abuse

It is an unfortunate reality that a significant proportion of older adults experience some form of abuse (Anetzberger, 2009). Prevalence is estimated at 1%–10% of the older population. Elder abuse takes many forms, including physical or sexual abuse, neglect, and financial abuse (Anetzberger, 2009). Physical abuse involves active physical violence against the elder. Sexual abuse involves varying forms of sexual imposition. Neglect is characterized by failure to provide adequate care. Financial abuse is characterized by misappropriation of funds. Abuse may be perpetrated by informal caregivers (family members or friends) or by formal care providers (home health aides, therapists, or financial planners).

Clinicians have a responsibility to screen for abuse and are required to report suspected abuse to adult protective services. There are a number of screening instruments (Fulmer et al., 2004), although when the elder has dementia, self-report may not be accurate. Even elders who are cognitively intact may not report accurately, perhaps because they fear retribution or loss of independence. Thus, although screening assessments can be helpful, clinicians should attend to other signs of abuse, including weight loss, unexplained bruises, and unexplained changes in checking accounts. A very helpful checklist for occupational therapists has been developed by Lafata and Helfrich (2001).

FACILITATORS OF OCCUPATIONAL FUNCTION

Clinicians consider each patient's age as they plan assessment and interventions to optimize occupational function.

Evaluation

Careful evaluation is vital to successful intervention focused on supporting functional performance of older adults. Perhaps the most attention has been given to assessment of self-care (Wilkins, Law, & Letts, 2009). In assessing older adults, however, it is important to be cognizant of the goals of the individual (Canadian Association of Occupational Therapists, 2002). Assessment should focus on the individual's goals and proceed to determination of factors that support or impede those goals. The Occupational Therapy Practice Framework (AOTA, 2008) recommends completing an occupational profile and an analysis of occupational performance. The two combined provide information about what the individual needs and wants to do and what factors limit ability to accomplish those tasks.

Several instruments may be helpful in determining those goals. The Canadian Occupational Performance Measure (Law et al., 2005) involves interview of the client and joint identification of goals for therapy. These goals then become the measures of outcome. Other helpful assessments include the Melville/Nelson Evaluation

System (Melville & Nelson, n.d.), the Assessment of Motor and Process Skills (Fisher, 1995), the Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE) (Arnadottir, 1990), and the Activity Card Sort (Baum & Edwards, n.d.).

Legislation, particularly the Omnibus Budget Reconciliation Act (OBRA) (Glantz & Richman, 1991), requires that people in nursing homes have an environmental assessment, but such assessment should be done in community settings as well. A number of good environmental assessment instruments are available including the SAFER-HOME (Chiu & Oliver, 2006; Mann & Hicks, 2009; Tideiksaar, 2009) (see Chapter 10).

Instruments are also being developed to assess driving ability (Pellerito, 2006). In addition, it is important to evaluate risk for falls (Tideiksaar, 2009) for the reasons discussed above. It is important to evaluate both the physical and the social environment as well.

Some assessment is mandated by third-party payers. For example, the U.S. government has implemented a minimum data set (MDS) (Centers for Medicare and Medicaid Services, n.d.[a]) for residents of nursing homes, and the Outcomes Assessment Information (OASIS) (Centers for Medicare and Medicaid Services, n.d.[b]) for home health.

Intervention

An important role for occupational therapists working with older adults is prevention or remediation of functional disability (AOTA, 2008). Intervention may include prevention, ongoing screening for previously unidentified issues or concerns, environmental modifications, modification or substitution of activities, educational interventions, and collaboration with older adults and their families to individualize care plans (client-centered care). Evidence Table 32-1 lists studies proving the benefits of occupational therapy for older adults.

Screening

During the course of all intervention activities, occupational therapists should be alert to potential problems (Wilkins, Law, & Letts, 2009). If individuals who are nutritionally compromised or who have recently had a life-changing loss receive early intervention, disability may be minimized or avoided. For example, if a client becomes unable to drive because of increasing visual impairment, the therapist may acquaint him or her with community transit services or help make contact with friends and relatives who can provide occasional transportation. Such an intervention helps reduce the likelihood of social isolation, which can lead to depression and perhaps to significant disability. Screening should include record review, consultation with the client, family, and other professionals, and considerations for ultimate living

Evidence Table 32-1 | Best Evidence for Occupational Therapy Practice for Older Adults

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Independent living for community-dwelling elderly people	Assistive devices, skills training, evaluation of home hazards, comprehensive occupational therapy interventions	Over 3,800 participants represented in the studies reviewed		Systematic literature review of 17 studies	Strong evidence for the efficacy of advising on assistive devices as part of a home-hazard assessment	Two randomized controlled trials reported statistically significant effect sizes (odds ratios = 0.39 and 0.97) for training in assistive devices	Steultjens et al. (2004)
Environmental interventions for prevention of falls	Home assessment interventions	Over 3,200 participants represented in the studies reviewed		Meta-analysis of six clinical trials	The highest effects are with interventions conducted with high-risk groups	Pooled analysis of six trials ($n = 3,298$) demonstrated a 21% reduction in falls risk (relative risk)	Clemson et al. (2008)
Community-based occupational therapy for older adults with dementia	Cognitive and behavioral interventions to train patients in the use of aids to compensate for cognitive decline and to train caregivers in coping behaviors and supervision	One hundred thirty-five participants with moderate to mild dementia	Ten sessions were provided over a 5-week period	Randomized controlled trial and cost-effectiveness study Level: IA1a	Mean costs lower in the intervention group; significant difference in proportions of successful treatments at 3 months	Average total cost savings of $2,641 per couple receiving occupational therapy $p < 0.05$	Graff et al. (2008)
Lifestyle redesign program	Small group sessions with modular content areas led by an occupational therapist; community outings	Four hundred sixty older adults (well elderly)	Up to 10 individual 1-hour sessions, as well as the group sessions	Randomized controlled trial Level: IA1a	Intervention group showed positive change scores in bodily pain, vitality, social functioning, mental health, mental functioning, life satisfaction depressive symptomatology and quality-adjusted life years	$p < 0.05$ for all variables mentioned; effect sizes ranged from 0.14 to 0.23	Clark et al. (2011)
Review of research evidence on productive aging	Review of 14 articles published in *American Journal of Occupational Therapy* 2008–2009			Four systematic reviews, one instrument development, seven basic research articles, one effectiveness study, and one link between occupational engagement and health	Strongest evidence found in area of driving		Murphy (2010)

situation such as PACE Programs (www.medicare.gov /Nursing/Alternatives/PACE.asp) designed to keep older adults in their homes.

Environmental Modifications

Another highly effective intervention is to reduce some demands through alteration of the environment (Procedures for Practice 32-2).

Technological Aids to Function

Numerous technological assists can maximize function (Procedures for Practice 32-3). Some are simple, such as an alarm on the doorknob to warn family members that a person is wandering away or automatic off-switches on stoves to reduce fire hazard. Others, such as the computer-operated Smart House, are highly sophisticated and expensive.

Procedures for Practice 32-2

Environmental Modifications for Elderly Individuals

Cognitive Problems

- Reduce clutter.
- Label drawers and cabinets by their contents; for individuals who have dementia or other serious cognitive deficits, pictures may be easier to understand than words.
- Use color, texture, and lighting changes to provide location cues, such as changes from carpet to tile signaling the move from dining area to hallway.
- Use timers as reminders for specific functions.
- Put safety off-switches on stoves and furnaces.

Visual Problems

- Use high tone colors and low gloss finishes to improve visual acuity and depth perception (Tideiksaar, 2009).
- Encourage use of other sensory systems such as touch and hearing.
- Maintain a consistent environment for individuals with visual impairments.
- Reduce clutter, simplify, and reorganize the environment to establish routines.
- Write with felt-tipped pens and in bold print to help improve visibility (Mann & Hicks, 2009).
- Access optometrists, ophthalmologists, and staff at sight centers or the Society for the Blind.
- Provide high-intensity, low-glare light; avoid fluorescent lights; and put glare-reducing screens over televisions and windows (Tideiksaar, 2009).
- Teach compensatory techniques to individuals with visual field deficits (Lewis, 2003).
- Consider assistive technologies such as portable magnifiers, computer-screen readers, electronic books with speech function, talking wrist watches, devices to assist with pouring liquids, and tactile maps.

Hearing and Communication Problems

- Refer for a thorough evaluation from a speech pathologist, audiologist, or otolaryngologist.

- Speak slowly and clearly and use a deep voice with someone who has high-frequency loss.
- Make sure the individual can see you when you speak (Hooper & Dal Bello-Haas, 2009).
- Write messages if necessary.
- Modify the environment to improve acoustics and reduce ambient noise.
- Select activities for which verbal interaction may not be essential.
- Check that hearing aids are fitted and used properly and that batteries are fresh; remember that these aids do not restore normal hearing and may not help everyone with hearing impairment.
- Use visual cues, such as flashing lights, to get the client's attention. Address safety needs.
- Consult with other professionals and implement assistive technologies such as iPad, alternative communication strategies with assistive devices, or textual and pictorial communication. See further discussion in Chapter 18.

Neuromuscular, Motor, or Mobility Problems

- Make sure the environment is free of hazards such as slippery floors and architectural barriers.
- Adjust the height of chairs, beds, dressers, and toilet seats; provide a bath chair and grab bars.
- Provide task-oriented treatment in the individual's environment with numerous repetitions.
- In institutional settings, keep in mind OBRA regulations that mandate reduced use of restraints.
- Use alternative furniture or technologies such as floor-level bed and alarm systems.

Self-Care: Toileting and Continence Problems

- Make sure that the bathroom is physically accessible. Add grab bars and nonskid mats.
- Mark the bathroom clearly. Use large, clear words, pictures, and color code if necessary.
- Reduce liquid intake prior to bedtime.
- Institute regular reminders to use the bathroom.
- Institute timed voiding (regularly scheduled toileting) and prompted voiding (caregiver reminders) (Wiatrowski, Riccio, & Scheer, 2008)

Procedures for Practice 32-3

Assistive Technology for Problems Associated with Aging

- Telephones with amplifiers, large-print numbers, one-touch dialing and memory features; cordless, cellular, or digital phones; external speakers
- "Smart" technologies such as sensors in automobiles to facilitate parking; door answering systems; and sensors in the home to detect motion, falls, and intrusions
- Overhead track systems, stair glides, ramps, elevators, and other devices to assist with mobility
- Screen magnification, print enhancements, and voice synthesizers for computer-screen reading
- Assistive listening devices, telecommunication devices (TDDs) or computer software; closed captioning for television; and devices to convert auditory output to flashing lights for smoke detectors, telephones, and doorbells
- Life call systems that provide a link with emergency services
- Advances in technology for mobility, such as wheelchair seating systems, power carts, wheeled walkers with wheel locks and built-in seating systems, and adaptive controls for cars.

Procedures for Practice 32-4

Promoting Activity Choice for Intervention with Elders

- Link older adults with activities that express important personal meanings, especially connectedness with others, spirituality, service to others, and self-expression (Bonder, 2009b).
- Recognize individual variability in selection of activities that express personal meanings.
- Find out what specific self-care activities are perceived as vital to elders who are concerned about remaining in their homes.
- Employ reminiscence as a means to establish and maintain connections with others.
- Use activity inventories to stimulate an older client to think about what he or she values.
- Adapt the activity or help the client identify an activity that meets similar needs when preferred activities become too difficult for a client. Ascertain what component of the activity is meaningful.

Maintaining Wellness

The wellness movement (Gallup, 1999) is based on the principle of maximizing health and performance. Activities focused on stress management, exercise, nutrition, driving training, and safety are associated with this model (Bonder, 2009a). Wellness programs tailored for older adults focus on seven dimensions: physical, social, emotional, spiritual, professional/vocational, cognitive/intellectual, and environmental (International Council on Active Aging, n.d.).

Lifestyle Redesign

Lifestyle redesign is an approach that focuses on "health through occupation" (Clark et al., 1997). Participants are encouraged to recognize that meaningful occupation is important to both health and satisfaction. Small healthy lifestyle changes coupled with engagement in meaningful activities are critical to healthy aging (Clark et al., 1997; Waite, 2011). This model program consisted of weekly 2-hour small group sessions led by a licensed occupational therapist. Some examples of session modules include

- identification and implementation of feasible and sustainable activity-relevant changes
- development of plans to overcome mundane obstacles to enacting activity-relevant changes (e.g, bodily aches or transportation limitations)

There are limits to the application of technology with older clients. Some clients may resist learning to use the new technologies. Devices can break down and may be expensive to repair. Acquiring the devices may be expensive and not covered by insurance. Sometimes, a new and better device appears on the market as soon as a client has purchased an expensive piece of equipment. Many older adults, however, enjoy technological devices and gain considerable independence with them (Mann & Hicks, 2009).

Modification and Substitution of Activity

Activity analysis, a cornerstone of occupational therapy, can be particularly helpful in assisting older clients. The process involves matching present skills, interests, and motivation with activities that are stimulating, challenging, enjoyable, goal-directed, and purposeful. Some specific suggestions are presented in Procedures for Practice 32-4.

- participation in selected activities; rehearsal and repetition of changes to everyday routine
- time use and energy conservation
- assessing daily energy patterns; energy conservation and joint protection; adapting activities and daily routines
- home and community safety

Studies of this approach have established evidence that preventive and wellness care for older people must be a key element in health care provision (Clark et al., 1997, 2003, 2011). Interventions in the lifestyle redesign program were found to be cost effective and to improve vitality, social function, mental health, and overall life satisfaction. There was a decrease in body pain and depression in the program participants.

Cognitive Exercises

An emerging strategy for prevention of dementia is cognitive exercise (Clare et al., 2003). This is an intervention using structured practice on standardized tasks intended to maintain cognitive ability (primary prevention) or minimize cognitive loss (secondary prevention). The outcomes of CE have been studied through both correlational and experimental strategies (Hogan, 2005). Both approaches have limitations, and a recent review of the literature (Gates & Valenzuela, 2010) found that it is difficult to be certain about the impact of the intervention because of the wide variability in approaches to studying outcomes. Nevertheless, a significant body of research suggests that such CE may well be beneficial not only for preventing dementia but also for minimizing dysfunction (Gates & Valenzuela, 2010). CE has no identified risks, and there is evidence that participation in activities of any kind can enhance well-being (Kaminsky, 2010).

In prevention programs, occupational therapists work with other health care providers to maximize the individual's physical and functional well-being. The occupational therapist may emphasize socialization and physical fitness, modification of the environment to reduce the possibility of accidents, and identification of roles and activities that are satisfying to the individual.

Falls

One particularly important issue with regard to prevention is falls. As described above, falls are common and cause injuries associated with high mortality rates, making falls a serious concern for older adults. In addition, because they are aware of the potential for falls, many older adults have considerable fear of falling (Lach, 2005). Some older adults curtail their activities because of this fear; their accomplishment of desired occupations suffers even in the absence of a physical injury.

Falls are multifactorial in nature. Among the contributing factors are changes in sensation necessary to avoid falls (Tideiksaar, 2009), changes in musculoskeletal and vestibular function that compromise balance and gait (Nitz & Choy, 2004; Waddington & Adams, 2004), and environmental hazards such as wet or uneven surfaces (Tideiksaar, 2009). Risk factors include a previous fall, mobility limitations, polypharmacy, dizziness or orthostasis, and confusion or cognitive impairment. The risk of falling also increases as the number of risk factors increase (Tinetti & Kumar, 2010).

Recent outcomes research is mixed in reporting the most effective interventions for fall reductions. Home modifications, vitamin D, and Tai Chi were found to be cost effective in one study (Frick et al., 2010). A systematic review reported physical therapy, home modifications, and vitamin D to reduce falls with a more limited effect found for comprehensive management programs (Michael et al., 2010). Other studies show incorporation of exercise and strategies to improve balance during ADL to be effective in reducing falls (Clemson et al., 2010; Pai et al., 2010).

In conclusion, intervention with older adults requires understanding of the normal developmental processes that affect performance as well as the special life circumstances of older adults. To be most effective, intervention must address all spheres of function. The special factors that alter intervention with older adults must be taken into account. New model programs should be developed to address individual needs of communities and older adults (Kaminsky, 2010). With older adults, the goal of good quality of life as measured by engagement in satisfying activities is within reach for many elders. Thoughtful intervention by occupational therapists can ensure it.

case example

Mrs. P.: Optimizing Occupational Function Despite Limitations Associated with Aging

	Clinical Reasoning Process	
Occupational Therapy Intervention Process	**Objectives**	**Examples of Therapist's Internal Dialogue**
Patient Information	Appreciate the context	"Mrs. P. strikes me as a very independent woman—someone who is used to calling the shots. I will want to be very careful to respect that in her throughout this process."
Mrs. P. is a 73-year-old woman who lives alone in a ranch-style house in a small town. Her grown daughter visits about four times a year, and her son visits once a year. Mrs. P. was divorced 12 years ago and never remarried. Mrs. P. worked as a nurse for more than 20 years at a large university hospital. Now she works 2 days a week at a nursing home three blocks from her house, where she reviews charts for quality assurance. Mrs. P. has always enjoyed work and feels that the staff are close friends. Other than her income from the job, Mrs. P.'s only source of funds is Social Security.		
Throughout her adult life, Mrs. P. has been in a sorority consisting of about a dozen women who have been friends since they were young women. They live nearby. For many years, she was a member of a women's group that raised funds for the ballet in the nearby city. When she is at home, Mrs. P. enjoys working on a dollhouse that she built.		"Clearly, Mrs. P. has a strong social network. It impresses me that she has maintained strong connections with both her friends from work and her sorority sisters. I wonder if she would consider allowing these lifelong friends to help her out now."
Mrs. P. has a long history of health problems. She survived breast cancer when she was in her 40s, and 3 years ago she had surgery to remove a cancerous tumor from her colon. She has high blood pressure, controlled with medication. She also has a significant hearing loss that is gradually worsening.		
Reason for Referral to Occupational Therapy		"It's important for me to get a sense of how Mrs. P. is functioning in her own environment, and I am pleased that a home visit was ordered. She will likely be most comfortable here and I'll be able to get a clearer sense of what the barriers are to her occupational functioning."
Recently, Mrs. P.'s sorority sisters noted changes in her social behavior (missing meetings, not answering her phone, refusing social invitations) and contacted her son with their concerns. He urged his mother to make an appointment with her family physician, her primary care provider for the past 30 years. During the visit, the physician discovered that her high blood pressure has worsened, as has her hearing. She also reported being very tired and having difficulty managing around the house. The physician ordered a series of medical tests and asked a home health agency to send an occupational therapist to evaluate the home and Mrs. P.'s function. He assured her that her son agreed to pay for this evaluation.		
Results of Occupational Therapy Assessment		"I decided to use these instruments because they will help identify areas of occupation that are most important to Mrs. P. as we collaborate to develop an intervention plan, and they apply a theoretical model of practice (the Model of Human Occupation)."
Mrs. P. agreed to a home visit by the occupational therapist. The therapist decided to evaluate Mrs. P.'s home and her performance of basic self-care and instrumental activities of daily living. The therapist used the Check It Out Check-List (Pynoos & Cohen, 1990), the Interest Checklist, and the Self Assessment of Occupational Functioning. She also asked Mrs. P. to give her a tour of the house and to describe problems encountered in daily tasks.		

	Develop intervention hypotheses	"I have a number of core hypotheses as I approach this consultation: 1. Return to work is feasible and valued by employer and client 2. Consultation with physical therapy, physician, audiology, and social work is feasible. 3. Client's reasons for social withdrawal need further assessment. 4. Client continues to have interests in current occupations. 5. Client may be interested in alternative occupations to replace current work and leisure activities if these are not feasible."
	Select an intervention approach	"Consultative, adaptive, collaborative, client-centered, and rehabilitative approaches could all possibly be implemented."
	Reflect on competence	"I have knowledge and skills that I believe can help Mrs. P. Occupational therapy has strengths in energy conservation, adaptation of work and home for safety, meaningful occupations, and social skills. Physical therapy, audiology, physician, and social work could provide assistance with hearing, hypertension, financial, and social problems."
Recommendations 1. Develop an intervention plan in consultation with client, family, employer, and sorority sisters if appropriate. 2. Recommend consultation with physical therapy, social work, physician, and audiology. 3. Prioritize goals with interventions that are financially and functionally feasible in consultation with all stakeholders.	Consider the patient's appraisal of performance Consider what will occur in therapy, how often, and for how long Ascertain the patient's endorsement of plan	"Mrs. P. seems to want help to improve her functioning, but I do feel that I am somewhat limited as to how much I can do for her in just one session. I will want to make sure that I am addressing her priorities, and if she is interested, I am willing to work with her to explore availability of alternative resources to fund care." "I find myself wondering about whether or not other stakeholders are invested in the client over the long term. What are they willing and able to provide in support?"
Problem List and Solutions The therapist and Mrs. P. discussed these concerns and worked jointly toward identifying potential solutions. Because the therapist was asked to do an evaluation, not to provide long-term intervention, she must provide Mrs. P. with sufficient information to address her concerns. Home safety Mrs. P. acknowledged that the house was cluttered with old papers, knickknacks, and clothes. She was reluctant to throw anything away but agreed to have her daughter store some of the items for her. Mrs. P. also indicated that she had no funds to replace the worn carpet, although both agreed that worn spots and loose edges contribute to falls. She and the therapist identified several possible sources of funds and discussed the possibility of taking the carpet up entirely.	Assess the patient's comprehension Understand what she is doing	"Mrs. P. was very forthright about her concerns and could readily agree with some of my observations about the potential safety hazards related to all of her clutter. I can't tell whether her reluctance to get rid of things reflected difficulty with decision making or perhaps, her overall fatigue and deconditioning." "Mrs. P. is remarkably insightful. She realizes that falling at home or at work could have serious health consequences, but she may be self-limiting her activities more than is necessary. She seemed very receptive to my suggestions regarding how she could safely increase her activity level."

Physical deconditioning

Mrs. P. indicated that she had much less energy than she used to, quickly becoming short of breath when walking around the house. She agreed to begin a gradual plan of physical activity, starting with a stroll around the block each day.

Social isolation

Mrs. P.'s hearing loss was quite noticeable. The therapist encouraged her to see an audiologist to have her hearing evaluated. Mrs. P. expressed concern about paying for a hearing aid but agreed to ask her son for help.

Mrs. P. indicated that her friends were all in poor health and "no fun" anymore. She also said she was worried about falling at work. She was unwilling to discuss any alternatives for maintaining ties with her friends but agreed that she could discuss her concerns about work with her supervisor.

Next Steps

1. Client will consult with physician to address hypertension and fatigue.
2. Client will consult with physical therapy to address lack of endurance.
3. Client will consult with audiologist to address hearing loss.
4. Client will return to work.
5. Client will employ methods of energy conservation to work, self-care, and home maintenance tasks and will report ability to complete these tasks with fewer incidence and severity of fatigue symptoms.
6. Client will address safety hazards in the home such as clutter and unsafe flooring by removing these dangerous barriers.
7. Client will engage in activities with sorority sisters twice a week.

Mrs. P. and her occupational therapist developed a time line for Mrs. P. to call her doctor, her daughter, her son, and her boss, and Mrs. P. and her therapist agree that the therapist will make a follow-up call to check on her progress in 2 weeks. On follow-up, the therapist learned that Mrs. P. had accomplished a great deal. Mrs. P.'s physician determined that she had pernicious anemia and instituted monthly injections of vitamin B_{12}. Mrs. P. reported that she already felt more energetic.

Mrs. P. was now walking around her yard twice a day. Her daughter came to visit and helped her organize the house. Her son sent a check for a new hearing aid. Mrs. P. had not yet talked with her boss and was worried about doing it. She and the therapist practiced the conversation to provide Mrs. P. with a strategy. A week later, Mrs. P. called the therapist to tell her she was back at work.

Analysis of Reasoning

The therapist's initial task was to gather the information needed to clearly identify the problem. As the therapist secured information, it became evident that both Mrs. P. and her family needed to be consulted. Goals were identified based on their input. In this case, the occupational therapist provided an assessment and recommendations but left implementation of the plan to this capable client and family.

Anticipate present and future patient concerns	"I wonder if the employer is satisfied with Mrs. P.'s work performance. Is Mrs. P. enjoying her work?"
Analyze patient's comprehension	"I should ask Mrs. P. about her interactions with the sorority sisters and her family. Are there more frequent interactions? What is the quality of those interactions?"
Decide whether he or she should continue or discontinue therapy and/or return in the future	"Is Mrs. P. falling at home or at work and how frequently? How could I best evaluate for this? How about incidence of shortness of breath? I should consider these factors before deciding to discontinue intervention. Is the client able to manage daily activities, including work, without a worsening of hypertension or fatigue?"
	"If I am only able to intervene for one session, how could I most effectively address these complex issues using consultation, advocacy, and ethical/professional behavior? Can communication with the physician, the family, and other professionals involved address this concern adequately?"

Clinical Reasoning in Occupational Therapy Practice

Intervention to Prevent Performance Decrements

If clutter in Mrs. P.'s home is not reduced despite recommendations by the therapist to make this a top priority, what are some next steps that the therapist might consider to address this problem?

case example

Mrs. S.: Optimizing Occupational Function for an Older Adult in a Long-Term Care Facility

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	**Examples of Therapist's Internal Dialogue**

Patient Information

Mrs. S., an 80-year-old nursing home resident, has five children. Four of them live within 50 miles. Mrs. S. worked as the personal secretary for the provost of a small college for 20 years. She had a variety of interests, including reading, cooking, baking, participating in church and local theater, and gardening.

Mrs. S. faced a number of challenges in her life, including the early death of her father, the Great Depression, her husband's absence for 3 years of service in World War II, raising a child with schizophrenia, the early and sudden death of her husband (she was 51 years old when he died), and adjusting to a move from her home to an apartment and now to a nursing home.

Mrs. S.'s medical history is fairly typical for a person her age. She developed osteoarthritis in both knees, resulting in several arthroscopic surgeries and two total knee replacements. She was hospitalized for a brief bout of depression secondary to menopause. She has both near and far vision loss that are well corrected with eyeglasses. She has severe hearing loss in both ears that is partially corrected with hearing aids.

She also had a series of strokes that began when she was 70 years old. The strokes left her with mild spasticity, about 50% of proximal upper extremity active range of motion, and only a mass grasp in her left hand. She had full use of lower extremities except for a loss of about 15° of right active knee flexion and mild spasticity and weakness in the left lower extremity. She lost approximately 25% of the visual field on the left side to hemianopsia but can accommodate for this by turning her head. Mrs. S. also had mild dysarthria and dysphagia. She dribbled urine because of changes in bladder function and weak sphincter musculature. She wore a small protective pad and took medication to control this. She was hospitalized a year ago for an attempted suicide and major depression as a result of the breaking of her knee replacement and difficulty adjusting to the idea of another major surgery. She received psychiatric services and a long rehabilitation stay after she agreed to have the knee replacement. Her recovery from the knee replacement was very good except for her complaint of chronic pain in the knee that has not responded to medication.

Prior to the failure of her first knee replacement, she was totally independent in all basic activities of daily living (ADL). After her knee replacement and rehabilitation stay, a trial in her assisted living facility became problematic because of her declining ability to walk and transfer to the bathroom and her inability to do her own personal care. She and her family decided that Mrs. S. should be admitted to a nursing home, where she would receive closer supervision and assistance for her personal care.

| | Appreciate the context | "I should focus on past and current occupations and performance in areas of occupation. I want to take note of the current status of body functions and structures and how these may influence performance in the areas of occupation. It is important that I identify performance patterns, habits, and routines and try to make sense of all that relative to the cultural, spiritual, physical, social, personal, temporal, and virtual contexts of Mrs. S.'s past and current environment. For example, I wonder if possible changes in these factors have influenced her occupations, and what areas of occupation may be compromised by these changes?" |

Reason for Referral to Occupational Therapy

Nursing home staff was concerned about Mrs. S.'s safety and social withdrawal. Mrs. S. was still using a wheeled walker but found placing her left hand on the walker handle difficult. She was able to move from her bed to the bathroom independently but had several recent falls. She dressed independently if her clothes were placed on a chair beside her bed. However, she displayed poor judgment in activities such as bending too far over the edge of the bed and dangerously reaching for things she dropped on the floor. She also tripped over things while walking. She used a wheelchair on outings with her family and with the activities program at the nursing home. Mrs. S. rarely smiles, and nursing staff reports difficulty getting her to participate in group activities or outings, even though she was physically able to do so. Her family was supportive. Her oldest daughter had power of attorney and durable medical power of attorney. Mrs. S. paid privately for nursing home care and had funds remaining to cover about 2 more months of care. She was willing to pay privately for brief occupational therapy (OT) intervention.

Results of Occupational Therapy Assessment

After reviewing the medical records, the occupational therapist evaluated Mrs. S.'s life roles, tasks, activities, skills, abilities, and developed capacities. Mrs. S. was interviewed along with her oldest daughter and primary nurse. Some of the critical questions raised during the interviews:

- What safety issues are you most concerned about?
- What is your level of satisfaction with life right now? What do you think could be done to improve it?
- What things do you like to do right now? What things irritate you?
- If you could change five things around here to make things better for yourself, what would you change?
- What worries you most? What makes you happiest?
- Do you have any goals to improve yourself, your environment, or your living situation?

"Are there standardized or nonstandardized assessments that could be used to address the above issues?"

Develop intervention hypotheses

"I have a number of core hypotheses as I approach intervention planning:

1. The client is motivated to improve.
2. The caregivers are motivated to collaborate on the established goals.
3. The family is supportive and motivated to assist in achieving the goals.
4. Direct intervention as well as consultation and collaboration are necessary to achieve the goals.
5. The client has the potential to achieve the goals.
6. The other stakeholders have the resources to collaborate in accomplishing the agreed upon goals.
7. It is financially possible to consult other professionals such as physical therapy, urology, orthopedic surgery, pain management specialist, audiology, social work."

Select an intervention approach

"Rehabilitative, client-centered, consultative, adaptive, and collaborative therapy approaches may all apply to this client."

Reflect on competence

"Skills from other professionals will be needed to address many of the issues. Occupational therapy has strengths in the areas of safety, urinary incontinence, meaningful occupations, functional mobility, ADL, and psychosocial issues.

Recommendations

1. Interview client, family, caregivers, and nursing home staff to identify problems that are of highest priority for each stakeholder.
2. Further assess safety and performance of ADL.
3. Recommend consultation with physical therapy, social work, audiology, psychiatry, and urology.
4. Develop plan of care in consultation with all stakeholders.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"I need to address issues that are most important to the client, the family, and the caregivers. I wonder if there is consensus among all stakeholders about these issues and their relative importance. I will need to consider what can be done in the way of consultation, direct occupational therapy intervention, and collaboration with others considering the client's strengths and weaknesses, the motivation of all stakeholders, and the context. Who will be responsible for goal achievement using which model of team intervention?"

Summary of Short-Term Goals and Progress

The interviews and evaluation revealed the following problems:

- Mrs. S. tends to get upset and take things into her own hands when she has to wait for assistance. This results in unsafe or dangerous behavior and activities.
- Mrs. S. gets depressed and does not feel like socializing with others, especially residents with problems similar to hers or worse.
- Mrs. S. needs some meaningful activities to replace the wide variety of activities that formerly gave her pleasure.
- Mrs. S. needs some modifications to her environment to increase safety and orientation to reality and current events.
- Mrs. S. is easily embarrassed and has difficulty asking for personal assistance, especially with urination and personal hygiene.
- Mrs. S. would like more interaction and visits from her family.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

"How can I and the team best monitor falls, frequency of urinary incontinence, quality and quantity of participation in mandatory or optional leisure activities, and list of positive and negative feelings?"

"What can be done to assess motivation of client, staff, and family in monitoring follow-through with recommendations, and do I need to adjust instructions and goals depending on progress or lack of progress achieved?"

"I should consider standardized assessments of depression, occupational function, cognition/judgment, and ADL function."

Occupational Therapy Goals

The following goals were agreed upon by Mrs. S., her family, and the nursing staff:

1. Mrs. S. will request and wait for assistance or supervision for trips to the bathroom or will use a female urinal at bedside.
2. Mrs. S. will call for assistance should she drop any item on the floor that is not within easy reach of her long-handled reacher. Otherwise, she will continue to dress herself independently with setup at bed or chair level.
3. Mrs. S. will attend at least two outings per week with family or with the nursing home activities program. She will provide constructive criticism to the staff as to how the activity could be improved.
4. Mrs. S. will learn to propel her wheelchair so that she can safely navigate throughout the building without falling. She will be supervised for walks to the bathroom or in the hall.
5. Mrs. S. will choose and successfully complete three leisure activities within a month using adaptive equipment or techniques recommended by the occupational therapist.
6. Mrs. S. will complete a list of things that she is unhappy with as well as a list of things she is grateful for and review them with her daughter at least once a week to encourage her to express her feelings appropriately.

Next Steps

The occupational therapist decided to see Mrs. S. once or twice a week for a month to achieve these goals. Mrs. S. agreed to pay for the therapy because she did not qualify for skilled services under Medicare regulations.

Direct intervention

1. Instruction in safety for mobility within her room.
2. Adjustment of call signal button and chairs and removal of throw rugs and other barriers to safe mobility in the room.
3. Provision of long-handled reachers and instruction in use of them.
4. A session to assess safety issues during dressing and hygiene activities.
5. Suggestions for adaptive equipment for playing cards, reading, and plant care.
6. A daily calendar and structured time to read the paper or watch the news on television for current events.
7. A meeting with Mrs. S. and her family at the end of the month to review progress on goals and to make decisions about continuance of therapy or discharge.

The occupational therapist suggested referrals to physical therapy for a program to maintain or enhance mobility and physical conditioning, speech pathology to review issues related to dysphagia and dysarthria, and social work to help Mrs. S. and her family apply for Medicaid or other support, because financial concerns were becoming an issue. The therapist consulted the nursing and activities staff and provided written copies of suggestions for the staff to facilitate accomplishment of the therapy goals. Suggestions were also made to Mrs. S. and her family to explore a visit to a chronic pain specialist for the knee pain and to a urologist for follow-up on bladder control issues.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether he or she should continue or discontinue therapy and/ or return in the future

"Are the goals being met? Why or why not? Did the other consultants contribute to the interventions and what were the outcomes? How are the client, caregivers, and family responding? What barriers could be further addressed to more effectively address the problems and goals? Is additional support needed to ensure safety? Has the client reached maximum potential to achieve the goals based on progress notes and consultation with all stakeholders? What progress can be documented? Do all stakeholders agree that further therapy would be beneficial in reaching particular goals? Which particular goals?"

Clinical Reasoning in Occupational Therapy Practice

Intervention Despite Age-Related Deterioration

1. Therapy for Mrs. S. focused on ADL and safety. It was clear that she also needed to find activities that were meaningful to her. The therapist was able to make some suggestions. What else might have been helpful in addressing this aspect of Mrs. S.'s occupational performance?

2. What additional strategies might be employed to ensure that Mrs. S. remembers the safety precautions she has been taught?

Summary Review Questions

1. In a well elderly individual, what are the most typical changes in sensation? How can they affect function?
2. How do normal neuromuscular changes that accompany aging affect mobility? How can these changes ultimately affect occupational function?
3. What are some key differences in the cognitive complaints of adults with age-associated memory impairment versus AD? Describe ways the therapeutic response to these complaints may differ.
4. In general, what adjustments do older adults face in transitioning to retirement?

5. What is the first step an occupational therapist should take in assessing the status of an older individual?
6. What factors are important in selecting substitute activities for an older adult?
7. In deciding about technological interventions, what factors must be considered to ensure acceptance of the device?
8. What factors complicate intervention with an older adult who falls ill or is injured?
9. What are some myths about sexuality and older adults?
10. What evidence exists to support interventions for incontinence, fall prevention, and wellness/lifestyle redesign?

Glossary

Aging in place—Remaining in the home and community in which one has lived as a younger adult.

Catastrophic reaction—Emotional outburst characteristic of the middle stage of Alzheimer's disease, often as a consequence of excessive and confusing environmental stimuli.

Crystallized intelligence—Ability to use stored or previously learned information.

Dementia—Symptom caused by a number of conditions and characterized by loss of memory, language functions, ability to think abstractly, and ability to care for oneself.

Fluid intelligence—Ability to use new information.

Presbycusis—Age-related sensorineural hearing loss, especially for high-frequency sounds.

Practical memory—Ability to remember routines, schedules, important phone numbers, appointments, or other practical information needed to carry out every day activities.

Presbyopia—Age-related vision change caused by loss of flexibility of the lens, which leads to poor near vision.
