Occupational Therapy Evaluation and Intervention

It is essential to work with the client and family throughout progression of the disease as needs change. Cultural, social, and spiritual values must be understood because these factors will influence ongoing decisions about personal care and life support. The client and family members must regularly update decisions about care. Decisions range from when or whether a wheelchair or adaptive eating device should be used to whether the client should undergo a tracheostomy, choose tube feeding, or use a ventilator. Psychosocial support regarding decisions about the extent of life support and medical intervention should be provided by the entire health care team, with the physician and client having primary responsibility. Several studies have shown that caregivers and patients have different needs and perceptions of quality of life. It may be beneficial for patients and caregivers to have time for education and support separately to meet their individual needs.^{32,88,162}

Initial and ongoing OT assessment is essential to educate the client about ways to adapt functional activities as the disease progresses. Education is needed for nursing staff and physicians to understand the role of the occupational therapist in the treatment of clients with ALS.

Steady disintegration in the ability to speak, swallow, move, and perform activities of daily living (ADLs) makes it easy to overlook the presence of some common signs of cognitive or behavioral dysfunction, such as poor insight and deficits in planning.¹ Multiple cognitive domains may be affected in persons with ALS, including psychomotor speed, fluency, language, visual memory, immediate verbal memory, and executive function.¹⁷⁷

With impaired executive function, a person with ALS may have difficulty handling the visual, auditory, and other sensory data required for complex decision making.¹²⁵ These cognitive and behavioral issues are pertinent when considering teaching strategies and the need for caregiver counseling and support.

Role of the Occupational Therapist

ALS progresses rapidly, with ongoing deterioration in physical status and possibly cognitive deficits. The intervention plan should focus on the client's participation in occupational performance because the client's functional status changes frequently and intervention focused on physical performance is limited. As the client's function declines, there is a greater need for environmental support through providing durable medical equipment, modifying the home, and providing adaptive equipment. Depending on the client's level of understanding, life support choices, and acceptance of the disease, the OT intervention may focus on structuring the client's environment to support independence.⁴⁵ Some clients with ALS may choose to have the maximum environmental and life support available to extend life. In this case, the occupational therapist may provide periodic re-evaluations to determine the client's need for adapting self-care, work, and leisure activities. Other clients may request that no extraordinary life support be used, in which case the occupational therapist would assume a supportive role, perhaps helping these clients create a memory book to give to their loved ones. Table 35-2 provides a list of the functional deficits at various stages of the disease and interventions that may be required. When referring to this table, the OT practitioner must remember that each client's clinical picture is unique and that symptoms may appear in a different sequence than the table indicates. For example, a client with early-onset bulbar signs may require earlier intervention regarding swallowing assessment and communication devices; another client may not need a wheelchair until the very late stages. Olney's resource manual, *Daily Activities Made Easier for People with Amyotrophic Lateral Sclerosis*, provides practical solutions for ADLs and a variety of resources that address many of the problems that this population faces and is

an invaluable resource for practitioners, patients, and families.^{32,131}

Individuals and their families require an interdisciplinary approach to the rapid changes in function, complex psychosocial factors, and quality-of-life issues associated with ALS. The impact of the disease on the client's quality of life has been examined frequently. One study indicated that those who were less distressed and less depressed^{129,131,133} and had a more positive attitude lived longer.⁹¹ Fatigue and depression have been associated with a poor quality of life for an individual with ALS.¹²¹ The same study found that progression of the disease was not necessarily associated with a poor quality of life. Hecht and colleagues⁹¹ found that social withdrawal correlated with levels of disability; based on the results of this investigation, the authors recommended that mobility be improved with power wheelchairs and public transportation to prevent social withdrawal. Studies have also examined the impact of hope, spirituality, and religion as a means of coping with the disease.

OT Practice Notes

Formulation of an occupational profile during the occupational therapy evaluation can promote better understanding of the client's outlook and help determine the most appropriate interventions to improve quality of life with this rapidly progressing disease.

Summary

ALS is a rapidly progressing, fatal condition of unknown etiology. OT aims to maximize the client's function by providing interventions and periodic reassessment to compensate for declining motor function through modification of the environment, roles, and tasks and by helping the client and family achieve self-identified goals.

■ SECTION 2: | Alzheimer's Disease

CAROLYN GLOGOSKI

Dementia is the general word used for a group of symptoms caused by serious disorders of the brain. Memory loss and other related problems in language, perception, thinking, and judgment interfere with learning, communicating, relating, and even caring for self. Dementia is not just one disease but includes a number of diseases (e.g., vascular dementia, Lewy body dementia, frontotemporal dementia). The most common dementia is *Alzheimer's disease*, especially in persons older than 65 years.

AD is considered a primary dementia because it does not result from other diseases. Secondary dementia may be used to refer to symptoms of dementia that are associated with

■ **TABLE 35-2** | Interventions for Amyotrophic Lateral Sclerosis

Patient Characteristics	Interventions with Focus on Performance Areas of Occupation	Interventions with Focus on Client Factors
PHASE I (INDEPENDENT)		
<p><i>Stage I:</i> Mild weakness Clumsiness Ambulatory Independent in ADLs</p>	<p>Continue normal activities or increase activities if the client is sedentary to prevent disuse atrophy and depression Integrate energy conservation into daily activities, work, and leisure Provide opportunity for the individual to voice concerns (provide psychologic support as needed)</p>	<p>Begin range-of-motion program (e.g., stretching, yoga, tai chi) Add a strengthening program of gentle resistance exercise to all musculature while being careful to prevent overwork fatigue</p>
<p><i>Stage II:</i> Moderate, selective weakness Slightly decreased independence in ADLs; for example, difficulty climbing stairs, raising arms, buttoning clothing</p>	<p>Assess self-care, work, and leisure skills impaired by the loss of function; if the patient continues to work, focus on how to adapt tasks to the current deficits; assist with balance between work, home, and leisure activities; include significant others in treatment Use adaptive equipment to facilitate ADLs (e.g., button hook, reacher, built-up utensils, shower seat, grab bar) Integrate hand orthotic use into daily activities. Perform baseline dysphagia evaluation; re-evaluate throughout each stage of the disease</p>	<p>Continue stretching to avoid contractures Continue cautious strengthening of muscles with MMT grades above F+ (3+). Monitor for overwork fatigue Consider orthotic support (e.g., AFOs, wrist or thumb splints—short opponens splint)</p>
<p><i>Stage III:</i> Severe, selective weakness in the ankles, wrists, and hands Moderately decreased independence in ADLs Tendency to become easily fatigued with long-distance ambulation Slightly increased respiratory effort</p>	<p>Prescribe a manual or power wheelchair with modifications to eventually allow a reclining or tilt posture with a headrest, elevated leg rests, and adequate trunk and arm support Help the patient prioritize activities and provide work simplification. Reassess for adaptive equipment needs (universal cuff to eat) Assess and adapt the use of communication devices (e.g., regular phone to cordless or speaker phone; pen and paper to computer with an adapted typing aid) Provide support if loss of employment or other activities; explore alternative activities Begin discussing the need for home modifications, such as installing ramps or moving the bedroom to the lowest floor Provide education on the types of bathroom equipment available for energy conservation and safety</p>	<p>Keep the patient physically independent as long as possible through pleasurable activities and walking Encourage deep-breathing exercises, chest stretching, and postural drainage if needed</p>
PHASE II (PARTIALLY INDEPENDENT)		
<p><i>Stage IV:</i> Hanging-arm syndrome with shoulder pain and sometimes edema in the hand Wheelchair dependent Severe lower extremity weakness (with or without spasticity) Able to perform some ADLs but fatigues easily</p>	<p>Evaluate the need for arm slings, overhead slings, and mobile arm supports for eating, typing, and page turning Prescribe a power wheelchair if the patient wants to be independent with mobility; controls must be adaptable from hand to another mode of control Evaluate the need for assistive technology such as environmental control systems, voice-activated computer, and augmentative communication device</p>	<p>If arm supports are not used, provide arm troughs or a wheelchair lap tray for wheelchair positioning and wrist cock-up splints for full resting; hand splints may be needed for positioning Provide pain and spasm management through the following:</p>

■ TABLE 35-2 | Interventions for Amyotrophic Lateral Sclerosis—cont'd

Patient Characteristics	Interventions with Focus on Performance Areas of Occupation	Interventions with Focus on Client Factors
<p><i>Stage V:</i> Severe lower extremity weakness Moderate to severe upper extremity weakness Wheelchair dependent Increasingly dependent in ADLs At risk for skin breakdown caused by poor mobility</p>	<p>Help the patient prioritize activities, and consider negotiating roles with significant others Reinforce the need for home modifications Reinforce the need for a shower seat or transfer tub bench and a shower hose Assist with the patient's ability to participate in closure activities, such as writing letters or making tapes for children, completing a life history, and writing a log on household management for family</p> <hr/> <p>Instruct the family in methods to assist the patient in self-care, especially bathing, dressing, and toileting; aim to minimize the caregiver's burden and stress Train family members so that they learn proper transfer, positioning principles, and turning techniques Instruct in the use of a mechanical lift if needed for transfer out of bed (patients in slings require head support) Adapt and select essential control devices for the telephone, stereo, and television; electric hospital bed controls for independent use Adapt the wheelchair for a respiratory unit if needed to allow continued community access</p>	<p>Heat and massage as indicated to control spasm and pain Antiedema measures Active assisted or passive range-of-motion exercises for the weak joints; Caution in supporting and rotating the shoulder during abduction and joint accessory motions Isometric contraction of all musculature to tolerance</p> <hr/> <p>Instruct the family and patient in skin inspection techniques Instruct in the use of an electric hospital bed and antipressure device Adapt the wheelchair for a respiratory unit if needed; reassess the adequacy of the wheelchair cushion for relief of pressure</p>
PHASE III (DEPENDENT)		
<p><i>Stage VI:</i> Dependent, with all positioning in a bed or wheelchair Completely dependent in ADLs Extreme fatigue</p>	<p>Eating: evaluate for dysphagia, and recommend an appropriate diet; the therapist may recommend tube feedings if the patient is at high risk for aspiration; recommend a suction machine for handling secretions and preventing aspiration Augmentative speech devices may be recommended, in addition to speech therapy</p>	<p>Continue with passive range-of-motion exercises for all joints Provide sensory stimulation with massage and skin care</p>

ADL, activities of daily living; AFO, ankle-foot orthosis; MMT, manual muscle test.

Modified from Yase Y, Tsubaki T, editors: *Amyotrophic lateral sclerosis: recent advances in research and treatment*, Amsterdam, 1988, Elsevier; and Umphred DA, editor: *Neurological rehabilitation*, ed 3, St. Louis, Mo, 1995, Mosby.

other physical diseases (PD, ALS, MS, HD) and are discussed elsewhere in this chapter. AD, unlike the other neurologic disorders discussed in this chapter, is formally classified as a mental disorder by the American Psychiatric Association.¹¹ The exact cause of AD is still unknown. Because of the damage to brain cells and irreversible cognitive decline, the disease results in impaired higher mental processes, altered behavior, and disturbances in mood. The disorder progresses gradually and produces multiple cognitive deficits, a significant decline from previous levels of functioning, and noticeable impairment in social and occupational functioning. Effects on the motor and sensory

systems are not apparent until later in the disease process. Dementia is a significant health care problem because of the increasing number of individuals who are living longer, the higher incidence of dementia in older persons, the very high cost of supervised care, and the extensive use of medical resources.⁹³ Almost three times as much money is spent by Medicare for persons with AD and other dementias as for beneficiaries without AD.^{4,6} Early recognition of cognitive decline by physicians, occupational therapists, and all other health care professionals is critical. Slower progression of the disease, greater understanding of functional decline, improved quality of life, and time to prepare for the future

for older adults and their families could be an outcome of early recognition. AD is often overlooked or mistaken for other disorders, especially in the early stages.

OT Practice Notes

Occupational therapists have an essential role in helping a client with Alzheimer's disease enjoy life and remain as self-sufficient as possible and in supporting families and caregivers over the course of this difficult disease.

Incidence

AD accounts for more than two thirds of cases of dementia, and the incidence increases dramatically as people age.^{4,6,41,61,184,225} It is estimated that close to 13% of adults 65 years or older have AD. The disease affects more than 5 million people in the United States, and 4.9 million are older than 65 years. Age is the strongest primary risk factor. The incidence of AD more than doubles for every 5 years above the age of 65. It is estimated that 40% to 50% of the population of old-old (85+ years) adults have AD. Many more Americans are surviving into their 80s and 90s because of advances in medical technology. In a recent study of 97-year-olds, 61% of the population had some form of dementia.¹⁰⁴ As the population of old-old adults continues to grow, the number of persons with AD is also expected to grow. Family history and genetics are other risk factors for AD.⁷⁰ Early-onset, familial forms of AD are linked to genetic mutations on chromosomes 1, 14, and 21.^{81,117,150,199} Late-onset AD has been linked to the apolipoprotein E-4 (APOE-4) allele on chromosome 19, but it should be noted that this allele has also been found in older persons who do not have AD.^{150,151,172} It is generally agreed that although genetic factors pose some risk for late-onset AD, it is the interactive effects of diet, lifestyle, and environment affecting each person differently. This field of research is known as epigenetics. Three new genes thought to have a role in late-onset AD have recently been discovered by researchers.^{69,150} Two of these genes are responsible for protein encoding (*CLU*—clearing β -amyloid; *PICALM*—recycling cell membrane proteins at synapses), and a third gene, *CRI* (complement receptor 1), is responsible for the inflammatory response and clearing of β -amyloid. Scientists conducting AD research are currently exploring the idea that changes in the regulation of genes—turning them on and off through the interactive effects of nature and nurture—and not just gene mutations can make someone more or less susceptible to AD.¹⁵⁰ Previous head trauma is a well-established risk factor for AD; other factors that result in increased risk include diabetes mellitus, APOE gene variation, current smoking, and depression. Limited evidence shows increased risk associated with use of estrogens and

nonsteroidal anti-inflammatory drugs, and the evidence is inconsistent for risk factors associated with heart disease, high blood pressure, and obesity. Researchers are also exploring the effects of certain inhaled anesthetics, lead exposure, and timing of the use of hormone replacement therapy after menopause.¹⁴⁸⁻¹⁵⁰

Although the incidence of dementia is growing rapidly, it does not occur in all older adults. Many older adults experience a normal slowing of information processing, called age-related cognitive decline. Clinically significant cognitive deficits do not develop in this population.¹¹ Mild cognitive impairment (MCI), a condition that involves problems with memory, language, or other essential cognitive functions that is serious enough to be noticeable to others and to show up on tests, develops in a proportion of the older adult population, but this impairment is not severe enough to interfere with daily life.¹⁴⁸ In some, but not all persons with MCI, AD eventually develops. A study by Driscoll and colleagues found that persons with MCI showed brain atrophy, but the group in whom AD eventually developed exhibited a pattern of atrophy in the region of the temporal lobes.⁵⁸ A term sometimes used by laypersons to refer to older adults with memory loss or cognitive impairments is *senility*. Senility is not a medical term. Use of the word *senility* perpetuates stereotypical impressions that progressive cognitive decline occurs in normal aging. Such ideas prevent early recognition and accurate diagnosis of dementia.

Pathophysiology

AD is the result of degenerative changes in the CNS. Neuroanatomic (structural) and neurochemical changes occur in genetically and/or environmentally susceptible brains.¹³⁴ Many neurons die, stop functioning, or lose their connections with other neurons. Disruption of communication, metabolism, and neuron repair occurs. The result of these changes is progressive and diffuse neuronal loss in the cerebral cortex and hippocampus.^{150,194} Three noticeable pathologic changes have been found through microscopic examination of brain tissue after death: accumulation of amyloid in the space between neurons, increased neuritic plaques and neurofibrillary tangles, and loss of neurons and synapses. Early AD is associated with decreased cholinergic markers in areas of the brain with an increased distribution of plaques and tangles. Many of the changes in the brains of persons with AD can be seen only at autopsy, although neuroimaging techniques (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and positron emission tomography [PET]) provide further diagnostic information such as enlarged ventricles. The degenerative changes in the brain involve several processes that affect neurotransmission and result in neuronal death.¹⁹⁴ Studies suggest that the sequence of disease events in individuals with AD involves amyloid deposits in the earliest stages that are not yet associated with actual

cognitive impairment.^{136,150,209} Later, abnormal tau protein accumulates and causes loss of synapses, neurons, and brain volume. An inflammatory process causes the tau proteins in cortical and limbic neurons to undergo microtubular dysfunction, which prevents neurons from sending nutrients and hormones along the axons. The paired filaments of these intracellular proteins actually become cross-linked in an abnormal metabolic process. These filaments form neurofibrillary tangles that eventually lead to neuron death as the neuron transport system collapses. Neurofibrillary tangles are also seen in the temporal areas and to a lesser degree in the parietal association areas.

Neuritic plaques are large, extraneuronal bodies consisting of accumulated β -amyloid and neuronal debris—small axons and dendrites. Neuronal plaques predominate in the temporal and parietal areas in early AD. This material degenerates and takes up cellular space. Extracellular accumulation of too much insoluble β -amyloid in neuritic plaques contributes to the neuron degeneration. When neurons lose their connections, they cannot function and eventually die. The neuron degeneration and death spread through the brain, connections between other neurons break down, and affected regions begin to shrink in a process called *brain atrophy*. By the final stage of AD, damage is widespread, and brain tissue has shrunk significantly. The production of high levels of insoluble β -amyloid is associated with early-onset familial AD and has been linked to genetic markers on chromosomes 1, 14, and 21.^{81,117,199} In late-onset AD, the accumulation of amyloid deposits may be affected by APOE-4 on chromosome 19 and can also affect the development of neurofibrillary tangles.¹⁹⁷ Scientists anticipate that an understanding of the mutation in chromosomes associated with early-onset AD will help them better understand late-onset AD.¹⁵⁰ Late-onset AD is more likely related to a combination of genetic, environmental, and lifestyle factors that affect the regulation of gene expression, which can differ from person to person.⁵¹

Cholinergic dysfunction also occurs in individuals with AD, and this depletion in neurotransmitter is the process responsible for the expression of clinical symptoms, such as deficits in memory and word-finding problems, in early AD. Specifically, cholinergic deficits, thought to be linked to APOE-4, include less choline acetyltransferase activity in the frontal cortex, hippocampus, and temporal cortex.^{169,171,194} These areas of the brain are associated with such symptoms of AD as recent memory impairment and problems in executive functions.

Clinical Picture

Initially, the signs and symptoms of AD may seem puzzling because the disease can affect different people in different ways.⁴ The symptom that is most prominent is the progressive inability to remember new information. Recently, the Alzheimer's Association compiled a checklist, "Know the 10

Signs,"⁵ an Early Detection Matters education campaign that assists older adults and their families in early recognition and contact with their primary care physician. The symptoms and patterns of behavior in persons with AD are often described in terms of stages, but it is important to recognize that it can be difficult to place a person with AD in a specific stage because stages may overlap.¹⁹⁶ The simplest description of staging, useful for caregivers and consumers, defines the progression of AD in terms of a three-point stage scale: early, middle, and late stages.⁸⁰ A more clinically and diagnostically complex scale, such as the seven-point Global Deterioration Scale (GDS),^{182,183} is used in research or modified for diagnostic purposes and is often used as part of an assessment battery. It is important to realize that not all persons with AD will progress at the same rate or have the same pattern of symptoms despite the GDS staging framework.

The primary symptom of AD is impairment in recent memory that worsens with time, with at least one other cognitive deficit being present, such as apraxia, aphasia, agnosia, or impaired executive function, according to the American Psychiatric Association.¹¹ Memory impairment involves increased difficulty learning new information and recalling information after more than a few minutes.^{150,205} Over time, the ability to learn deteriorates further and the ability to recall old memories also declines. Symptoms such as speech and language problems, impaired recognition of previously familiar objects, and impaired ability to perform planned motor movement are more variable and may not be seen in all persons with AD. Expression of symptoms depends on the areas of the brain most affected by the disease. Executive function (the ability to initiate, plan, organize, implement safely, and judge and monitor performance) inevitably deteriorates as AD progresses. Visuospatial dysfunction is common. Changes in mood and behavior consisting of personality shifts and the development of depression, anxiety, and increased irritability are often observed in the early stages of AD.¹³⁰ Later in the course of the disease, troubling behavioral problems such as agitation, psychosis (i.e., delusions and hallucinations), aggression, and wandering can emerge.^{4,6,148,150} Motor performance areas such as gait and balance may become impaired, and sensory changes usually arise in the middle to later stages of the course of AD (see Table 35-3). Frequently, delirium and depression complicate the clinical picture. The life expectancy following the diagnosis of AD is typically 8 to 10 years but can range from 3 to 20 years, with a variable rate of progression.¹³⁷

Deterioration in the individual's functional performance usually occurs in a hierarchic pattern. This pattern of decline initially consists of a gradual progression from mild impairments in work and leisure performance to more moderate difficulty in performing instrumental activities of daily living (IADLs), especially finances and driving. Eventually, there is progressive loss of the ability to perform even basic self-care ADL tasks. The pattern of disability is usually

■ **TABLE 35-3 | Progression of Alzheimer’s Disease and Intervention Considerations**

Client Characteristics	Intervention Using Occupational Performance	Intervention Using Performance Patterns and Client Factors
STAGE I: VERY MILD TO MILD COGNITIVE DECLINE		
Feels loss of control, less spontaneous; may become more anxious and hostile if confronted with losses	Listen to client concerns; collaborate with the client in identifying areas that are challenging, and identify associated feelings (depression or anxiety)	Encourage physical exercise and wellness behavior
Mild problems with memory and less initiative; difficulty in word choice, attention, and comprehension; repetition sometimes necessary; conversation more superficial; mild problems with gnosis or praxis	Begin training the caregiver to serve as a case manager ²¹	Help the client and caregiver establish a daily routine, and post it in a central place
Seems socially and physically intact except to intimates; decline in job performance	<p>Provide educational and other resources for acquiring information on the disease, support, and relaxation, as well as on support groups or activities for both the client and caregiver</p> <p>Identify roles, frequency of activity, and configuration; encourage continuation of or increase in enjoyable activities by keeping a log and planning enjoyable activity daily or weekly²¹; use activity or task as a focus in socialization</p> <p>Explore the meaning of occupations and occupational role changes with the client and caregiver</p> <p>Identify needs, preferences, and goals of the caregiver. Discuss driving skills, and plan for future evaluation and restrictions</p>	<p>Use environmental aids such as calendars, appointment books, adhesive notes, and notebooks to enhance memory and reinforce engagement in occupation</p> <p>Identify appropriate environments, or adapt for activities that are currently challenging</p> <p>In teaching new tasks, use auditory, visual, and kinesthetic input, and provide supportive or positive feedback; grade activity for success to decrease anxiety</p> <p>During communication training, rehearse with client how to use “I” statements and assertively express self and needs in response to changed ability and the feelings aroused</p> <p>Educate and train the caregiver in how to empower the client to keep active and facilitate initiation of tasks</p>
STAGE II: MILD TO MODERATE DECLINE (PROBLEMS FROM STAGE I ARE EXACERBATED)		
Use of denial, labile moods, anxious or hostile at times; excessive passivity and withdrawal in challenging situations; possible development of paranoia	Emphasize to the caregiver the importance of the environment in managing dementia at home ⁵⁰	Maintain routines and design environmental support (e.g., lists, posters, and pictures) and level of assistance for cues to remember daily routine and important events
Moderate memory loss, with some gaps in personal history and recent or current events; decreased concentration; possible tendency to lose valued objects; difficulty with complex information and problem solving; difficulty learning new tasks; visuospatial deficits more apparent	Analyze and adapt meaningful leisure, home management, and other productive activities to allow the client to safely participate and exert initiation, independence, and control	Avoid tasks involving new learning; help simplify surroundings and tasks; make objects accessible, establish expectations for use of objects, simplify instructions, and clarify the meaning of “success”

■ **TABLE 35-3 | Progression of Alzheimer’s Disease and Intervention Considerations—cont’d**

Client Characteristics	Intervention Using Occupational Performance	Intervention Using Performance Patterns and Client Factors
<p>Need for supervision slowly increases; decreased sociability; moderate impairment in IADLs that are complicated and mild impairment in some ADLs (e.g., finances, shopping, medications, community mobility, cooking complex meals); no longer employed; complicated hobbies dropped</p>	<p>Identify needs, and design ways to adapt and grade activity by simplifying complex tasks; train the caregiver to provide cognitive support (verbally) of the client in IADLs and some ADLs²¹</p> <p>Encourage scrutiny of family structure and resources to respond to increasing need for supervision; consider outside resources (e.g., day care, legal planning, friendly visitor volunteer, public transportation for the disabled)</p>	<p>Help the caregiver interpret behavioral problems by understanding the source of frustration and the effects of memory loss on behavior</p> <p>Maintain socialization, and structure opportunities in which others initiate socialization to ensure satisfying relationships in group activity and other social activities</p> <p>Use reality orientation activities, photo albums, and pictures around the home as a reminder of the past, past competence, and opportunities for socializing</p> <p>Encourage stretching, walking, and other balance activities</p>
<p>STAGE III: MODERATE TO MODERATELY SEVERE DECLINE IN COGNITION (PROBLEMS FROM STAGE II ARE EXACERBATED—DIFFICULTIES INVOLVING PHYSICAL STATUS EXACERBATED)</p>		
<p>Reduced affect, increased apathy; sleep disturbances; repetitive behavior; hostile behavior, paranoia, delusions, agitation, and violence possible if the client becomes overwhelmed</p>	<p>Maintain involvement in meaningful activity and reactivate alternative roles; identify and design tasks in home management activity; the client can assist the caregiver in design of productive activity related to the former work role^{114,115,215}</p>	<p>In managing problematic behavior (e.g., assaultive behavior), teach caregivers to identify the problem, understand and consider possible precipitants of the behavior (e.g., feelings; antecedent events; who, where, when; medical problem or task; environment; or communication problem), and adapt own behavior or change the environment^{42,55,229}</p>
<p>Progressive memory loss of well-known material; some past history retained; client unaware of most recent events; disorientation to time and place and sometimes extended family; progressively impaired concentration; deficits in communication severe; apraxia and agnosia more evident</p>	<p>Help the caregiver problem-solve and recognize the degree of need for initiation, verbal cues, and physical assistance in performing ADLs; provide time orientation; simplify the environment</p>	<p>It is essential to maintain consistent daily routines as a means of facilitating participation in overlearned tasks, maintain function, and continue to define the self⁴²</p>
<p>Slowed response, impaired visual and functional spatial orientation</p>	<p>Support socialization at home and with the family or in structured settings outside the home</p>	<p>Teach the family that overlearned tasks are possible but require a safe environment; overall, tasks take longer, need to be simplified, and require set-up and grading to consist of two or fewer steps</p>

■ **TABLE 35-3** | Progression of Alzheimer's Disease and Intervention Considerations—cont'd

Client Characteristics	Intervention Using Occupational Performance	Intervention Using Performance Patterns and Client Factors
Unable to perform most IADLs; in ADLs, assistance eventually needed with toileting, hygiene, eating, and dressing; beginning signs of urinary and fecal incontinence; wandering behavior	Ensure safety in the home and other environments by making adaptations suited to the level of client functioning (e.g., alarms, restricted use of heating devices and sharp instruments, cabinet latches, identification bracelet, visual cues for locating item, and visual camouflaging) ^{43,68,97,198}	<p>Make further environmental adaptations to compensate for deficits in perception and ensure safe mobility</p> <p>Rehearse and review names of the family and others by using pictures</p> <p>Encourage standby or assisted ambulation, stretching, and exercise on a regular basis</p> <p>In new environments, cue and assist the client in navigation, and provide more light and pictorial representations for cueing</p>
STAGE IV: SEVERE COGNITIVE DECLINE AND MODERATE TO SEVERE PHYSICAL DECLINE		
Memory impairment severe; may forget family member's name but still recognizes familiar people; can become confused even in familiar surroundings	For ADLs (hygiene, feeding), instruct caregivers (family or nursing assistants) on the need for simple communication, one-step commands, step-by-step verbal cues, and physical guidance	Encourage the caregiver to use respite programs and maintain personal recreation and leisure activity
Gait and balance disturbances; difficulty negotiating environmental barriers; generalized motor slowing	Encourage continued socialization by the family; socialization depends on initiation of conversation by others and may not consistently include a response from the client	Encourage assisted ambulation methods until the client is no longer able to use them
Often unable to communicate except by grunting or saying a single word; psychomotor skills deteriorate until unable to walk; incontinent of both urine and feces; unable to eat; frequently becomes necessary to place the client in a nursing home at this time	Use dysphagia techniques to promote swallowing, prevent choking, and encourage eating	Maintain proper positioning in the bed and wheelchair; instruct the family in skin inspection
	Instruct the family in transfer techniques	<p>Provide controlled sensory stimulation involving sound, touch, vision, and olfaction to maintain contact with reality</p> <p>Begin a program of active and assisted and passive ROM exercises</p>

ADL, activities of daily living; AFO, ankle-foot orthosis; IADLs, instrumental activities of daily living; MMT, manual muscle test; ROM, range of motion. Adapted from Baum C: Addressing the needs of the cognitively impaired elderly from a family policy perspective, *Am J Occup Ther* 45:594, 1991; Morscheck P: An overview of Alzheimer's disease and long term care, *Pride J Long-Term Health Care* 3:4, 1984; Glickstein J: *Therapeutic interventions in Alzheimer's disease*, Gaithersburg, Md, 1997, Aspen; Gwyther L, Matteson M: Care for the caregivers, *J Gerontol Nurs* 9, 1983.

characterized by lower extremity ADL problems (walking) before decline in upper extremity ADL functions.^{87,208} The trend in AD is for cognitive deficits to increase and executive function to become more impaired (see Table 35-3). Motivation and perception can influence functional performance but may not be routinely considered in individuals with AD (Levy, 2005).⁶⁸

Medical Management

According to Larson,¹⁰⁹ medical management of individuals with AD in primary care settings generally includes several areas. Many aspects of what is termed medical management may also be performed by certain other members of an interdisciplinary health care team, including the nurse, social worker, physical therapist, or occupational therapist. First, early recognition and diagnosis of AD are needed.^{109,148,193} Second is the issue of how to intervene on behalf of a person with AD who is living in the community before institutionalization or more restrictive care becomes necessary. The third area concerns intervention issues as the disease progresses. Last is the role of health care providers in recognizing and addressing the treatment of other conditions that lead to excess disability in a person with AD.

The brain damage caused by AD begins much earlier than the appearance of cognitive impairment. Although dementia is relatively common in persons older than 80 years, it is often not diagnosed in such individuals until approximately 2 to 4 years after the onset of dementia symptoms.^{108,109,111,128} Recent evidence suggests that AD eventually develops in as many as 23% of persons with MCI.^{38,148,220} Wilson and colleagues identified olfactory impairment in persons in whom AD later developed.²²⁶ Identification of motor, visuospatial, and other sensory deficits, even before impaired memory is evident, is a current area of research that may aid in earlier detection of AD.^{148,150} The Alzheimer's Association has made a concerted effort to help in the earlier diagnosis of older adults through their Early Detection Matters program.⁶ A comprehensive physical examination, laboratory evaluation, mental status examination, brief neurologic examination, and informant and family interview are essential in diagnosing AD. It is important to identify and treat medical conditions (e.g., metabolic disturbances, infections, alcohol use, vitamin deficiencies, chronic obstructive pulmonary disease, heart disease, and drug toxicity) that can contribute to comorbidity. Findings on MRI, PET, and CT can be useful, but overreliance on these techniques should be avoided because their value lies in identifying relatively uncommon, treatable causes of cognitive impairment. A comprehensive and skillful interview with a reliable informant is essential to the evaluation and diagnostic process to recognize decline by comparing current changes with past performance. Informant questionnaires, interviews, and screening measures may be performed by many health care professionals other than physicians and are important in the diagnostic process.

National Institute on Aging¹⁴⁵—funded Alzheimer's Disease Centers can diagnose AD with up to 90% accuracy,¹⁵⁰ although autopsy is the only diagnostic tool with 100% accuracy. Cognitive testing and testing of cerebrospinal fluid are two developing areas for earlier detection and diagnosis.

The goal of health care providers in the successful management of an individual with dementia, whether in the community or in a semi-institutional or institutional setting, is to “minimize behavior disturbances, maximize function and independence, and foster a safe and secure environment”²⁰⁵ (p. 1367). Dementia is associated with increased mortality.³⁴ Regular health maintenance visits in primary care settings to identify treatable illnesses such as depression, PD, low folate levels, arthritic conditions, urinary tract infections, and other conditions that may complicate dementia are important for all older adults, especially those with AD.^{113,194} New evidence suggests that the cellular abnormalities of vascular disease (high blood pressure, cerebrovascular disease, cardiovascular disease, diabetes) exacerbate the cellular abnormalities found in AD, increase the risk, and may speed the progression of AD.¹⁵⁰ Depression and dementia may easily be mistaken for each other, or they may coexist.²⁰⁵ Careful attention to whether the onset of symptoms has been gradual (dementia) or more recent (depression) is an important diagnostic issue because affective and cognitive symptoms frequently occur together.¹⁸¹ The cognitive impairments and especially functional performance may improve in individuals with both dementia and depression after they are treated for depression. Delirium (i.e., impairment in attention, alertness, and perception) and dementia frequently coexist as well, especially in hospital settings.²⁰⁵ Both conditions involve global cognitive impairment, but delirium is usually acute in onset, shows fluctuating symptoms, disrupts consciousness and attention, and interferes with sleep. Adverse drug reactions are more common in AD because of the vulnerable, impaired brain.¹¹⁰ Drug toxicity, often a cause of delirium, is treatable.

Hearing, vision, and other sensory impairments are known to make dementia worse and cause greater strain on the caregiver.^{218,219} Falls with hip fractures are 5 to 10 times more common in persons with AD than in normal persons of the same age and frequently result in earlier institutionalization for the individual and the need for higher levels of care.³⁶ Unsafe mobility quickly becomes an overwhelming burden for caregivers, especially those who are aged. Occupational therapists can assess the tasks, context, and environmental features of the living situation in which the person with AD resides and find ways to analyze activities and make compensations so that living is more meaningful and safe.

According to Small and colleagues²⁰⁵ and the most recent progress report on AD from the National Institutes of Health,¹⁵⁰ pharmacotherapy for the treatment of individuals with AD should be assessed carefully and justified at

regular intervals.¹⁹² Although OT practitioners do not prescribe medications, knowledge of pharmacotherapy is useful. Cholinesterase inhibitors such as galantamine and donepezil may improve cognition and functional performance, at least in the short term. The drug memantine blocks receptors for glutamate and has been used in individuals with moderate to severe AD.¹⁵⁰ Promising research is under way in this area. Cognitive health is highly related to the health of blood vessels in the brain. Controlling blood pressure, using cholesterol-lowering drugs, eating a Mediterranean diet, and maintaining physical activity are strategies for vascular health and are also thought to reduce the risk for AD. Antidepressant medications, especially selective serotonin reuptake inhibitors, are often prescribed to manage the behavioral manifestations of AD—but it should be noted that these medications are not approved by the Food and Drug Administration for the treatment of AD. It is important to note that some of the tricyclic antidepressants (e.g., amitriptyline, imipramine, and clomipramine) and monoamine oxidase inhibitors can have troublesome side effects in older adults. Atypical antipsychotics such as clozapine, risperidone, and olanzapine may be used to reduce agitation and psychosis.^{123,205} Benzodiazepines are prescribed for treating anxiety and infrequent agitation but have been found to be less effective than antipsychotics when the symptoms are severe.²⁰⁵

Role of the Occupational Therapist

Most individuals with AD live in the community, alone or with family or friends, rather than in institutions. A predominant feature of AD is significant and progressive deterioration in function from previous levels of performance because of advancing brain atrophy and pathologic tissue changes. Families and significant others associated with persons with AD become progressively involved as the disease itself progresses and provide increasing oversight and personal assistance.⁷⁷ Changes in the brain caused by AD result in deficits in client factors, which in turn lead to deterioration in occupational performance skills and occupational performance areas and major changes in occupational roles. Over time, more structured, supervised living environments are usually needed. Increased difficulty in performing everyday functions creates challenges for the individual with AD and has an impact on quality of life for the client, family, and caregivers as the disease progresses. Effective OT interventions must be directed at supporting occupational performance for the individual and creating as much quality of life as possible. Intervention should focus on supporting and maintaining capabilities and adapting tasks and environments or otherwise compensating for declining function in individuals with AD while trying to help them retain as much control as possible over their lives in the least restrictive environment.¹⁰ Adult day care centers can often provide an alternative to assisted living or skilled nursing facilities; they offer a safe, structured day program

for persons with cognitive impairments who still reside at home and allow them to be in the least restrictive setting and able to return to their caregivers in the evenings. The Program of All-Inclusive Care is one model of day care available in some communities and offers innovative, high-quality care for older adults at high risk for needing institutional care (Trice, 2006).⁷⁹

Ethical Considerations

Support for the caregiver is a must. Collaboration with and training of the caregiver is essential in the management of clients with dementia. Family members should encounter an open and encouraging environment in which to discuss safety, security, and dependence issues. Legal, financial, and health concerns that require advance directives (e.g., medical and legal), trusts, restrictions in activity (e.g., driving, financial matters, and medication management), and contingency and transitional care plans (e.g., day care, residential care, and long-term care) are important in preparation for the inevitable progression of the disease.^{109,204}

Behavioral problems can be expected in clients with AD until the terminal or bed-bound stage. Encouragement to use respite care, in-home support services, and caregiver support groups is important. Caregivers also need effective strategies for dealing with behavioral disturbances and disruptions in mood. The use of environmental adaptations, therapeutic interpersonal approaches, referral to other disciplines, and sharing of resources helps in collaborating with the client's family and handling these problems. Health professionals use education, training, counseling, and support to help caregivers deal with their feelings, manage behavior, and maintain quality of life for themselves and for the client with AD. Awareness of the multidimensional effects of this illness on the individual, the family, and the society at large is important to promote more effective and efficient care.¹⁷⁸ Specialized homes and units known as Alzheimer's Care Centers are available.⁷⁹ The model of care is one of wellness support instead of an illness model of care. The idea is to maximize and support independence, maintain safety, and focus on the strengths and remaining skills of the individual. The Alzheimer's Association⁵ has developed "Dementia Care Practice Recommendations" for dementia care centers, and these guidelines are supported by the American Occupational Therapy Association. The fundamentals are provision of food and fluid, management of pain, resident wandering, falls, physical free restraint, and social engagement.^{5,79}

Evaluation

An OT screening is often performed before the evaluation. OT services are indicated for individuals who have demonstrated a recent decline in function; whose behavior poses

a safety hazard to family, staff, other residents, or self; or who may experience improved quality of life.³⁰ Much of the therapist's time in community settings and in long-term care is spent helping families and caregivers develop strategies and environmental adaptations to cope with the overwhelming stress of safely managing a cognitively impaired individual.²¹ The other major focus is promoting the best quality of life that is possible while ensuring that no matter the setting, a person with AD has choice, dignity, and self-determination.

The type of assessment and the depth of the evaluation process used are influenced by the setting, the stage of progression of AD, the reimbursement process, the presence of other medical and mental health disorders, and the cooperation and interest of the caregiver or care staff. The consequences of caregiving and the needs of the caregiver can vary greatly, depending on gender, family relationships, culture, and ethnicity. The caregiver's understanding of dementia, reaction to dementia-related behavior, use of problem-solving skills, use of the environment, use of formal and informal support systems, and decision-making style greatly affect the caregiver's ability to participate in the care plan and treatment of persons with dementia.^{19,49,60,118,227} In some cases the occupational therapist must engage in the dual role of serving as an advocate for the person with AD.

Evaluation should be comprehensive despite changing reimbursement. Much information can be gathered before an interview and intervention session by asking caregivers, family members, and staff informants to complete questionnaires and rating scales. These scales assess occupational performance, functional abilities, and skills with the use of measures such as the Functional Behavior Profile,²³ the Activity Profile,²¹ the Caregiver's Strain Questionnaire,¹⁸⁸ the Katz Activities of Daily Living Scale,¹⁰³ and the Instrumental Activities of Daily Living Scale.¹¹² Informant rating measures should routinely be followed by an interview either before or during the first visit. The use of a few brief screening instruments for mental status (e.g., the MMSE),⁶⁵ depression,^{26,228} and anxiety¹¹³ provides baseline data and a wealth of information about factors that are likely to influence performance. It is always useful, with any evaluation, to triangulate information to achieve reliability. This means talking with other family members, roommates, and care staff and, of course, the occupational therapist's own observations.⁴⁰

The functional evaluation of an individual with AD depends on the stage of cognitive decline.¹⁰ The American Occupational Therapy Association's statement on services for persons with AD suggests that tasks involving work, home management, driving skills, and safety should be targeted in the early stages of the disease. In the later stages, the focus shifts to self-care, mobility, communication, and leisure skills.

The concerns and observations of the caregiver are important, but observation of task performance by the therapist is also necessary. Unfortunately, many of the

functional ADL scales developed for use in older adults have targeted physical performance and are not appropriate for persons experiencing cognitive decline.⁷³ Fortunately, several excellent, standardized measures that determine whether individuals are able to use their cognitive skills to perform ADL and IADL tasks have been developed over the last 15 years. The Kitchen Task Assessment determines the level of cognitive support that a person with AD needs to complete a cooking task successfully.²² More recently, Baum and colleagues compiled the Executive Function Performance Test,²⁴ a performance-based standardized assessment of cognitive function that has been standardized in administration and scoring.² The Allen Cognitive Level (ACL) test determines the quality of problem solving that an individual uses while engaged in perceptual motor tasks.² Levy has written at great length about use of the ACL test for clients with cognitive impairments.^{115,116} Consistent with the Allen theoretic approach, the Cognitive Performance Test was developed to identify cognitive deficits that are predictive of functional capacity by using several ADL and IADL tasks.^{3,37} Another measure, the Assessment of Motor and Process Skills (AMPS), has been used in individuals who have dementia.^{63,158} The AMPS measures motor (e.g., posture, mobility, and strength) and process (e.g., attentional, organizational, and adaptive) skills by using task performance in IADLs. The Disability Assessment for Dementia (DAD) uses informant ratings to determine the ability of an individual with AD to complete tasks in both ADLs and IADLs.⁷³ The DAD also provides information relevant to executive functioning, such as the person's ability to initiate, plan, and execute the activity. The Independent Living Scales was originally developed to assess older adults and assist in making a determination of an individual's problem solving and performance as applied to memory and orientation, money management, home maintenance and transportation, health and safety, and social development.¹²⁰ Further information regarding the evaluation of cognitive function and ADL performance is provided in Chapters 10 and 26. After obtaining a thorough evaluation and a good understanding of the disease process and the functional level of the person with AD, the therapist can begin to look at the all-important question of what aspects of the occupational performance context, especially the environment and care provider interactions, must be modified to optimize safety, function, and quality of life of the person with AD.¹⁵⁸

Intervention Methods

The goals of OT are to provide services to persons with dementia and their families and caregivers that emphasize remaining strengths, maintain physical and mental activity for as long as possible, decrease caregiver stress, and keep the person in the least restrictive setting possible.^{12,14,89,101} Although AD is the primary problem, the occupational therapist has to consider the complexities of making interventions in an older adult who may be experiencing

additional sensory loss and numerous medical problems such as arthritis, orthopedic issues, chronic obstructive pulmonary disease, diabetes, and heart disease in addition to AD. Intervention planning takes into account the physical issues associated with aging, co-occurring disorders such as depression and anxiety, the progressive nature of the disorder, the expected decline in function, and the care setting itself. OT interventions for clients with dementia are directed toward maintaining, restoring, or improving functional capacity; promoting participation in occupations that are satisfying and that optimize health and well-being; and easing the burdens of caregiving.²¹ Gitlin and colleagues recently instituted a program to improve the overall pleasure of persons living at home who have dementia.⁷⁸ This program was designed to decrease the distress of caregivers when caring for a person with AD who exhibits erratic and disturbing behavior. A program called the Tailored Activity Program (TAP) is an OT service that evaluates the interests and capabilities of a person with dementia and provides customized activities for each individual. TAP then trains families to use these activities as part of the daily care routines. Caregivers reported “being less upset with the behavioral symptoms” when using the tailored activities (p. 428). Methods that therapists use in the intervention process include activity analysis, caregiver training, behavior management techniques, environmental modification, use of purposeful activity, and provision of resources and referrals. Services are provided in many different settings, such as home care, adult day care, and semi-institutional or institutional long-term care. The intervention setting and the stage of the illness help frame the focus of intervention, determine the recipients of service, and prescribe the methods used (see Table 35-3). A useful role for an occupational therapist working with an individual with dementia and his or her family is to assist the individual with AD in making the many transitions that will probably take place—from home to hospital to assisted living, residential care, or skilled nursing home—as the disease progresses, as well as medical problems that bring about crises. With each move to a new residential setting the therapist can determine the interrelationship of the client’s physical, cognitive, sensory, and social world. OT can be instrumental in determining how this newest transition might influence occupational performance, health, and well-being. At each transition, interventions can target arriving at the best person-environment fit, recommending environmental adaptations, providing assistive devices, and promoting collaborative relationships between care providers to support occupational engagement and desired roles while enabling independence and safety at each transition⁷⁹

Summary

AD is a neurologic condition characterized by the gradual development of multiple cognitive impairments. The effect of these impairments is a significant and progressive decline

from previous levels of functioning. The course of the disorder is variable, but loss of function generally occurs in a hierarchic pattern, beginning with work and progressing to difficulties with home management, driving, and safety, until even basic self-care skills such as dressing, functional mobility, toileting, communication, and feeding are affected.

OT interventions should be directed at enhancing the abilities of a client with AD by continually adapting tasks of daily living and modifying the physical and social environment as the client experiences progressive loss of function. Given many of the current limitations in treatment time imposed by third party payment, therapists may find it helpful to use some of the self-report and informant report measures identified in this chapter as a means of gathering information more efficiently during the evaluation process. Several standardized measures have also been identified to assist in the assessment of functional performance and establishment of a baseline of performance. Recommendations for OT treatment of AD have been identified. The focus of intervention must be flexible and depends on an understanding of the particular expression of the disease process in the client, the specific treatment setting, and the needs of the caregiver. Generally, the goals of OT services for persons with dementia are to maintain or enhance function, promote continued participation in meaningful occupation, optimize health and quality of life, and work collaboratively with the caregiver to ease the burden of caregiving.

SECTION 3: | Huntington’s Disease

WINIFRED SCHULTZ-KROHN

Incidence

HD is a fatal, degenerative neurologic disorder that affects 5 to 10 of every 100,000 individuals.^{76,167} The disorder is transmitted in an autosomal dominant pattern. Each offspring of an affected parent has a 50% chance of having HD. Genetic studies have identified a mutation on chromosome 4 as the cause of this disease.^{144,167,176,180} Presymptomatic diagnosis of HD is possible with genetic testing when the family history shows this disease.^{165,167} Diagnosis is also made through clinical examination when the family history is unavailable or unknown.

Pathophysiology

The neurologic structure associated with HD is the corpus striatum. Deterioration of the caudate nucleus is more severe and occurs earlier than atrophy of the putamen.^{44,163} The corpus striatum plays an important role in motor control, and deterioration in this area contributes to the chorea associated with HD. The caudate nucleus is also

linked to cognitive and emotional function through connections with the cerebral cortex. Progressive loss of tissue occurs in the frontal cortex, globus pallidus, and thalamus as the disease advances.¹⁶⁷ Degeneration of the corpus striatum results in a decrease in the neurotransmitter γ -aminobutyric acid. Additional deficiencies in acetylcholine and substance P, both neurotransmitters, are noted in clients with HD. The triggering mechanism for the neuronal degeneration has not been clearly identified, but it is linked to genetic coding on chromosome 4.¹⁸⁰

Clinical Picture

HD is characterized by progressive disorders in both voluntary and involuntary movement, in addition to a significant deterioration in cognitive and behavioral abilities.^{167,200} A client usually experiences an insidious onset of symptoms in the third to fourth decade of life, but cases have been reported in teenage and younger clients.²²⁴ Clients who are positively identified by genetic testing should be carefully monitored for the first indications of HD symptoms. Not all individuals who have potential for the development of HD because of a family history have elected to undergo genetic testing, a fact that may affect determination of the time at which the first symptoms emerged. The course of progression of HD is often divided into three stages—early, middle, and late—but with the advent of genetic testing, an additional presymptomatic stage has been added.²²¹ During the presymptomatic stage, monitoring of symptoms is critical, and a decrease in the speed of finger tapping (an item on the Unified Huntington's Disease Rating Scale [UHDRS]) may mark the beginning of the early stage of HD. The symptoms progress over a 15- to 20-year period, with long-term care or hospitalization of the client ultimately being necessary.^{167,205} Death is often the result of secondary causes, such as pneumonia.¹⁶⁵

The initial symptoms vary but are most often reported as alterations in behavior, changes in cognitive function, and choreiform movements of the hands.^{221,224} The early symptoms of cognitive disturbances are most likely related to degeneration of the caudate nucleus. The client may appear forgetful or display difficulty concentrating. During the early stages of HD a client may have difficulty maintaining adequate work performance. Family members frequently identify the initial behavioral changes seen in a person with HD as increased irritability or depression. Irritability and depression may be attributed inappropriately to the decline in work performance rather than to the disease process. Emotional and behavioral changes are often the earliest symptoms of HD.^{17,66} Chorea, seen in clients with HD, consists of rapid, involuntary, irregular movements.¹⁶⁶ During the early stages of HD, chorea is often limited to the hands. A client may mask the initial chorea by engaging in behavior such as manipulating small objects with the hands. These irregular movements are exacerbated during stressful conditions and decrease during voluntary motor

activities in the early stages of HD. Chorea is absent when the client is sleeping. Onset of HD in the teenage years is associated more frequently with early symptoms of rigidity rather than chorea.^{221,224}

Cognitive and emotional abilities progressively deteriorate over the course of the disease.²²⁴ Disturbances in memory and decision-making skills become more apparent during the middle stages of HD. Establishing and maintaining meaningful habits and routines for an individual who has HD are important ways to support continued participation in occupational pursuits. A client may be able to complete familiar tasks at work or in the home, but if the environment is changed or if additional demands are placed on the individual, task performance is significantly compromised. Further deterioration in cognitive abilities in a person with HD may result in dismissal from employment. The cognitive deficits most frequently associated with HD are problems involving mental calculations, performance of sequential tasks, and memory.⁶⁶ Verbal comprehension is often spared until the middle or later stages of the disease, and even then, dysarthria is a more significant issue than difficulty in comprehension until the late stage of HD.

As HD progresses, depression often worsens and suicide is not uncommon.^{221,224} Clients with HD are frequently hospitalized because of various psychiatric problems, including depression, emotional lability, and behavioral outbursts. Although the loss of function may contribute to the client's level of depression, depression is clearly identified as a specific characteristic of HD.^{66,143} This affective disorder is frequently treated with various antidepressants. Periods of mania have also been reported in approximately 10% of individuals with HD.

As the disease progresses, the chorea becomes more severe and may involve the entire body, including the face.¹⁶⁷ Disturbances in gait are often observed during the middle stages of the disease, and balance is frequently compromised.⁶⁶ An individual with HD may display a wide-based gait pattern and have difficulty walking on uneven terrain. This staggering gait is at times misinterpreted by others in the client's life as evidence of alcoholism.¹⁶⁶ The client also has progressive difficulty in performing voluntary movements.¹⁶⁷ Performance of voluntary motor tasks is slowed (bradykinesia), and initiation of movement is compromised (akinesia). Although handwriting ability may be spared initially, the client displays increasing difficulty with this task as the disease progresses. Letter size is enlarged, and letter formation, such as slant and shape, is distorted. Saccadic eye movements and ocular pursuits may be slowed at this stage of HD.¹⁶⁵ Slight dysarthria compromising communication may be noted.⁶⁶ Dysphagia occurs, and the client may choke on various foods. Difficulty may be noted in coordination of both chewing and breathing while eating.

In the later stages of HD, choreiform movements may be reduced because of further deterioration of the corpus striatum and globus pallidus.¹⁶⁷ Hypertonicity and rigidity often replace the chorea as the disease progresses, and the client

experiences a severe reduction in voluntary movements. Severe difficulties in eye movement are common during the final stage of the disease.¹⁶⁵ At this stage the client often needs significant support from others or resides in a long-term care facility. The client is usually unable to talk, walk, or perform basic ADLs without significant assistance.¹⁴⁴

Medical Management

Medical management of clients with HD can address the symptoms, but no effective course of treatment has been identified to arrest progression of this disease.¹⁷⁹ Intervention based on replacing the deficient neurotransmitters has not been effective in changing the course or rate of progression of HD. Tricyclic antidepressants are often used to treat the depression seen in clients with HD, but monoamine oxidase inhibitors are contraindicated because of possible exacerbation of chorea.²²⁴ Haloperidol may be used to decrease the negative effects of chorea on the performance of functional activities.¹⁶⁷ Haloperidol is prescribed cautiously and only when the chorea significantly compromises a person's daily activities. Medical management is focused on three areas: managing symptoms and reducing the burden of the symptoms, maximizing function, and providing education to the client and significant others regarding the course of progression of the disease.¹⁴³ A team of professionals, including an occupational therapist, is advocated when working with a client who has HD.

A team of various medical professionals is needed to support an individual with HD, as well as family members and significant others in the client's life.^{92,102} Perception of the illness experience and the coping strategies used by a client with HD are an important part of the overall medical services provided.⁹² Likewise, the significant others in the client's life need support and guidance in developing coping strategies as their loved one who has HD experiences progressive deterioration.¹⁰²

Systematic evaluation of a client with HD must be performed at regular intervals to identify the rate of symptom progression and modify intervention strategies. Standardized instruments are available for determining the presence and severity of various symptoms.^{96,200} One evaluation tool, the UHDRS, combines aspects from several instruments into a scale that can be administered within 30 minutes. The UHDRS is often administered by a team. This tool provides an accurate means of determining a change in the areas of "motor function, cognitive function, behavioral abnormalities, and functional capacity."⁹⁶ The UHDRS has been used to assess the rate of decline and demonstrates good reliability (Klempir et al, 2006). The occupational therapist should perform additional assessments before an intervention plan is developed. An evaluation would address functional daily living skills; cognitive abilities such as problem solving, motor performance, and strength; and personal interests and values. The occupational therapist must consider the client's role within the family and community and incorporate these

data into the intervention plan. An evaluation at both the home and work site would provide needed information that could be modified if necessary.

Role of the Occupational Therapist

The role of the OT practitioner varies depending on the stage of the disease.⁹⁸ During the early stages of HD, an occupational therapist should address the cognitive components of memory and concentration. A client may still be employed at this stage. Strategies such as establishment of a daily routine, use of checklists, and task analysis to break tasks down into manageable steps can be very helpful. These strategies provide the external structure and support needed to help a person with HD maintain functional abilities at both the workplace and home. A work site evaluation can identify changes that would allow a person with HD to continue working. Modifications may include the use of tools such as organizers, electronic planners, and reminders to prompt an individual to complete regularly occurring tasks in the workplace. Family members should also be instructed in the use of these techniques. Environmental modifications such as providing a quiet workplace and reducing extraneous stimuli will decrease the impact of compromised memory and concentration on performing functional tasks in the workplace. Even during the early stages, work performance may deteriorate and the client may be dismissed because of an inability to meet the job essentials. This increases the stress experienced by the client from a financial perspective and from loss of a role as a worker.

Psychologic issues during this stage of the disease frequently include anxiety, depression, and irritability.^{66,90} A client may express guilt that any of his or her children have a 50% chance of HD developing.¹⁶⁶ The diagnosis of HD is often not confirmed until a person is 30 to 40 years old unless genetic testing is performed and confirms HD. The client may already be married and have children by that time. Decisions whether children should undergo complete predictive genetic testing may be a significant stressor for a client with HD and for his or her family members. As mentioned previously, not all individuals elect to be genetically tested, and sporadic cases of HD do arise when no family member has HD. During this early stage of HD, clients may use denial as a coping strategy even though choreiform movements are present in the hands.⁹²

Maintaining social contacts and engaging in purposeful activities are important in designing interventions for clients with HD.¹⁶⁶ Changes in cognitive abilities and unpredictable or exaggerated emotional responses may result in the loss of a job and decreased income for the family, even during this early stage of the disease.⁶⁶ This additional stress should also be considered when developing an intervention plan. The OT intervention plan must include community support services for clients with HD. OT services should include providing clients with information regarding support groups, opportunities to engage in community

activities, and connecting with virtual resources through the Internet.

The motor disturbances during the early stages of HD are usually limited to fine motor coordination problems.⁶⁶ The characteristic chorea may be noticed only as a twitching of the hands when the client is anxious. OT should provide modifications to diminish the effect of chorea and fine motor incoordination on performance of functional activities.⁹⁸ This would include modifications in clothing and selection of clothing that does not require small fasteners such as small buttons, snaps, or hooks. Shoes with Velcro or elastic closure are recommended to compensate for diminished fine motor skills. Home modifications should be instituted at this stage to allow a client with HD to become familiar with the changes. Developing the skills for using adaptive equipment or modifications and then converting these skills into habits are critical during the early stage of HD. Typical modifications are the use of cooking and eating utensils with built-up handles, unbreakable dishes, a shower bench or seat with tub safety bars, and sturdy chairs with high backs and armrests. Throw or scatter rugs should be eliminated wherever possible in the home, and walkways should be kept free of clutter. The occupational therapist should establish a home exercise program with the client to address flexibility and endurance of the entire body. These exercises will be incorporated into the client's daily routine. As the movement disorder progresses with increased chorea and difficulty in oculomotor control, the client will no longer be able to safely drive a car, and further loss of community mobility may be experienced. This further loss of independent function and control must be considered within the OT intervention plan. Alternative methods of community mobility must be explored.

As HD progresses, the role of OT changes to meet the client's needs.⁹⁸ During the middle stages of HD, further deterioration in cognitive abilities often requires the person to resign from a job. Engagement in purposeful activities is greatly needed at this stage and should be a focus of the OT intervention plan.^{90,166} Decision-making and arithmetic skills show further deterioration, and family members may need to arrange for others to handle the client's financial matters.^{66,147} Generally, comprehension of verbal information is better preserved than the ability to perform sequential tasks during this stage. The occupational therapist should encourage the family to use simple written cues or words to help a family member with HD complete self-care and simple household activities. For example, selecting clothing items for a person with HD and placing the clothes in a highly visible area can provide the prompt to change from pajamas to clothes in the morning. Arranging the bathroom with visual cues, such as putting the toothpaste and toothbrush by the sink, can remind the client to brush his or her teeth in the morning and evening.

During the middle stage of HD, the client may display increasing levels of irritability and depression.²²⁴ Clients with HD may attempt suicide. The OT intervention plan

should focus on the client's engagement in purposeful activities, particularly leisure activities. When selecting craft activities, the therapist should always consider the client's interests but should also strive to ensure that no sharp instruments are required.^{90,147} Modification of craft activities allows a client with HD to successfully complete a task with minimal support.³¹ Materials often require additional stabilization to compensate for the client's movement disorders, and any tools used in the leisure activity, such as a wood sander and paintbrushes, should have enlarged or built-up handles.

Motor problems become more apparent during the middle stage of HD and necessitate further modifications in daily living tasks.^{98,200} The client's compromised balance may require that tasks such as dressing, brushing teeth, shaving, and combing hair be performed while the client is seated. The client may require the use of a walker or wheelchair at this stage. A Rollator Walker is preferred over a standard walker without wheels. The walker may need to be fitted with forearm supports to provide additional support when the client is ambulating. Once a wheelchair becomes necessary, it should have a firm back and seat; however, additional padding is often required on the armrests because of the client's chorea. Many clients with HD are better able to move the wheelchair with their feet than with their hands. The height of the wheelchair seat should be adjusted to allow clients to use their feet to move the chair if possible.

Fatigue is a common issue during the middle stage of HD and can be addressed by taking frequent breaks during the day. Breaks must be scheduled because a person with HD may not readily recognize fatigue. Clothing should have few or no fasteners, and shoes should be sturdy with low heels.¹⁴⁷ Additional adapted equipment that may prove helpful for clients with HD includes shower mitts, electric razor or chemical hair removal method, covered mugs, and nonslip placemats.⁹⁸ The choreic movements may become so severe that use of a bed with railings is necessary. Padding should be used on the railings, and additional cushions should be used on the bed.

Because of the excessive movements associated with chorea, clients with HD often need to consume 3000 to 5000 calories per day to maintain weight.¹⁴⁷ Clients with HD display higher energy expenditure than do individuals without HD and consequently have issues with weight loss and difficulty maintaining appropriate weight.²¹⁶ Smaller, high-calorie meals should be provided five times a day. This schedule may require additional support from family members or a personal care attendant. Dysphagia, poor postural control, and deficient fine motor coordination compromise the client's ability to eat.⁹⁸ Positioning during feeding is crucial, and the trunk should be well supported during mealtime. Clients with HD should be able to support their arms on the table while the feet are stabilized. The feet may be supported on the floor or wrapped around the legs of the chair for additional support. Problems with

dysphagia can be addressed with positioning, oral motor exercises, and changes in diet consistency. Soft foods and thickened fluids are preferable to chewy foods, foods with mixed texture, and thin liquids. Nutritional support has been used successfully for clients with HD to maintain appropriate weight.²¹⁶ Appropriate body weight is important to maintain overall health of clients with HD.

During the final stages of HD, the client often depends on others for all self-care tasks because of the lack of voluntary motor control.^{98,144} In some clients, the chorea may diminish and be replaced by rigidity. The occupational therapist provides important input on positioning and the use of splints to prevent contractures at this stage. Because of the risk for aspiration, oral feedings are provided by trained personnel; alternatively, the client may receive nutrition through a feeding tube.¹⁴⁷ A combination of oral feedings and tube feedings may be used during this stage.

Although cognitive abilities continue to deteriorate, the level of functional decline is difficult to assess because of dysarthria and loss of motor control.⁶⁶ Dementia is part of the HD profile and must be considered during development of the intervention plan. For example, a person in the late stage of HD may still recognize family members and enjoy watching television. The occupational therapist should explore the use of various environmental controls to allow the client control of and access to the immediate environment.¹⁶ Providing a touch pad or switch for selecting television channels may prove beneficial for the client.

Behavioral outbursts have been reported in approximately a third of clients with HD living in long-term care facilities.¹⁴⁴ OT can decrease the frequency of these outbursts by organizing consistent daily schedules and routines for clients with HD.

Summary

Although HD is a progressive, degenerative process, OT has much to offer clients with this disease.^{90,98,147,166} The diminishing ability to control the environment has been identified as one of the variables contributing to the deterioration in function in clients with HD. Throughout the course of the disease, OT addresses the client's ability to exercise a degree of control over the environment and engage in purposeful activity.

SECTION 4: | Multiple Sclerosis

DIANE FOTI

Incidence

MS is a progressive, inflammatory neurologic disease that damages the myelin sheath in the CNS. Onset usually occurs between the ages of 20 and 45 years. The prevalence

in the United States is approximately 350,000.¹¹⁹ It is more prevalent in women than in men.³⁹ The highest prevalence of the disease is in Caucasians of northern European ancestry. Retrospective studies show that MS also occurs in people younger than 20, with 2% to 10% having a history of MS symptoms before the age of 18.^{48,213}

The myelin is typically damaged in discrete regions of the white matter, with the axon remaining preserved. Disruption of the myelin sheath has differing effects on axonal conduction, depending on the degree of breakdown and the length of the damaged segment.³⁹ When axons are conducting impulses in a slower manner because of inflammation of the myelin sheath, a person with MS may have intermittent symptoms of sensory distortion, incoordination, visual loss, or weakness. This inflammatory process accounts for the unpredictability of the disease.

In advanced cases of MS, acute and chronic plaques develop throughout the white matter, especially in the spinal cord, optic nerve, and periventricular white matter, including the corpus callosum. Axons may be damaged and severed in advanced cases and result in extensive loss of function. MRI may show lesions and changes in brain volume.^{29,100}

Etiology

The specific cause of MS is unknown, although it is suspected to be the result of a combination of environmental and genetic factors. The current theory is that MS is an immune system reaction that acts on the nervous system.¹²⁶ Studies have shown that 30% to 60% of new clinical attacks of the disease occur after a cold, flu, or common viral illness. Some researchers theorize that the immune system mistakes a portion of the myelin protein for a virus and destroys it. Other researchers believe that the viral infection damages the myelin and releases small amounts into the body, which results in an autoimmune reaction.²⁰²

Clinical Picture

The symptoms that occur in individuals with MS are related to the area of the CNS affected.⁹ Early symptoms may consist of paresthesias, diplopia, visual loss in one eye, fatigability, emotional lability, and sensory loss in the extremities. Other initial symptoms are trigeminal neuralgia and worsening of symptoms when body temperature is elevated. Symptoms that occur with an elevated body temperature are generally temporary and resolve in time. Cognitive deficits are reported to occur in 30% to 70% of persons with MS but do not necessarily correlate with a physical decline.^{7,85,156} Cognitive deficits have been documented in individuals with a disease duration of less than 2 years and with few neurologic signs.⁸

In advanced stages of the disease process, the individual may have varying degrees of paralysis from total lower extremity paralysis to involvement of the upper extremities, dysarthria, dysphagia, severe visual impairment, ataxia,

spasticity, nystagmus, neurogenic bladder, and impaired cognition.

The course of MS is unpredictable. It is marked by episodes of exacerbation and remission.¹⁵⁶ An exacerbation may be an episode as minor as fatigue and sensory loss or as extensive as total paralysis of all extremities and loss of bladder control. Remission may involve total resolution of the symptoms, slight return of some function with the symptoms remaining, or a short plateau in which no new symptoms occur but the current symptoms remain.

The three typical patterns seen in MS are (1) relapsing and remitting, (2) secondary progressive, and (3) primary progressive.⁹ The relapsing and remitting form of MS involves 85% of the MS population and leads to episodes of exacerbation and remission that result in a slow, stepwise progression as the deficits accumulate. The secondary progressive course begins with a pattern of relapses and remissions but evolves into the progressive form of the disease. Before the introduction of disease-modifying drugs, approximately 50% of clients with relapsing and remitting MS progressed to the secondary progressive form of the disease. The relapsing remitting form of MS was first diagnosed in Marguerite and, recently, the secondary progressive course of the disease. She is now experiencing sustained diminished fine motor abilities and sensation in her left hand. She also has weakness in one lower extremity requiring the use of an ankle-foot orthosis.

Though not as common as adult-onset MS, children account for 3% to 10% of the MS population.^{74,168} Ninety-five percent of children with MS initially experience a relapsing and remitting course of the disease. Over time, secondary progressive MS will develop in approximately 60% of children.²¹³

The primary progressive form of MS (10% of the MS population) is distinguished by a downward course and little recovery after exacerbations. Individuals with this form eventually become nonambulatory and incontinent of urine and may have dysphagia and dysarthria, severely compromised lower extremity function, and varying limitations in upper extremity function.

Studies vary on precisely how life expectancy is affected, but for most people with MS, life expectancy is not greatly reduced. Approximately 50% live for at least 30 years after onset of the disease, and 50% die of complications of MS. Most people with MS will live into the years when they are experiencing other changes related to normal aging, which can complicate the clinical picture.^{7,9,120,126} There are two atypical patterns of MS, a benign course and the progressive relapsing form. Clinical signs of the benign course of MS are a younger age at onset, female sex, and onset with sensory symptoms. The symptoms usually resolve within 6 weeks, and there may be only a few residual deficits. If the disability is minimal after 5 years, the course is considered benign.^{65a} The progressive relapsing form of MS is rare (5% of the MS population). It is identified as steadily progressive but has specific relapses.⁹ Typically, the course of the disease

■ Box 35-2

Predictors of Poor or Favorable Prognosis at the Onset of Multiple Sclerosis

Predictors of a Poor Prognosis

- Progressive course
- Age at onset >40 years
- Cerebellar involvement
- Polysymptomatic onset
- Male sex

Predictors of a Favorable Prognosis

- Minimal disability 5 years after onset of the disease
- Complete, rapid remission of the initial symptoms
- Age at onset <40 years
- Only 1 symptom during the first year
- Onset with sensory symptom or mild optic neuritis

From Multiple sclerosis and the aging process, Formulary, Proquest Nursing & Allied Health Source, November 17, 2005.

can generally be determined after 5 years of the initial symptoms (Box 35-2).

Medical Management

Medical management is dependent on the type of MS. Disease-modifying drugs are used in those with relapsing and remitting MS, and for all forms of the disease anti-inflammatories are used to treat exacerbations.¹⁵⁶ For the relapsing and remitting form of MS, disease-modifying medications are thought to have an effect in slowing progression of the disease. Four different medications for this group have recently been introduced: interferon beta-1b (Betaseron), interferon beta-1a (Avonex or Rebif), glatiramer (Copaxone), and Rebif.^{95,156} Patients treated with these medications, administered by self-injection, showed a one-third reduction in frequency of exacerbations. Studies regarding the effectiveness of these medications in individuals with the progressive form of the disease are ongoing. The anti-inflammatory medications used to treat exacerbations, such as prednisone and methylprednisolone, help reduce symptoms and shorten the duration of the exacerbation.³⁹

Mitoxantrone (Novantrone) is the first drug approved in the United States for secondary progressive MS. It is a form of chemotherapy that can also be offered as a treatment option for those with secondary progressive, progressive relapsing, or worsening relapsing remitting MS. Novantrone is reported to help in reducing neurologic disability and the frequency of clinical relapses.

Medical management is focused primarily on treating the symptoms of the disease. Symptom management includes treatment of spasticity, bladder management, prevention of bladder infection, and management of pain and fatigue. Spasticity is often managed with medications; unfortunately, this may also worsen the muscle weakness.

Bladder management may involve the use of incontinence pads or catheters, along with prevention of bladder infections. Fatigue should be managed with good nutrition, prevention of overfatigue with energy conservation methods, regular exercise, establishment of routines for rest and sleep, and control of stress.¹⁴⁰ Bowel incontinence is rarely a problem related to a neurologic deficit but is usually a functional impairment resulting from immobility.

Changes in cognition and mood often occur in persons with MS. Cognitive deficits are reported to occur in 30% to 70% of the MS population but do not necessarily correlate with a physical decline.^{7,8,85,157} The volume of lesions seen on MRI correlates with cognitive decline in complex attention, processing speed, and verbal memory.²⁰⁶ One investigation evaluated overall brain atrophy and size of the ventricles in relation to cognitive abilities. The results suggested a relationship between an increase in the size of the third ventricle and a decrease in cognition.²⁹ Emotional changes such as depression may also be present. Persons with MS and other chronic conditions experience a higher rate of depression than the general population does.¹⁵² Depression may have different causes and should be assessed by the team. Depression may be caused by a physiologic response to the disease process, may be a psychologic response to the diagnosis, or might be a side effect of one of the disease-modifying medications. Depression may occur at any stage of the disease process. It should be addressed promptly because it may contribute to fatigue and an inability to cope with challenges and make adaptations as needed.¹⁵² Dementia may develop in individuals who exhibit euphoria and indifference. Dementia occurs in less than 5% of the population with MS.⁸⁶

The most widely accepted tool to measure clinical impairment in a person with MS is the Expanded Disability Status Scale (EDSS).¹⁶⁴ The scale should be completed by a physician because it includes a detailed neurologic examination. The EDSS combines an assessment of neurologic function and a scale to measure a client's ambulatory and functional mobility status. There are limitations with this tool; it does not allow specific assessment of all ADLs and is not sensitive to potential cognitive and sexual deficits in MS.¹⁶⁴ The OT practitioner should be familiar with the EDSS because it is often mentioned in the literature as a baseline for evaluating disability and has been adopted by the International Federation of MS Societies.^{99,222} The MS Functional Composite was developed to measure leg function and ambulation, arm and hand function, and cognition.^{46,141} It can be used for periodic baseline function and may be more sensitive for use as baseline cognitive evaluation than the EDSS.

Role of the Occupational Therapist

OT practitioners provide services for persons with MS in a number of settings. The type and degree of intervention provided will be determined by the setting, the type of

reimbursement, and the client's and caregiver's responses to intervention.

Evaluation includes an occupational profile to guide the evaluation process. The occupational therapist then selects the necessary instruments to assess occupational performance of ADLs, IADL education, work, play, leisure, and social participation. During the performance of various occupations, the following skills should be evaluated: motor and praxis, sensory-perceptual, emotional regulation, cognitive, and communication skills. This is generally accomplished with a combination of standardized and non-standardized assessments, through the use of interviews with the family and client, and by observation. The MS Society recommends a number of standardized evaluations appropriate for the OT evaluation.¹⁵³ Optimally, a home evaluation should be completed. Because not all settings allow a home evaluation, the occupational therapist should interview the client and caregiver regarding the home environment and potential barriers. Since MS has an unpredictable course, the client may need referral for other resources and periodic re-evaluation by an occupational therapist. If the client has a cognitive deficit, a family member or significant other should be included in the evaluation process to provide accurate information. It is essential that actual performance evaluations be used for persons with MS because studies have shown that self-report is frequently inaccurate.⁸⁴ Having an understanding of the client's cultural, social, and spiritual perspective will provide insight into available support systems and their impact on the client's adaptation to the disability.

Assessment of sensorimotor skills is discussed thoroughly in previous chapters. Because endurance and fatigue are such significant factors, it is important to not rely solely on the results of assessment of a specific client factor. For example, a manual muscle test is not likely to accurately reflect the degree of weakness experienced throughout the day. Observing a client performing a functional activity over a certain period or gathering information about the client's daily activity patterns will provide the clinician with a more accurate evaluation of fatigue.⁹⁵ The National MS Society recommends use of the Modified Fatigue Scale (MFS) or the Fatigue Questionnaire to understand specific problems resulting from fatigue.¹⁴⁰ In the case of Marguerite, the MFS assessment may help determine the impact of fatigue on her daily activities.

When evaluating a client's activity patterns, the OT practitioner should also ask about sleep patterns. Disrupted sleep patterns sometimes contribute to fatigue in the MS population. The information can be shared with the client's physician so that appropriate intervention can be undertaken either medically or with counseling that addresses the habits and routines that may contribute to the client's disrupted sleep.¹⁵

MS may also affect visual abilities, and compromises may be noted in visual tracking, scanning, and acuity. An objective evaluation will help determine the type of deficits, when

the deficits occur, and more specifically how they affect ADLs and IADLs.

Perceptual processing and cognitive status should be reassessed periodically. The data gathered will help identify specific deficits and their potential impact on functional activities so that the OT practitioner can incorporate this information into family training.¹⁵⁵ Cognitive deficits vary from a slight decrease in short-term memory and attention span to poor orientation and severely impaired short-term memory. The literature is mixed on the relationship between cognitive deficits and the degree of physical deficits.⁵³ Assumptions should not be made regarding the presence or absence of cognitive deficits based on physical deficits or abilities or on an individual's basic social skills. A person with significant physical deficits may have fewer cognitive deficits than an ambulatory person with MS. The client's perceptual and cognitive deficits are factors that must be considered when deciding whether the client needs close, constant supervision or can stay home alone. Various standardized cognitive and perceptual assessments are included in previous chapters of this text. Basso developed a screening tool for cognitive dysfunction in individuals with MS. Basso's tool was found to be both sensitive to functional impairment and cost-effective.²⁰ This tool can be used by an occupational therapist or practitioners in other disciplines when evaluating a person with MS for cognitive deficits. ADLs may be evaluated with a check-off list, a standardized evaluation such as the Assessment of Motor and Process Skills,⁵⁶ or other standardized assessments for ADLs.¹³

Evaluation of the cultural, social, and physical environment is important to consider with each client. MS is usually identified during the phase of life in which a person is raising a family and developing a career, as in the case study example of Marguerite. She is in the "sandwich" generation, simultaneously caring for her children and her mother. Because the disease is unpredictable and fluctuating, it leads to disruptions in normal daily activities and in family life. These disruptions create stress for the spouse or partner, children, and other family members. The occupational therapist must determine the type of support that the client can expect from family members.

The occupational performance assessment should include listening to the client and family describe performance patterns to identify typical daily habits, routines, and roles. Evaluating and treating the client at different times during the day will probably reflect different levels of fatigue. Understanding the performance patterns of rest periods, quality and amount of sleep, exercise patterns, intensity of activity (activity demands) during various times of the day, week, or month, and the time of the day when activities are most challenging is critical in developing treatment planning strategies. Understanding the performance patterns may help the OT practitioner understand how the side effects of the disease-modifying medications affect activity and also how to encourage integrating use of the medication into daily routines while managing side effects.

Ethical Considerations

A client with multiple sclerosis is able to ambulate to the car but has cognitive deficits that are exacerbated by fatigue in the afternoon. Because the client has discontinued work, the family members do not want to take away driving privileges as well. However, by continuing to drive, the client places himself and others at risk for injury. The occupational therapist may need to educate the family about the deficits by providing examples of the ways in which cognition is evaluated and by discussing the ways in which cognitive deficits affect driving and other daily activities. The occupational therapist is responsible for reporting the driving risk to the client's physician.

Emotional and behavioral issues vary depending on the premorbid personality, progression of the disease, coping skills, and social environment of the person with MS. Cognitive deficits and denial of the progressive nature of the disease may lead to behavior that places the client at risk and makes management difficult. If family members do not understand or recognize the client's behavioral problems, further complications may arise when the behavior is not restricted or modified by the family. Other emotional and cognitive issues include a client who is depressed or labile, has poor memory, refuses assistance from outside caregivers, or uses poor judgment regarding safety with medications and transfers. Each client demonstrates a unique set of behavioral issues and requires individual evaluation and an intervention approach that encompasses the family, client, and caregivers.

Goal Setting

For a client with a progressive disease such as MS, goal setting focuses on the client's need to adapt as the disability progresses. Families often need to negotiate role changes to accommodate the person with MS, who may not be able to participate consistently in a previously established family role. The client's ability to adapt depends on the family and client's acknowledgment of deficits and willingness to consider alternatives. OT intervention may include (1) problem-solving compensatory strategies; (2) time and energy management; (3) role delegation; and (4) the use of adaptive equipment to compensate for motor, sensory, endurance, cognitive, and visual deficits. The National Multiple Sclerosis Society has developed guidelines and recommendations for care at home that address many ADL issues requiring OT treatment. These guidelines are by no means all-encompassing regarding interventions for ADLs and IADLs but provide a solid starting point to problem-solve with the patient and family.¹⁵⁵ For specific techniques related to the individual's deficits, see Chapter 10.

Marguerite's OT intervention may involve analyzing her daily and weekly routine to identify activities that can be eliminated, modified, or delegated. She may consider grocery shopping online or delegating this task to her husband. Marguerite will need to evaluate the number of activities in which her children participate and the possibility of carpooling. She may need adaptive equipment for activities that require bilateral strength and dexterity because of the loss of sensation and dexterity in her left hand. Marguerite may be referred to an OT group designed for persons who have MS to learn energy management techniques.¹²⁷

The benefits of an exercise program should be discussed with clients who have MS. An individual may already have an exercise program recommended by a physical therapist, and coordination would be important so that the client is able to engage in a manageable exercise program. The OT role may involve helping clients with energy management issues fit the program into their usual routine. It has long been thought that exercise will result in exacerbation and worsening of symptoms. Recent studies report benefits such as improved quality of life, reduced fatigue, and improved ambulation from a regular exercise program.^{138,159,223} Energy management recommendations should include assessment of the client's typical exercise routine.

Summary

Because MS affects each person in a unique way, individual evaluation is essential to determine the client's deficits and strengths. Individuals with MS may range from being ambulatory with primarily fatigue and energy management issues to partially limited in mobility and hand function to an individual who is a full-time wheelchair user requiring assistance with ADLs. Working with clients who have MS requires the practitioner to use expertise in evaluation and intervention from all areas of OT. With a pattern of relapses and remissions over the course of the disease process, development of an OT intervention plan is particularly challenging. Because the client may expect return of function, he or she may deny deficits and refuse to adapt to a change in status; this attitude can create safety problems. The OT practitioner focuses on assessing the current level of functioning and the best methods for the client to adapt to current changes in status.¹³² The occupational therapist may also assist the family in making long-range, realistic plans. For example, if the family is planning to remodel the bathroom, the therapist may encourage consideration of a roll-in shower and not just a standard shower stall with a shower seat.

Working with clients with MS requires a multidisciplinary approach. In addition to the occupational therapist, a physician, physical therapist, registered nurse, social worker, and psychologist may be involved as team members. Because the social environment may create complex and difficult problems, good communication among all team

members is needed to ensure that the team goals are congruous. The occupational therapist has a unique perspective to offer the team regarding the client's strengths and weaknesses since cognitive, perceptual, psychosocial, and motor abilities are assessed and treated in a functional context.

SECTION 5: | Parkinson's Disease

WINIFRED SCHULTZ-KROHN

Incidence

PD is one of the most common adult-onset, degenerative neurologic disorders,⁵⁷ second only to AD.²⁰¹ Three classic symptoms are associated with PD: tremor, rigidity, and bradykinesia. The incidence rate for PD varies greatly, from 10 to greater than 400 per 100,000.²³⁰ Prevalence increases with age, and the disease affects 1.4% of the population older than 55 years,¹⁸⁶ but approximately 3% of all PD cases are initially recognized in individuals younger than 50 years.²⁰¹ Approximately 10% to 30% of clients with PD report first-degree relatives who also have PD. Gender differences have been noted; the prevalence of PD in men between the ages of 55 and 74 is slightly higher than that in women of the same age. After the age of 74, however, women show a slightly greater prevalence of PD than do men. The diagnosis is most often made after the age of 60.

The etiology of PD has not been definitively established.^{18,83} Previous literature referred to familial and sporadic forms of PD, but those distinctions are being revised in light of current genetic research. Although a positive family history has been established as a risk factor for PD, a single predictive genetic marker has not been absolutely identified. To date, mutations have been found in several genes that are associated with PD, including α -synuclein, parkin, ubiquitin carboxyl terminal hydrolase, SCA2, and DJ-1.²⁰¹ These mutations have been found to have a role in abnormal protein processing in cells.¹⁸ Current genetic work has identified a gene mutation in familial PD, and this genetic mutation has also been identified in clients with sporadic PD, thus providing further evidence of a genetic determination for this disease process.²⁰¹

Previously, environmental factors were considered a possible cause of PD.⁸³ The possibility of an exogenous agent producing PD gained considerable recognition when narcotic addicts began using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). After using MPTP, many addicts quickly exhibited parkinsonism that "strictly mimics the clinical and anatomical features of Parkinson's disease"⁸³ (p. 143). Although environmental factors have not been completely eliminated as contributing factors in the etiology of PD, they appear to play less of a role than do various genetic mutations.

Pathophysiology

The neurologic structure associated with PD is the substantia nigra, specifically the pars compacta portion.¹⁶¹ The pars compacta receives input from other basal ganglia nuclei and appears to serve as a modulator of striatal activity.¹⁶⁷ The substantia nigra nuclei undergo significant deterioration as the disease progresses. The significant reduction in dopaminergic neurons in the substantia nigra pars compacta produces a decrease in activity within the basal ganglia and an overall “reduction in spontaneous movement”¹⁶⁷ (p. 426). The substantia nigra serves as one of the major output nuclei for the basal ganglia to other structures.¹⁶³ In addition to the loss of dopaminergic neurons, intracytoplasmic inclusions are found on postmortem examination within the substantia nigra.¹⁶¹ These intracytoplasmic inclusions are also known as Lewy bodies.⁵⁹ Although the greatest amount of neurodegeneration is found in the pars compacta substantia nigra, destruction of other neurologic structures has been reported.¹⁶¹ Deterioration is also seen in the remainder of the substantia nigra, locus caeruleus, nucleus basalis, and hypothalamus.

Clinical Picture

PD is a slowly progressive, degenerative movement disorder.¹⁶⁷ The diagnosis of PD is usually made after the age of 55. Although PD is not considered fatal, the degeneration of various neurologic structures severely compromises performance of functional tasks. A person in whom PD is diagnosed may live an additional 20 to 30 years, with a progressive loss of motor function that eventually requires specialized care.⁵⁹ A person with PD has increased risk for pneumonia, which may be fatal.

PD is characterized by dysfunction in both voluntary and involuntary movements.¹⁶⁷ The classic triad of symptoms includes tremor, rigidity, and a voluntary movement disorder. By the time that these “motor symptoms are clinically recognized, 60% of the dopaminergic” cells of the substantia nigra have deteriorated.²⁰¹ The disturbances in voluntary movement are identified as difficulty initiating movement (akinesia) and slowness in maintaining movement (bradykinesia). The bradykinesia and akinesia are often the most disabling motor symptoms for a client with PD.^{82,83} The delay in initiating movement patterns and the slowness in executing the motion compromise functional tasks such as driving, dressing, and eating.

In addition to the slowness of movement, rigidity is a characteristic of PD. Rigidity is the stiffness within a muscle that impedes smooth movement. This stiffness occurs in both directions for each plane of motion at a specific joint.¹⁷⁵ The characteristic resting tremor with a rate between 4 and 5 Hz is a disturbance in involuntary movement.¹³⁵ This tremor often diminishes with activity, but in some clients the tremor persists during performance of functional activities.

Additional symptoms of PD are disturbances in gait and postural reactions, a masked face with decreased facial expressions, and emotional disturbances, including depression and psychosis.^{82,167} Deterioration in gait is seen throughout the course of the disease.¹⁹⁰ Initially, gait may be fairly normal, but as the disease progresses, changes in stride length and speed of gait are apparent. The characteristic festinating gait is often seen; as the client walks, stride length decreases in length and speed slightly increases, thereby creating a shuffling effect. Reduced arm swing during ambulation is evident, and trunk rotation is markedly decreased during walking. Another motor disturbance associated with gait is the phenomenon of “freezing.”⁷⁵ Freezing occurs when the person ceases to move, often after attempting to initiate, maintain, or alter a movement pattern. During gait, freezing may be seen as the client attempts to change directions or approach a narrow hallway or stairs. As the client attempts to alter the trajectory of walking to turn and enter another room, he or she may cease moving. Freezing can also be seen during other motor tasks, such as writing, brushing teeth, and speaking.

Postural abnormalities associated with PD include a flexed, stooped posture with the head positioned forward.¹³⁹ The client tends to stand with flexion at the knees and hips. In addition to the stooped posture, balance reactions are compromised.¹⁷⁴ Righting and equilibrium reactions are markedly reduced in effectiveness, and a person with PD may experience frequent falls.

Approximately 50% of individuals with diagnosed PD exhibit depression,¹⁷⁴ which is not merely reactive to the severity of the symptoms or the chronic nature of the disease.⁵⁹ The depression seen in individuals with PD appears to be related to a serotonergic deficit, similar to that in clients without PD who have depression. Complicating the feature of depression is a decrease in facial expressiveness caused by akinesia.¹⁷⁴ This decrease in spontaneous facial expression, or the so-called masked face, is characteristic of clients with PD. Initially, decreased facial expressions are seen unilaterally, but as the disease progresses, spontaneous expression decreases on both sides of the face.⁵⁹ Individuals with PD may also self-limit social interaction because they are embarrassed by their decreased facial expressions and movement disorders. Psychosis is also a common complication for clients with PD, and they may experience hallucinations and delusions.⁸² These disturbances compromise cognitive abilities and often limit functional skills.

Mental status is fairly normal throughout the early stages of PD, but visual-spatial perception is frequently compromised.¹⁷⁴ Higher-order cognitive disorders are common in clients with PD. Clients with PD often have difficulty shifting attention among various stimuli. Processing simultaneous information is frequently difficult for an individual with PD, and tasks that require a sequential process are somewhat easier to perform. Driving a car presents a particular challenge because it necessitates processing of multiple forms of information in a simultaneous manner. Some

self-care tasks, such as brushing teeth, have a clear sequence that can be followed; these activities can be performed with less demand on cognitive functioning. Although dementia is seldom seen in clients with an earlier-onset form of PD, approximately a third of people older than 70 years who have PD display dementia.

Additional symptoms associated with PD include autonomic dysfunction, dysphagia, and dysarthria.¹⁷⁴ A client with PD may have bowel and bladder problems, with reduced intestinal motility producing constipation. Clients often report an increase in the frequency and urgency of urination. Clients also frequently complain of orthostatic hypotension, but syncope is rare.⁵⁹ Clients with PD occasionally report periods of sweating and abnormal tolerance of heat and cold.¹⁷⁴ Because speech volume is often decreased, persons with PD frequently seem to whisper. Articulation is imprecise, and speech is monotone. Dysphagia tends to occur in the later stages of PD, and clients may be at risk for choking and aspiration pneumonia as a result of the dysphagia.

The course of the disease varies from person to person, but the first clinical symptom identified is typically a unilateral resting tremor in the hand.¹³⁵ Hoehn and Yahr established a scale identifying the progression of symptoms in PD.⁹⁴ A client in stage I exhibits unilateral involvement, typically a hand tremor, but no impairment in functional abilities is reported. Such a client is able to complete personal ADLs and IADLs, but performance often requires additional effort and energy. Depending on job demands, a client with stage I PD is frequently employed but may require modifications of the work site. During this stage the client's handwriting may become very small, with letters that are cramped together.⁵⁹ This change in handwriting is referred to as micrographia. The client may also complain of muscle cramping when required to write for extended periods. Slight rigidity may be seen when the client is asked to rapidly open and close the involved hand.

Stage II denotes a progression of symptoms and the development of bilateral motor disturbances.⁹⁴ Although the course of PD is variable, this stage is usually seen 1 to 2 years after initial diagnosis. Even though tremors or rigidity may be noted bilaterally, the client can still perform ADL skills. Performance of IADL skills may require modification because of motor difficulties. Work, depending on the job requirements, often requires additional modifications, and the client may need several rest breaks during the day. The client should make decisions at this point regarding the benefits of remaining employed relative to the energy expenditure. Posture becomes slightly stooped, with flexion at the knees and hips. A person with stage II PD is still able to ambulate independently. As PD progresses to stage III, the client experiences delayed righting and equilibrium reactions. Balance is impaired; the client has difficulty performing daily tasks that require standing, such as showering and meal preparation. Employment may be difficult because of its energy demands. Safety while walking is a concern

because of the client's reduced balance, and home modifications are necessary at this stage. A person with stage IV PD has significant deficits in completing daily living tasks. The client is still able to ambulate at this stage, but motor control is severely compromised and negatively affects dressing, feeding, and hygiene skills. Stage V is the final stage of PD. The client is typically confined to a wheelchair or bed and depends on others for most self-care activities. The rate of progression through these stages varies from person to person, but PD is a slowly progressive disorder.

The extent of PD symptoms in individual clients has been measured with the Unified Parkinson's Disease Rating Scale.⁶² This scale evaluates a client's motor skills, functional status, and extent of disability. Motor skills are evaluated by a trained observer.¹⁸⁵ Functional status and extent of disability are measured through a client interview that includes items addressing ADL skills and cognitive and emotional factors.¹²² This instrument has been used for research and clinical practice to measure the effectiveness of various interventions in reducing PD symptoms (Table 35-4).

Medical Management

The most frequently used medical management strategy for PD is prescription of a dopamine agonist to make up for the depletion of dopamine caused by destruction of the substantia nigra.^{57,191} Levodopa is the medication most commonly used for the treatment of PD.¹⁷⁰ This oral medication is actually a precursor to dopamine because dopamine is too large to cross the blood-brain barrier. Levodopa provides substantial relief from tremors and rigidity during the initial stages of PD. After approximately 5 to 10 years of chronic use of levodopa, motor side effects are reported.¹⁷⁴ Those most often reported are dyskinesias and motor fluctuations. This so-called on-off phenomenon is related to the levodopa dosage. A decrease in tremors and rigidity occurs during the "on" period after the administration of levodopa, but the client may also experience various dyskinesias, such as abnormal movements of the limbs. As the dosage of levodopa wears off, the motor symptoms, specifically tremors and rigidity, associated with PD return. Timing of the medication and the periods of "on-off" are important considerations in planning the client's daily activities. Even though abnormal movements are observed during the "on" period, the client has greater freedom of movement to complete functional activities.

As PD progresses, control of various motor symptoms through the use of levodopa becomes less effective.¹⁷⁴ Surgical intervention, known as stereotactic surgery, has been used. In this surgery, specific lesions are made in neurologic structures to decrease the severity of PD symptoms. Stereotactic surgery on the globus pallidus internus has been used to decrease the severity of motor symptoms associated with PD and thus reduce the dosage of levodopa needed.^{105,160} This surgical procedure is known as pallidotomy. Pallidotomies have also been shown to reduce the dyskinesias

■ **TABLE 35-4** | Progression of Symptoms in Parkinson's Disease

Stage	Symptoms	Occupational Therapy Management
I	Unilateral tremor, micrographia, poor endurance for previous occupations, fatigue	Work evaluation if the client is employed; work simplification for work and home settings; develop the habit of taking frequent rest breaks; use of utensils with enlarged handles
II	Bilateral motor disturbances, mild rigidity reported, difficulties with simultaneous tasks, difficulties with executive function	Energy conservation techniques related to ADLs; develop daily flexibility exercises focused on trunk rotation; driving assessment and alternatives for community mobility; use of task analysis to structure sequential tasks
III	Balance problems with delayed reactions, difficulties in skilled sequential tasks	Environmental modifications in the home, including raised toilet seats, chairs with armrests, removal of throw rugs; use of visual cues and supports for sequential tasks
IV	Fine motor control severely compromised, oral motor deficits	Modifications to support participation in self-care tasks, changes in food textures
V	Client severely compromised motorically, dependent with ADLs	Use of environmental controls to allow access to the environment

ADLs, activities of daily living.

associated with long-term use of levodopa.¹⁷⁴ Stereotactic surgery has likewise been used to create lesions in portions of the thalamus to reduce the tremor and rigidity associated with PD.¹⁰⁷

Neural transplantation has been used selectively for clients with PD.³³ This process involves harvesting fetal mesencephalic neural tissue and then transplanting this tissue into the basal ganglia of clients with PD.⁴⁷ The results of fetal brain transplants have been varied. In some clients the tremors and rigidity were substantially reduced, but other clients experienced dyskinesias following transplantation of such tissue.¹⁷³ The best success with this procedure has been reported when bilateral implants are placed in the putamen from multiple fetuses. The transplanted fetal tissue produces dopamine and thereby reduces the debilitating symptoms of progressive PD. Clients must continue to use levodopa, but at a reduced dosage.

Role of the Occupational Therapist

OT services vary depending on the client's stage of PD. Typically, an OT program would provide compensatory strategies, client and family education, environmental and task modifications, and community involvement.

During the initial stages of the disease, the occupational therapist should develop an occupational profile with the client and significant others to establish intervention priorities.¹⁸⁹ Clients have expressed the desire to retain a sense of self and normalcy within their family, even in the face of deteriorating abilities. The focus of intervention is on developing habits and routines to foster participation in desired occupations as the disease process progresses. Educating the client and significant others regarding the course of the

disease is an important step in this process, one that aids in selection of occupations. For example, the case study at the end of this chapter introduces Carl. He identified traveling and painting as important occupations, and interventions were designed to help him continue participating in these occupations as the disease progressed.

During the early stages of the disease, the client and family should be informed of community resources and support groups. In one study, clients with PD were found to be far more dependent on others for personal care and household activities than were same-age peers without PD.²¹⁴ This dependence can place additional stress on the family. Involvement in a community-based group may provide the support needed to accommodate the changes in family roles and interaction.¹⁸⁹

Even during the early stages of the disease process, clients with PD have difficulty in executive functioning.⁶⁷ An investigation by Foster and Hershey compared clients who had PD, but no dementia, with age-matched controls on several assessments of executive functioning. Clients with PD were in stage I or II. Clients with PD performed significantly worse on working memory and executive functioning. Furthermore, lower executive functioning "was associated with reduced activity participation after controlling for motor dysfunction and depressive symptoms." The authors urge occupational therapists to assess executive functioning even during the early stages of PD and develop strategies to support client participation in desired occupations.

Modification of household items may decrease the impact of tremors during the initial stage of the disease process. The use of built-up handles for eating and writing utensils should be introduced during the initial stages of PD. Handwriting often becomes small and difficult to read

during the initial stage of PD. Time management techniques should be introduced at this stage. Paying bills, signing forms, or doing other written work should be completed soon after taking levodopa with the use of utensils that have built-up handles. Even though the tremors are not severe during the early stages of PD, clothing fasteners should be modified. The use of slip-on shoes or Velcro closures for clothing should be considered at this time. Although a client may be able to complete the fastening of clothing during this stage of PD, the occupational therapist must consider the amount of energy and time needed to perform such a task. In addition to the modification of specific tasks, household changes should be made at this time. Loose rugs should be removed from floors and furniture placed close to the wall to decrease obstacles. Chairs should have armrests to allow the client to push up from the chair to stand. Although balance is not significantly compromised during the early stages of PD, the family and client should become familiar with the new arrangement of furniture before it becomes a necessity. Bath and toilet railings and a raised toilet seat should be provided within the home. Because fatigue is a common complaint, clients should develop the habit of taking frequent breaks during the day. Modifying the household setting early in the course of PD allows the client and family members to adjust to changes and incorporate these changes into daily routines before they become a necessity.

A work evaluation should be performed during the early stage of the disease process to assess safety risks, potential hazards, and work simplification techniques that could be used. An ergonomic assessment of the work site and modifications in tools would be appropriate. In the case of Carl, computer modifications were considered. A client may have the option of reducing the number of work hours, but that decision may result in reduced medical benefits. These decisions and available options are part of the OT intervention process during the early stage of the disease.

During the initial stage of PD, the occupational therapist should establish a daily exercise program that addresses full range of motion.²⁰⁷ It is preferable to have a client with PD perform a short exercise program for 5 to 10 minutes daily rather than a longer program three times a week. Exercises should include alternating movements from various planes since many clients with PD display difficulty in smooth shifting of movements.¹²⁴ Postural flexibility exercises should be included in the program, with specific attention directed to trunk extension. The most common postural change noted with progression of PD is a stooped stance. In addition to flexibility exercises, occupational therapists should instruct clients in the use of relaxation techniques and controlled breathing. Inhaling slowly through the nose and exhaling through pursed lips two or three times in succession, combined with improved postural alignment, can promote relaxation.

As the disease progresses, additional exercises can improve gait.²¹² Rhythmic auditory stimulation in the form of music

with an accentuated initial beat has been found to significantly improve stride length and speed in clients with PD. Dancing can also enhance gait patterns, in addition to providing a social environment for clients with PD. As akinesia becomes more apparent, a client with PD should be instructed to use a rocking motion to begin movement activities. Rocking forward and backward a few times while seated can produce the momentum needed to rise from a chair.

As a person with PD progresses to the middle stages of the disease, the client experiences further deterioration in motor skills, particularly the execution of skilled sequential movements.⁵² These types of movements are needed to complete personal care and household tasks. Curra and associates found that external cues improve the speed and sequential performance of novel motor tasks.⁵² The occupational therapist should suggest modifying activities to include visual cues, verbal prompts, and rehearsal of movements. These strategies increase a client's ability to perform personal care and household activities.

During the middle stages of PD, clients may have decreased oral motor control.¹⁷⁴ Dysphagia and drooling may embarrass them and further restrict social engagements. The occupational therapist should encourage oral motor exercises and provide education regarding food selection. Food consistencies can be altered to improve the client's ability to eat.

The ability to complete personal care tasks has been identified as a critical variable in a client's perception of quality of life.⁶⁴ Although progressive movement problems are characteristic of PD, the occupational therapist can minimize the impact that the movement disorder has on functional activities. Tremors have more negative effects on postural control compared to self-care tasks since compensatory strategies can reduce the impact of tremors on completion of ADLs.⁷¹ The use of group OT sessions has been demonstrated to be effective in reducing the impact of postural instability in clients with PD. An additional benefit of group sessions is the reported improvement in perception of quality of life in clients attending the sessions.

Access to community mobility and support programs should be included in the OT intervention plan during the middle stages of PD. A client with PD is often dependent on others for transportation. The use of community mobility services can decrease the client's dependence on family members for shopping and errands.

During the last stages of PD, movement disorders and rigidity may eliminate the client's ability to perform personal care tasks such as dressing and grooming.⁹⁴ Depression caused by decreased ability to perform these tasks can significantly compromise a person's quality of life.⁶⁴ OT services should be provided to further modify the home environment for access and control. The use of environmental control units, such as a switch-operated television or radio, can be helpful. The switch plate should be activated with only light touch. Voice- or sound-activated environmental control units may not be as useful because of

Case Study | Carl

Carl is a 62-year-old college professor in whom PD was diagnosed at the age of 57. He is married and lives in a small one-story home with his wife. He has two adult children who live in another state. Carl reports that he enjoys traveling, reading, painting, and attending concerts.

Carl recently considered taking early retirement because of the increase in tremors in both his hands, which made correcting papers difficult. He also reports some problems with endurance as a result of stiffness. Carl indicates that he is no longer able to paint because of the tremors in his hands. He also reports that he is unsure whether he should continue driving because of these tremors.

The results of OT evaluation indicate that Carl is cooperative and motivated for therapy. Although he does not state that he is depressed, his wife reports features of depression, such as decreased interest in going to concerts and planning summer vacations to see their adult children and grandchildren. His wife also reports that Carl seems depressed about his possible early retirement and loss of status as a college professor.

Carl is able to complete most personal ADLs independently but has difficulty stepping into and out of the tub and shower. His wife reports that she is afraid that he will fall and that she often assists him in getting into and out of the shower. Carl also has difficulty tying his tie and buttoning his shirt. Tremors are noted bilaterally in his hands, and slight rigidity is present during passive range of motion. Dynamic balance is slightly compromised on uneven surfaces and stairs.

Carl has been taking Sinemet (levodopa and carbidopa medication) for the past 3 years to decrease the rigidity and tremors. He does not report any dyskinesias.

When asked about his personal goals, Carl replies, "I guess I'll have more time to read now."

OT was initiated to accomplish the following:

1. Improve ADL performance:
 - Instruct in the use of a buttonhook.

- Make suggestions regarding clothing modifications such as clip-on ties and slip-on shoes.
 - Instruct in the use of momentum to initiate movement, such as rocking back and forth to rise from a chair.
2. Modify the home environment:
 - Remove throw rugs and obstacles in walkways.
 - Provide a tub seat and shower extension hose.
 - Provide a raised toilet seat.
 - Provide a cushion on dining room chairs.
 3. Assess the work setting for modifications:
 - Assess for computer access.
 - Instruct in energy conservation and urge him to take frequent breaks and schedule activities during the "on" phase of medications.
 4. Investigate leisure pursuits:
 - Provide modifications in his easel such as using forearm supports to allow him to continue to paint.
 - Provide information regarding community-based PD support groups.
 5. Instruct in a daily active range-of-motion exercise program:
 - Trunk extension and rotation exercises.
 - Bilateral upper extremity exercise.
 - Use of music during the exercise program.

Carl responded well to OT intervention. Although he was able to complete the academic school year, he decided to retire afterward. He stopped driving, but his wife began to drive them to concerts and art exhibits. He was able to complete personal ADLs safely with the use of adapted equipment and home modifications. He resumed painting during the "on" periods of his medication schedule by using forearm supports attached to an angled table. He attended a Parkinson's support group two times a week and began to socialize with members of that group. Carl reported that the daily exercises seemed to decrease his stiffness, and he and his wife took frequent strolls in the park when weather permitted. He and his wife also joined a book club.

decreased vocal volume and poor control of articulation during speech production. The client's ability to control the immediate environment can compensate for the losses experienced during the final stages of PD. The client may no longer be able to dress himself or herself, but through the use of various switches the client can select preferred television or radio programs, control room lighting, and operate a computer with minimal motor action.

Summary

Although PD is a progressive, neurodegenerative disorder, OT has much to offer clients with this disease.^{64,71} The diminishing ability to perform personal care activities and engage in self-selected tasks has been identified as one of the variables contributing to depression and the decreased quality of life in clients with PD. Throughout the

progressive course of PD, OT addresses the ability of the client to engage in meaningful activities. The client's wishes and family circumstances are incorporated into the OT intervention plan at every stage of the disease process.

Review Questions

1. What are the symptoms of ALS at onset?
2. What is the underlying neurologic process in ALS?
3. What body functions remain intact throughout the ALS disease process?
4. What is the prognosis for ALS? Given this prognosis, what is the goal of the occupational therapist?
5. What are the symptoms of ALS at each stage of the disease?
6. What interventions are appropriate at each stage of ALS?
7. What are the initial symptoms of AD?

8. What is the underlying degenerative neurologic process associated with AD?
9. What changes in symptoms occur over the course of AD?
10. How do the changes in symptoms affect occupational performance in clients with AD?
11. What is the prognosis for a client with AD?
12. What OT interventions are appropriate for a client at each stage of AD?
13. What environmental modifications should be made to accommodate a client with AD?
14. What are the symptoms of MS at onset?
15. What is the underlying neurologic process in MS?
16. What are the three typical patterns of MS? How do they differ?
17. What symptoms of MS are managed with medication? What are the side effects of medication management?
18. How is medication management of the relapsing and remitting form of MS different from that in the other forms of MS?
19. What does the OT evaluation include for a person with MS?
20. Why is it important to include the family in the evaluation and treatment process for a client with MS?
21. What are the initial symptoms of HD?
22. What is the underlying degenerative neurologic process associated with HD?
23. What changes in symptoms occur over the course of HD?
24. How do the changes in HD symptoms affect occupational performance?
25. What is the prognosis for a client with HD?
26. What OT interventions are appropriate for a client with HD at the various stages of the disease?
27. What environmental modifications should be made to accommodate a client with HD?
28. What are the initial symptoms of PD?
29. What is the underlying degenerative neurologic process associated with PD?
30. What changes in symptoms occur over the course of PD?
31. How do the changes in PD symptoms affect occupational performance?
32. What is the prognosis for a client with PD?
33. What OT interventions are appropriate for a client with PD?
34. How does the medication schedule of levodopa affect the daily routine of a client with PD?
35. What environmental modifications should be made to accommodate a client with PD?

Spinal Cord Injury

CAROLE ADLER

■ Chapter Outline

Results of spinal cord injury

Complete versus incomplete neurologic classifications

Clinical syndromes

Central cord syndrome

Brown-Séquard syndrome (lateral damage)

Anterior spinal cord syndrome

Cauda equina (peripheral)

Conus medullaris syndrome

Prognosis for recovery

Medical and surgical management of the person with spinal cord injury

Complications of spinal cord injury

Skin breakdown, pressure sores, or decubitus ulcers

Decreased vital capacity

Osteoporosis

Orthostatic hypotension

Autonomic dysreflexia

Spasticity

Heterotopic ossification

Sexual function

Occupational therapy intervention

Evaluation

Occupational and psychosocial status

Physical status

Functional status

Establishing intervention objectives

Intervention methods

Acute phase

Active phase

After discharge from acute rehabilitation

Aging with spinal cord injury

Research

Summary

■ Key Terms

Tetraplegia/quadriplegia

Paraplegia

Autonomic dysreflexia

Spasticity

Heterotopic ossification

Decubitus ulcer

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Understand the difference between complete and incomplete spinal cord injury and the classification system used to describe such levels of injury.
2. Recognize and identify the various spinal cord injury syndromes.
3. Briefly describe the medical and surgical management of the individual who has experienced a traumatic spinal cord injury.
4. Identify some of the complications that can limit optimal functional potential.
5. Describe the changes in sexual functioning in males and females after spinal cord injury.
6. Identify the specific assessment tools that must be considered before developing intervention objectives.
7. Analyze the critical issues in factors to consider when developing intervention objectives during the acute, active, and discharge phases of the rehabilitation process.
8. Identify in detail the functional outcomes, including equipment considerations and personal and home care needs, that can be reached at each level of complete injury under optimal circumstances.
9. Analyze how the effects of spinal cord injury accelerate the normal aging process, and explain how functional status may change.

Threaded Case Study: | Laurence, Part 1

Laurence is a 44-year-old Caucasian man who sustained a C7 complete (ASIA A) spinal cord injury (SCI) as a result of a fall. He also sustained facial lacerations and bilateral radial wrist fractures, which necessitated casting without internal fixation. Laurence is divorced with no biologic children. He has a 21-year-old stepdaughter with whom he is very close. He is a firefighter and has a background in auto mechanics. Laurence is very athletic, a triathlete and marathon runner. Just before his accident, Laurence had moved into a second-story apartment.

Laurence was referred to occupational therapy (OT) on the day of his injury and was initially evaluated in the intensive care unit (ICU) within 24 hours of the injury. Because of the acute nature of his injury and the immediacy of his needs related to client factors, the occupational profile and history, which are normally the first priority in the OT evaluation, were temporarily postponed until his physical and environmental control needs could be addressed. He was immobilized in cervical traction and bilateral wrist casts on a kinetic bed. His specific manual muscle test revealed 3+ (Fair+) to 4 (Good) strength in deltoids, biceps, and triceps. Wrists could not be tested secondary to bilateral wrist casts, and finger flexion was noted to be 2- (Poor-) bilaterally. Sensory examination was intact to the C7 dermatome. Vital capacity was low secondary to the absence of innervation of intercostals and abdominal musculature, and Laurence required respiratory treatments four times per day to mobilize lung secretions. Because of his immobilization, he required assistance for all aspects of his activities of daily living (ADLs), including bed and wheelchair mobility.

OT intervention objectives included (1) maintaining optimal range of motion (ROM) in all joints for maximal upper extremity function and seated positioning; (2) achieving optimal strength and endurance in available musculature; (3) achieving optimal independence in all ADLs, including bathing, toileting, and skin care; (4) achieving independent wheelchair mobility on all indoor and outdoor surfaces; (5) receiving appropriate durable medical equipment (DME) to

meet both short- and long-term needs (e.g., manual and power wheelchairs, cushion, and bathing and toileting equipment); (6) achieving optimal independence in the instrumental activities of daily living (IADLs), such as returning to safe and accessible housing; and (7) being educated in all aspects of care and independently instructing caregivers in assistance needed.

Laurence has had a very difficult time accepting the fact that he had a complete SCI. He could not imagine how he could function at work and in his community as a person with quadriplegia. The occupations of most importance to him were to resume his work as a firefighter and to continue in his previous athletic activities. Clearly, the severity of his injury makes him unable to return to those occupations as he knew them. His work and church community offered a tremendous amount of support, yet he continued to be depressed and angry over his loss of mobility and independence. He received regular psychological counseling and attended a weekly peer support group.

Throughout this chapter, consider the long-term consequences of Laurence's injuries to his ability to engage in occupation to support participation in his life contexts. Keep in mind the effects of SCI on client factors, performance skills and patterns, and the relationship of activity demands to selection of the optimal equipment to enhance mobility and other areas of occupation.

Critical Thinking Questions

1. Considering Laurence's level of SCI, what expectations would there be for functional recovery, and what interventions would the therapist provide to maximize his independence in performance of ADLs and IADLs?
2. What DME and adaptive equipment will maximize efficiency in his mobility and ADLs?
3. How will the therapist approach OT interventions and realistic expectations regarding work, social participation, leisure, and other important lifestyle options considering Laurence's depression and anger over his situation?

Rehabilitation of the client with a spinal cord injury (SCI) is a lifelong process that requires readjustment to nearly every aspect of life. Occupational therapists and occupational therapy (OT) assistants play a significant role in physical and psychosocial restoration and help the client achieve maximal independence. Through accurate evaluation, retraining, and adaptive techniques and equipment, occupational therapists provide their clients with the tools and resources needed to resume engagement in occupation to support participation in life situations to their maximal physical and functional potential.

SCIs have many causes, trauma being the most common. Trauma can result from motor vehicle accidents, violent injuries such as gunshot and stab wounds, falls, sports accidents, and diving accidents.^{5,12} Normal spinal cord function may also be disturbed by diseases such as tumors, myelomeningocele, syringomyelia, multiple sclerosis, cancer, and amyotrophic lateral sclerosis. Some of the intervention principles outlined in this chapter may apply to these conditions; however, the emphasis is on rehabilitation of the individual with a traumatic SCI.

Results of Spinal Cord Injury

SCI results in quadriplegia (labeled tetraplegia by the American Spinal Cord Injury Association) or paraplegia. Tetraplegia, which will be referred to as quadriplegia throughout the remainder of the chapter, is any degree of paralysis of the four limbs and trunk musculature. There may be partial upper extremity (UE) function, depending on the level of the cervical lesion. Paraplegia is paralysis of the lower extremities (LEs) with involvement of the trunk and hips, depending on the level of the lesion.^{5,12}

SCIs are referred to in terms of the regions (cervical, thoracic, and lumbar) of the spinal cord in which they occur and the numerical order of the neurologic segments. The level of SCI designates the last fully functioning neurologic segment of the cord. For example, C6 refers to the sixth neurologic segment of the cervical region of the spinal cord as the last fully intact neurologic segment.^{3,5} Complete lesions result in the absence of motor or sensory function of the spinal cord below the level of the injury.

Incomplete lesions may involve several neurologic segments, and some spinal cord function may be partially or completely intact.^{2,3}

Complete versus Incomplete Neurologic Classifications

The extent of neurologic damage depends on the location and severity of the injury (Figure 36-1). In a complete injury, total paralysis and loss of sensation result from a complete interruption of the ascending and descending nerve tracts below the level of the lesion. In an incomplete injury, there is some degree of preservation of the sensory or motor nerve pathways below the level of the lesion. Segments at which normal function is found often differ in the

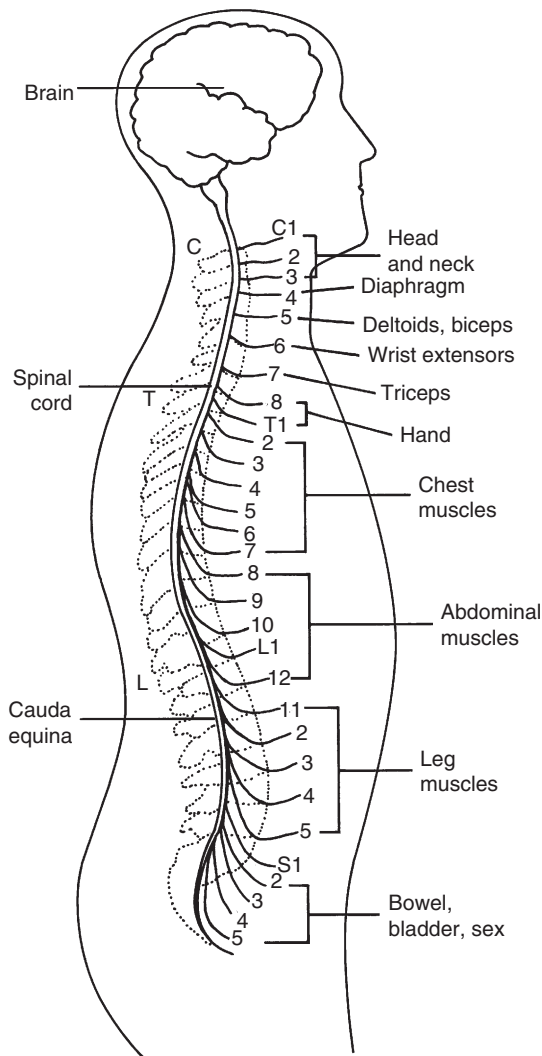

FIGURE 36-1 Spinal nerves and major areas of body they supply.

(From Paulson S, editor: *Santa Clara Valley Medical Center spinal cord injury home care manual*, ed 2, San Jose, CA, 1994, Santa Clara Valley Medical Center.)

side of the body and in terms of sensory versus motor testing.

It is essential that a very careful neurologic examination be done before determining whether an injury is complete or incomplete.

The American Spinal Injury Association (ASIA) uses the findings from the neurologic examination to classify injury types to further objectify specific clinical findings:

- ASIA impairment scale classification A indicates a complete lesion; there is no motor or sensory function preserved in the sacral segments S4 through S5. Any preservation of strength without sensory sparing in the sacral segments of S4 through S5 is considered a zone of partial preservation (ZPP) and still considered a complete (ASIA A) neurologic classification.

- ASIA classification B indicates an incomplete lesion in which sensory but not motor function is preserved below the neurologic level and must include the sacral segments S4 through S5.
- ASIA classification C indicates an incomplete lesion in which motor function is preserved below the neurologic level and more than half of the key muscles below the neurologic level have a muscle grade of less than 3 (Fair).
- ASIA classification D indicates an incomplete lesion in which motor function is preserved below the neurologic level and at least half of the key muscles below the neurologic level have a muscle grade of 3 or more.
- ASIA classification E indicates that motor and sensory functions are normal.¹
- Incomplete injuries are categorized according to the area of damage: central, lateral, anterior, or peripheral.

After thorough muscle and sensory testing, Laurence's neurologic diagnosis was C7 ASIA A. Key musculature innervated by the C7 nerve root (triceps) was graded at 4 (Good). He had 2 (Poor) strength in his finger flexors, extensors, and thumb flexors. Because sensation was intact to the C7 dermatome level and completely absent below and in the sacral segments, his diagnosis was clearly ASIA A with a ZPP at C8.

Clinical Syndromes

After SCI, the individual enters a stage of spinal shock that may last from 24 hours to 6 weeks. This period is one of areflexia, in which reflex activity ceases below the level of the injury.³ The bladder and bowel are atonic or flaccid. Deep tendon reflexes are decreased, and sympathetic functions are disturbed. This disturbance results in decreased constriction of blood vessels, low blood pressure, a slower heart rate, and no perspiration below the level of injury.^{10,16}

The spinal cord is usually not damaged below the level of the lesion. Therefore, muscles that are innervated by the neurologic segments below the level of injury usually develop spasticity, because the monosynaptic reflex arc is intact but separated from higher inhibitory influences. Deep tendon reflexes become hyperactive, and spasticity may be evident. Sensory loss continues, and the bladder and bowel usually become spastic ("upper motor neuron" bladder) in clients whose injuries are above T12. The bladder and bowel usually remain flaccid ("lower motor neuron" bladder) in clients whose lesions are at L1 and below. Sympathetic functions become hyperactive. Spinal reflex activity (mass muscle spasms) usually becomes evident in the areas below the level of the lesion.^{2,12,14}

Four weeks after his injury, Laurence began to develop spasticity in his LEs and abdominal muscles. When he was assisted into bed, he said, he felt as if "the breath was knocked out of me" as a result of abdominal tightness.

This sensation created a considerable amount of anxiety for him until he learned more about the effects of abdominal spasms and how the involuntary tightness of the abdominal muscles would make it difficult for him to exhale—hence, the sensation of shortness of breath. His LEs were very tight and difficult to manage during his morning dressing program with the occupational therapist because of the extensor spasms that he was experiencing upon exertion. His therapist discussed this challenge with Laurence's doctor, who prescribed spasticity medication to inhibit the spasms that were interfering with LE dressing and pretransfer and posttransfer setup. Because his therapist could observe firsthand the effect of Laurence's spasticity on his daily activities, this therapist's feedback to Laurence's physician considerably influenced the dosage of his spasticity medications.

Central Cord Syndrome

Central cord syndrome occurs when there is more cellular destruction in the center of the cord than in the periphery. Paralysis and sensory loss are greater in the UEs because these nerve tracts are more centrally located than those of the LEs. Central cord syndrome is often seen in older people in whom arthritic changes have caused a narrowing of the spinal canal; in such cases, cervical hyperextension without vertebral fracture may precipitate central cord damage.

Brown-Séquard Syndrome (Lateral Damage)

Brown-Séquard syndrome results when only one side of the cord is damaged, as in a stabbing or gunshot injury. Below the level of injury, there is motor paralysis and loss of proprioception on the ipsilateral side and loss of pain, temperature, and touch sensation on the contralateral side.

Anterior Spinal Cord Syndrome

Anterior spinal cord syndrome results from injury that damages the anterior spinal artery or the anterior aspect of the cord. This syndrome involves paralysis and loss of pain, temperature, and touch sensation. Proprioception is preserved.

Cauda Equina (Peripheral)

Cauda equina injuries involve peripheral nerves rather than directly involving the spinal cord. This type of injury usually occurs with fractures below the L2 level and results in a flaccid-type paralysis. Because peripheral nerves possess a regenerating capacity that the cord does not, this injury is associated with a better prognosis for recovery. Patterns of sensory and motor deficits are highly variable and asymmetrical.

Conus Medullaris Syndrome

Conus medullaris syndrome involves injury of the sacral cord (conus) and lumbar nerve roots within the neural canal, which usually results in an areflexic bladder, bowel, and LEs.

Prognosis for Recovery

The prognosis for substantial recovery of neuromuscular function after SCI depends on whether the lesion is complete or incomplete. If there is no sensation or return of motor function below the level of lesion 24 to 48 hours after the injury in carefully assessed complete lesions, motor function is less likely to return. However, partial to full return of function to one spinal nerve root level below the fracture can be gained and may occur in the first 6 months after injury. In incomplete lesions, progressive return of motor function is possible, yet it is difficult to determine exactly how much and how quickly return will occur.¹⁴ Frequently, the longer it takes for recovery to begin, the less likely it is that it will occur.

The following statements can be used as guidelines to predict and assist therapists and their clients in understanding the recovery process after a new SCI:¹¹

- The severity of the original injury determines whether recovery will occur. Unfortunately, no test to measure this severity exists at this time, and predictions must be based on what has happened to others in the past with similar neurologic findings.
- Incomplete injuries are associated with a better chance of further recovery than are complete injuries, but even with incomplete injuries there is no guarantee that further recovery will occur.
- Most of the recovery that will occur starts within the first few weeks. Therefore, each day that goes by without any return of function means that the likelihood of recovery is reduced.
- No amount of hard work will cause nerve function to return. If hard work were all it took, very few people would end up with permanent paralysis.
- Rehabilitation will not affect the degree of recovery. The purpose of rehabilitation is to prevent further medical complications through education, to maintain and improve the strength and skills that are present, to maximize function in self-care activities, to facilitate mobility, and to optimize lifestyle options for the patient and their family, therefore, maintaining the body and the individual's general well being in a "recovery ready" state.

Medical and Surgical Management of the Person with Spinal Cord Injury

After a traumatic event in which SCI is likely, the conscious client should be carefully questioned about cutaneous numbness and skeletal muscle paralysis before being moved. Emergency medical technicians, paramedics, and air transport personnel are trained in SCI precautions and extrication techniques for moving a person who has sustained a possible SCI from an accident site. Movement of the spine must be prevented during the transfer procedures. A firm

stretcher or board to which the person's head and back can be strapped should be procured before moving the person. After the patient is transferred to the stretcher or board, he or she should be strapped to the board or stretcher and carefully transferred via air or ground transport to the nearest hospital emergency room. Axial traction on the neck should be maintained, and any movement of the spine and neck prevented during this process. Careful examination, stabilization, and transportation of the patient may keep a temporary or minimal SCI from becoming more severe or permanent. Initial care is directed toward preventing further damage to the spinal cord and reversing neurologic damage, if possible, by stabilization or decompression of the injured neurologic structures.^{5,10,12} Anti-inflammatory and steroidal drugs are administered immediately after injury in an effort to minimize swelling to the specific lesion and therefore minimize neurologic damage, although the significance of their effect on neurologic recovery remains unclear.

The examining physician carries out a careful neurologic examination to aid in determining the site and type of injury. The client is in a supine position for this procedure, with the neck and spine immobilized. A catheter is usually placed in the client's bladder to drain urine. Anteroposterior and lateral x-ray films may be taken, with the individual's head, neck, or spine immobilized, to help determine the type of injury. A computed tomography (CT) scan or magnetic resonance imaging (MRI) may be needed for further evaluation. In early medical treatment the goals are to restore normal alignment of the spine, maintain stabilization of the injured area, and decompress neurologic structures that are under pressure.

Bony realignment and stabilization can be achieved by placing the client on a rotating kinetic bed (Figure 36-2) that allows skeletal traction and immobilization. The bed's

FIGURE 36-2 Kinetic bed with custom arm positioner. Designed and fabricated by the Occupational Therapy Department, Santa Clara Valley Medical Center, San Jose, California.

constant rotation allows continuous pressure relief, mobilization of respiratory secretions, and easy access to the client's entire body for bowel, bladder, and hygiene care. Open surgical reduction with internal fixation and spinal fusion may be indicated.

The goals of surgery are to decompress the spinal cord and achieve spinal stability and normal bony alignment.^{5,12} Surgery is not always necessary, and adequate immobilization may allow the individual to heal. As soon as possible, a means of portable immobilization is provided—usually a cervical collar or halo vest for cervical injuries (Figure 36-3, A) and a thoracic brace or body jacket for thoracic injuries (Figure 36-3, B). This approach enables the client to be transferred to a standard hospital bed and, subsequently, to be upright in a wheelchair and involved in an active therapy program in as little as 1 to 2 weeks after injury. Initiating an upright sitting tolerance program shortly after injury can substantially reduce the incidence and severity of further medical complications, such as deep vein thrombosis, joint contractures, and the general deconditioning that can result from prolonged bed rest.

The benefits of early transport to an SCI center have been documented.⁷ Clients treated initially in a spinal cord acute-care unit rather than a general hospital had shorter acute-care lengths of stay. Clients treated in general hospitals tended to have a higher incidence of skin problems and spinal instability. It has been found that individuals sent to rehabilitation centers specializing in the treatment of SCI made functional gains with greater efficiency.¹⁶ Spinal cord centers are equipped to offer a complete, multidisciplinary program executed by an experienced team of professionals who specialize in this unique and demanding disability.

Laurence was injured at his work site, which happened to be very close to a hospital in which a designated SCI center was located. In addition to his cervical spine injury,

he sustained bilateral wrist fractures and facial lacerations as a result of the nature of the fall from the equipment on which he had been standing. Standard practice at this particular hospital is to contact the physiatrist on call for an immediate opinion regarding trauma care.

Complications of Spinal Cord Injury

Skin Breakdown, Pressure Sores, or Decubitus Ulcers

Sensory loss increases the risk of skin breakdown. Persons with sensory loss cannot feel the pressure and shearing of prolonged sitting or lying in one position or the presence of pain or heat against the body. Pressure causes the loss of blood supply to the area, which can ultimately result in necrosis. Heat can quickly burn and destroy tissues. Shearing can destroy underlying tissue. Any combination of the aforementioned factors will hasten skin breakdown. The areas most likely to develop skin breakdown are bony prominences over the sacrum, ischium, trochanters, elbows, and heels; however, other bony prominences, such as the iliac crest, scapula, knees, toes, and rib cage, are also at risk.

All rehabilitation personnel must be aware of the signs of developing skin problems. At first the area reddens and then blanches when pressed. Later, the reddened or abraded area does not blanch, which indicates that necrosis has begun. Finally, a blister or ulceration appears in the area. The problem is often more severe below the level of the skin surface. The visible sore may be only the tip of the iceberg. If allowed to progress, a sore can become severe, destroying underlying tissues even as deep as the bone.

Skin breakdown can be prevented by relieving and eliminating pressure points and protecting vulnerable areas from excessive shearing, moisture, and heat. Routine turning of clients in bed, specialized mattresses and wheelchair seat

cushions, protection of bony prominences with various types of padding, and the performance of weight shifts are some of the methods used to prevent pressure sores.

The use of hand splints, body jackets, and other orthoses can also cause skin breakdown, particularly when protective sensation in those areas is impaired. The therapist must inspect the skin, and the client must be taught to examine his or her skin on a consistent, daily basis, using a mirror or caregiver assistance to watch for signs of developing problems. Skin damage can develop within 30 minutes; therefore, frequent weight shifting, repositioning, and vigilance are essential if skin breakdown is to be prevented.^{12,14}

Decreased Vital Capacity

Decreased vital capacity is a problem among people who have sustained cervical and high thoracic lesions. Such individuals have markedly limited chest expansion and a decreased ability to cough because of weakness or paralysis of the diaphragm and the intercostal and latissimus dorsi muscles. This scenario can result in a tendency toward respiratory tract infections. Reduced vital capacity affects the overall endurance level for activity. Endurance can be improved by assisted breathing and by vigorous respiratory and physical therapy. Strengthening of the sternocleidomastoids and the diaphragm, manually assisted cough, and deep breathing exercises are essential to maintain optimal vital capacity.^{12,14}

Laurence's vital capacity was 50% of normal capacity for a man of his size. He required assistance to cough because he did not have the force to clear his secretions upon exhaling. His endurance was low during his 4- to 5-hour therapy program. He required much education in this area because he was previously a triathlete and in exceptional cardiovascular shape.

Osteoporosis

Osteoporosis is likely to develop in individuals with SCIs because of disuse of long bones, particularly of the LEs. Osteoporosis may be sufficiently advanced for pathologic fractures to occur a year after the injury. Pathologic fractures are most common in the supracondylar area of the femur, proximal tibia, and distal tibia, the intertrochanteric area of the femur, and the neck of the femur. Pathologic fractures are usually not seen in UEs. Daily standing with a standing frame may slow the onset of osteoporosis;^{12,14} however, this is a controversial method and not embraced in all rehabilitation programs. A standing program must fit into the patient's activities of daily living (ADLs) after discharge to be effective on an ongoing basis. Not all reimbursement sources will cover the cost of standing equipment.

Orthostatic Hypotension

A lack of muscle tone in the abdomen and LEs leads to pooling of blood in these areas, with a resultant decrease in blood pressure (hypotension). This problem occurs when

the patient moves from a supine to upright position or changes body position too quickly. Symptoms are dizziness, nausea, and loss of consciousness.⁴ The client must be reclined quickly and, if sitting in a wheelchair, should be tipped back with legs elevated until symptoms subside. With time, this problem can diminish as sitting tolerance and level of activity increase; however, some people continue to have hypotensive episodes. Abdominal binders, compression garments, antiembolism stockings, and medications can help reduce symptoms.

Autonomic Dysreflexia

Autonomic dysreflexia is a phenomenon seen in persons whose injuries are above the T4 to T6 level. It is caused by reflex action of the autonomic nervous system in response to some stimulus, such as a distended bladder, fecal mass, bladder irritation, rectal manipulation, thermal or pain stimuli, or visceral distention. The symptoms are immediate pounding headache, anxiety, perspiration, flushing, chills, nasal congestion, paroxysmal hypertension, and bradycardia.

Autonomic dysreflexia is a medical emergency and life threatening. The client should not be left alone.^{5,12,14} The condition is treated by placing the client in an upright position and removing anything restrictive, such as abdominal binders or elastic stockings, to reduce blood pressure. The bladder should be drained or leg bag tubing checked for obstruction. Blood pressure and other symptoms should be monitored until they return to normal. The occupational therapist must be aware of symptoms and treatment because autonomic dysreflexia can occur at any time after the injury.

Individuals who are susceptible to this condition are encouraged to carry an emergency card describing the condition and treatment because many emergency rooms and medical personnel may be unfamiliar with it.

Spasticity

Spasticity is a nearly universal complication of SCI.¹⁴ It is an involuntary muscle contraction below the level of injury that results from lack of inhibition from the brain. Patterns of spasticity change over the first year, gradually increasing in the first 6 months and reaching a plateau about 1 year after the injury. A moderate amount of spasticity can be helpful in the overall rehabilitation of the patient with an SCI. It helps to maintain muscle mass, assists in the prevention of pressure sores by facilitating blood circulation, and can be used to assist in range of motion (ROM) and bed mobility. A sudden increase in spasticity can alert the individual to other medical problems, such as bladder infections, skin breakdown, and fever.

Because it can interfere with function, severe spasticity can be quite frustrating to both the client and the therapist. It may be treated more aggressively with a variety of medications. In select instances, local injections of nerve blocks or Botox may benefit some individuals. In severe cases, neurosurgical procedures can be performed.^{5,12,14}

Heterotopic Ossification

Heterotopic ossification (HO), also called ectopic bone, is bone that develops in abnormal anatomic locations.¹⁶ It most often occurs in the muscles around the hip and knee, but occasionally it can also be noted at the elbow and shoulder. The first symptoms are swelling, warmth, and decreased joint ROM. The onset of HO is usually 1 to 4 months after injury. Early diagnosis and initiation of treatment can minimize complications. Symptoms are often discovered during physical or occupational therapy treatments even when radiologic findings are negative. Treatment consists of medication and the maintenance of joint ROM during the early stage of active bone formation to preserve the functional ROM necessary for good wheelchair positioning, symmetrical position of the pelvis, and maximal functional mobility. If HO progresses to the phase of substantially limiting hip flexion, pelvic obliquity while in the sitting position is likely to occur. This problem contributes to trunk deformities such as scoliosis and kyphosis, with subsequent skin breakdown at the ischial tuberosities, trochanters, and sacrum.^{5,12}

Sexual Function

The sexual drive and the need for physical and emotional intimacy are not altered by SCI. However, problems of mobility, functional dependency, and altered body image, as well as complicating medical problems and the attitudes of partners and society, affect social and sexual roles, access, and interest and satisfaction. Education is essential for the individual with an SCI as well as all clinicians and, as an important area of occupation (both in ADLs and social participation), is a critical part of the rehabilitation process. Lack of sensation over one part of the body is accompanied by increased or altered sensation over other parts of the body. The sexual response of the body after SCI needs to be explored in the same way a person learns what muscles are working and where he or she can feel.

In males, erections and ejaculations are often affected by SCI. However, because this problem is variable, it should be evaluated individually. The motility of sperm in men with SCI is frequently decreased, even when other function is near normal.¹ Significant advances in treatment are identifying the possible sources of infertility caused by SCI and ways to reverse the problem.

In women, menstruation usually ceases for an interval of weeks to months after injury. It will usually start again and return to normal in time. There may also be changes in lubrication of the vagina during sexual activity. In contrast to males, however, there is no change in female fertility. Females with SCI can conceive and give birth. Special attention must be given to the interaction of pregnancy and childbirth with SCI, especially with regard to blood clots, respiratory function, bladder infections, autonomic dysreflexia, and the use of medications during pregnancy and breast-feeding.

To avoid pregnancy, women with SCI must take precautions, and the type of birth control used must be considered carefully. Birth control pills are associated with blood clots, especially when combined with smoking, and probably should not be used. The intrauterine device (IUD) is not recommended, even for able-bodied females. Diaphragms may be difficult to position properly when there is loss of sensation in the vagina or decreased hand function. Foams and suppositories are not very effective. The use of condoms by the male partner is probably the safest method.

Disabled individuals quickly sense the attitudes of professionals and caregivers toward their sexuality. Awareness and acceptance by professionals is increasing, and sexual counseling and education are a regular part of many rehabilitation programs for all types of physical disabilities. Some clients lack basic sex education. Others feel asexual because of their disability and altered self-esteem and are isolated from peers; thus, they may feel uncomfortable with any type of sexual interaction. For these reasons, sexual education and counseling must be geared to the needs of the individual client and his or her significant other. In some instances, social interaction skills require improvement before sexual activity can be considered, and occupational therapists play an important role in providing information and a forum to deal with these issues. (See Chapter 12 for more information on sexuality with physical dysfunction.)

Laurence was divorced at the time of his accident. He was very close to his stepdaughter and was having a difficult time dealing with the dissolution of his family. While in the hospital, his ex-wife and stepdaughter resumed their relationship with Laurence in hopes of resolving their conflicts. After acknowledging the permanency of his disability, Laurence felt considerable depression, anger, and low self-esteem. Even with the resumption of family support and the large professional community of support he was given, he could not imagine himself as a sexual person who could offer his family and friends the love and relationships he had known in the past.

Occupational Therapy Intervention

Evaluation

Evaluation of the client is an ongoing process that begins on the day of admission and continues long after discharge on an outpatient follow-up basis. Depending on whether the patient is in an acute inpatient rehabilitation, outpatient, or home setting, the occupational therapist should continually evaluate the client's functional progress and the appropriateness of intervention and equipment. An accurate and comprehensive formal initial evaluation is essential. Initial data gathered from the medical chart will provide personal information, a medical diagnosis, and a history of other pertinent medical information. Input from the multidisciplinary team will enhance the occupational therapist's ability to predict realistic optimal outcomes accurately.

Discharge planning begins during the initial evaluation. Therefore, the individual's social and vocational histories, as well as personal contexts such as past and expected living situations, are necessary for planning an intervention program that meets the client's ongoing needs. Intervention should begin as soon as possible. It is possible to quickly gather enough information to begin addressing high-priority areas such as splinting, positioning, and family training without having to wait for the evaluation to be completed.

Occupational and Psychosocial Status

The top-down and client-centered approaches recommended in the Occupational Therapy Practice Framework, Second Edition (OTPF-2), suggest that the evaluation process begin with an occupational profile, which includes obtaining an occupational history and ascertaining the goals of the client as they pertain to resuming performance of favored occupations. Frequently, given the acute nature and overwhelming impact of an SCI, some of the physical problems associated with client factors crucial to survival must initially be given priority for evaluation. Efforts may be directed toward determining baseline neurologic, clinical, and functional status from which to formulate an early intervention program. However, while the occupational therapist is initially addressing these critical physical client factors, he or she can be simultaneously engaging the client in an occupational profile, learning the client factors related to values, beliefs, and spirituality, along with the areas of occupation that comprise and give meaning to the client's life. By involving the client as central to the intervention plan and identifying occupational goals as primary, the more physical aspects and client factors (body structure and body functions) are put into perspective as underlying and supportive to these occupational goals.

Through conducting the occupational profile and occupational history and beginning interventions, the occupational therapist has the opportunity to learn about and observe the client's psychosocial adjustment to the disability and life in general through the nature of the activities and occupations in which the patient participates.¹² The evaluation phase is important for establishing rapport and mutual trust, which will facilitate participation and progress in later and more difficult phases of rehabilitation. The client's motivation, determination, and contexts—including socioeconomic background, education, family support, personal attitudes toward disability, problem-solving abilities, and financial resources—can prove to be invaluable assets or limiting factors in determining the outcome of rehabilitation. A therapist must carefully observe the client's status in each of these areas before recommending the course of intervention.

Physical Status

Before evaluation of the client's physical status (or "client factors: body functions and body structures"), specific medical precautions should be obtained from the primary

and consulting physicians. Skeletal instability and related injuries or medical complications will affect the way in which the client is moved and the active or resistive movements allowed.

Passive range of motion (PROM) should be measured before specific manual muscle testing to determine available pain-free movement. This evaluation also identifies the presence of or potential for joint contractures, which could suggest the need for preventive or corrective splinting and positioning (see [Chapter 21](#)).

Shoulder pain, which ultimately causes decreased shoulder and scapular ROM, is extremely common in those individuals with C4 through C7 quadriplegia. Among the possible causes is scapular immobilization resulting from prolonged bed rest and nerve root compression subsequent to the injury. Shoulder pain should be thoroughly assessed and diagnosed so that proper intervention can be provided before the onset of chronic discomfort and functional loss.

Accurate assessment of the client's muscle strength is critical in determining a precise diagnosis of neurologic level and establishing a baseline for physical recovery and functional progress. Because the occupational therapist's skills with activity analysis greatly enhance his or her effectiveness in treating the client with SCI, a precise working knowledge of musculoskeletal anatomy and specific manual muscle testing techniques is essential. Use of accepted muscle testing protocols ensures accurate technique during performance of this complex evaluation. The muscle test should be repeated as often as is necessary to provide an ongoing picture of the client's strength and progress (see [Chapter 22](#)).

Sensation is evaluated for light touch, superficial pain (pin prick), and kinesthesia, which determines areas of absent, impaired, and intact sensation. These findings are useful in establishing the level of injury and determining functional limitations ([Figure 36-4](#)).¹

If the client is evaluated in the acute stage, spasticity is rarely noted because the client is still in spinal shock. When spinal shock subsides, increased muscle tone may be present in response to stimuli. The therapist should then determine whether the spasticity interferes with or enhances function.

An evaluation of wrist and hand function determines the degree to which a client can manipulate objects. This information is used to suggest the need for equipment such as positioning splints or universal cuffs or, later, consideration of a tenodesis orthosis (wrist-driven flexor hinge splint). Gross grasp and pinch measurements indicate functional abilities and may be used as an adjunct to manual muscle testing to provide objective measurements of baseline status and progress for clients who have active hand musculature.⁸

Clinical observation is used to assess endurance, oral motor control, head and trunk control, LE functional muscle strength, and total body function. More specific

assessment in any of these areas may be required, depending on the client's specific needs.

An increased number of combined SCI and head-injury diagnoses suggests that a specific cognitive and perceptual evaluation may be necessary.⁹ Assessing a client's ability to initiate tasks, follow directions, carry over learning day to day, and handle problem-solving tasks contributes to the information base necessary for appropriate and realistic goal setting (see [Chapters 25 and 26](#)). Understanding the client's learning style, coping skills, and communication style is also essential.

In Laurence's case, he had no memory of his fall and several hours of the time that elapsed after his accident. He also exhibited a slight memory deficit, as shown by his poor carryover of tasks from day to day during the first 2 weeks of his rehabilitation. He received a full cognitive assessment and was determined to be below his baseline for cognition and memory. His therapists helped him complete a memory book of his daily activities to assist in carryover. Because his therapists believed that his extreme depression contributed to his poor memory, he was seen daily for individual counseling. His memory and affect significantly improved over the next several weeks.

Functional Status

Observing as the client performs ADLs is an important part of the OT evaluation. The purpose of this observation is to determine present and potential levels of functional ability. If the client is cleared of bed-rest precautions, evaluation and simultaneous intervention should begin as soon as possible after injury. Light activities such as feeding, light hygiene at the sink, and object manipulation may be appropriate, depending on the level of injury (see [Chapter 10](#)).

Direct interaction with the client's family and friends provides valuable information regarding the client's support systems while in the hospital and, more important, after discharge. This information is relevant to later caregiver training in areas in which the client may require the assistance of others to accomplish self-care and mobility tasks

Establishing Intervention Objectives

Establishing intervention objectives in concert with the client and with the rehabilitation team is important. The primary objectives of the rehabilitation team may not be those of the client. Psychosocial factors, cultural factors, cognitive deficits, environmental limitations, and individual financial considerations must be identified and integrated into a comprehensive intervention program that will meet the unique needs of each individual. Every client is different; therefore, a variety of intervention approaches and alternatives may be necessary to address each factor that may affect goal achievement.⁷ Increased participation can be expected if the client's priorities are respected to the extent that they are achievable and realistic.

The occupational therapist's general objectives for intervention with the person with SCI are as follows:

1. To maintain or increase joint ROM and prevent problems associated with body functions and other body structures (skin) via preparatory activities such as active and passive ROM, splinting, positioning, and client education
2. To increase the strength of all innervated and partially innervated muscles and address problems associated with other body functions (e.g., sensation, higher level cognitive functions, emotional functions) through preparatory activities and engagement in purposeful activities and occupations
3. To increase physical endurance and other performance skills and performance patterns through engagement in purposeful activities and occupations
4. To maximize independence in performance in all areas of occupation, including ADLs, IADLs, rest and sleep, education, work, play, leisure, and social participation
5. To aid in the psychosocial adjustment to disability
6. To evaluate, recommend, and educate the client in the use and care of necessary durable medical and adaptive equipment
7. To ensure safe and independent home and environmental accessibility through consultation and safety and accessibility recommendations
8. To assist the client in developing the communication skills necessary for training caregivers to provide safe assistance
9. To educate the client and his or her family regarding the benefits and consequences of maintaining healthy and responsible lifestyle habits in relation to long-term function and the aging process

The client's length of stay in the inpatient rehabilitation program and the ability to participate in outpatient therapy determine the appropriateness and priority of the aforementioned activities.

Intervention Methods

Acute Phase

During the acute, or immobilized, phase of the rehabilitation program, the client may be in traction or wearing a stabilization device such as a halo brace or body jacket. Medical precautions must be in force during this period. Flexion, extension, and rotary movements of the spine and neck are contraindicated.

Evaluation of total body positioning and hand splinting needs should be initiated at this time. In clients with quadriplegia/tetraplegia, scapular elevation and elbow flexion (as well as limited shoulder flexion and abduction while on bed rest) can cause pain in the shoulders and ROM limitations. UEs should be intermittently positioned in 80 degrees of shoulder abduction, external rotation with scapular depression, and full elbow extension to assist in

alleviating this common problem. The forearm should be positioned in forearm pronation because the client is at risk for supination contractures, such as at the C5 level. At Santa Clara Valley Medical Center, the OT department has designed and fabricated a device that can be used to maintain the arm in an appropriate position while the patient is immobilized on a kinetic bed (see Figure 36-2).

Selection of appropriate splint style and accurate fabrication and fit of the splint by the occupational therapist enhance client acceptance and optimal functional gain. If musculature is not adequate to support the wrist and hands properly (radial wrist extensors—extensor carpi radialis longus [ECRL] and extensor carpi radialis brevis [ECRB]) below 3+ (F+) for functional or cosmetic reasons, splints should be fabricated to support the wrist properly in extension and the thumb in opposition and to maintain the thumb web space while allowing the fingers to flex naturally at the metacarpophalangeal (MP) and proximal interphalangeal (PIP) joints. Splints should be dorsal rather than volar in design to allow maximal sensory feedback while the patient's hand is resting on any surface. If at least 3+ (F+) strength of wrist extension is present, a short opponens splint should be considered to maintain the web space and support the thumb in opposition. This splint can be used functionally while the client is trained to use a tenodesis grasp.

Active and active-assisted ROM of all joints should be performed within strength, ability, and tolerance levels. Musclere-education techniques for wrists and elbows should be employed when indicated. Progressive resistive exercises for wrists may be carried out. The client should be encouraged to engage in self-care activities such as feeding, hygiene, and keyboard and writing activities if possible, using simple devices such as a universal cuff or a custom writing splint. Even though the client may be immobilized in bed, discussion of anticipated durable medical equipment (DME), home modifications, and caregiver training should be initiated to allow sufficient time to prepare for discharge. When indicated, bedside activities that might be of interest to the client, such as modified call systems, laptop computer setup on bed tables, and avocational activities can be explored.

During the immobilization phase of Laurence's rehabilitation, he was given a U-cuff for self-feeding, which was fitted over his wrist cast. A typing splint was fabricated for him for page turning and computer use while he was lying on his side in bed.

Active Phase

During the active, or mobilization, phase of the rehabilitation program, the client can sit in a wheelchair and should begin developing upright tolerance. A high priority at this time is determining a method of relieving sitting pressure for the purpose of preventing decubitus ulcers, or pressure sores, on the ischial, trochanteric, and sacral bony prominences. If the client has quadriplegia yet has at least F+ (3+) shoulder and elbow strength bilaterally, pressure can be

FIGURE 36-5 Forward weight shift using loops attached to wheelchair frame. A client with C6-level quadriplegia with symmetrical grade 4 deltoids and biceps and wrist extensors.

relieved on the buttocks by leaning the client forward over the feet. Simple cotton webbing loops are secured to the back frame of the wheelchair (Figure 36-5). A person with low quadriplegia (C7 with F+ or better triceps) or a person with paraplegia with intact UE musculature can perform a full depression weight shift off the arms or wheels of the wheelchair. Some clients with C6 quadriplegia can also perform this type of weight shift by mechanically locking the elbows in extension while simultaneously externally rotating the shoulders and using their strong shoulder muscles to support their weight. Weight shifts should be performed every 30 to 60 minutes until skin tolerance is determined.

Active and passive ROM exercises should be continued regularly to prevent undesirable contractures. Splinting or casting of the elbows may be indicated to correct contractures that are developing. Some clients will have active wrist extension, which will be used to substitute for absent grasp through tenodesis action of the long finger flexors. With these clients, it is desirable to develop some tightness in these tendons to give some additional tension to the tenodesis grasp. The desirable contracture is developed by ranging finger flexion with the wrist fully extended and finger extension with the wrist flexed, thus never allowing the flexors or extensors to be in full stretch over all of the joints that they cross (Figure 36-6).¹⁴

Elbow contractures should never be allowed to develop. Full elbow extension is essential for allowing propping to maintain balance during static sitting and for assisting in transfers. With zero triceps strength, a person with C6-level quadriplegia can maintain forward sitting balance by shoulder depression and protraction, external rotation, full elbow extension, and full wrist extension (Figure 36-7).

Progressive resistive exercise and resistive activities can be applied to innervated and partially innervated muscles. Shoulder musculature should be exercised so as to promote proximal stability, with emphasis on the latissimus dorsi

A

B

FIGURE 36-6 Tenodesis action. **A**, Wrist is extended when fingers are passively flexed. **B**, Wrist is flexed when fingers are passively extended.

FIGURE 36-7 A client with C6-level quadriplegia; forward sitting balance is maintained (without triceps) by locking elbows. This is a valuable skill for maintaining sitting balance, bed mobility, and transfers.

(Courtesy of Luis Gonzalez, Media Resource Department, Santa Clara Valley Medical Center.)

(shoulder depressors), deltoids (shoulder flexors, abductors, and extensors), and the remainder of the shoulder girdle and scapular muscles. The triceps, pectoralis, and latissimus dorsi muscles are needed for transfers and for shifting weight when in the wheelchair. Wrist extensors should be strengthened to maximize natural tenodesis function,

thereby maximizing the necessary prehension pattern in the hand for functional grasp and release. Strengthening wrist extensors also increases the client's ability to use the tenodesis splint more effectively, mechanically transferring the strength of the wrist extensors to the finger pieces of the splint for a stronger pinch.

The intervention program should be graded to increase the amount of resistance that can be tolerated during activity. As muscle power and endurance improve, increasing the amount of time in wheelchair activities will help the patient participate in activities and occupation throughout the day.

Many assistive devices and equipment items can be useful to the person with SCI. However, every attempt should be made to have the client perform the task with no equipment or with as little as possible. Modified techniques are available that enable an individual to perform efficiently without the need for expensive or bulky equipment.

When appropriate, the universal cuff for holding eating utensils, toothbrushes, pens, and typing sticks is a simple and versatile device that offers increased independence. A wrist cock-up splint to stabilize the wrist with attachment of the universal cuff may be useful for clients with little or no wrist extension. A plate guard, cup holder, extended straw with straw clip, and nonskid table mat can facilitate independent feeding. A wash mitt, soap holder, or soap-on-a-rope appears to make bathing easier; however, the added difficulty of donning and doffing such equipment must be considered. A sliding board is a valuable option for safe transfers. Through intervention, optimal muscle strength and coordination can occur, enabling the client to outgrow the use of initially necessary equipment.

During the active phase, the ADL program may be expanded to include independent feeding with devices, oral and facial hygiene, upper-body bathing, bowel and bladder care (e.g., digital stimulation and intermittent catheterization), UE dressing, and transfers using the sliding board.

B, Use of a service dog as a treatment option to facilitate bilateral upper extremity use. (Courtesy of Luis Gonzalez, Media Resource Department, Santa Clara Valley Medical Center.)

Communication skills in writing and using the telephone, tape recorder, stereo equipment, computer, and calculator keyboard should be an important part of the intervention program (Figure 36-8). Training in the use of the mobile arm support and overhead slings (see Chapter 30, Section II), wrist-hand orthosis (flexor hinge or tenodesis splint), and assistive devices is also part of the OT program.

The occupational therapist should continue to provide psychological support by allowing and encouraging the client to express frustration, anger, fears, and concerns.¹² The OT clinic in an SCI center can provide an atmosphere where clients can establish support groups with other inpatients and outpatients who can share their experiences and problem-solving advice with those in earlier phases of their rehabilitation. Direct OT intervention to address psychosocial issues of SCI can include training in stress management; coping-skills training; and education regarding social connectedness, sexuality, and relationship-building strategies; and the connection between occupation and emotional health. Such intervention is particularly helpful when conducted by the occupational therapist in the supportive clinic atmosphere described previously. Occupational therapists have also found it beneficial to involve successful former clients as expert peer participants or co-leaders during such psychosocial intervention groups and individual sessions.¹³

The assessment, ordering, and fitting of DME such as wheelchairs, seating and positioning equipment, mechanical lifts, beds, and bathing equipment are extremely important parts of the rehabilitation program. Such equipment should be specifically evaluated, however, and ordered only when definite goals and expectations are known. Inappropriate equipment can impair function and cause further medical problems, such as skin breakdown or trunk deformity; the therapist must take into account all functional, positioning, environmental, psychological, and financial

considerations in evaluating the client's equipment needs. The desired equipment—especially wheelchairs, seat cushions, back supports, positioning devices, and bathing equipment—should be available for demonstration and trial by the client before final ordering. It is imperative that the therapist involved in the evaluation and ordering of this costly and highly individualized equipment be not only familiar but have considerable experience with currently available products and be knowledgeable in ordering equipment that will provide the client with optimal function and body positioning on a short- and long-term basis. A good working relationship with an experienced and certified assistive technology provider (ATP), a durable medical equipment vendor who assists in selection of custom assistive technology for the consumer's needs, and provides training in the use of the selected device(s) is preferable. Advancements in technology and design have provided a wide variety of equipment from which to choose, and working with another professional specializing in such equipment will help ensure correct selection and fit. (See Chapter 11, Section II, for a more detailed discussion of wheelchairs, seating, and positioning equipment.)

In addition to enhancing respiratory function by supporting the client in an erect, well-aligned position that maximizes sitting tolerance and optimizes UE function, wheelchair seating must assist in the prevention of deformity and pressure sores. An appropriate and adequate wheelchair cushion helps distribute sitting pressure, assists in the prevention of pressure sores, stabilizes the pelvis as necessary for proper trunk alignment, and provides comfort. Whether it is the occupational therapist's or the physical therapist's role to evaluate and order the wheelchair and cushion, both should work closely together to ensure consistent training and use for the individual needs of each client.

The intervention and equipment needs of clients with high-level SCI (C4 and above) are unique and extremely specialized, ranging from mouthsticks and assistive technology to ventilators and sophisticated power wheelchairs and drive systems (see Table 36-1, levels C1-C3, and C3-C4). Commercially available products such as cell phones, electronic readers, and notebook computers have greatly enhanced the options available to high-level quadriplegics.

The use of experienced resources in determining appropriate short- and long-term goals and equipment needs enhances the quality and functional ability of a client who otherwise would be quite dependent. Rehabilitation centers specializing in the care of persons with high-level quadriplegia should be sought for their expertise in addressing all aspects of care for this unique client population.

When the discharge location is determined and the individual can tolerate leaving the hospital for a few hours, a home evaluation should be performed. The therapist, client, and family members can then view and attempt activities in the home in anticipation of return to a safe and accessible environment.

OT Practice Notes

The therapist must be knowledgeable about safety and accessibility options for a variety of environments and often must advise architects or contractors to ensure that appropriate modifications are made. The therapist must be aware of accessibility requirements in the home, as well as those required in the workplace by the Americans with Disabilities Act of 1990 (ADA; see [Chapters 14 and 15](#)).

Accompanied by his occupational therapist, Laurence went to his new rental home to determine its safety and accessibility in light of his mobility and ADL needs. Modifications to both the front and rear entrances, as well as bathroom modifications, were recommended. He and his therapist discussed the recommendations with the contractor who would be performing the work on the house to determine the feasibility of door widening and ramping in terms of the house's structural stability. It was important that Laurence participate in the plans not only because he needed to manage this part of his life but also because he needed to learn about regulations related to the Americans with Disabilities Act (ADA) and his rights as a renter (see [Chapter 15](#)). Laurence took control of managing his housing needs, as well as his discharge supplies and follow-up services. His sense of helplessness was subsiding as he began to assume control of his life again.

After Discharge from Acute Rehabilitation

Decreases in the amount of time devoted to inpatient rehabilitation have moved the extended phase of intervention to an outpatient basis or home therapy context. Adaptive

driving, home management, leisure activities, and work skill assessments using hand- or power-based tools are feasible and appropriate intervention modalities for evaluating and increasing UE strength, coordination, and trunk balance; however, they may not be a priority during inpatient hospitalization. OT training in such activities can improve the client's socialization skills and can also assess and improve problem-solving skills and potential work habits.

OT services can offer valuable evaluation and exploration of the vocational potential of persons with SCI. Because of the sheer magnitude of the physical disability, vocational possibilities for clients with high levels of SCI are limited. Many clients must change their vocation or alter former vocational goals. Decreased motivation, threat of loss of health benefits, and lack of perseverance on the part of many patients make vocational rehabilitation challenging.

The occupational therapist can assess the client's level of motivation, functional aptitudes, attitudes, interests, and personal vocational aspirations during the process of the intervention program and through the use of ADLs, IADLs, mobility, and work simulation occupations. The therapist can observe the client's attention span, concentration, problem-solving ability, judgment, and other high-level cognitive functions, as well as his or her manual ability with splints and devices, accuracy, speed, perseverance, work habits, and work tolerance level. The therapist can serve as a liaison between the client and the vocational rehabilitation counselor by offering valuable information gleaned from observation during the client's performance of activities and occupations. When suitable vocational objectives have been selected, they may be pursued in an educational setting or in a work setting, usually out of the realm of OT.

Aging with Spinal Cord Injury

Following survival of acute SCI, the primary goal of rehabilitation is independence. Independence as the measure of quality of life for people with disabilities is a concept accepted and often perpetuated by professionals and survivors alike.¹⁵

Occupational therapists work in concert with these clients to identify and prioritize their favored and meaningful occupations and provide intervention to enable them to resume their engagement in these occupations for participation in a satisfying life. Occupational therapists treating clients with SCI have considerable responsibility in influencing the level of independence, whether in the acute setting, during active rehabilitation, or in follow-up care throughout the life of the client. Understanding the aging process in both able-bodied individuals and those with disabilities is necessary for providing appropriate options and fostering attitudes that enhance the quality of the client's life at any age.

Physical aging is a natural, inevitable process. The signs of the process can occur at varying rates for each individual,

Text continued on p. 978

TABLE 36-1 | Expected Functional Outcomes

Level	Functionally Relevant Muscles Innervated	Movement Possible	Patterns of Weakness	NSCISC Sample Size
C1-C3	Sternocleidomastoid: cervical paraspinal; neck accessories	Neck flexion, extension, rotation	Total paralysis of trunk, upper extremities, lower extremities; dependent on ventilator	FIM = 15/ assist = 12
C4	Upper trapezius; diaphragm; cervical paraspinal muscles	Neck flexion, extension, rotation; scapular elevation; inspiration	Paralysis of trunk, upper extremities, lower extremities; inability to cough, endurance and respiratory reserve low secondary to paralysis of intercostals	FIM = 28/ assist = 12
C5	Deltoid, biceps, brachialis, brachioradialis, rhomboids, serratus anterior (partially innervated)	Shoulder flexion, abduction, and extension; elbow flexion and supination; scapular adduction and abduction	Absence of elbow extension, pronation, all wrist and hand movement; total paralysis of trunk and lower extremities	FIM = 36/ assist = 35
C6	Clavicular pectoralis; supinator; extensor carpi radialis longus and brevis; serratus anterior; latissimus dorsi	Scapular protractor; some horizontal adduction, forearm supination, radial wrist extension	Absence of wrist flexion, elbow extension, hand movement; total paralysis of trunk and lower extremities	FIM = 43/ assist = 35
C7-8	Latissimus dorsi; sternal pectoralis; triceps; pronator quadratus; extensor carpi ulnaris; flexor carpi radialis; flexor digitorum profundus and superficialis; extensor communis; pronator/flexor/ extensor/abductor pollicis; lumbricals (partially innervated)	Elbow extension; ulnar/wrist extension; wrist flexion; finger flexions and extensions; thumb flexion/ extension/abduction	Paralysis of trunk and lower extremities; limited grasp and dexterity secondary to partial intrinsic muscles of the hand	FIM =43/ assist = 35
T1-9	Intrinsics of the hand including thumbs; internal and external intercostals; erector spinae; lumbricals; flexor/ extensor/abductor pollicis	Upper extremities fully intact; limited upper trunk stability; endurance increased secondary to innervation of intercostals	Lower trunk paralysis; total paralysis of lower extremities	FIM =144/ assist =122
T10-L1	Fully intact intercostals; external obliques; rectus abdominis	Good trunk stability	Paralysis of lower extremities	FIM =71/ assist =57
L2-S5	Fully intact abdominals and all other trunk muscles; depending on level, some degree of hip flexors, extensor, abductors; knee flexors, extensors; ankle dorsiflexors, plantar flexors	Good trunk stability; partial to full control of lower extremities	Partial paralysis of lower extremities, hips, knees, ankle, foot	FIM =20/ assist =16

and aging affects most systems of the body (see Chapter 46). In individuals with SCI, aging is usually accelerated by the secondary effects of the disability, such as the presence of muscle imbalance, infections (urinary and respiratory), deconditioning, pain, and joint degeneration secondary to overuse.^{12,17} Issues to be considered at an age much earlier than normal are urinary problems brought on by years of catheterization, bladder infections, and urinary retention. Also to be considered are osteoporosis, arthritis and joint degeneration, constipation, weakening of already precarious skin, substance abuse, and the need for an increasing amount of personal care over time.

Approximately 20 years after injury appears to be a point at which some of the aging problems begin to increase. Because at least one of four SCI survivors experienced an SCI more than 20 years ago,¹⁵ a significant portion of SCI survivors are prematurely experiencing the problems of aging. Individuals with SCI onset in their later years have very different patterns of functional outcomes, program needs, and financial resources than do those with onset in their earlier years. For someone who acquired quadriplegia in his or her 20s, when the majority of SCIs occur, the degenerating conditions of normal aging become evident prematurely, usually before the 40s.⁴ Thus, someone who was independent during transfers at home and the loading of a wheelchair in and out of the car may now require assistance getting in and out of bed; because his or her shoulders have deteriorated, this person may have to trade the car for a van that requires costly modifications. Similarly, someone who is at a level normally associated with functional independence (e.g., T10-level paraplegia) may, in fact, need personal care assistance and possibly a power wheelchair because of degenerative changes in shoulders, elbows, and wrists. The occupational therapist should make good trunk alignment and seating a priority from the onset to prevent fixed trunk and pelvic deformities such as kyphosis and scoliosis, which can lead to considerable skin problems and uncorrectable cosmetic deformities years later. In addition, it is necessary to be aware of how the lightest possible weight of a manual wheelchair and the optimal distance from shoulder to push rim when propelling a chair can positively affect a weak or imbalanced shoulder complex. Also to be considered is the advantage of the cardiopulmonary conditioning that such an activity can provide. The occupational therapist must simultaneously consider those benefits while weighing the benefit of a power wheelchair for joint and energy conservation.

When SCI is compounded by the increased fatigue and weakness often associated with normal aging, the functional status of the individual with SCI may decline. Occupational therapists may cite this change to justify additional services or equipment. Many considerations must be weighed to make appropriate short- and long-term decisions. Consulting experienced experts, who have a perspective on both acute and long-term injuries and issues, can provide valuable insight into intervention decisions.

Research

Current research conducted in clinical settings and scientific laboratories around the world focuses on understanding the nature of SCI and defining the nervous system's response to this injury. There is now a sense of optimism in the scientific community that it will be possible someday to restore function after SCI. This optimism is based on the combined research efforts of scientists in many disciplines. It is important for occupational therapists treating SCI to be aware of the scientific and technological advances so as to better educate clients, while at the same time providing them with the most realistic and comprehensive rehabilitation interventions for their immediate and long-term needs.

Summary

SCI can result in substantial paralysis of the limbs and trunk. The degree of residual motor and sensory dysfunction depends on the level of the lesion, whether the lesion was complete or incomplete, and the area of the spinal cord that was damaged.

After an SCI, bony realignment and stabilization are established surgically, by way of an external immobilization device, or through a combination of both methods. The many possible complications of SCI include skin breakdown, rapid loss of bone density, and spasticity.

The goal of OT is to facilitate the client's achievement of optimal independence and functioning. Areas of focus are physical restoration of available musculature; self-care; independent living skills; short- and long-term equipment needs; environmental accessibility; and educational, work, and leisure activities. The psychosocial adjustment of the client is instrumental, and the occupational therapist offers emotional support and intervention toward this end in every phase of the rehabilitation program.

Table 36-1 presents expectations of functional performance of SCI at 1 year after injury and at each of the eight levels of injury (C1-C3, C4, C5, C6, C7-C8, T1-T9, T10-L1, L2-S5). The outcomes reflect a level of independence that can be expected of a person with motor-complete SCI, given optimal circumstances.

The categories presented reflect expected functional outcomes in the areas of mobility, ADLs, instrumental activities of daily living (IADLs), and communication skills. The guidelines are based on the consensus of clinical experts, available literature on functional outcomes, and data compiled from Uniform Data Systems (UDS) and the National Spinal Cord Injury Statistical Center (NSCISC).

Within the functional outcomes for people with SCI listed in Table 36-1, essential ADLs and IADLs, including the attendant care likely to be needed to support the predicted level of independence at 1 year after injury, have been identified. These outcome areas include the following categories of ADLs and IADLs:

- Respiratory, bowel, and bladder function. The neurologic effects of SCI may result in deficits in the ability to perform basic body functions. Respiratory function includes the ability to breathe with or without mechanical assistance and to adequately clear secretions. Bowel and bladder function includes the ability to manage elimination, maintain perineal hygiene, and adjust clothing before and after elimination. Adapted or facilitated methods of managing these bodily functions may be required to attain expected functional outcomes.
- Bed mobility, bed/wheelchair transfers, wheelchair propulsion, and positioning/pressure relief. The neurologic effects of SCI may result in deficits in the ability of the individual to perform the activities required for mobility, locomotion, and safety. Adapted or facilitated methods of managing these activities may be required to attain expected functional outcomes in standing and ambulation.
- Standing and ambulation. SCI may result in deficits in the ability to stand for exercise or psychological benefit or to ambulate for functional activities. Adapted or facilitated methods of management may be outcomes in standing and ambulation.
- Eating, grooming, dressing, and bathing. The neurologic effects of SCI may result in deficits in the ability of the individual to perform these ADLs. Adapted or facilitated methods of managing ADLs may be necessary to attain expected functional outcomes.
- Communication (keyboard use, handwriting, and telephone use). The neurologic effects of SCI may result in deficits in the ability to communicate. Adapted or facilitated methods of communication may be required to attain expected functional outcomes.
- Transportation (driving, attendant-operated vehicle, and public transportation). Transportation activities are critical for individuals with SCI to become maximally independent in their community. Adaptations may be required to help the individual meet the expected functional outcomes.
- Homemaking (meal planning and preparations and home management). Adapted or facilitated methods of managing homemaking skills may be required to attain expected functional outcomes. Individuals with complete SCI at any level will require some level of assistance with some homemaking activities. The hours of assistance required for homemaking activities are presented in Table 36-1.
- Assistance required. Table 36-1 lists the number of hours that may be required from a caregiver to assist with personal care and homemaking activities. Personal care includes hands-on delivery of all aspects of self-care and mobility, as well as safety interventions. Homemaking assistance is also included in the recommendation for hours of assistance and includes activities previously presented. The number of hours presented in both the panel recommendations and the self-reported Craig Handicap Assessment and Reporting Technique (CHART) data is representative of skilled and unskilled and paid and unpaid hours of assistance. The 24-hour-a-day requirement noted for the C1 through C3 and C4 levels includes the expected need for unpaid attendant care to provide safety monitoring.
- Adequate assistance is required to ensure that the individual with SCI can achieve the outcomes set forth in Table 36-1. The hours of assistance recommended do not reflect changes in assistance required over time, as reported by long-term survivors of SCI, nor do they take into account the wide range of individual variables that may affect the required hours of assistance. The Functional Independence Measure (FIM) estimates are widely variable in several of the categories. Whether the representative individuals with SCI in the individual categories attained the expected functional outcomes for their specific level of injury is unclear, as is whether there were mitigating circumstances, such as age, obesity, or concomitant injuries, that would account for variability in assistance reported. An individualized assessment of needs is required in all cases.
- Equipment requirements. Minimum recommendations for DME and adaptive devices are identified in each of the functional categories. The most commonly used equipment is listed, with the understanding that variations exist among SCI rehabilitation programs and that use of such equipment may be necessary to achieve the identified functional outcomes. Additional equipment and devices that are not critical for the majority of individuals at a specific level of injury may nonetheless be required for some individuals. The equipment descriptions are generic to allow for variances in program philosophy and financial resources. Rapid changes and advances in equipment and technology will be made and therefore must be considered.
- Healthcare professionals should remember that the recommendations set forth in Table 36-1 are not intended to be prescriptive; rather, they should serve as a guideline. The importance of completing an individual functional assessment of people with SCI before making equipment recommendations cannot be overemphasized. All DME and adaptive devices must be thoroughly assessed and tested to determine medical necessity, to prevent medical complications (e.g., postural deviations, skin breakdown, pain), and to foster optimal functional performance. Environmental control units and telephone modifications may be needed for safety and maximal independence, and each person must be individually evaluated to determine the need for this equipment. Recommendations for disposable medical products are not included in this document.
- FIM. Evidence for the specific levels of independence provided in Table 36-1 relies both on expert consensus and on data from FIM in large-scale, prospective, and

longitudinal research conducted by NSCISC. FIM is the most widely used disability measure in rehabilitation medicine, and although it may not incorporate all of the characteristics of disability in individuals recovering from SCI, it captures many basic disability areas.

- FIM consists of 13 motor and five cognitive items that are individually scored from 1 to 7. A score of 1 indicates complete dependence, and a score of 7 indicates complete independence (Box 36-1). The sum of the 13 FIM motor score items can range from 13, indicating complete dependence for all items, to 91, indicating complete independence for all items. FIM is a measure usually completed by health care professionals; different observers, including the client, family members, and caregivers, can contribute information to the ratings. Each of these reporters may represent a different type of potential bias.
- Although the sample sizes of FIM data for certain neurologic level groups are quite small, the consistency of the data suggests that the interpretation is reliable. Other pertinent data regarding functional independence must be factored into outcome analyses, including medical information, patient factors, social role participation, quality of life, and environmental factors and supports.
- In Table 36-1, FIM data, when available, are reported in three areas. First, the expected FIM outcomes are

documented on the basis of expert clinical consensus. The second number reported is the median FIM score, as compiled by NSCISC. The interquartile range for NSCISC FIM data is the third set of numbers. In total, the FIM data represent 1-year postinjury FIM assessments of 405 survivors with complete SCI and a median age of 27 years. The NSCISC sample size for

■ Box 36-1

Functional Independence Measure Levels

(7) Complete independence (timely, safely)	No helper
(6) Modified independence (device)	

Modified Dependence

(5) Supervision	Helper
(4) Minimal assist (subject = 75% or more)	
(3) Moderate assist (subject = 50% to 74%)	

Complete Dependence

(2) Maximal assist (subject = 25% to 49%)	
(1) Total assist (subject = 0% to 24%)

Threaded Case Study | Laurence, Part 2

The case of Laurence, presented in the beginning of this chapter, discussed a common occurrence of a client who believed he would recover from his SCI and return to his previous lifestyle and occupations. Clearly, because he had a complete, C7, 8 ASIA A injury, he did not recover motor or sensory function below his level of injury. Although his occupational therapist offered him hope for recovery, it was also essential for his therapist to provide positive but realistic expectations and options. Upon discharge from acute rehabilitation, Laurence returned to a newly rented single-story home that required ramps at the front and back entrances and bathroom modifications. Laurence initially received 4 hours of attendant care daily. He required assistance only for completion of his daily bath and bowel program, as well as for homemaking tasks. He required a transfer tub bench with a commode cutout for the bath and bowel program that his caregiver performed for him.

He was evaluated for the lightest-possible weight, customizable manual wheelchair to offer him independent manual wheelchair mobility at home and in his community. He does not require a power wheelchair at this time; however, he is aware that he may require one in the future. He has been educated on the premature degenerative changes that will likely occur in his shoulders from pushing a manual wheelchair and

transferring himself to many necessary surfaces. He has been educated on skin care and the need for a maximal pressure-relieving wheelchair cushion. He was specifically evaluated for the optimal wheelchair sitting position that will offer him good trunk and pelvic alignment and pressure relief.

After Laurence received in-home OT services for home setup and community transition issues, his need for personal care diminished; he now requires only homemaking assistance. He regularly visits a neighborhood gym to maintain upper extremity strength and endurance, and he will soon be driving a modified van. He and his occupational therapist had many discussions regarding how he could pursue a teaching position within the fire department, given that he could not return to his previous assignment. His department is very willing to work with him in modifying his responsibilities to accommodate his limitations. His vocational plans are on hold until his van and driving training are completed.

Laurence continues with psychotherapy to deal with his change in function and lifestyle. He has had a very difficult time maintaining his friendships and personal relationships with his family. As time passes, he has begun to adapt to his lifestyle, if not necessarily accept it, and is still hoping that researchers will discover a cure for spinal cord injury in his lifetime.

FIM and Assistance Data is provided for each level of injury. Different outcome expectations should clearly apply to different client subgroups and populations. Some populations are likely to be significantly older than the referenced one. Functional abilities may be limited by advancing age.^{14,17}

- Home modifications. To provide the best opportunity for individuals with SCI to achieve the identified functional outcomes, a safe and architecturally accessible environment is necessary. An accessible environment must take into consideration, but not be limited to, entrance and egress, mobility in the home, and adequate setup to perform personal care and homemaking tasks.

Review Questions

1. List three causes of SCI. Which is most common?
2. Describe the patterns of weakness in quadriplegia and paraplegia.
3. Describe the functional and prognostic differences between complete and incomplete lesions.
4. When reference is made to C5 in quadriplegia, what is meant in terms of level of injury and functioning muscle groups?
5. What are the characteristics of spinal shock?
6. What physical changes occur after the spinal shock phase?
7. What is the prognosis for recovery of motor function in complete lesions and incomplete lesions?
8. What are the purposes of surgery in management of SCI?
9. What are some medical complications common among clients with SCI that can limit achievement of functional potential?
10. How should postural hypotension be treated?
11. How should autonomic dysreflexia be treated?
12. What is the role of the occupational therapist in the prevention of pressure sores?
13. Why is vital capacity affected in individuals with SCI?
14. What effect does reduced vital capacity have on the rehabilitation program?
15. Which level of injury features full innervation of the rotator cuff musculature, biceps, and extensor carpi radialis and partial innervation of the serratus anterior, latissimus dorsi, and pectoralis major?
16. What additional muscle power does the client with C6-level quadriplegia have over the client with C5-level quadriplegia? What is the major functional advantage of this additional muscle power?
17. What are the additional critical muscles that the client with C7-level quadriplegia has, as compared with the client with C6-level quadriplegia?
18. What additional functional independence can be achieved because of this additional muscle power?
19. What is the first spinal cord lesion level that features full innervation of the UE musculature?
20. Which assessments do occupational therapists use to evaluate the client with SCI? What is the purpose of each?
21. List five goals of OT for the client with SCI.
22. How is wrist extension used to affect grasp by the individual with quadriplegia?
23. How does the individual with C6-level quadriplegia substitute for the absence of elbow extensors?
24. What contracture is encouraged in clients with SCI? Why? How is it developed?
25. What splint allows the client with C6-level quadriplegia to achieve functional prehension?
26. What are some of the first self-care activities that the client with a C6-level SCI should be expected to accomplish?
27. List four assistive devices commonly used by persons with quadriplegia, and tell the purpose of each.
28. How can ordering an ill-fitting wheelchair affect the UE function and skin care of someone with C6-level quadriplegia?
29. Describe the role of OT in the vocational evaluation of a client with SCI.
30. What are two considerations when predicting the future functional outcomes for a 25-year-old client with T4-level paraplegia?
31. Why would a person with paraplegia require homemaking assistance if he is independent in all self-care and mobility activities?

Disorders of the Motor Unit

37

MARTI SOUTHAM
AMY SCHMIDT
ALISON HEWITT GEORGE

■ Chapter Outline

Peripheral neuropathies
Guillain-Barré syndrome
Poliomyelitis and postpolio syndrome
Peripheral nerve injuries
Axillary nerve injury
Brachial plexus injuries
Long thoracic nerve injury
Psychosocial interventions for peripheral nerve injuries
Neuromuscular junction: myasthenia gravis
Role of the occupational therapist
Muscular dystrophies
Role of the occupational therapist
Summary

■ Key Terms

Motor unit	Peripheral nerve injuries
Lower motor neuron system	Postpolio syndrome
Peripheral neuropathies	Brachial plexus
Guillain-Barré syndrome	Myasthenia gravis
Poliomyelitis	Muscular dystrophy

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the characteristics of motor unit disorders.
2. Discuss the clinical manifestations of motor unit disorders.
3. Discuss the impact of motor unit disorders on occupational performance.
4. Identify assessments and interventions for an occupational therapy program for the various motor unit disorders discussed in this chapter.

The symptoms, course, medical treatment, and occupational therapy (OT) assessment and intervention for clients who have motor unit disorders most commonly seen in OT practice are presented in this chapter. The motor unit is the basic functional unit of the peripheral nervous system and consists of four elements: the cell body of the motor neuron located in the anterior horn of the spinal cord; the axon of the motor neuron, which travels via spinal nerves and peripheral nerves to muscle; the neuromuscular junction; and the muscle fibers innervated by the neuron (Figure 37-1). Disorders of the motor unit may be of

neurogenic, neuromuscular, or myopathic origin and generally cause muscle weakness and atrophy of skeletal muscle. Those with a neurogenic basis are the lower motor neuron disorders, affecting the cell bodies and peripheral nerves of the motor unit. Those with a neuromuscular or myopathic basis affect the neuromuscular junction or the muscle itself.⁴³

This chapter discusses the physical, psychosocial, and emotional factors that occupational therapists address when assessing and providing interventions for people with motor unit disorders.

Threaded Case Study | Edith, Part 1

Although this case study is specific to Guillain-Barré syndrome, many of the aspects of Edith's occupational profile and occupational performance needs apply to the other diagnoses in this chapter.

At age 67, Edith had been enjoying her retirement, primarily spending time with her husband, three children, and five grandchildren. She had recently recovered from the flu and was looking forward to a day at the park with her family. While showering, she suddenly lost strength in her legs and collapsed. While lying on the shower floor, she noticed that her arms also felt weak. Her cognition was intact, but she was physically helpless. Her husband called 9-1-1. It was fortunate that she received immediate medical care because she later required mechanical assistance to breathe. After extensive neurologic testing, Edith was diagnosed with Guillain-Barré syndrome (GBS). Neither she nor her family had ever heard of GBS.

Edith suddenly found herself dependent in all of her life roles and occupations. She was hospitalized in the intensive care unit (ICU) for several weeks, was dependent on a ventilator to breathe, and needed physical assistance because of her total body paralysis. Her muscles were painful, sore, and tender, and pain medications helped to manage the discomfort.

Jen, the occupational therapist assigned to the ICU, interviewed Edith, and together they identified the occupational needs and client factors that should be addressed. Jen performed passive range of motion (ROM) exercises, fabricated static hand splints to maintain a functional resting position and to prevent contractures, provided proper bed positioning, and taught the family about GBS. Jen also provided support, encouragement, and active listening, employing therapeutic use of self during the intervention. Edith often spoke about her spiritual beliefs and reported that she found hope and strength with prayer and meditation. She spoke of her favorite previous performance pattern of reading her Bible every morning and said she felt depressed because she was now unable to physically hold a book or turn pages. After receiving training and modifications from Jen, Edith was able to listen to the Bible on CD, using a mouth switch to turn it on and off; this modification allowed her to resume her previous valued morning routine.

Edith made slow but steady gains in physical abilities and was transferred to an acute rehabilitation hospital to actively

participate in an intensive interdisciplinary therapy program. Lara, the occupational therapist on the rehabilitation unit, evaluated Edith's specific functions as they related to supporting performance and engagement in occupations and activities targeted for intervention. The goals from the Canadian Occupational Performance Measure²⁶ included the following: (1) to be able to feed herself, brush her teeth, and shower; (2) to cook for her family; (3) to be able to go shopping at the mall with her granddaughter; and (4) to be able to drive to her friend's house to play cards. Detailed upper extremity manual muscle testing, muscle belly tenderness screening, ROM measurements, and sensation testing were completed during the evaluation phase.

Intervention strategies focused on using compensatory methods and improving strength and endurance. Lara taught Edith adaptive strategies to eat, groom, and bathe. The use of adaptive equipment, work simplification, and energy conservation techniques were encouraged while Edith engaged in activities such as cooking and light cleaning. Lara supported Edith's community mobility and accompanied Edith to the mall with her granddaughter. After the brief outing, Edith expressed a sense of increased self-confidence and accomplishment. She practiced card playing with other clients in a group environment. She also participated in a daily individualized strengthening program.

Lara provided Edith with community resources to aid in her independence. For example, the Guillain-Barré Syndrome Foundation International (GBSFI) offers local support groups, literature, and conferences to GBS survivors and caregivers. In addition, her family received extensive training from the interdisciplinary team members to assist with application of learned strategies and equipment in the home and community. Driving was not addressed at an inpatient level, but Edith was referred to an outpatient training program.

Critical Thinking Questions

1. What are the phases of Guillain-Barré, and what occupational therapy interventions might be used in each phase?
2. In what ways were the client's psychosocial needs addressed during recovery?
3. Describe energy conservation techniques that you think would be appropriate for Edith while engaging in her valued occupation of cooking.

Occupational therapists, with their holistic view of persons with physical disabilities, are uniquely positioned to recognize and include interventions that address mental health concerns for persons with disorders of the motor unit. The sudden onset of severely disabling peripheral neuropathies, such as Guillain-Barré, or the chronic aspects of living with fatigue and experiencing role alterations will have ramifications for the client, the family, and their social network as described in the case study of Edith.

Neurogenic Disorders

Peripheral Neuropathies

The motor neurons in the anterior horn of the spinal cord mediate voluntary movement and reflexes that produce motor behavior. Muscle strength and endurance contribute to coordinated and skilled movement and the ability to

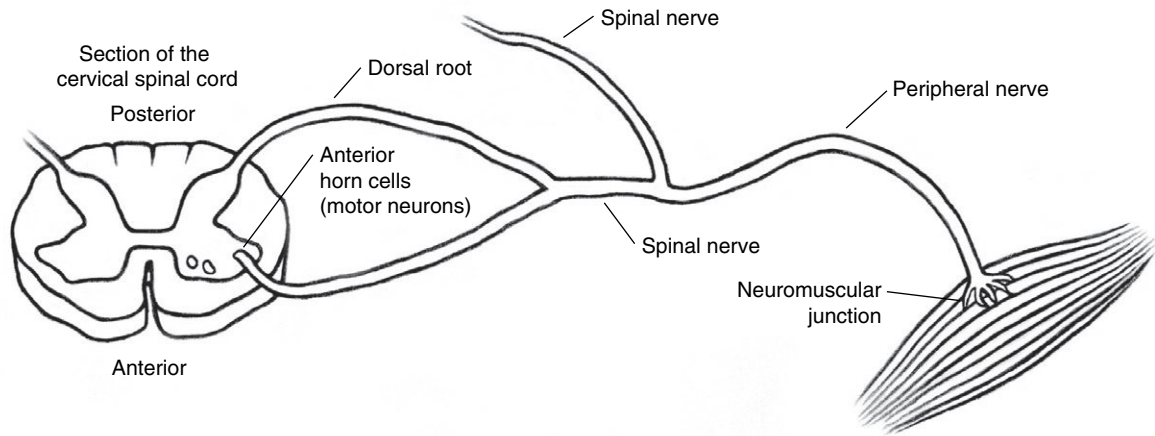

FIGURE 37-1 Motor unit consisting of motor neuron cell body in the anterior horn of the spinal cord, the axon of the motor neuron (which travels via spinal nerves and peripheral nerves to muscle), the neuromuscular junction, and the muscle fibers innervated by the neuron.

move through available range of motion. The characteristics of movement are determined by the pattern and firing frequency of specific motor units. Muscle contraction is the output of the motor system.⁴³

The lower motor neuron system includes the cell bodies in the anterior horn of the spinal cord and their axons (which pass by way of the spinal nerves and peripheral nerves to the neuromuscular junction) and the nuclei of cranial nerves III through X (located in the brain stem) and their axons. The motor fibers of the lower motor neurons contain somatic motor components, including the alpha motor neurons, which innervate skeletal muscles (extrafusal fibers), and gamma motor neurons, which innervate muscle spindles (intrafusal fibers). A lesion in any of these neurologic structures results in peripheral neuropathy or a lower motor neuron dysfunction.⁴³

Peripheral neuropathies involve lesions of the lower motor neuron system and may be located in the anterior horn cells of the spinal cord, spinal nerves, peripheral nerves, and cranial nerves or their nuclei in the brain stem. Lesions can result from nerve root compression, trauma (e.g., bone fractures and dislocations, lacerations, traction, or penetrating wounds and friction), toxins (e.g., lead, phosphorus, alcohol, benzene, or sulfonamides), infections (e.g., poliomyelitis or Guillain-Barré syndrome), neoplasms (e.g., neuromas and multiple neurofibromatosis), vascular disorders (e.g., arteriosclerosis, diabetes mellitus, peripheral vascular anomalies, and polyarteritis nodosa), degenerative diseases of the central nervous systems (e.g., amyotrophic lateral sclerosis), and congenital malformations.⁵⁰ “Like static on a telephone line, peripheral neuropathy distorts and sometimes interrupts messages between the brain and the rest of the body.”³⁵

OT assessments for motor unit disorders follow a similar sequence and are described in [Table 37-1](#). An occupational profile is developed during an interview with the client

and caregivers. The Canadian Occupational Performance Measure²⁶ is an excellent instrument to establish goals and measure intervention outcomes. Performance skills, performance patterns, client factors, and activity demands in context must also be clinically assessed. Specific assessments such as range of motion, manual muscle testing, scales designed to measure coping and depression, and activities of daily living assessments are appropriate for each of the motor unit disorders described in this chapter.

Two complex syndromes, Guillain-Barré and postpolio, will be discussed in detail in the following section. The concepts are applicable to the other motor unit disorders described later in the chapter.

Guillain-Barré Syndrome

Guillain-Barré (ghee-YAN bah-RAY) syndrome (also known as acute idiopathic neuropathy, infectious polyneuritis, and Landry’s syndrome) is an acute, inflammatory disorder in which the body’s own immune system attacks part of the peripheral nervous system. The immune system destroys the myelin sheath that surrounds the axons of many peripheral nerves or even the axons themselves, damaging the nerves’ ability to transmit signals to the muscles. Guillain-Barré syndrome (GBS) has no known cause or cure, and it is not understood why this disorder strikes some people and not others.³³ The onset of GBS often is after an upper respiratory or gastrointestinal viral infection, usually within 1 to 2 weeks. The syndrome is also occasionally triggered by surgery or vaccinations.^{4,33}

This acute and complex disorder came to public attention when it struck a number of people who received the 1976 swine flu vaccine. It continues to claim thousands of new victims each year, striking any person, at any age, regardless of gender or ethnic background.¹⁶ Affecting males and females equally, the annual incidence of GBS in the United States is approximately one person in 100,000.³³

■ **TABLE 37-1** | Occupational Therapy Assessments and Descriptions

Assessments	Descriptions
Occupational profile	Interview client (and family members and caregivers, if appropriate) to gain information about problems and concerns, successful and unsuccessful strategies when engaging in occupations, ways in which contexts influence functional abilities, activity demands, and priorities of meaningful occupations.
Canadian Occupational Performance Measure ²⁶	The interview is conducted before and after intervention to describe problems, level of satisfaction with performing activities, and level of perceived performance abilities in areas of self-care, productivity, and leisure. Testing methods must be measurable to assess intervention results.
Performance skills in areas of occupation: activities of daily living, instrumental activities of daily living, education, work, play, leisure, social participation	Following the occupations that the client prioritizes in the occupational profile, the therapist can perform formal assessments and observation of the client's performance during activity engagement in the appropriate context, with attention paid to motor, process, and communication/interaction skills. (See Chapter 18 for additional assessment details and Chapter 16 for a description of specific leisure assessments.)
Performance patterns	Client (independently or with assistance from caregivers or occupational therapist) maintains a log of activities and symptoms to analyze in collaboration with the occupational therapist to discover habits and routines that are detrimental or helpful to occupational performance. Re-establishment or adjustment of roles should be discussed and implemented.
Client factors: manual muscle testing, range of motion testing, eating and swallowing assessments, pain scale, sensory testing, depression scale, Ways of Coping Scale, clinical observations during activities of daily living.	The therapist should perform specific assessments of the client's bodily function, including systems that support participation in meaningful occupations (e.g., neuromusculoskeletal, pain, joint range of motion, sensation, cardiovascular, respiratory, swallowing, skin). Because fatigability is so prevalent in these disorders, assessments should be adequately spaced and preferably performed when clients are feeling their best (often in the morning). Assessment of emotional stability, motivation, sexual activity, depression, ways of coping, and so forth is critical to forming an overall picture of the client's strengths and weaknesses.
Activity demands	Analysis of the required sequence, body functions, and body structures is necessary to complete the activity. Analysis must include assessment of the tools or equipment used to perform the activity and any adaptations that could be made to ensure success.
Contexts	The therapist should always consider the client's culture, physical environment, socioeconomic status, personal and spiritual beliefs, temporal aspects, and virtual contexts.

Data from American Occupational Therapy Association: Occupational therapy practice framework: domain and process, ed 2, *Am J Occup Ther* 62:625-688, 2008.

The initial symptoms of Guillain-Barré syndrome most often include varying degrees of weakness and sensory changes in the legs. GBS is characterized by rapidly progressive ascending weakness of bilateral extremities, usually proceeding from distal to proximal (feet to trunk). Descending paralysis with predominant proximal muscle weakness rarely appears.^{4,33} Because the myelin sheaths of the peripheral nerves are injured or degraded, the nerves cannot transmit signals efficiently. The muscles begin to lose their ability to respond to the brain's commands. The brain also receives fewer sensory signals from the rest of the body, resulting in an inability to feel textures, heat, pain, and other sensations.

Clients often report initial sensations such as tingling, “crawling-skin,” or painful sensations. Because the signals to and from the arms and legs must travel the longest distances, they are most vulnerable to interruption. Therefore, muscle weakness and tingling sensations usually first appear distally in the hands and feet and progress proximally.³³

Typically, the weakness and abnormal sensations first noticed in the legs progress to the arms and upper body, and some muscles are almost totally paralyzed. As the demyelination continues, the client may experience problems with breathing, speaking, swallowing, blood pressure, or heart rate. The client may require use of a respirator to assist

with breathing and is monitored closely for an abnormal heart rhythm, infections, blood clots, and high or low blood pressure. After the first clinical manifestations of the disease, the symptoms can progress over the course of hours, days, or weeks. By the third week of the illness, 90% of all clients are at their weakest. Some may be completely paralyzed and dependent on the respirator.³³

Cooke and Orb defined three phases of Guillain-Barré syndrome.¹⁰ The *initial, or acute, phase* begins with the client's first conclusive symptoms and lasts until there is no further decline in physical status. This phase may last from 1 to 3 weeks.¹⁸ The *plateau phase* begins when the client's physical state is stable, with no further deterioration of physical status and no evidence of physical recovery. The plateau phase generally lasts a few weeks, during which the physical status of the client remains unchanged. The *recovery phase* is that period when the client slowly begins to recover physical abilities and symptoms gradually decrease. This phase can last up to 2 years, depending on the extent of paralysis.

Being paralyzed is a frightening experience for people with GBS, their family members, and friends. Clients can be expected to proceed through varying stages of adapting to the acute and residual effects of this physical disability.³⁸ However, the prognosis is generally good for the majority of clients; therefore, it is appropriate to be optimistic during intervention sessions and encourage clients and families to look forward to recovery (Table 37-2).

There is no known cure for GBS. However, there are interventions that lessen the severity of the illness and accelerate the recovery in most individuals. There are also a number of ways to treat the complications of the disease.³³ Immunomodulatory therapy (plasmapheresis or intravenous immunoglobulin IVIg) is the recommended medical treatment at the onset of GBS. Plasmapheresis has shown clinical improvements, reducing the time required for ventilation and critical care, time to achieve ambulation, and hospital length of stay.^{4,29} This process is used to separate the whole blood from the plasma and then return the whole blood to the client without the plasma to reduce the length of the acute phase. Immunoglobulin therapy involves the injection of proteins that the immune system uses naturally to fight invading organisms. Giving high doses of these immunoglobulin proteins can lessen the immune attack on the nervous system.³³

Role of the Occupational Therapist

The client with GBS may be referred to OT when medically stable. An occupational profile of the client will be developed through OT assessments related to the level of dysfunction that the client is experiencing. For example, physical abilities are assessed using range of motion (ROM) and manual muscle testing (MMT), sensation testing, and swallowing assessment. Functional assessments of quality of movement, coordination, and self-care may also be performed. It is critical to assess emotional and psychosocial

■ **TABLE 37-2 | Guillain-Barré Syndrome: Prognosis and Outcomes**

Recovery Status	Percentage of Clients	Description
Recover well spontaneously	85%	70% of those who recover well have some residual deficits such as distal numbness, weakness, fatigue; these may interfere with some daily functions but usually are not severe.
Significant impairments	10%	Fatigue and severe weakness in specific muscle groups significantly impair daily function.
Death	5%	Death is usually the result of pneumonia, sepsis, adult respiratory distress syndrome, autonomic dysfunction, or pulmonary embolism.

Data from Lawn N, Wijdicks E: Fatal Guillain-Barré syndrome, *Neurology* 52:635, 1999; Nicholas R, Playford ED, Thompson AJ: A retrospective analysis of outcome in severe Guillain-Barré syndrome following combined neurological and rehabilitation management, *Disabil Rehabil* 22(10):451, 2000.

factors of the client and family. See Table 37-1 for OT assessments.

After the initial OT evaluation, an intervention plan is developed. Frequent revisions may be necessary, depending on the client's recovery status. During the initial phase of intervention, problematic client factors are immediately addressed in conjunction with the healthcare team. These may include providing daily passive ROM, positioning, and splinting to prevent contracture and deformity and to protect weak muscles. Passive ROM should begin with gentle movement of the joints and should not exceed the point of pain. Particular attention should be paid to determining residual weakness in the intrinsic muscles of the hands. Passive activities (e.g., watching television) and non-strenuous social visits from family and friends are encouraged. Muscle belly tenderness (a flu-type muscle soreness) is closely monitored, and activities are modified as needed.⁶ Many clients may benefit from the use of electronic aids for daily living (EADLs). EADLs increase the level of independence in the client's control of the environment through the use of technology. For example, a client with GBS might lack the strength and motor skills to operate the television, lights, telephone, and radio in the environment. With the use of EADLs, the client may be able to use the head, mouth, or other parts of the body to operate control switches and successfully control the environment.

An intensive interdisciplinary rehabilitation program is typically implemented during the recovery phase as the client begins to regain physical movement. After the evaluation process, the OT intervention plan, developed in collaboration with the client, must be carefully designed to respect muscle belly tenderness and to prevent fatigue and further damage to the nerves. Because muscle belly tenderness usually decreases in the proximal musculature before it decreases distally, proximal musculature movements can be facilitated first while distal joints continue to be supported (e.g., using mobile arm supports).⁶ Activity is gradually increased with close monitoring of pain or fatigue after each intervention session. The therapist should continue to monitor for increased muscle belly tenderness, muscle imbalance, and substitution patterns. Progressive resistive exercises should be used conservatively, with attention to joint protection and fatigue. Throughout the course of recovery, the therapist should guard against fatigue and irritation of the inflamed nerves. Instruction to the client and family in key concepts such as energy conservation, work simplification, avoidance of overstretching, and overuse of muscles is critical to recovery.⁴⁴

As the client's strength increases, activities promoting more resistance can be incorporated into the intervention program. Self-care (grooming, eating, dressing, bathing, and toileting) and other activities of daily living (ADLs), instrumental activities of daily living (IADLs), and leisure occupations should be included as soon as the client is capable of participating in them. Activities should be graded for success as strength and endurance improve. Adaptive equipment, frequent rest breaks, and creative strategies are typically necessary during this phase. Mobile arm supports may be used to alleviate muscle fatigue, promote active assistive use of upper extremities, and encourage independence with occupations. Activities and occupations should be varied among gross motor, fine motor, resistive, and nonresistive exercises to prevent undue fatigue.⁴⁴

OT Practice Notes

Engagement in light occupations that are meaningful to the client is essential for building the self-confidence necessary to resume previous life roles and interests. For example, a client may be able to participate in enjoyable leisure occupations such as scrapbooking, surfing the web, planning a family gathering, and reading books to grandchildren (see Chapter 16).

People with GBS face not only physical difficulties but emotionally painful periods as well.³¹ It is often extremely difficult for clients to adjust to sudden paralysis and dependence on others for help with routine daily activities.³⁸ Eisendrath, Matthay, and Dunkel found severe anxiety, fear,

and panic in the acute progressive phase.¹³ When clients reached the plateau phase, they often expressed anger and depression. When improvement began during the recovery phase, severe depression occurred as clients contemplated the long, slow convalescence and the possibility of permanent neurologic deficits. An occupational therapist can support the client by facilitating feelings of self-worth, a positive attitude, and encouragement through the engagement in valued occupations.^{38,46} A psychologist or physician should also closely monitor the client's mood and provide necessary interventions as a member of the intervention team.

After becoming medically stable and being discharged from the hospital, many GBS survivors find themselves living at home without proper medical follow-up and therapy. Families are left to their own devices to successfully create real-life solutions to functional limitations and to locate and use resources. Schmidt conducted a survey of 90 voluntary participants from the Guillain-Barré Syndrome Foundation International to explore the extent of functional limitations within home, work, community, and leisure roles after hospitalization.⁴⁴ The majority of the participants stated that they had to independently research information about GBS because their doctors and team members either lacked the knowledge or did not provide them with any verbal or written information. One participant noted, "My family had to learn everything about GBS on the Internet. My doctors and nurses didn't know anything about it. We had to educate them (doctors, nurses, therapists, etc.)." These families reported feeling most frustrated about the fact that healthcare professionals did not address significant psychosocial issues such as depression, anxiety, fear, and hopelessness. Physically demanding tasks that required fair to good strength and endurance were scored the lowest in satisfaction and ability by participants. The great majority of respondents (98%) reported that they were living with limiting factors affecting their ability to participate in life, such as fatigue, weakness, pain, sensation disturbances, coordination problems, and psychosocial changes. Nearly half of the participants agreed that they would benefit from OT services to improve the use of their upper extremities and to learn ways to manage daily fatigue and maintain their current health status. This study indicates the need for continued OT to optimize occupational performance and occupational roles many years after the onset of the syndrome and apparent recovery.

The complex process of adjusting to the disabling condition, problem solving, learning, and redesigning a life for a GBS survivor is a long-term, therapeutic experience. The lifestyle redesign process can be initiated by the occupational therapist at the inpatient rehabilitation phase; however, there must be a continuum of care established for follow-up treatment. An occupational therapist working in an outpatient or home setting can skillfully guide clients back to the resumption of their previous life roles, assist clients in returning to productive community involvement and leisure

occupations (see Chapter 16), and teach engagement and participation in meaningful occupations.^{28,31,44}

Poliomyelitis and Postpolio Syndrome

Transmission of the poliomyelitis virus has been severely curtailed throughout the world as a result of the Global Polio Eradication Program; only 1579 confirmed cases of polio were reported globally in 2009, and polio was endemic in four countries.⁸ The peak of polio cases in the United States was in 1952, with more than 21,000 persons paralyzed. A great number of children were infected during the summer and fall months. According to the Centers for Disease Control and Prevention (CDC), the last case of indigenous polio acquired in the United States was in 1979. A program to eradicate polio in the Western hemisphere, led by the Pan American Health Organization, eliminated polio in this region of the world in 1991.⁸ Poliomyelitis is a highly contagious viral disease that enters through the mouth via the fecal-oral route (i.e., it is spread in unsanitary conditions with poor hand-washing techniques). The virus moves from the throat into the digestive tract and is shed through fecal material for several weeks. The poliovirus enters the bloodstream and, in some cases, infects the motor neurons of the anterior horn and brain stem. Up to 95% of individuals who contract the disease are asymptomatic but can still spread the disease. According to the CDC, flaccid paralysis results in less than 1% of all polio infections, and most people recover completely. If weakness or paralysis lasts more than 12 months, it is usually permanent.⁸

The CDC recognizes three types of paralytic polio: spinal polio, bulbar polio, and bulbospinal polio. Spinal polio was the most commonly diagnosed type between 1969 and 1979, involving 79% of the reported cases. This type produced asymmetric flaccid paralysis predominantly in the legs. Bulbar polio (2% of cases) infected the cranial nerves, leading to muscle weakness in oral and facial musculature, and a combination of the two types resulted in bulbospinal polio (19% of cases).⁸ Marked atrophy could be seen in the involved extremities, and deep tendon reflexes were often absent. Sensation and cognition remained intact. The asymmetry of muscles pulling on various joints sometimes produced deformities, such as subluxation, scoliosis, and contractures.^{45,53}

Even though substantial efforts have dramatically reduced the presence of poliomyelitis, the effects of polio still exist. Between 12 and 20 million people in the world who had polio are still alive (approximately 2 million of these people live in the United States). After an interval of 30 to 40 years, 25% to 40% of these adults are currently dealing with new muscle pain and increasing weakness or are developing new weakness or paralysis. This exacerbation is referred to as postpolio syndrome (PPS). According to the CDC,

Factors that increase the risk of postpolio syndrome include increasing length of time since acute poliovirus infection,

presence of permanent residual impairment after recovery from the acute illness, and female sex. The pathogenesis of postpolio syndrome is thought to involve the failure of oversized motor units created during the recovery process of paralytic poliomyelitis.⁸ Fortunately, postpolio syndrome is not contagious.

According to Postpolio Health International,³⁹ six criteria should be considered for this diagnosis: previous paralysis due to poliomyelitis, period of partial or complete recovery, gradual or sudden onset of progressive new muscle weakness, or muscle fatigue, new difficulties with breathing and swallowing, a year or more of these symptoms, and other causes of symptoms ruled out (see Table 37-3). PPS progresses slowly with intermittent periods of stability. People who had severe cases of acute polio experience a greater degree of disability resulting from PPS than do those whose initial response to the poliovirus was mild. Fatigue is the most debilitating symptom because it limits activity. The fatigue may be severe and out of proportion to the apparent physical demands of the activity and can be overwhelming. People with PPS risk additional disabling problems such as muscle atrophy, scoliosis, osteoporosis, fractures, contractures, and depression.^{19,56,57} An increase in difficulty with ADLs and IADLs accompanies the symptoms. Problems with ambulation, transfers, stairs, home management, driving, dressing, eating and swallowing, and bladder and bowel control may occur, and people report a poorer functional status and health-related quality of life.^{25,56} Unless there is severe pulmonary or swallowing involvement in postpolio syndrome, the symptoms are rarely life threatening.

Role of the Occupational Therapist

Occupational therapists should consider that the psychological and emotional aspects of PPS may be as disabling as the physical symptoms. Persons who originally had polio most likely assumed that the disease was over, that disability was in the past, and that any residual weakness was static. Therefore, the onset of new symptoms and the accompanying disruption of occupational performance and lifestyle may be devastating as the client, family, and friends are confronted for a second time with the notion of being disabled. A supportive and realistic approach by the health-care team, along with client and family education, is the key to lifestyle modification.^{56,57}

Occupational therapy has an important role to play in helping the client to stabilize function. Goals to adjust lifestyle may be accomplished by collaborating with the client and family to use work simplification, energy conservation, and adaptive equipment as needed. These measures, along with a healthy diet and enjoyment of remaining abilities, may improve the client's engagement in meaningful occupations and participation in the various contexts of his or her life.^{36,57}

When assessing a client with the diagnosis of PPS, the occupational therapist collaborates with the client and

■ **TABLE 37-3** | Six Criteria for Postpolio Syndrome

Criteria	Description
Prior paralytic poliomyelitis	Documented polio diagnosis, motor neuron loss, residual weakness, muscle atrophy, and electromyography (EMG) showing denervation of muscles
Period of partial or complete recovery	Evidence of acute paralytic polio with recovery and stable neurologic functions for an interval of about 15 years or more
Gradual or sudden onset of progressive and persistent new muscle weakness or abnormal muscle fatigability	Decreased endurance, muscle and joint pain; onset possibly occurring after surgery, trauma, or periods of inactivity
New difficulties with breathing and swallowing	Unlikely but possible development of problems with breathing and swallowing
Symptoms as listed here that may persist for at least a year	Length of time that client reports having symptoms sometimes relevant in the diagnosis of postpolio syndrome
Other causes of these symptoms ruled out	Exclusion of other neurologic, medical, and orthopedic problems

Data from Jubelt B, Agre JC: Characteristics and management of postpolio syndrome, *J Am Med Assoc* 284:412, 2000; Postpolio Health International: *Information about the late effects of polio*. Retrieved on July 14, 2005, from www.post-polio.org/ipn/aboutlep.html.

Case Study George

During his ninth birthday party, in February of 1955, George fell after another child kicked a ball, which hit George's legs. By the next morning, he could not get out of bed or stand on his own. He was admitted to a hospital and diagnosed with polio. George was placed in an iron lung that did the breathing for him. This was at the height of the polio epidemic, and the hospital wards and even the halls were filled with children in iron lungs. The complete confinement was terrifying, as was the constant presence of medical staff and equipment.

Over the years, George gradually recovered and was able to walk unassisted and participate fully in life. Recently, however, at the age of 60, George has begun experiencing new weakness in his legs, muscle pain, disproportionate fatigue related to activities, and an unstable gait. He is afraid that he is getting polio again. George quit his full-time job, stopped playing tennis, and became disengaged from his social life because he feared the full re-emergence of polio and did not want anyone to know. His wife was very concerned and scheduled an appointment for George with their doctor, who prescribed occupational therapy, physical therapy, and counseling.

Analysis

George is among the many people worldwide who are affected by postpolio syndrome. Through occupational and physical therapy and counseling, he will be able to resume a near-normal life. His fears must be addressed because they will hamper whatever remaining function he has. Through occupational therapy, George can learn to pace his activities, protect his joints, recognize fatigue before it becomes severe, and modify his leisure occupations so that he can lead an enjoyable life.

caregivers (if appropriate) to develop the occupational profile. After discussing the client's problems and concerns, the therapist can explore what strategies the client has used and how useful the client reports those strategies to be. The occupational therapist selects specific assessments, such as ROM, MMT, and assessment of client's equipment for proper fit and function, to provide additional needed information (see Table 37-1).

Information gained from the evaluation process is used to prioritize and select valued, relevant activities for the client with PPS. The Knowledge of Polio Test can reveal what the client and family understand about polio and its sequelae.⁵⁵ Education about the effects of polio when the client was a child, combined with information about current symptoms, is important. In most cases, little family education was available in the 1950s and 1960s, when the client first contracted polio.⁴⁵

Fatigue and pain are the two symptoms most frequently mentioned by clients with PPS. Scoliosis is found in nearly all survivors of polio. Even though scoliosis itself generally does not produce pain, the strain it puts on joints and muscles through abnormal biomechanics can produce degenerative disk disease, as well as pain in the shoulders, knees, and other joints and muscles.⁵³ Decreased vital capacity and difficulty breathing with deventilation during sleep is observed frequently in these clients. If the client complains of frequent awakening during the night or breathing problems, the therapist should refer the client to a pulmonologist immediately.^{53,57}

A client-centered intervention plan is designed to help the client and caregiver improve functional outcomes. Adaptive strategies and preventative measures are key factors to include in the OT intervention plan. Prognosis and

selection of intervention methods depend on the progression of the disorder. Functional and leisure activities that are meaningful to the client are used in combination with work simplification, pacing the activity for energy conservation, passive and active ROM exercises, muscle re-education, proper posture and body mechanics, joint protection, and training in the use of assistive and adaptive devices and mobility aids, as needed. In all cases, the therapist must teach the client to carefully monitor fatigue level and to modify or stop the activity when necessary.⁵⁷ Establishing priorities of goals is critical to reach the desired outcome, and intervention goals should be coordinated with the client and members of the interdisciplinary team for a comprehensive rehabilitation program. Psychosocial aspects of the disorders must be addressed in the intervention plan.^{22,38}

Understanding the client's psychosocial reactions to the various disabilities associated with PPS will help the therapist and client select interventions that will facilitate rehabilitation efforts and the patient's adjustment to new limitations. Changes in physical capacities, abnormal fatigue, and curtailment of valued life skills confront the client with psychological issues of coping, adjustment, and adaptation. These changes may be as traumatic as they were at the time of the original illness. It is important to be aware of the stages of adapting to a chronic disabling condition.^{38,39} Feelings of denial, anger, and hopelessness and the sense of being a burden should be identified and addressed as a part of the OT intervention. Helping clients and families connect with support groups can make a difference in psychosocial acceptance and motivation.⁵⁷ If the client's psychological needs are beyond the scope of the OT practice, referral to a psychologist is appropriate.

Because the client with PPS may be psychologically fragile when facing increasing levels of disabilities, the occupational therapist should introduce lifestyle changes gradually because modifying performance patterns and introducing adaptive equipment could threaten the client's self-image. Small changes may be more acceptable than major ones, even if the latter are obviously necessary. The client's spiritual beliefs must be considered when developing an intervention plan, and "activities of the spirit" may be helpful to foster a sense of hope.⁹

The benefits of exercise are controversial. Muscles affected by PPS may actually function at levels of strength lower than estimated from the results obtained on the MMT, and upper extremity strength varies markedly throughout the ROM. Thus, careful observation is essential during engagement in occupations. Exercise must be carefully supervised because it may aggravate pain and overwork of muscles innervated by a limited number of motor units.^{14,57} Signs of excessive activity are further weakness, discomfort, pain, muscle spasm, and chronic fatigue.^{36,45,56,57}

Chronic pain can be managed or alleviated by prescribed pharmaceuticals, improving body mechanics during occupations, supporting weakened muscles through splinting and adaptive equipment, and promoting lifestyle and

role modifications through a multidisciplinary treatment approach that is based on cognitive-behavioral therapy (CBT), a method that is frequently used by chronic pain management programs and may be employed by occupational therapists. CBT teaches clients about the dynamics of pain and coping strategies such as stress management, relaxation and visualization, appropriate use of play and humor, recognition of fatigue and implementation of activity pacing, monitoring of self-talk, and family training.^{7,12,24,46,47,53} Strategies can be taught to reduce or eliminate nonessential activities, thus reducing overuse of muscles and resultant pain. Energy conservation for the most valued activities may mean delegating less valued ones to others or performing them with the assistance of equipment, such as orthoses, assistive devices, or ambulation aids.^{40,45,56,57} Body weight reduction may be medically recommended for some clients to reduce pain, and occupational therapists can work in conjunction with dietitians to address weight loss through cooking groups that create the recommended high-protein diet.⁴⁰

It is important to make referrals to appropriate health-care professionals depending on the needs of the client and family. These healthcare professionals may include an orthotist, physical therapist, pulmonologist, and psychologist.⁵⁷

GBS and PPS are two disorders requiring OT services; they have been presented in detail to outline the process used for individuals with these disorders. The remaining portion of this chapter describes other disorders related to the motor unit that result in compromised occupational performance. The principles behind the interventions described for both GBS and PPS have application to the following disorders.

Peripheral Nerve Injuries

Thus far, this chapter has described diseases affecting the anterior horn cell and peripheral nerves. This section of the chapter will cover three specific upper extremity peripheral nerve injuries: axillary nerve, brachial plexus, and long thoracic nerve injury. The brachial plexus includes the nerves from C5 through T1.³⁷ These nerve fibers, both sensory and motor, intertwine closely to the vertebral column. The fibers join to form trunks of the brachial plexus, and from the trunks arise the divisions at which further interweaving of fibers occurs. The divisions give rise to the cords of the brachial plexus, and from the cords the terminal branches or named peripheral nerves arise. From an anatomic presentation, this complexity has the potential to preserve function if one root is compressed. For example, the radial nerve is composed of fibers originating from C6, C7, C8, and T1. For a list of nerves, muscles innervated, and actions performed, see [Table 37-4](#). (See [Chapter 39](#) for additional information on peripheral nerve injuries, peripheral pain syndromes, and the management of these disorders.)

■ **TABLE 37-4** | Clinical Manifestations of Peripheral Nerve Lesions of the Brachial Plexus

Spinal Nerves	Nerve	Motor Distribution	Clinical Manifestations
C5	Dorsal scapular	Rhomboid major and minor, levator scapulae	Loss of scapular elevation, adduction, downward rotation
C5-6	Suprascapular	Supraspinatus, infraspinatus	Weakened lateral rotation of humerus
C5-6	Subscapular	Subscapularis, teres major	Weakened internal rotation of humerus
C5-6	Axillary	Deltoid, teres minor	Loss of shoulder abduction, flexion, and external rotation and extension
C5-7	Musculocutaneous	Biceps brachii, brachialis, coracobrachialis	Loss of forearm flexion and supination
C5-7	Long thoracic	Serratus anterior	Winging of the scapula
C6-8	Thoracodorsal	Latissimus dorsi	Loss of arm adduction and shoulder extension
C6-8, T1	Radial	All extensors of arm, wrist, fingers, thumb, abductor pollicis longus, supinator, brachioradialis	Wrist drop, extensor paralysis, inability to supinate
C6-8, T1	Median	Flexors of wrist, hand, and digits; forearm pronators; opponens pollicis; abductor pollicis brevis; flexor pollicis brevis; first and second lumbricales	“Ape-hand” deformity, weakened grip, thenar atrophy, unopposed thumb
C8-T1	Ulnar	Supplies muscles on ulnar side of forearm and hand; adductor pollicis, abductor digiti minimi, opponens digiti minimi, flexor digiti minimi brevis, flexor digitorum profundus (digits 4, 5), third and fourth lumbricales, flexor carpi ulnaris, palmaris brevis, dorsal and palmar interossei, flexor pollicis brevis (deep head)	“Claw-hand” deformity, also known as an intrinsic minus hand deformity, interossei atrophy, loss of thumb adduction

From Hislop HJ, Montgomery J: *Daniels and Worthingham's muscle testing: techniques of manual examination*, ed 6, Philadelphia, 1995, WB Saunders.

Many people are injured every year by car accidents, falls, sports mishaps, gunshots, and violent acts (e.g., blunt and sharp wounds) that result in severed, crushed, compressed, or stretched peripheral nerves.³⁵ The most obvious manifestation of peripheral nerve injury is muscle weakness or flaccid paralysis, with symptoms depending on the extent of the nerve damage. Deep tendon reflexes are depressed or absent. Sensation along the cutaneous distribution of the nerve is also altered or lost. Trophic changes, such as dry skin, hair loss, cyanosis, brittle fingernails, painless skin ulcerations, and slow wound healing in the area of involvement, may be present.

Extensive peripheral nerve damage may produce deformity if contractures, joint stiffness, and poor positioning are allowed to occur. Disfigurement of the hands is particularly noticeable and may produce psychological distress. Other complications may include osteoporosis of bone and epidermal fibrosis of the joints. See [Table 37-4](#) for descriptions of clinical manifestations of peripheral nerve lesions of the brachial plexus.

Axillary Nerve Injury

The axillary nerve is composed of the C5-C6 spinal nerves and arises from the upper trunk of the brachial plexus. The motor branches of the axillary nerve innervate the deltoid muscle and the teres minor muscle (see [Table 37-4](#)).²¹ The axillary nerve is “the most commonly injured nerve in the shoulder, and the most common cause of injury is anterior dislocation of the shoulder or fracture of the neck of the humerus.”²⁷ Nerve damage may occur as a result of the actual dislocation or of the reduction; other causes include compression (e.g., crutches) or trauma (e.g., blunt or lacerating wounds). As a result, the client has weakness or paralysis of the deltoid muscle, which causes limitations in shoulder flexion, abduction, extension, and weakness in lateral rotation of the arm. In addition to the loss of muscle power, atrophy of the deltoid muscle produces asymmetry of the shoulders, which may cause issues with body image.²⁷

See [Table 37-1](#) for OT assessments. ROM assessment and MMT, as well as clinical observation of the client's ability to use the arm functionally, are critical.

Interventions for axillary nerve injury require that the shoulder dislocation be reduced and that the arm be supported for a brief time in a sling. When the physician prescribes OT for rehabilitation of shoulder function, interventions include passive and active ROM of shoulder flexion and extension and shoulder abduction and adduction exercises while the client is supine or lying on the noninjured side to minimize gravity (Table 37-5). Functional movements are graded as the muscles become stronger.

Brachial Plexus Injuries

The nerve roots that innervate the upper extremity originate in the anterior rami between the C5, C6, C7, C8, and T1 spinal segments. This network of peripheral nerves is collectively called the brachial plexus. This important nerve complex can be palpated just behind the posterior border of the sternocleidomastoid as the head and neck are tilted to the opposite side.¹⁷

Most brachial plexus injuries are typically unilateral and occur during birth.³² Obstetrical brachial plexus injury occurs if the baby's shoulders become impacted, which causes the brachial plexus nerves to stretch or tear. For example, if the infant's shoulder is stuck in the birth canal and the head is pulled, the neck is stretched, which can subsequently stretch or tear the brachial plexus. In adults, traumatic brachial plexus injuries are caused by damage to the nerve roots from a variety of causes (e.g., car or motor-cycle accidents, sports misadventures, falls, blows to the neck with blunt or sharp objects, radiotherapy). The two types of brachial plexus lesions are Erb-Duchenne syndrome and Klumpke's (Dejerine-Klumpke) syndrome.^{17,27,41} These disorders are also referred to as Erb's palsy and Klumpke's palsy.

Erb-Duchenne syndrome is seen with lesions to the upper trunk of the brachial plexus, which consists of C5 and C6 nerve fibers. The incidence among newborns is 2 to 5 per 1000 births with 80% to 90% full recovery within 3 to 24 months.⁴⁸ The incidence among adults is not known. Typically, the muscles of the shoulder and elbow are affected, whereas hand movement is retained. Paralysis and atrophy occur in the deltoid, brachialis, biceps, and brachioradialis muscles (see Table 37-4). Upon observation, the arm hangs limp in internal rotation and adduction of the shoulder. The elbow is extended, the forearm pronated, and the wrist flexed, resulting in the "waiter's tip position." Even though hand muscles are unaffected, functional movement of the upper extremity is extremely limited.^{17,27,48}

Klumpke's syndrome results from compression or traction to the lower trunk of the brachial plexus (comprising nerves arising from C8 and T1) and is seen less often than Erb-Duchenne syndrome. Traction during birth or later in life that is caused by a strong upward pull on the upper extremity when it is in an abducted position can result in this disorder. The involved nerves innervate muscles whose actions are wrist and finger flexion and abduction and adduction of the fingers (see Table 37-4). Consequently, paralysis to the distal musculature of the wrist flexors and the intrinsic muscles of the hand results in a "claw-hand deformity," also referred to as an intrinsic minus hand deformity (Figure 37-2).^{17,27,48} See Table 37-1 for OT assessments.

OT interventions initially involve partial immobilization and positioning. Passive ROM is critical in maintaining joint flexibility, and the client's family or caregiver should be taught to perform these exercises with the client two or three times daily. Intervention includes a variety of tactile and proprioceptive sensory input to increase sensory awareness. Preventing contractures is critical to a functional outcome. For individuals with Erb-Duchenne syndrome, performance of passive and active assistive exercises and fabrication of a sling that fits around the humerus to support the arm are important. If strength improves, resistive exercises and activities can be implemented and the sling may

Case Study William

William, a 60-year-old husband and teacher, was in a car accident that dislocated his right dominant shoulder. He was taken to the emergency room, given a sling, and sent home. Over the next few days, he noticed that he could neither flex nor abduct his humerus more than approximately 45 degrees. His physician reviewed his x-rays, repositioned the humerus, and diagnosed axillary nerve injury. Once the glenohumeral joint was stable, she prescribed occupational therapy to recover arm function.

During his therapy sessions, Marla, his occupational therapist, instructed William and his wife about joint protection, range of motion (ROM) exercises, and use of a reacher. As William's strength improved, Marla explored meaningful activities with him. After he enthusiastically mentioned a map project illustrating the places where he and his family had traveled, the two of them worked together to mount the map on poster board. Marla graded the activity and encouraged William to use long, sweeping movements of his right shoulder in flexion/extension and abduction/adduction when spreading the glue. William then sanded the frame and painted it, again using gliding shoulder movements. His home program also included smooth, gliding shoulder movements (e.g., wiping the counters, which his wife happily endorsed).

Analysis

Injury to the axillary nerve is one of the most common peripheral nerve injuries. Once the dislocation of the humerus has been reduced and the nerve begins to regenerate, rehabilitation of function may be possible. In this case, the occupational therapist was able to identify an activity that related to William's role as husband and home project enthusiast. This meaningful occupation caught his attention and engaged him in participation to accomplish the task.

■ **TABLE 37-5** | Occupational Therapy Interventions for Peripheral Nerve Injuries

Nerve Injury	Intervention	Example of Activities
Axillary nerve	Passive ROM to prevent deformity and improve circulation; necessary to protect teres minor and deltoid muscles from stretch during the passive ROM activities	Passive ROM performed two or three times daily while client is supine or lying on uninjured side to minimize effects of gravity; family or caregiver instructed in techniques; client instructed in self-ranging techniques performed on a daily basis
	Adaptive equipment	Instruction in use of long-handled assistive devices to compensate for upper extremity abduction deficit
	Joint protection	Instruction in joint protection to allow nerve time to heal and to prevent further injury; instruction in adaptive equipment, as needed for activities of daily living and leisure, work, and play occupations
	EMG biofeedback	Biofeedback potentially beneficial in providing the client with visual and auditory incentives during muscle re-education sessions
	Retrograde massage	Use of retrograde massage if edema occurs in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day
	Graded activities	Shoulder movement critical to recovery; incorporation of long, sweeping shoulder movements in the client's meaningful activities; graded from horizontal to vertical.
Brachial plexus	Passive ROM to maintain joint flexibility	Passive ROM performed while supine twice daily, with emphasis on shoulder flexion, abduction, and external rotation; family or caregiver instructed in techniques
	Tactile stimulation to upper extremity to increase awareness	Massage, vibration, application of various textures to the arm
	Proprioceptive stimulation to upper extremity	Joint approximation through progressive weight bearing to increase awareness; always necessary to ensure proper alignment of joints
	Bilateral integration to improve body scheme	Use of developmentally appropriate bilateral activities (e.g., toys, crafts, or activity that requires two hands)
	Pool therapy	Therapeutic exercises with gravity minimized in water; swimming or weight lifting possible as client's strength improves
	Electrical stimulation	As prescribed by physician after EMG
	Slings	For damage to C5 and C6, sling fabricated to fit around humerus to support arm and allow hand to engage in occupations; especially important if arm is flaccid and the individual is able to walk—prevents further traction injury to nerves
	Splints	Resting splint for flaccid hand/wrist seen with damage to C8 and T1 to maintain part in functional position and prevent contractures; other splints available or fabricated for specific joints; air splints sometimes used to provide stability in elbow extension to bear weight with damage to C7
Retrograde massage	For edema in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day	
Long thoracic nerve	Shoulder stabilized to limit scapular motion while nerve heals	After medical treatment, encouragement of maximal functional independence during activities and education in use of long-handled devices to compensate for shoulder limitations
	If nerve regeneration is not complete, possible consideration of surgery to relieve the excessive mobility of the scapula Retrograde massage	For edema in hand or arm; client, family, or caregivers instructed in technique to be performed several times per day

ROM: Range of motion.

Data from Stormont M: Margaret Stormont's guidelines for therapists: treating children with brachial plexus injuries. Retrieved on August 25, 2005, from www.ubpn.org/awareness/A2002stormont.

FIGURE 37-2 Klumpke's syndrome: paralysis to the distal musculature of the wrist flexors and the intrinsic muscles of the hand that results in a "claw-hand deformity" or intrinsic minus hand.

be removed or used intermittently during walking to support the shoulder.^{41,48} For those with Klumpke's syndrome, a short opponens hand splint that supports the thumb in opposition is often used. It is important to provide occupations that are appropriate to developmental ages and stages and that appeal to the client and encourage active use of the extremity in bilateral activities. Surgery to improve nerve growth and upper extremity function may be recommended if improvement is not spontaneously observed within a few months.^{41,48} Other interventions are described in Table 37-5.

Long Thoracic Nerve Injury

The long thoracic nerve, arising from C5-C7 nerve roots, innervates the serratus anterior muscle, which anchors the apex of the scapula to the posterior of the rib cage. The serratus anterior's action is scapular abduction and upward rotation (see Table 37-4).²¹ Although injury to this nerve is not common, the nerve can be injured in a number of ways: carrying heavy weights on the shoulder (e.g., backpacks), blows to the neck, compression caused by prolonged lying on the lateral trunk, and wounds. The resulting clinical picture involves winging of the scapula, difficulty flexing the glenohumeral joint above shoulder level, and difficulty protracting the shoulder or performing scapula abduction and adduction.^{17,27} Asking the client to perform a wall pushup is a commonly used screening assessment technique. If the long thoracic nerve is impaired, the scapula on that side will elevate and move medially, with the inferior angle rotating medially to produce a winging of the scapula.²⁷ Other OT assessments are described in Table 37-1.

Lesions of the radial, median, and ulnar nerves and cumulative trauma disorders affecting the hand are discussed in Chapter 39.

Psychosocial Interventions for Peripheral Nerve Injuries

Brachial plexus, thoracic, and axillary nerve injuries are life changing, affecting the psychological and emotional states of clients and their families and friends. Clients often experience depression, which may be a reaction to the traumatic event that caused the injury or may become chronic and serious. Occupational therapists can be helpful in this regard by discovering activities that are meaningful to the client and adapting them for success. The client's self-image is challenged and may require revision to accommodate the client's changed health status. For example, if the deltoid muscle has atrophied, the client can wear a foam or thermoplastic pad under clothing to round out the shoulders. Use of these aesthetic pads may increase the client's willingness to venture out into society. Referrals to support groups or a psychologist also may help clients adjust to a changed appearance.^{38,51} Participation in leisure occupations has been found to help people with physical disabilities redefine themselves (see Chapter 16), and occupational therapists should consider leisure as an important area of occupation to include in an intervention plan.²

Neuromuscular Disorders

Neuromuscular Junction: Myasthenia Gravis

Myasthenia gravis (MG) is the most common chronic disease involving a disorder of chemical transmission at the nerve-muscle synapse, or neuromuscular junction. The term *myasthenia gravis* is derived from Greek and Latin and means "grave muscle weakness."⁵⁴ It is caused by an autoimmune response in which antibodies are produced that block, alter, or destroy the nicotinic acetylcholine receptors on the postsynaptic membrane and interfere with synaptic transmission at the nerve-muscle junction. Because neurotransmission is defective, skeletal (voluntary) muscles, typically the cranial muscles, become weak and easily fatigued. The incidence of MG in the United States is approximately 14 in a population of 100,000, but it may be underdiagnosed, especially among very old persons. The latest statistics show that with the aging of the population, males are diagnosed more often than women, with symptoms beginning after 50 years of age.^{3,23,42,49,50}

Most clients diagnosed with MG initially experience symptoms in the oculomotor muscles that cause eyelid drooping, referred to as ptosis, and double vision, referred to as diplopia. Oropharyngeal muscle weakness, which results in difficulty in chewing, swallowing, and speaking, is seen in some clients. Weakness of limb musculature is not typically an initial symptom. People with MG tend to be stronger in the morning, but their strength and endurance

■ **TABLE 37-6** | Myasthenia Gravis: Initial Symptoms, Description, and Percentage of Clients with Symptoms

Initial Symptoms	Description	Approximate Percentage of Clients with Initial Symptoms
Oculomotor dysfunction	Severe drooping of eyelids (ptosis), double vision (diplopia), inability to move eyes in certain directions	70%
Otopharyngeal muscle weakness	Difficulty in chewing, swallowing, speaking; in severe cases, problems breathing and coughing resulting in aspiration	20%
Limb weakness	May be limited to specific muscles or may progress to generalized fatigue	10%

Data from Cabrera CS et al: Myasthenia gravis: the otolaryngologist's perspective, *Am J Otolaryngology* 23(3):169, 2002; Howard JF: *Myasthenia gravis: a summary*. Retrieved on July 22, 2005, from www.myasthenia.org/information/summary; Rowland LP: Diseases of chemical transmission at the nerve-muscle synapse: myasthenia gravis. In Kandel ER, Schwartz JH, Jessell TM, editors: *Principles of neural science*, ed 4, New York, 2000, McGraw-Hill; Kernich CA, Kaminski HJ: Myasthenia gravis: pathophysiology, diagnosis and collaborative care, *J Neuroscience Nurs* 27(4):207, 1995; Yee CA: Getting a grip on myasthenia gravis, *Nursing* 32(1):1, 2002.

decrease as the day progresses and muscles fatigue. Therefore, the client may experience increased double vision, severe drooping of the eyelids, difficulty with speech or swallowing, and fatigue with repetitive activity as muscles tire (Table 37-6).

Most clients with MG have abnormalities of the thymus glands, and some have thymic tumors. Removal of the thymus gland (thymectomy) is standard therapy for most clients, but response time for symptom reduction varies with individuals and may take between 2 and 5 years after surgery. Clients without thymomas have a better response to surgery than those with a tumor. Clients are also treated with corticosteroids (prednisone) and immunosuppressive and cholinesterase-inhibiting drugs.⁴² High-dose intravenous immune globulin has been reported to decrease symptoms in 50% to 100% of clients for a period of weeks to months. For clients with symptoms that suddenly worsen, those about to have surgery, or those who have not responded well to other interventions, plasma exchange is used as a short-term treatment. Nearly all people with MG improve for weeks to months after plasma exchange.^{23,50}

Most people with MG usually experience maximal weakness during the first year after diagnosis. The course of the disease fluctuates but is usually progressive. However, according to the Myasthenia Gravis Foundation of America (www.myasthenia.org), the current prognosis for most patients with this disease is good; most live normal or nearly normal lives. Remissions or a decrease in symptoms and an improvement in strength and function can last for years. However, emotional upset, extended exertion, infections, medications, thyroid conditions, elevated body temperature, or childbirth may induce exacerbations of unpredictable severity.²³ With modern diagnosis and treatment effectiveness, the mortality rate of MG is nearly zero.⁴⁹

Role of the Occupational Therapist

Because similarities exist among the diagnoses of motor unit disorders, OT evaluation follows the same pattern with specific assessments selected according to the disorder (see Table 37-1). A significant area for assessment in MG is eating and swallowing because of the dangers of aspiration. Because some clients may experience difficulty with diaphragmatic and intercostal muscle strength, they may have trouble coughing to clear secretions. An occupational therapist with advanced training in dysphagia should assess and treat clients with severe eating and swallowing dysfunction (see Chapter 27).

Interventions for clients with MG depend on the results of the OT evaluation, which includes client and caregiver goals. The therapeutic program should not cause fatigue; therefore, the therapist must be aware of the client's medication regimen and ability to tolerate activity and the time of day that the client has the most energy. The client's muscle strength must be monitored on a regular basis, and the occupational therapist keeps a running record to document any important changes that must be reported to the medical team. Specific intervention protocols for MG are scarce, but a recent study described the ways in which subjects with MG self-managed fatigue. "Effective self-care actions include stress reduction techniques, pacing all activities, and increased rest and sleep."¹⁵

An important aspect of treatment is to educate the client and family members to use energy conservation and work simplification strategies when engaging in ADLs, IADLs, and leisure occupations (see Chapters 10, 14, and 16). Adaptive and assistive devices may be introduced to decrease effort during daily activities. Because vision may be impaired, the occupational therapist should visit the client's home to assess architectural barriers, bathroom safety, and furniture arrangements; otherwise, the client might fall. If chewing and swallowing are problems, an eating program

 **Case Study**
Jan

For several months, Jan, a 45-year-old photographer, had noticed unusual changes in her body. Her eyelids felt heavy, and her vision would blur when she was reading; it felt as if she was cross-eyed. Jan's speech became slurred if she was in a lengthy conversation. More recently, she had become aware that when she was drinking thin liquids, such as coffee, she would frequently choke. When she visited her doctor and received the results of medical tests, she was shocked to hear that she had an autoimmune disorder called myasthenia gravis. Jan's physician referred her to a surgeon for removal of her thymus gland, and she was given a prescription for prednisone.

Jeri, an occupational therapist trained in dysphagia, assessed Jan's swallowing abilities and recommended that thickening agents be added to liquids to decrease choking. As Jan improved, Jeri performed ongoing swallowing assessments and was able to gradually add thinner liquids so that Jan could again enjoy coffee. Jan reports that the most important thing that anyone did for her was when Jeri helped her enroll in a myasthenia gravis support group, where she experienced empathy, was given resources, and, to her surprise, found herself laughing again.

Analysis

People with myasthenia gravis can be helped through a variety of therapies to lead a near normal life. When a swallowing disorder is present, an occupational therapist with advanced training must perform a dysphagia assessment and make recommendations to prevent aspiration and pneumonia. A social support system is critical to the well-being and recovery of people with this disease.

should be designed and monitored by an experienced occupational therapist (see Chapter 27).

Because of the client's facial appearance (e.g., drooping eyelids), fear of choking, or steroid-related changes in appearance, the psychosocial effects of MG may be distressing to clients and their family and friends. The therapist should always treat the client with empathy and encourage honest discussion. For general well-being, the client must be able to express his or her feelings about these physical changes.³⁸ The client and family members may also be referred to an MG support group, a psychologist, or both.

Myopathic Disorders

Muscular Dystrophies

The muscular dystrophies are a group of more than 30 genetic diseases. The dystrophies have in common the progressive degeneration of muscle fibers while the neuronal

innervation to muscle and sensation remains intact. As the number of muscle fibers declines, each axon innervates fewer and fewer of them, resulting in progressive muscle weakness. Some forms of muscular dystrophy (MD) have an onset in childhood, whereas others may not appear until middle age or later. The disorders also differ in terms of the distribution and extent of muscle weakness, rate of progression, and pattern of inheritance.³⁴ The major types of muscular dystrophy (MD)—Duchenne, Becker, facioscapulohumeral, myotonic and limb girdle—are described in Table 37-7.

Because this group of diseases is degenerative, the decline of muscle function cannot be prevented. As yet, there is no cure. Medical management is largely supportive. “Drug therapy includes corticosteroids to slow muscle degeneration, anticonvulsants to control seizures and some muscle activity, immunosuppressants to delay some damage to dying muscle cells, and antibiotics to fight respiratory infections.”³⁴ Gene therapy is being investigated but is not yet available.⁴¹

Rehabilitation measures are vital in delaying deformity and achieving maximal function within the limits of the disease and its debilitating effects. In addition to occupational therapy, rehabilitation may include physical therapy, speech therapy, and respiratory therapy services.³⁴

Role of the Occupational Therapist

The primary goal of OT is to help the client with MD maintain maximal independence as long as possible. Self-care activities and assistive devices that promote independence during home, school, leisure, and work activities are a vital part of the treatment program.⁴¹ Leisure occupations need to be considered in a comprehensive OT intervention plan to ensure balance in all areas of the client's life. Play and laughter are particularly important to the health, well-being, and social adjustment of the growing youth (see Chapters 6 and 16).

A comprehensive team evaluation of the client's abilities and disabilities should be administered. The team includes the physician, occupational therapist, physical therapist, and psychologist. A social worker may advise the family on community resources. The occupational therapist assesses the client's functional status in ADLs and IADLs, ROM exercises, and muscle strength, as well as the fit and proper use of adaptive equipment, engagement in leisure activities, and emotional status. (See Table 37-1 for assessments.)

After the evaluation process is complete, an OT intervention plan is developed to address specific concerns. Active exercise may be helpful in maintaining strength, but overexertion and fatigue must be prevented. Because people with MD may experience cardiac complications, occupational therapists must be aware of the client's medical history and use exercise judiciously, observing cardiac precautions when necessary. Incorporating exercise into meaningful, age-related activities that are monitored by a therapist can promote engagement in participation. Parachute games,

■ **TABLE 37-7** | Major Types of Muscular Dystrophy

Type	Description	Age of Onset and Progression
Duchenne	Affects boys only because it is inherited as an X-linked recessive trait Results from gene mutation that regulates the protein involved in maintenance of muscle integrity.	Onset age: 3-5 years—begins in muscles of pelvic girdle and legs By 12 years unable to walk; uses wheelchair Weakness spreads upward to shoulder girdle and trunk By 20 most need respirator to breathe with death usually occurring by age 30
Becker	Similar to Duchenne, with milder symptoms, X-linked recessive, affects boys	Onset age: 2-16 years Slower progression of weakness, Survival into middle age
Fascioscapulohumeral	Affects both genders Autosomal dominant Affects primarily the muscles of the face and shoulder girdle (hence its name)	Onset age: Adolescence Slow progression of weakness resulting in a near normal life span
Myotonic	Affects both genders Causes weakness but also myotonia—prolonged muscle spasm or delayed muscle relaxation after vigorous contraction—especially in fingers and face; floppy, high-stepping gait; appearance of long face and drooping eyelids	Onset age: Varies, often adult Involves cranial muscle and distal limb weakness rather than proximal May be mild or severe Associated symptoms progress to involve cardiac abnormalities, endocrine disturbances, cataracts, and, in men, testicular atrophy and baldness
Limb girdle	Affects both genders Progressive weakness affecting pelvic girdle and shoulder girdle first	Onset age: teens to early adulthood Weakness leads to loss of ability to walk within 20 years Relatively slow progression Death in mid to late adulthood

obstacle courses, and swimming may be implemented with frequent built-in rest breaks.¹⁸

Two recent pilot studies involving clients with MD and exercise show that improvements are possible; investigators recommend further research. Clients with myotonic dystrophy showed significant improvement in hand function and in self-rated occupational performance on the Canadian Occupational Performance Measure after a 3-month hand training OT intervention.¹ An experimental pilot study quantitatively evaluated that qigong may be used as an adjunct therapy program. Subjects with MD reported perceived maintenance of general health and positive coping when compared to the control group. The treatment group tended to “maintain balance function during training and performance of qigong whilst there was a decline when not training.” The researchers concluded that qigong brought about a decreased rate of decline and is worthy of further study.⁵²

Adaptive equipment and environmental modifications are often used as OT interventions. Instruction in work

simplification and energy conservation, as well as in creative and effective strategies to perform ADLs, IADLs, and various other occupations, are important in the OT program.^{18,41} A powered wheelchair, a wheelchair lap board, suspension slings, or mobile arms supports may be indicated to facilitate greater independence in self-feeding, writing, reading, use of a computer, and tabletop leisure activities when there is substantial shoulder girdle and upper limb weakness. Built-up utensils are helpful when grip strength declines. Home and workplace modifications will be necessary for most clients. Client and family education is an important part of a team rehabilitation program.⁴¹ A supportive approach to the client and family is helpful as function declines and new mobility aids, assistive devices, and community resources become necessary.¹⁸

Wheelchair prescription and mobility training in either a manual or powered wheelchair are included in the OT intervention program. The wheelchair may require a special seating system or supports to minimize the development of scoliosis, hip and knee flexion contractures, and ankle

plantar flexion deformity.^{18,41} Powered wheelchairs are often recommended to conserve energy and decrease strain on shoulders and trunk. Instruction in methods to maneuver power chairs can cause overexertion, and this activity, like any other, must be graded for difficulty. A recent study found that young people (i.e., those between 7 and 22 years of age) diagnosed with either MD or cerebral palsy who were inexperienced powered wheelchair drivers significantly improved their wheelchair driving performance through the use of simulator training. The researchers concluded that this method of instruction conserved energy and was effective.²⁰

Chronic pain in children, adolescents, and young adults (i.e., persons between 8 and 20 years of age) with physical disabilities has not been widely studied, but recent research indicates that chronic pain interferes with ADLs and IADLs in young people with MD, cerebral palsy, spinal cord injury, acquired and congenital limb deficiency, and spina bifida.³⁰ Pain appears to be more prevalent in female subjects than male subjects during the performance of daily routines, and it interfered most often with physical activities, and it negatively affected mood. McKearnan reported that the young people in this study frequently reported pain associated with physical therapy, OT, and therapeutic home programs.³⁰ They also complained that the use of splints, orthotics, and prosthetics was sometimes painful. Therapists must be aware of their client's pain levels and modify activities, splints, and orthotics as needed. Helping clients with MD to manage pain will most likely lead to improved quality of life.

The sense of self is challenged as clients with MD realize that they will experience a progressive loss of bodily function. Occupational therapists must realize that these clients are constantly forced to redefine themselves as they go through life, making "continuous trade-offs as function is lost."³⁸ A critical element in OT intervention is to help the client and family members find meaningful activities in which to participate either as individuals or as a family. For example, connecting with spiritual activities that engage clients and families on the deepest level could be critical to a sense of hope and well-being.⁹ Alternatively, encouraging families to use humor and to play and laugh together can promote bonding, reduce fear and anxiety, and produce positive physical and emotional feelings.^{5,11}

Psychosocial issues related to MD involve the whole family. Parents go through phases of shock, fear, and despair when the diagnosis is made and as the child ages and function decreases (e.g., when the wheelchair is prescribed). Encouraging parents not to be overprotective and to continue to promote their child's independence is an important aspect of therapy. Further, therapists can anticipate times in the growing child's life when psychosocial support will be most essential and can offer education and support during intervention sessions. Some potentially disturbing developmental milestones for the client and family occur when the child starts school (at approximately age 5), when the child

loses the capacity for independent ambulation (at 8 to 12 years), when adolescent social life is limited, and, of course, when young adulthood arrives with the expectation that death is imminent.^{18,41} Referral to a psychologist, family counselor, or spiritual advisor during these times should be considered.

Summary

The motor unit consists of the lower motor neuron, neuromuscular junction, and muscle. Some motor unit dysfunctions are reversible, and others are degenerative. The role of the occupational therapist is to assess functional capabilities in all occupational performance areas and contexts. ADLs and IADLs (including self-care, home management, mobility, and work-related tasks), energy conservation, work simplification, joint protection, spiritual approaches, and appropriate humor may be used to restore or maintain function. Proper positioning, exercise programs, and pain management techniques are used as indicated to facilitate recovery and increase functional capacity. Orthoses, assistive devices, communication aids, and mobility equipment and training in their use may be necessary. Psychosocial considerations and client and family education are important aspects of the OT program.

Review Questions

1. Name the components of the motor unit and one disorder that may result in dysfunction for each component.
2. Describe Guillain-Barré syndrome and the occupational therapy interventions used for clients with this disorder.
3. Describe the symptoms of postpolio syndrome.
4. What are the elements of the occupational therapy program for the client with postpolio syndrome?
5. List at least six clinical manifestations of peripheral nerve injury.
6. Describe the occupational therapy treatment strategies, including any contraindications, for peripheral nerve injuries.
7. Describe a method of managing pain that an occupational therapist may use.
8. Discuss the clinical signs of myasthenia gravis.
9. Describe the role of occupational therapy for clients who have myasthenia gravis.
10. What is the primary treatment precaution in myasthenia gravis?
11. Name and differentiate the four types of muscular dystrophy.
12. What are the treatment goals for muscular dystrophy?
13. Discuss ways that occupational therapists address the psychosocial needs of clients with each of the motor unit disorders.

Threaded Case Study | Edith, Part 2

Return to the case study presented at the beginning of this chapter, and compare your answers with the ones given here.

What Are the Phases of Guillain-Barré, and What Occupational Therapy Interventions Might Be Used in Each Phase?

Cooke and Orb define three phases of Guillain-Barré syndrome.¹⁰ The initial, or acute, phase begins with the client's first conclusive symptoms and lasts until there is no further decline in physical status. This phase may last from 1 to 3 weeks.¹⁸ During this phase, Edith's condition progressed from generalized weakness to paralysis of her extremities and muscles of the trunk and diaphragm. She was completely dependent in activities of daily living and required a ventilator to breathe. Jen, the occupational therapist assigned to the intensive care unit, established four goals with Edith and her family.

Goal	Intervention
1. Maintain full range of motion (ROM) in all joints.	1. Perform passive ROM two times per day to all joints.
2. Prevent contractures.	2. Fabricate resting hand splints, and educate client, family, and nursing aides in proper ways to position Edith in bed.
3. Teach client and family about Guillain-Barré syndrome (GBS).	3. Provide and discuss with clients handouts, reading materials, and GBS websites.
4. Provide a strategy for Edith to listen to the Bible.	4. Instruct Edith in ways to use the control switch with her tongue to turn the CD player on and off.

Phase 2, the plateau phase, began when Edith's physical status stabilized, with no further deterioration. She was transferred to a regular hospital unit. She was able to breathe on her own, speak softly, and sit up in bed in a semireclining position with pillows positioned for support. Some strength had returned to her proximal musculature, but her hands remained paralyzed and she fatigued easily. The plateau phase lasted a few weeks during which Edith's physical status remained unchanged. The goals for this phase were essentially the same as for the acute phase except that now Edith could choose to either read the Bible by turning the pages with a mouth stick or listen to the CD using the mouth stick to turn the player on and off. She could also control the television set with the mouth stick and was able to view her favorite shows. Family and friends were encouraged to visit but were cautioned not to fatigue her.

The recovery phase began when Edith's strength and sensation began to return to her distal extremities. She was transferred to the rehabilitation unit. The occupational therapist, Lara, and Edith came up with four goals during the recovery phase. The use of adaptive equipment such as built-up handles, work simplification and energy conservation

techniques (e.g., breaking the task down into steps and resting between steps), and the use of electric appliances were encouraged during activities. Edith practiced playing cards with other clients in a group environment. Lara set her up with a cardholder and a battery-powered card shuffler when her hands were too weak to hold the cards, but Edith eventually was able to play independently. Edith went to the mall with her granddaughter and Lara. During the outing, Lara taught them, in the context of shopping, how to gauge fatigue and to rest for 5 or 10 minutes when feeling tired. She also served as a role model, pacing the activity by limiting the initial shopping trip to 30 minutes and encouraging gradual lengthening of the experience over time. Lara provided Edith with community resources to aid in her independence. For example, the Guillain-Barré Syndrome Foundation International (GBSFI) offers local support groups, literature, and conferences to all GBS survivors and caregivers. In addition, Edith's family received extensive training from the interdisciplinary team members to assist with carryover of learned strategies and equipment in the home and community. Driving was not addressed at an inpatient level, but Edith was referred to the OT driver training program, where she would be assessed when her strength returned.

In What Ways were the Client's Psychosocial Needs Addressed during Recovery?

Edith's fears about being paralyzed were addressed in several ways. Edith and her family were taught about the disease and encouraged to have hope because most people with GBS recover well. Edith's spiritual needs were met by making it possible for her to continue her morning Bible routine; she initially used a tongue switch to turn a Bible CD on and off and then was able to use a mouth stick to turn pages until her hands recovered strength. Edith expressed a desire to be as independent as possible in activities of daily living, to cook for her family, and to enjoy family outings and card playing. These activities were all made possible through occupational therapy adaptive interventions. Her family members and friends were encouraged to visit, gradually increasing the length of time that they stayed.

Describe Energy Conservation Techniques That You Think would be Appropriate for Edith While Engaging in Her Valued Occupation of Cooking during the Recovery Phase

First, Edith and Lara reviewed the recipe and listed the necessary items while seated at the kitchen table. Edith used a wheeled kitchen cart to gather items and carry them to the counter. Lara provided her with a reacher to obtain items on high shelves. When the items were assembled, Edith sat and rested on a bar stool near the counter while she and Lara reviewed the next step. Electric appliances were used to chop and stir the ingredients. Edith rested after this step. Lara showed Edith how to slide containers along the counter to the stove without lifting. They walked back to the table to play a game of cards while the meal cooked. When the food was cooked, Edith placed plates and utensils on the kitchen cart with the one-dish meal and wheeled the cart to the table to enjoy her meal.

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Understand the distinct disease processes of osteoarthritis and rheumatoid arthritis.
2. Describe common similarities and differences in the symptoms of osteoarthritis and rheumatoid arthritis.
3. Identify joint changes and hand deformities commonly seen with osteoarthritis and rheumatoid arthritis.
4. Recognize medications commonly used in the treatment of arthritis and their side effects.
5. Understand the physical and psychosocial effects of arthritis and their impact on occupational functioning.
6. Identify important areas to evaluate in clients with arthritis.
7. Identify the intervention objectives of occupational therapy for clients with arthritis.
8. Design an appropriate individualized intervention plan based on diagnosis, stage of disease, limitations in functional activity, and client goals and lifestyle.
9. Identify key resources helpful to persons with arthritis and to health care providers.
10. Identify evaluation and treatment precautions related to arthritis.

Threaded Case Study | Nina, Part 1

Nina is a 52-year-old woman with a 4-year history of rheumatoid arthritis. She lives with her husband in a large two-story home. Her primary roles are managing her household and caring for her two grandchildren (ages 7 and 9) after school. Additionally, she is self-employed as an accountant who contracts her services to three small companies in nearby cities. Nina values being active and productive. Her part-time job serves as both a source of enjoyment and needed household income. In her leisure time, she participates in church activities and attends her grandchildren's school and sporting events.

Nina was referred to outpatient occupational therapy after an exacerbation of her arthritis that resulted in increased pain, fatigue, and difficulty engaging in many important daily occupations. On initial evaluation, Nina identifies her primary concerns as maximizing her functional level and reducing her pain so that she can resume full participation in work, house cleaning, and child care. Clinical examination reveals pain and limitations in active range of motion in all upper extremity joints, especially her wrists and fingers. Mild synovitis is

present at her wrist and metacarpophalangeal joints, but no other joint changes are noted. Pain and stiffness are interfering with daytime activities and are also making sleep difficult. Her energy level is significantly decreased, and she reports feeling tired all the time. Although she still manages to watch her grandchildren for 2 hours each afternoon, she is unable to care for her house to her liking and is able to work only half of her usual 20 hours a week; she is fearful of losing her contracts.

Critical Thinking Questions

1. What components of evaluation would you choose to assess regarding Nina's prior and current clinical and functional status?
2. Which aspects of the disease process are most problematic, and what are the major performance skills, performance patterns, contexts, activity demands, and client factors influencing Nina's ability to engage in her employment and other areas of occupation?
3. What interventions would you use to help Nina reach her goal of being able to continue working?

Overview of Rheumatic Diseases

The term *arthritis* is of Greek derivation and literally means “joint inflammation.” It is used to describe many different conditions that fall under the larger umbrella of rheumatic diseases. Rheumatic diseases encompass more than 100 conditions characterized by chronic pain and progressive physical impairment of joints and soft tissues (e.g., skin, muscles, ligaments, tendons). These conditions include osteoarthritis (OA), rheumatoid arthritis (RA), systemic lupus erythematosus, ankylosing spondylitis, scleroderma, gout, and fibromyalgia. One in every five adults in the United States has signs and symptoms of arthritis, and these have been reported to be the main reason that adults older than 65 years visit a physician.²¹ Arthritis is a major public health problem that costs the U.S. economy nearly \$128

billion in medical care and indirect expenses annually.²² Rheumatic diseases are a leading cause of disability with significant economic, social, and psychologic impact.⁴ Between 2003 and 2005, approximately 46 million Americans were affected by arthritis and other rheumatic conditions, with an estimated 19 million experiencing limitations in their ability to participate in daily activities and 8 million limited in their ability to work.^{21,101} As the population continues to age, the prevalence of arthritis-related conditions is expected to increase to an estimated 67 million by the year 2030, with disability occurring in 25 million people.⁴⁸

Occupational therapists are likely to encounter clients with rheumatic diseases in their practice settings, whether the condition is manifested as a primary or secondary type. To recognize problem areas and plan effective intervention strategies, the occupational therapist should know the

TABLE 38-1 Primary Features of Osteoarthritis and Rheumatoid Arthritis

	Osteoarthritis	Rheumatoid Arthritis
Prevalence	Affects 27 million Americans	Affects 1.3 million Americans
Peak incidence	Increases with age, <50 years old more common in males and >50 years old more common in females	Ages 40-60, 3:1 female-to-male ratio
Onset	Usually develops slowly, over period of years	Usually develops suddenly, within weeks or months
Systemic features	None	Fever, fatigue, malaise, extra-articular manifestations
Disease process	Noninflammatory, characterized by cartilage destruction	Inflammatory, characterized by synovitis
Joint involvement	Individual	Polyarticular, symmetric
Joints commonly affected	Neck, spine, hips, knees, MTPs, DIPs, PIPs, thumb CMCs	Neck, jaw, hips, knees, ankles, MTPs, shoulders, elbows, wrists, PIPs, MCPs, thumb joints
Morning stiffness	<30 minutes	At least 1 hour, often >2 hours

CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

unique features of each disease, its underlying pathology, and its typical clinical findings; the therapist should also be familiar with commonly prescribed medications and their adverse reactions. Given the scope and intended purpose of this book, it is neither appropriate nor possible to adequately describe every rheumatic disease. Therefore, this chapter focuses on two of the most prevalent diseases: OA and RA. Armed with an understanding of the noninflammatory and inflammatory disease processes that they represent, the therapist can apply many of the evaluation and intervention principles to other rheumatic conditions. Table 38-1 provides a quick summary of the contrasting features of OA and RA.^{4,5,10,29,46,54,94,96,97}

Osteoarthritis

OA, also referred to as degenerative joint disease, is the most common rheumatic disease and affects approximately 27 million people in the United States.^{4,46,54} It ranks third among health problems in the developed world.^{15,52} Its prevalence strongly correlates with age. In fact, evidence of characteristic cartilage damage is almost universal in persons older than 65 years.¹⁵ Before the age of 50, men are more likely to have OA; past the age of 50, women predominate.¹⁰ In addition to age and gender, risk factors include heredity, obesity, anatomic joint abnormality, injury, and occupation leading to overuse of joints.¹⁰ It is interesting to note that because RA may cause malalignment or instability of joints, it often results in premature OA.²³

OA is classified as primary or secondary. Primary OA has no known cause and may be localized (i.e., involvement of one or two joints) or generalized (i.e., diffuse involvement generally including three or more joints). Secondary OA

can be related to an identifiable cause, such as trauma, anatomic abnormalities, infection, or aseptic necrosis.^{13,29}

OA is a disease that causes the cartilage in joints to break down with resultant joint pain and stiffness. Unlike RA, which is systemic (affecting the entire body), OA limits its attack to individual joints. Also in contrast to RA, the basic process of OA is noninflammatory, although secondary inflammation caused by joint damage is quite common. Once considered simply “wear and tear” arthritis, OA is now thought to involve more than just the passive deterioration of cartilage. The agent that initiates OA is not well understood, but it is known to involve a complex dynamic process of biomechanical, biochemical, and cellular events.⁵⁴ These are affected by local, systemic, genetic, environmental, and mechanical factors, which directly or indirectly influence the vulnerability of cartilage.¹⁰ It is, in essence, the “final common pathway” for a variety of conditions.¹⁵

A healthy joint is lined by articular cartilage that is relatively thin, highly durable, and designed to distribute loads and limit stress on subchondral bone (Figure 38-1).¹⁵ OA destabilizes the normal balance of degradation and synthesis of articular cartilage and subchondral bone and involves all of the tissues of a diarthrodial (i.e., synovial-lined) joint.^{10,15} OA is basically a two-part process: deterioration of articular cartilage and reactive new bone formation.⁶⁵ This breakdown of joint tissue occurs in several stages. First, the smooth cartilage softens and loses its elasticity, which makes it more susceptible to further damage. Eventually, large sections of the cartilage wear away completely and result in reduced joint space and painful bone-on-bone contact. The ends of the bone thicken, osteophytes (bony growths) are formed where ligaments and capsule attach to bone, and the joint may lose its normal shape (Figure 38-2).

Fluid-filled cysts may form in the bone near the joint, and bone or cartilage particles may float loose in the joint space.^{4,64}

Clinical Features

OA is characterized by joint pain, stiffness, tenderness, limited movement, variable degrees of local inflammation, and crepitus (an audible or palpable crunching or popping

in the joint caused by the irregularity of opposing cartilage surfaces).⁴⁷ It can affect both axial and peripheral joints. The most common joints are the distal interphalangeal (DIP), proximal interphalangeal (PIP), and first carpometacarpal (CMC) joints of the hand; the cervical and lumbar apophyseal joints; the first metatarsophalangeal (MTP) joints of the feet; and the knee and hip joints.^{4,29,54} Symptoms are usually gradual and may begin as a minor ache with motion. Pain and stiffness typically occur with activity and are relieved by rest, but eventually they become present at rest and at night. Morning stiffness (lasting less than 30 minutes) and stiffness after periods of inactivity (known as gelling) may develop. With advanced disease, patients may complain of the “bony” appearance of their joint, which is a result of osteophyte formation and possibly muscle atrophy.^{29,54}

Diagnostic Criteria

The diagnosis of OA is initially made on the basis of the patient’s history and physical examination, with a lack of systemic symptoms ruling out inflammatory disorders such as RA. The cardinal symptoms are use-related pain and stiffness or gelling after inactivity. The clinical diagnosis is typically confirmed with radiographs of the affected joint, which will show osteophyte formation at the joint margin, asymmetric joint space narrowing, and subchondral bone sclerosis.²⁹ Magnetic resonance imaging (MRI) may be used to improve diagnostic imaging; MRI is able to more sensitively detect loss of cartilage, osteophytes, and subchondral cysts. The American College of Rheumatology classification criteria for osteoarthritis of the hand are listed in [Box 38-1](#).

Medical Management

OA currently has no cure. Goals in the treatment of OA are to relieve symptoms, improve function, limit disability, and avoid drug toxicity.^{54,81} Pharmacologic treatment may be

systemic or local. Commonly prescribed systemic medications include analgesic agents and anti-inflammatory agents (Table 38-2).³ Analgesic agents provide relief to painful joints and may be non-narcotic or narcotic for advanced and severe OA that fails to respond to other measures. Anti-inflammatory agents provide pain relief, with the added benefit of decreasing local joint inflammation. Because of the risk for gastrointestinal and renal toxicity, these drugs are typically used when analgesics are ineffective. Nonsteroidal anti-inflammatory drugs (NSAIDs) and cyclooxygenase-2 (COX-2) inhibitors fall into this category. Though proved effective in treating OA, NSAIDs must be chosen and monitored carefully to minimize potentially serious side effects. COX-2 inhibitors are thought to provide clinical benefits similar to NSAIDs but with a lower incidence of gastric problems; however, more experience by prescribing physicians and longer-term use will help better define their role. The withdrawal of two popular COX-2 inhibitor drugs from the market (Vioxx in 2004 and Bextra in 2005) because of links with an increased risk for heart attack and stroke points to the need for further study. The remaining COX-2 inhibitor (Celebrex) now carries a black box warning.³ Local pharmacologic treatment of OA includes topical agents and intra-articular corticosteroid injections, alone or as an adjunct to systemic medications. Among topical agents are aspirin and capsaicin creams, as well as the first topical NSAID approved for treating OA pain (Voltaren gel).³ Cortisone injections in a joint are often limited to fewer than three per year because of the possible risk for progressive cartilage damage.¹⁹

Use of nonpharmacologic agents, also known as nutraceuticals, is extremely common in persons with OA as alternative or complementary treatments and seems to be gaining favor in the general public.^{51,54,74,81} These agents

include nutritional supplements such as glucosamine sulfate and chondroitin sulfate. Although they may have some effect in improving symptoms or slowing the progression of OA, studies citing their efficacy have not yet been of optimal quality.⁵⁴ However, even if their benefits have not been proved convincingly, use of nutraceuticals typically carries little risk. Even so, patients should be aware that supplements are not regulated like prescription medications. Use of complementary and alternative treatments should be discussed with one's physician to minimize potential negative effects.⁵¹

Surgical Management

Operative intervention may be performed to slow joint deterioration, improve joint integrity, restore joint stability, or reduce pain, with the overarching goal of improving the patient's overall function. Common surgical procedures for OA include arthroscopic joint débridement, resection or perforation of subchondral bone to stimulate the formation of cartilaginous tissue, use of grafts to replace damaged cartilage, joint fusion, and joint replacement.^{19,54}

Rheumatoid Arthritis

RA is a chronic, systemic inflammatory condition that affects approximately 1.3 million Americans.^{5,46} The etiology of RA is not well understood, other than that a yet-unknown trigger causes an autoimmune inflammatory response in the joint lining of a genetically predisposed host.^{96,97} Onset can take place at any age, but prevalence does increase with age. The peak incidence occurs between 40 and 60 years of age, with the rate of disease two to three times higher in females.^{5,94,97} Its onset is commonly insidious, with symptoms developing over a period of several weeks to several months.

The disease manifests itself as synovitis, which is inflammation of the synovial membrane that lines the joint capsule of diarthrodial joints. The function of normal synovial tissue is to secrete a clear fluid into the joint for the purpose of lubrication.^{2,23} In RA, synovial cells produce matrix-degrading enzymes that destroy cartilage and bone. Joint swelling results from excessive production of synovial fluid, enlargement of the synovium, and thickening of the joint capsule. This weakens the joint capsule and distends tendons and ligaments. As the inflammatory process continues, the diseased synovial membrane forms a pannus that actively invades and destroys cartilage, bone, tendon, and ligament (Figure 38-3). Scar tissue can form between the bone ends and cause the joint to become permanently rigid and immovable.

Articular manifestations of RA fall into two categories: (1) reversible signs and symptoms related to acute inflammatory synovitis and (2) irreversible cumulative structural damage caused by recurrent synovitis over the course of the disease. Structural damage typically begins between the first and second years of the disease and progresses as a linear

■ **TABLE 38-2** | Common Arthritis Medications and Side Effects

Class	Medication	Possible Side Effects
Analgesics		
Non-narcotic	Excedrin, Tylenol	Usually none if taken as prescribed
Narcotic	Darvon, Tylenol with codeine, Vicodin	Dizziness or lightheadedness, drowsiness, nausea, vomiting, drug tolerance, and physical dependence with long-term use
Nonsteroidal Anti-inflammatory Drugs (NSAIDs)		
Traditional	Advil, Aleve, Motrin, Naprosyn	Abdominal pain, dizziness, drowsiness, gastric ulcers and bleeding, greater susceptibility to bruising or bleeding, heartburn, indigestion, lightheadedness, nausea, tinnitus, kidney and liver effects
COX-2 inhibitors	Celebrex	Same as traditional NSAIDs, except less likely to cause gastric ulcers and susceptibility to bruising or bleeding; increased risk for heart attack and stroke
Salicylates	Anacin, Bayer, Bufferin	Abdominal cramps, gastric ulcers, increased bleeding tendency, confusion, dizziness, tinnitus, nausea, vomiting, deafness
Corticosteroids		
	Cortisone, methylprednisolone, prednisone	Cushing's syndrome (weight gain, moon face, thin skin, muscle weakness, osteoporosis), cataracts, hypertension, elevated blood sugar, insomnia, mood changes, nervousness or restlessness
Disease-Modifying Antirheumatic Drugs (DMARDs)		
	Gold salts	Sun sensitivity, blood and kidney effects
	Imuran	Immunosuppression
	Methotrexate	Liver and blood effects, decreased fertility
	Penicillamine	Blood and kidney effects
	Plaquenil	Visual damage with long-term use
Biological Response Modifiers (Subset of DMARDs)		
	Enbrel	Headache, injection site irritation
	Humira	Injection site irritation, upper respiratory infection
	Remicade	Infusion reaction, injection site irritation, upper respiratory infection

COX, cyclooxygenase.

function of the amount of prior synovitis.^{35,94} Almost 90% of joints ultimately affected by RA become involved during the first year.^{77,94} Progressive joint damage in the majority of patients results in significant disability within 10 to 20 years.⁹⁶

The course of RA is variable from person to person. Approximately 20% of those affected have a single episode of inflammation with a long-lasting remission. The majority of people with RA experience a series of exacerbations and remissions, with periodic flare-ups of inflammation followed by complete or incomplete remissions.⁶³ Outcomes are similarly variable. Patients' functional abilities vary according to the course of the disease, the severity of the symptoms, and the amount of joint damage. Because RA is

a systemic disease, certain extra-articular features occur in about half of patients.^{94,97} These features include fatigue, rheumatoid nodules, and vasculitis. Ocular, respiratory, cardiac, gastrointestinal, renal, and neurologic manifestations are also seen as secondary complications. Patients with severe forms of RA may die between 10 and 15 years earlier than expected as a result of accompanying infection, pulmonary and renal disease, gastrointestinal bleeding, and especially cardiovascular disease.⁷⁰

Clinical Features

RA is characterized by symmetric polyarticular pain and swelling, prolonged morning stiffness, malaise, fatigue, and low-grade fever. Joints most commonly affected are the PIP,

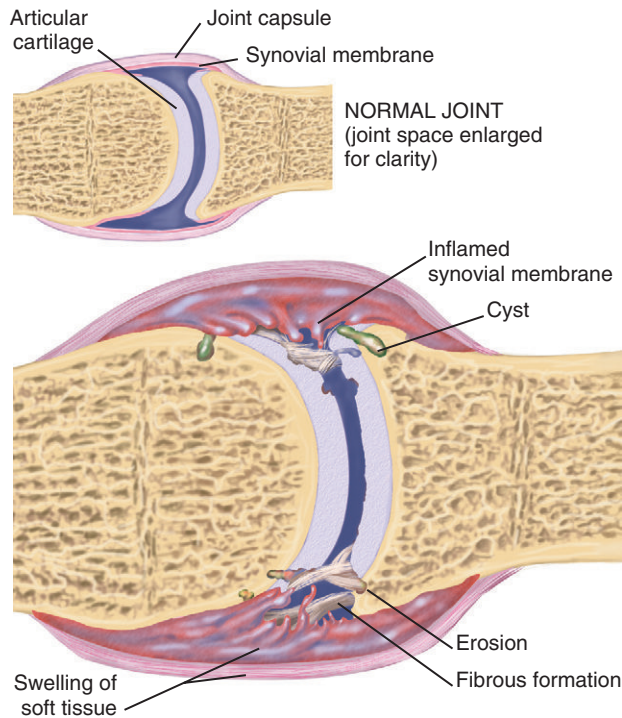

FIGURE 38-3 Joint changes in patients with rheumatoid arthritis. (From Jarvis C: *Physical examination and health assessment*, ed 5, Philadelphia, 2008, Saunders.)

metacarpophalangeal (MCP), and thumb joints of the hands, as well as the wrist, elbow, ankle, MTP, and temporomandibular joints; the hips, knees, shoulders, and cervical spine are also frequently involved.^{94,96} Even though joint involvement is bilateral, disease progression may not be equal on both sides. For instance, a patient's dominant hand may show more severe involvement and different joint changes or deformities than the other hand. Clinical features vary from patient to patient and also in individual patients over the course of their disease. Pain can be acute or chronic. Acute pain occurs during disease exacerbations, or flare-ups. Chronic pain results from progressive joint damage. Synovial inflammation is manifested as warm, spongy, and sometimes erythematous, or red, joints. This is seen in active phases of the disease process. Rheumatoid nodules, a cutaneous manifestation of RA, develop in 25% to 30% of persons with RA during periods of increased disease activity. These soft tissue masses are commonly found over the extensor surface of the proximal end of the ulna or at the olecranon.^{94,96} Morning stiffness is an almost universal feature of RA. Unlike the shorter-duration stiffness seen with OA, RA morning stiffness can last 1 or 2 hours. It frequently disappears during periods of disease remission. The duration of morning stiffness tends to correlate with the degree of synovial inflammation, and its presence and length are useful measures for monitoring

the course of RA.⁷⁰ Feelings of malaise, fatigue, and depression also fluctuate, with many patients experiencing worse symptoms in the afternoon. These nonspecific symptoms may precede other typical signs of RA by weeks or months.⁹⁴

The inflammatory process has been described as having four stages: acute, subacute, chronic active, and chronic inactive.⁶⁴ Stages may overlap, and patients may move back or forward through them, depending on the course of their disease. Clinical symptoms seen in the acute stage include limited movement; pain and tenderness at rest that increase with movement; overall stiffness, weakness, tingling, or numbness; and hot, red joints. In the subacute stage, the limited movement and tingling remain. A decrease in pain and tenderness indicates that the inflammation is subsiding. Stiffness is limited to the morning, and the joints appear pink and warm. The chronic active stage is characterized by less tingling, pain, and tenderness and increased tolerance of activity, although endurance remains low. No signs of inflammation are present in the chronic inactive stage. The patient's low endurance and pain and stiffness at this stage result from disuse. Overall functioning may be decreased as a result of fear of pain, limited range of motion (ROM), muscle atrophy, and contractures.⁶⁴

The characteristic joint deformities will develop as late manifestations of the disease in more than 33% of patients with RA. Deformity of the small joints of the hand will develop within the first 2 years in more than 10%.⁹⁶ Wrist radial deviation, MP ulnar deviation, and swan neck and boutonnière deformities of the digits are the joint changes most often seen. Joint changes, or deformities, can result from a variety of mechanisms, including joint immobility, destruction of cartilage and bone, and alterations in muscles, tendons, and ligaments.⁹⁷ Tenosynovitis (inflammation of the tendon sheath) and the presence of nodules within the flexor tendon sheaths can cause trigger finger. Patients may also exhibit symptoms of nerve compression of the median or ulnar nerves at the wrist. Tendon rupture may also be seen, usually in the extensor tendons of the fifth, fourth, and third digits. Stages of the disease based on joint deformity and radiographic changes are defined in [Box 38-2](#).

Diagnostic Criteria

No single test leads to a definitive diagnosis of RA. Diagnosis is based on clinical evaluation of characteristic signs and symptoms, laboratory findings, and radiologic findings.^{70,94,96} The American College of Rheumatology criteria for the classification of RA require that the patient demonstrate at least four of seven criteria for a diagnosis of RA to be made ([Table 38-3](#)). A positive laboratory test is not necessary to establish a diagnosis of RA, but such tests may help confirm the clinical impression. Rheumatoid factor is an antibody found in the blood serum of approximately 85% of persons with RA, but it can also be found in other inflammatory diseases associated with synovitis. The

Box 38-2

American College of Rheumatology Classification of Progression of Rheumatoid Arthritis

Stage I: Early

No destructive changes on roentgenographic examination*
Possible presence of radiographic evidence of osteoporosis

Stage II: Moderate

Radiographic evidence of osteoporosis, with or without slight subchondral bone destruction; possible presence of slight cartilage destruction*
No joint deformities, although possible limitation of joint mobility*
Adjacent muscle atrophy
Possible presence of extra-articular soft tissue lesions, such as nodules and tenosynovitis

Stage III: Severe

Radiographic evidence of cartilage and bone destruction, in addition to osteoporosis*
Joint deformity, such as subluxation, ulnar deviation, or hyperextension, without fibrous or bony ankylosis*
Extensive muscle atrophy
Possible presence of extra-articular soft tissue lesions, such as nodules and tenosynovitis

Stage IV: Terminal

Fibrous or bony ankylosis*
Criteria for stage III

*These criteria must be present to permit classification in any particular stage or grade.

Data from Steinbrocker O, Traeger CH, Batterman RC: Therapeutic criteria in rheumatoid arthritis, *JAMA* 140:659, 1949.

presence of rheumatoid factor correlates with increased severity of symptoms and increased systemic manifestations. The erythrocyte sedimentation rate correlates with the degree of synovial inflammation and is useful in ruling out noninflammatory conditions such as OA and tracking the course of inflammatory activity.^{94,96} Radiographs may show nothing other than soft tissue swelling early in RA, but in more than half of patients, radiographic changes will develop within the first 2 years after onset of the disease.^{70,94,96}

Medical Management

RA currently has no known cure. The major goals in the treatment of RA include (1) reducing pain, swelling, and fatigue; (2) improving joint function and minimizing joint damage and deformity; (3) preventing disability and disease-related morbidity; and (4) maintaining physical, social, and emotional function while minimizing long-term toxicity from medications.^{70,96} Maintaining normal joint anatomy can be accomplished only by controlling the disease before irreversible damage occurs. Major advances in the treatment of RA have occurred over the past several years as a result

of improved understanding of the pathogenetic mechanisms of the disease, development of therapies that more specifically target the pathophysiologic processes, and recognition that early initiation of aggressive drug therapies can alter the outcome and reduce the severity and disability of RA.^{70,96}

Drug categories used for RA include NSAIDs, corticosteroids, and disease-modifying antirheumatic drugs (DMARDs; see Table 38-2).³ Because the fast-acting NSAIDs can decrease joint pain and swelling but cannot alter progression of the disease, they are rarely, if ever, used alone for the treatment of RA. The anti-inflammatory effects of the large number of medications in this category are about equal. COX-2 inhibitors show no evidence of greater efficacy than other NSAIDs but are thought to pose a lower risk for serious gastrointestinal side effects.⁹⁴ Corticosteroids have a long history in the medical management of RA and still remain a key element. They produce rapid and potent suppression of inflammation with improvement in joint pain and fatigue. Because of the significant adverse effects of corticosteroids, they are frequently used on a temporary basis in patients with active disease and significant functional decline while awaiting the full therapeutic effect of DMARDs. DMARDs lack a pain relief effect, but they may actually affect the course of the disease. Because of their slow-acting nature, weeks or months of drug therapy may be necessary before a clinical benefit is recognized. The potency of these drugs requires that patients be closely monitored for side effects.

Traditionally, the approach to treatment of RA began with less toxic medications such as NSAIDs and progressed to the stronger drugs needed later in the disease course. The approach is now more aggressive, with early use of DMARDs to control the disease process as soon as possible, as completely as possible, and for as long as possible.^{70,103} Drug therapy constantly changes, depending on the patient's needs and response to treatment, as well as the physician's treatment philosophy. This uncertainty can be frustrating for the patient, who may have to experiment with myriad new medications when current drugs become ineffective or side effects too severe. It is important for the occupational therapist and other team members to know the specific medications that the patient is taking and what adverse reactions may arise.

Surgical Management

Because of the extensive joint damage caused by RA, surgical intervention is frequently indicated to relieve pain and improve function. Several surgical procedures may be of benefit to patients with RA. Synovectomy (excision of diseased synovium) and tenosynovectomy (removal of diseased tendon sheaths) are performed to relieve symptoms and slow the process of joint destruction, but they do not prevent progression of the disease. These procedures are most commonly performed in the wrist and hand. Tendon surgery, including relocation of displaced tendons, repair of

■ **TABLE 38-3** | American College of Rheumatology Criteria for Classification of Rheumatoid Arthritis

Criterion	Definition
Morning stiffness	Morning stiffness occurs in and around the joints and lasts at least 1 hour before maximal improvement
Arthritis of three or more joint areas	At least three joint areas simultaneously have had soft tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints.
Arthritis of hand joints	At least one area is swollen (as defined above) in a wrist, MCP, or PIP joint
Symmetric arthritis	Simultaneous involvement of the same joint areas (as defined in the second example) occurs on both sides of the body (bilateral involvement of PIPs, MCPs, or MTPs is acceptable without absolute symmetry)
Rheumatoid nodules	Subcutaneous nodules over bony prominences or extensor surfaces or in juxta-articular regions are observed by a physician
Serum rheumatoid factor	Abnormal amounts of serum rheumatoid factor are demonstrated by any method for which the result has been positive in <5% of normal control subjects
Radiographic changes	Radiographic changes are typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs and must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritic changes alone do not qualify)

For classification purposes, a client shall be said to have rheumatoid arthritis if he or she has satisfied at least four of these criteria. The first four criteria must have been present for at least 6 weeks. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is not to be made.

MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

From Arnett FC, Edworthy SM, Bloch DA, et al: The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis, *Arthritis Rheum* 31:315, 1988.

ruptured tendons, and release of shortened tendons, may be performed to correct hand impairments. Tendon surgery occurs most frequently on the extensor tendons of the wrist and hand. Tendon transfers and peripheral nerve decompression (such as carpal tunnel release) are also performed to optimize function. Arthroplasty (joint reconstruction) and arthrodesis (joint fusion) are options when joint restoration is not possible. These procedures may be performed to relieve pain, provide stability, correct deformity, and improve function. Common sites for arthroplasty include the hip, knee, and MCP joints. Common sites for arthrodesis include the wrist, thumb MCP and interphalangeal (IP) joints, and cervical spine.^{19,64}

Occupational Therapy Evaluation

It is important to recognize that every client with arthritis has a unique manifestation of clinical problems and functional impairment. A strong client-centered and occupation-based approach is helpful in determining each client's specific needs. The evaluation process for clients with arthritis includes many of the same elements as for any physical disability. Special considerations related to arthritis include closer attention to pain, joint stiffness, joint changes/deformity, fatigue, and coping strategies, especially as they

relate to limitations in activity. Because clients with arthritis typically experience good days and bad days, many symptoms and problems are unpredictable. Thorough systematic assessment of the client's functional, clinical, and psychosocial status is key to prioritizing problems and planning effective intervention.

The extent of specific components of the evaluation will often be driven by the main reason for referral. Clients seen for preoperative hand assessment, postoperative hip replacement, education after diagnosis, splinting while in a flare-up, or a decline in functional status will all require the therapist to customize evaluation priorities.

Because of the chronic nature of rheumatic diseases, some clients are able to clearly state their specific needs and should be afforded the opportunity to do so. Other clients may be overwhelmed by multiple problems or a newly made diagnosis and will look to the therapist to guide the intervention process. Regardless of the client's status, close collaboration and partnership among the client, family, therapist, and other team members is crucial in helping deliver the best treatment possible.

The occupational therapy (OT) evaluation process consists of (1) a client history; (2) occupational profile; (3) occupational performance status; (4) cognitive, psychologic, and social status; and (5) clinical status.

Client History

A thorough history should be obtained through review of the client's report and medical record. Important details include diagnosis, dates of onset and diagnosis, secondary medical conditions, current medications and medication schedule, alternative or complementary therapies, and surgical history.⁸⁵ Asking the client questions such as "What type of arthritis do you have?," "How long have you had it?," "What medications are you currently taking?," and "What other things are you doing to manage your arthritis?" can provide helpful insight regarding the client's level of understanding about his or her condition, medical treatment, and health habits. Previous experiences with OT and physical therapy should also be ascertained to build on them. The therapist must ask and actively listen to the client's current primary complaints through questions such as "What is bothering you most about your arthritis?," "How is your arthritis limiting your ability to do things right now?," and "What are you hoping therapy can help you with?"

This was Nina's first referral to OT. She was knowledgeable about her diagnosis and medications but uncertain about the potential benefits of therapy. Through her responses to key questions, Nina was able to clearly state that her pain and difficulty performing household and work activities were her main priorities.

Occupational Profile

It is helpful to begin the process of assessing occupational performance with an occupational profile. Obtained through an open-ended interview, the profile yields important details about the client's previous and current roles, occupations, overall activity level, and ability to participate in meaningful activities. It can also provide insight into the client's sense of self-efficacy, adjustment to disability, and themes of meaning in his or her life.^{55,62} An effective method to obtain a client's occupational profile is to have the client describe how he or she spends a typical day. This typical-day assessment allows the therapist to become familiar with the client's routines, use of time, sleep/wake habits, energy and fatigue patterns, important people and environments, activity contexts, and other details that may not otherwise come up in conversation. Because arthritis involves fluctuant symptoms, the client should be asked to describe how time is spent on a good day and a bad day so that the therapist can compare the two and understand how arthritis affects the client's daily life and how effectively the client is able to balance activity and rest. It is helpful to ask the client to estimate the percentage of good versus bad days per week or month. It may also be advantageous to explore time spent on weekend days versus weekdays; the client may reveal other occupations, such as those involving spirituality, social participation, and leisure. This fluid dialog also serves to develop rapport, establish the client as the valued expert in his or her occupations and lifestyle, and frame the role of OT in the client's rehabilitation.

Occupational Performance Status

Once the client's typical and preferred occupations are identified, his or her level of independence engaging in these functional activities can be assessed by interview or by observation. If observation is used, the activity should occur as close as possible to the time that it is normally performed because the client's abilities may fluctuate at different times of the day. For instance, stiffness and pain may make dressing very difficult in the early morning, but if this task is assessed in the afternoon, the client's status may appear much better. Ideally, the activity should also be done in the client's own home, community, or work contexts.⁷ In addition to assessing the client's level of independence during activities of daily living (ADLs), instrumental activities of daily living (IADLs), school, work, sleep and rest, play, leisure, and social engagements, it is important to note any assistive devices (e.g., mobility aids or adaptive equipment) and compensatory techniques that the client may use. The activity demands of the occupation performed (e.g., tools, equipment, and skills required), as well as the specific contexts in which it is performed (e.g., the client's living situation, others in the home, and architectural set-up relative to occupational performance), should be detailed in tandem with existing physical, environmental, or social barriers. Finally, the amount of time required to complete certain activities should be explored. A client who experiences significant morning stiffness or limited endurance often chooses to accept assistance in an activity such as dressing to save time or conserve energy to participate in a more meaningful occupation later in the day. This strategy may contribute to the client's overall satisfaction with and participation in life, and it should be respected as such.

In RA, functional status may be classified according to the American College of Rheumatology's revised criteria for the classification of functional status in clients with RA (Table 38-4). This system was devised for rapid, global assessment of functional status by health professionals.⁴⁷ The therapist should be familiar with this system because it is often used in clinical research and can provide a general framework for defining advancing disability.^{43,106} Nina would be considered class III because of limitations in her work activities.

A decrease in occupational functioning in clients with arthritis may be due to pain, joint changes or instability, loss of motion, weakness, fatigue, change in the living environment, or change in social support, among other contributing circumstances. The effects of medication can also limit performance. The challenge for the therapist is not only to identify deficits in occupational performance but also to determine the factors that are causing them. Asking the client why an activity cannot be done yields the important client perspective.⁷ Nina was having difficulty with many occupations, including sleeping, playing actively with her grandchildren, managing her home, and performing her job to her level of satisfaction. She reported having to give

TABLE 38-4 | American College of Rheumatology Classification of Global Functional Status in Patients with Rheumatoid Arthritis

Classification	Description
Class I	Completely able to perform usual activities of daily living (self-care,* vocational, and avocational)
Class II	Able to perform usual self-care and vocational activities, but limited in avocational activities
Class III	Able to perform usual self-care activities, but limited in vocational and avocational activities
Class IV	Limited in ability to perform usual self-care, vocational, and avocational activities

*Usual self-care activities include dressing, feeding, bathing, grooming, and toileting. Avocational (recreational or leisure) and vocational (work, school, homemaking) activities are client desired and age and sex specific.
 Courtesy American College of Rheumatology ©2004.

up or cut back on activities because of increased pain, stiffness, and fatigue from her recent flare-up.

Cognitive, Psychologic, and Social Status

The effects of arthritis are not merely physical and functional. Clients with arthritis should be screened for cognitive and psychosocial deficits. Although arthritis does not directly affect cognition, pain, sleep disturbances, depression, and medication can all have profound effects on attention span, short-term memory, and problem-solving skills.⁶⁴ People with a chronic illness must develop coping strategies to deal with the disability. Coping strategies are particularly crucial for persons with arthritis, who may face serious changes in physical function, life roles, and appearance because of deformity and pharmacologic side effects. Because arthritis is both unpredictable and painful, normal responses to the disability include depression, denial, need to control the environment, and dependence. Psychosocial adaptation is affected by the complex interplay of physical, psychologic, and situational factors.^{55,72} Approximately 20% of persons with RA are estimated to suffer from major depression.²⁸ About half of individuals with RA or OA may experience loss of social relationships.¹⁰⁵ Constant pain and fear of pain, changed body image, perception of self as a sick person, continuous uncertainty about the course and progression of the disease, sexual dysfunction, altered roles, and loss of income resulting from inability to work can lead to significant psychologic stress.^{55,72} Evidence has shown that the disability associated with RA relates to psychosocial factors almost to the same extent as to biomedical factors.³² Occupational therapists must understand the ways in which

their clients manage stress in their lives because these stressors may exacerbate the disease.⁵⁵ Family relationships and cultural backgrounds also affect the client's health care behavior and response to disability.⁷⁶ The therapist should be sensitive to all factors that will influence rehabilitation. Referral to other health professionals (such as psychiatrists, psychologists, and social workers) should be made if needed.⁷²

Nina reported that she had increasing difficulty concentrating on tasks because she was unable to get adequate restful sleep. She expressed frustration about her inability to keep her house in order and anxiety about losing income because she was unable to work her customary hours. She was also fearful about her health because her arthritis had been adequately controlled for the past few years and she had not experienced any flares.

Clinical Status

For clients with arthritis, the elements of inflammation, ROM, strength, hand function, stiffness, pain, sensation, joint instability and deformity, physical endurance, and functional mobility should be included through either brief screening or detailed evaluation. As with assessment of function, the time of day and anti-inflammatory or analgesic medications taken should be noted because these factors may influence the results. In addition, future re-evaluations should be performed under the same conditions.⁶⁴ When the client's functional deficits are identified first, assessment of client factors can be much more focused. Additionally, asking the client a question such as "What joints are you having the most problems with?" can help prioritize assessment needs. Given Nina's initial findings, the detailed evaluation focused primarily on synovitis, pain, stiffness, ROM, strength, physical endurance, and functional mobility. Even though joint deformities were not immediately evident, the therapist was careful to search for signs of instability that would place Nina's joints at risk for deformity.

The clinical evaluation may take considerable time. It should be approached in a systematic manner with the results clearly documented. The occupational therapist may need to perform assessments over several sessions, especially if the client is experiencing significant pain or fatigue. Intervention can begin immediately and does not necessarily depend on completion of the evaluation. The evaluation actually begins with a general observation of the client's posture, willingness to move, and pain behavior during the initial interview.

The presence and location of inflammation or synovitis should be noted because these signs indicate an active disease process. Several types of swelling may be present and should be described. An effusion (excess fluid in the joint capsule) is seen as fusiform swelling that is spindle shaped and conforms to the shape of the joint. Boggy swelling is thin and full of fluid. Puffy, spongy, and soft to the touch, boggy swelling is seen in the early active stages of synovitis.

Chronic synovitis feels firm because the joint fills with synovial tissue.⁶⁴

Active and passive ROM can be measured. Depending on the reason for referral and the client's complaints, the therapist may not find it necessary to obtain goniometric measurements of all joints but instead focus only on the joints of most concern. Active motion will allow the therapist to see the amount of mobility that the client has available for function, whereas passive motion will elicit the joint's capacity to move. The client's range of active motion may be significantly less than the range of passive motion; this is known as lag and is caused by pain, weakness, or the mechanical inefficiencies attributable to joint damage. Goniometric measurement of hand joints may be difficult in the presence of deformity. Assessment of composite (combined motion of all joints) flexion, composite extension, and thumb opposition can provide more functional information.¹¹ Active opening and closing of the hand can be measured by the distance from the fingertips to the tabletop in maximal extension (opening) when the dorsal side of the hand is resting on the table and by the distance from the fingertips to the distal palmar crease (closing). While performing the ROM assessment, the therapist should note whether the client's joints feel stiff or unstable. A hard end-feel in the presence of contracture indicates bony blockage.⁶⁵ A firm end-feel that still has some give indicates that the joint capsule or ligaments are limiting motion.⁴⁵ The presence and location of crepitus, along with the motions that cause it, should also be noted because crepitus often indicates extensive joint damage. The source of crepitation may be bony, synovial, bursal, or tendinous (see [Chapters 20 through 22](#) for additional information).^{11,64}

Gross strength should be assessed with more specific manual muscle testing as indicated. One important detail to understand is that strength testing in clients with arthritis differs from normal testing procedures. Resistance is applied at the end range of pain-free motion rather than at the true end of the ROM. It is not unusual for clients with arthritis to have pain in the last 30 to 40 degrees of joint motion. When resistance is applied within the pain-free range, inhibition of muscle strength by pain will be avoided. It is also important to consider joint protection principles when applying resistance and to discontinue resistance if the client experiences pain. If use of resistance is contraindicated (as may be the case in an acute or active phase of arthritis, in which resistance may be harmful to inflamed tissue and joints), functional muscle or motion testing may be substituted.⁶⁴

Hand strength and function are important to test, but care must be taken to not stress painful or vulnerable joints during assessment. Grip and pinch may be measured by standard meters, but in the presence of severe weakness or hand deformity, adapted methods, such as use of a blood pressure cuff to measure force in millimeters of mercury, may be indicated.^{11,64} Although it is more comfortable for

the client, the results of strength testing in this manner are less reliable, with no established norms. Other specific devices for measuring grip strength in hands with arthritis, including pneumatic bulb dynamometers, are commercially available. As a result of joint deformity, the client may not be able to assume the standard testing positions for lateral and palmar pinch. Because it is important to assess pinch strength relative to function, pinch should still be tested, with notation made of the client's prehensile pattern (e.g., "4 pounds of pinch with meter placed in web space between thumb and second metacarpal"). The presence and location of muscle atrophy should be recorded because it indicates severe weakness and possible nerve compression that may require further investigation. Intrinsic atrophy can be seen as flattening of the thenar and hypothenar eminences and as hollowing between the metacarpals on the dorsal aspect of the hand.

Hand function can be assessed through standardized tests (e.g., the Jebsen-Taylor Hand Function Test)⁵⁰ or observation of the client performing common functional tasks that involve various grasp and prehensile patterns. These tasks can include opening a medication bottle, writing, holding a glass, picking up small pins, turning a doorknob and key, cutting with a knife, and fastening buttons. In addition to noting whether the client is able to perform each task, the value of this testing lies in observation of how the client uses his or her hands and determination of which factors interfere most with activity: instability, lack of motion, deformity, pain, weakness, or something else. The therapist cannot predict function solely on the basis of the hand's appearance. Deformities caused by arthritis often develop slowly, and many clients learn how to adapt their hand function gradually over time. It may be surprising to see significantly deformed hands performing tasks with relatively good function. The therapist should remember this when planning an intervention because it might eliminate a problem that is actually functional for the client.

Joint stiffness is a distinct feeling of excessive stiffness that eventually wears off.⁶⁴ It can occur as a result of low-grade inflammation, effusion, synovial thickening, muscle shortening, or spasm.^{12,65} The therapist can determine the extent of joint stiffness by asking the client which joints experience stiffness, under what conditions, and for how long. Morning stiffness and gelling should be considered separately and can be measured in hours or minutes. The duration of morning stiffness is often used as an objective indicator of the degree of disease activity present. The gelling phenomenon, stiffness after prolonged periods of inactivity, is so named because fluid in the joint and surrounding tissues sets up like gelatin.⁶⁵

Because pain is often the primary clinical manifestation of arthritis, it should be closely evaluated. Pain that interferes with the client's ability to engage in occupations should be of primary concern. The presence and location of joint pain should be noted. To elicit important details, the

therapist should ask questions such as “When does the pain occur?,” “What tends to make the pain worse?,” and “What seems to make the pain better?” An attempt should be made to distinguish between articular (joint) pain and periarticular (soft tissues surrounding the joint) pain. Secondary conditions such as tendonitis and bursitis are frequent causes of pain. Pain has different meanings for individuals and is often difficult to describe.⁸⁶ The therapist can obtain measurements of pain intensity by asking the client to rate the pain on a numerical scale of “1” (no pain) to “10” (greatest pain) or on a visual analog scale in which the client places a mark along a 10-cm line.⁴⁹ These scales can also be used to measure other subjective symptoms, including fatigue and degree of stiffness.⁴² Because pain related to arthritis is fluctuant, the client may be asked to rate pain at its current level, at its best, at its worst, and at various times of the day or to compare pain at rest versus pain with motion or activity. Interestingly, pain caused by acute inflammation in the early stages of RA tends to be greater than pain at the end stages, when severe deformities are present.¹¹ The presence and location of joint tenderness should also be noted. Tenderness is assessed by applying manual compression to the medial/lateral aspects of the joint (see Chapter 28 for additional information).⁶⁴

Sensation should be evaluated if the potential for peripheral nerve damage or compression caused by swelling exists. The therapist should obtain a subjective report from the client with regard to the presence of numbness or tingling. This report can be followed by screening of the touch/pressure threshold of the fingertips with monofilaments.⁸ If sensory impairment is noted, further assessment may be indicated. This may include provocative tests to replicate or aggravate symptoms so that areas of compression can be localized. Examples of these tests are the Phalen and Tinel tests in individuals with suspected median nerve compression at the carpal tunnel.⁶ When cervical spine involvement is known or suspected, dermatomal light touch, sharp-dull sensation, and proprioception should be evaluated (see Chapters 23 and 39 for additional information).

The examiner assesses joint laxity (instability) by applying stress to individual joints in the medial/lateral and anterior/posterior directions. When testing medial/lateral stability of the MCP joints, the examiner must first place the MCP joints in flexion to tighten the collateral ligaments, which are naturally loose during MCP extension. Unstable joints should be noted. Ligamentous laxity can be described as slight (5 to 10 degrees in excess of normal), moderate (10 to 20 degrees in excess), or severe (20 or more degrees in excess).⁶⁴ In the hand joints, instability with medial/lateral motion indicates laxity of the collateral ligaments, whereas excessive anterior/posterior motion is caused by laxity of the joint capsule and volar plate. Normal joint stability is highly variable, and whenever possible, it is helpful to compare it to the client’s uninvolved joints.⁶⁴

Evaluation of joint deformities is done primarily by observation and palpation. The location and type of

deformity should be noted. Comparison with previous evaluations, if available, allows the therapist to see how the deformities have progressed over the course of the disease. If a deformity is correctable, either actively or passively, it is considered flexible; if the deformity cannot be reduced, it is considered fixed. Patterns of deformity can be different in a client’s two hands, and a person with RA can also exhibit deformities caused by osteoarthritic joint damage.

Common hand deformities in persons with arthritis include the following:

- A boutonnière deformity is characterized by flexion of the PIP joint and hyperextension of the DIP joint (Figure 38-4). This zigzag collapse represents an alteration in muscle-tendon balance. Pathology begins at the PIP joint with secondary changes in the DIP joint. It occurs when synovitis weakens, lengthens, or disrupts the dorsal capsule and central slip of the extensor mechanism and consequently causes incomplete or weak to absent extension at the PIP joint. The lateral bands of the extensor mechanism displace volarly below the axis of the PIP joint and become flexors of that joint. Increased force on the lateral bands at the DIP joint, where they insert, causes hyperextension. Function of the finger is compromised by the inability to straighten the finger and the loss of flexion at the fingertip for pinching.^{2,11,64}
- A swan neck deformity is characterized by hyperextension of the PIP joint and flexion of the DIP joint, with possible flexion of the MCP joint (Figure 38-5). This zigzag collapse is also a result of muscle-tendon imbalance and joint laxity. It can originate from abnormalities at any finger joint. Causes of this deformity include

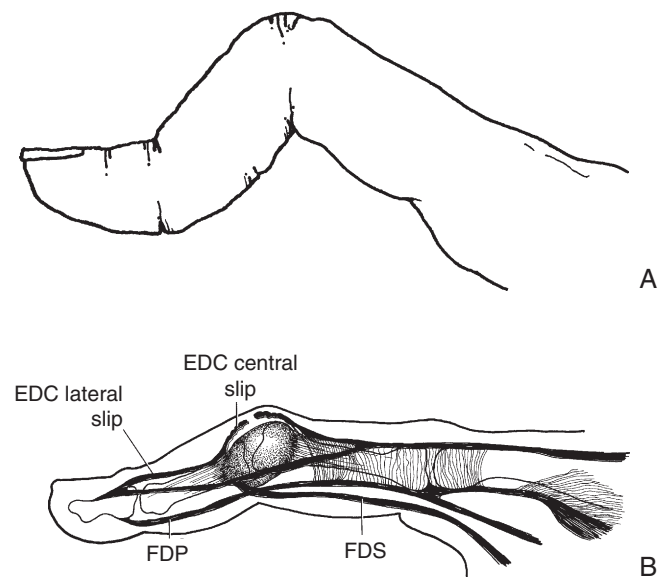

FIGURE 38-4 A, A boutonnière deformity results in distal interphalangeal hyperextension and proximal interphalangeal flexion. B, Boutonnière deformity caused by rupture or lengthening of the central slip of the extensor digitorum communis tendon.

intrinsic muscle tightness, stretching or rupture of the terminal extensor tendon at the DIP joint, and chronic synovitis that leads to stretching of the volar capsular supporting structures at the PIP joint. Here, the lateral bands of the extensor mechanism slip above the axis of

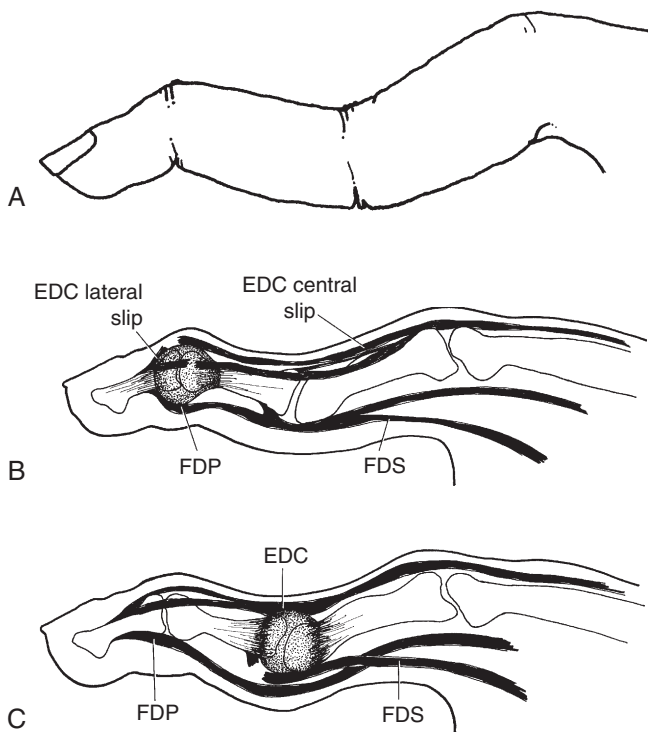

FIGURE 38-5 A, A swan neck deformity results in proximal interphalangeal hyperextension and distal interphalangeal flexion. B, Swan neck deformity resulting from rupture of the lateral slips of the extensor digitorum communis tendon. C, Swan neck deformity as a result of rupture of the flexor digitorum superficialis tendon.

the PIP joint, thereby hyperextending the PIP joint and flexing the DIP joint. Function of the finger is compromised by inability to flex the PIP joint, with loss of the ability to make a fist or hold small objects.²

- A mallet finger is characterized by flexion of the DIP joint. This is caused by rupture of the terminal extensor tendon as it crosses the DIP joint. The finger loses the ability to extend the distal phalanx.
- Nodes are bony enlargements that indicate cartilage damage caused by OA. Joints affected by RA can also have degenerative joint disease, so nodes may be seen in clients with RA as well. These osteophytes are hard to the touch and are typically not painful. They are most commonly seen at the DIP joint (Heberden's nodes) and the PIP joint (Bouchard's nodes; [Figure 38-6](#)).^{11,15,64,65}
- Nodules are granulomatous and fibrous soft tissue masses that are sometimes painful. They usually occur along weight-bearing surfaces such as the ulna or at the olecranon ([Figure 38-7](#)) and can be prognostic of the severity of RA.¹¹
- Deviation is characterized by a change in the normal joint position. It is typically described as radial or ulnar. In RA the most common pattern of deviation is radial deviation of the wrist and ulnar deviation (commonly referred to as ulnar drift) of the MCP joints ([Figure 38-8](#)). Deviation is caused by ligament weakening or disruption. Small joints are especially vulnerable because daily activities involving gripping and pinching apply strong forces to them.^{2,11,64}
- Subluxation is characterized by volar or dorsal displacement of joints. It is any degree of malalignment in which the articular structures are only in partial contact. In RA the most common sites of subluxation are the wrist and MCP joints.⁶⁴ Volar subluxation of

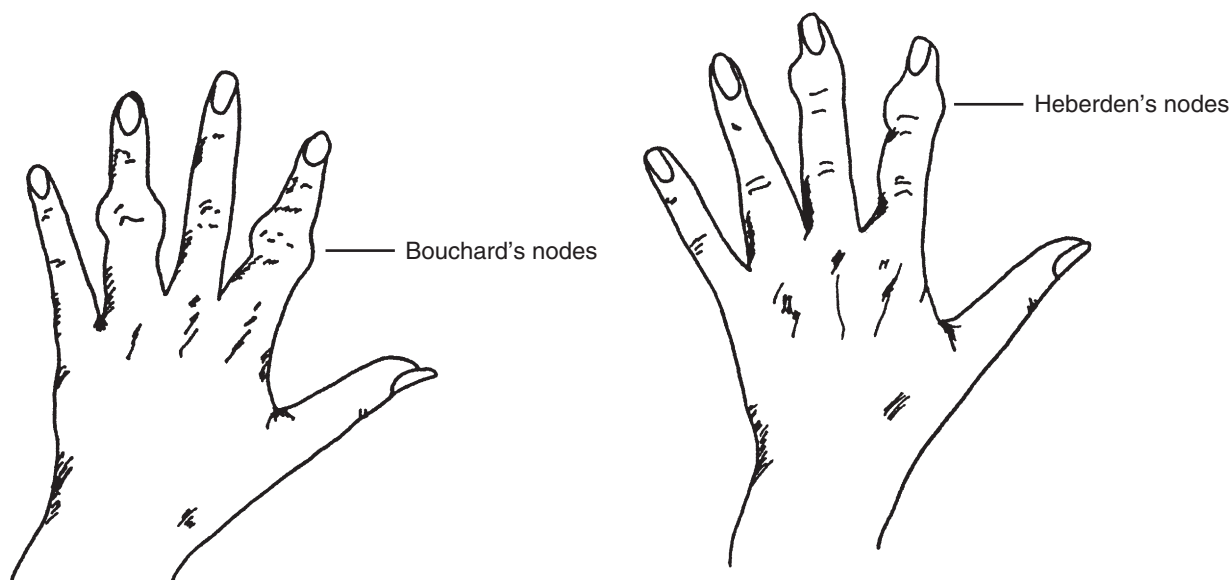

FIGURE 38-6 Osteophyte formation in the proximal interphalangeal joints (Bouchard's nodes) and the distal interphalangeal joints (Heberden's nodes) is a common finding with osteoarthritis.

FIGURE 38-7 Rheumatoid nodules present on the extensor surface of the elbow.

FIGURE 38-8 Ulnar drift of the metacarpophalangeal joint.

the wrist occurs as the carpal bones slip relative to the distal end of the radius as a result of weakening of the supporting ligaments by chronic synovitis. Because of their condyloid nature, the MCP joints have more planes of movement and are inherently less stable than the IP joints. Volar subluxation of the MCP joints occurs frequently and is often accompanied by ulnar drift and lateral displacement of the extensor tendons into the ulnar valleys between the metacarpal heads (Figure 38-9).^{2,11,64}

- Dislocation is characterized by joints whose articulating surfaces are no longer in contact. In severe cases of RA,

FIGURE 38-9 Volar subluxation and ulnar deviation of the metacarpophalangeal joints with lateral displacement of the extensor tendons characteristic of rheumatoid arthritis.

(From Alter S, Feldon T, Terrono AL: Pathomechanics of deformities in the arthritic hand and wrist. In Mackin EJ, Callahan AD, Skirven TM, et al, editors: *Rehabilitation of the hand and upper extremity*, ed 5, St Louis, Mo, 2002, Mosby, p 1550.)

volar dislocation of the carpals on the radius or dislocation of other joints can result from complete destruction of ligamentous integrity.^{11,64}

- Ankylosis (fusion of the bones of a joint) is characterized by lack of joint mobility. This spontaneous joint fusion can be bony (caused by ossification within or around the joint) or fibrous (caused by growth of fibrous tissue around the joint).⁶⁴
- Extensor tendon rupture is characterized by the inability to actively extend a joint in the absence of muscle weakness (Figure 38-10). The extensor digiti minimi is often the first to rupture. The extensor pollicis longus and extensor digitorum communis of the third, fourth, and fifth digits are also vulnerable.¹¹ Tendon rupture can occur as a result of rubbing of the tendon over rough bony surfaces or tendon damage caused by direct synovial invasion or increased pressure that decreases blood supply to the tendon.
- Trigger finger is characterized by inconsistent limitation of finger flexion or extension. It is often caused by a nodule on a flexor tendon or stenosis of a tendon sheath, which impedes the tendon's ability to glide.⁶⁴

FIGURE 38-10 Extensor tendon rupture of the fourth and fifth digits resulting in loss of active extension. Tenosynovitis of the extensor tendons and volar subluxation of the wrist caused by rheumatoid arthritis are contributing factors.

(From Harris ED, Budd RC, Genovese MC, et al: *Kelley's textbook of rheumatology*, ed 7, Philadelphia, Pa, 2005, Saunders.)

FIGURE 38-11 Mutilans deformity.

(From Klippel JH, Dieppe P, Ferri FF: *Primary care rheumatology*, St Louis, Mo, 1999, Mosby.)

The client often experiences “catching” or “locking” of a finger into flexion and has to passively extend the finger out of the flexed position.

- Mutilans deformity is characterized by very floppy joints with redundant skin (Figure 38-11). The cause is unknown, but the result is resorption of the bone ends, which shortens the bones and renders the joints completely unstable. This is most commonly seen at the MCP and PIP joints of the hands and the radiocarpal and radioulnar joints of the wrist.⁶⁴
- Thumb deformities can be manifested as any of the deformities previously described. Six patterns of thumb deformity have been classified by Nalebuff (Table 38-5).⁹⁵ Type I is the most common in RA, followed by type III, seen in both OA and RA.^{64,95} A boutonnière deformity (type I) is characterized by MCP joint flexion and IP joint hyperextension. A swan neck deformity (type III) is characterized by CMC joint subluxation, adduction, and flexion; MCP joint hyperextension; and

IP joint flexion. Also common in RA and OA is an adduction contracture of the thumb CMC joint caused by subluxation of the first metacarpal, radial deviation of the MCP joint, or shortening or weakness of intrinsic muscles.^{65,95} Subluxation causes a characteristic squared appearance of the CMC joint (Figure 38-12). Disruption of thumb biomechanics often leads to significant loss of hand function, especially given the fact that the thumb is thought to account for as much as 60% of hand function.⁴⁰

Physical endurance can be evaluated by observation during the assessment process and by client report. Pain, weakness, deconditioning, lack of sleep, and emotional stress can all lead to decreased stamina. The pattern and severity of fatigue should be noted.⁸⁵ Functional mobility, including ambulation, sitting, and standing tolerance and ability to transfer, should be assessed relative to occupational performance.

TABLE 38-5 Rheumatoid Thumb Deformities

Type	CMC Joint	MCP Joint	IP Joint
I (boutonnière)	Not involved	Flexed	Hyperextended
II (uncommon)	CMC flexed and adducted	Flexed	Hyperextended
III (swan neck)	CMC subluxed, flexed, and adducted	Hyperextended	Flexed
IV (gamekeeper’s)	CMC not subluxed; flexed and adducted	Hyperextended, ulnar collateral ligament unstable	Not involved
V	May or may not be involved	Volar plate unstable	Not involved
VI (arthritis mutilans)	Bone loss at any level	Bone loss at any level	Bone loss at any level

Goal Setting

The goals of therapy should be determined by careful consideration of the client’s stated goals, the client’s individual needs, and the stage of the disease process. The Canadian Occupational Performance Measure (COPM) is a useful client-centered tool that can be used for setting goals, planning treatment, and measuring outcomes.⁵³ It is designed to detect change in a client’s self-perception of occupational performance over time. It engages the client in defining problems in activity and helps the client more clearly understand the purpose of OT. The COPM involves a semistructured interview in which the client is asked to identify occupations that the client needs to, wants to, or is expected to perform but are not done satisfactorily. Occupational goals in the areas of self-care, productivity, and leisure (based on the Canadian Model of Occupational Performance [CMOP]) are listed, and the client is then asked to

rate his or her self-perception of the importance of, current performance of, and satisfaction with performance of each occupation. Through this process of collaboration with the client, occupation-based therapy goals can be identified, priorities determined, and a treatment plan designed to facilitate optimal outcome. The rating process is repeated at time of discharge for outcome purposes. The COPM has been used with people who have arthritis in both inpatient and outpatient settings.⁷ COPM goals for Nina were to return to work 20 hours a week, to clean her house independently, and to be able to take her grandchildren to the park after school.

Intervention Objectives and Planning

Treatment of clients with arthritis must take into account the progressive nature of the disease.²³ The overarching goal of therapy is to decrease pain, protect joints, and increase function. General objectives of OT are to (1) maintain or increase the ability to engage in meaningful occupations; (2) maintain or increase joint mobility and strength; (3) maximize physical endurance; (4) protect against or minimize the effect of deformities; (5) increase understanding of the disease and the best methods of dealing with its physical, functional, and psychosocial effects; and (6) assist with adjustment to disability.⁶⁴

The intervention plan should be designed for the individual client and based on the stage of disease, the severity of symptoms, general health status, lifestyle, and mutually agreed goals. Given the limited time for therapy, prioritizing treatment is essential. The therapist should focus on addressing the most important factors by answering the following question: “What are the essential interventions necessary to enable the client to function at an optimal level?” It is important to have the client and significant others be active participants throughout therapy. Everyone involved must understand the disease process and the rationale for the

■ **TABLE 38-6** | Treatment Objectives by Stage of Inflammatory Disease

Stage	Symptoms	Objectives	Treatment Considerations
I. Acute	Pain; inflammation; hot, red joints; tenderness; overall stiffness; limited motion	Decrease pain and inflammation Maintain ROM Maintain strength and endurance	Splinting for localized rest day and night, increased bedrest, joint protection, assistive devices, physical agent modalities Gentle active ROM and/or passive ROM to point of pain (no stretch), proper positioning Functional activities to tolerance, isometric exercises
II. Subacute	Inflammation subsiding; warm, pink joints; decreased pain and tenderness; stiffness limited to the morning	Decrease pain and inflammation Maintain ROM Maintain strength and endurance	Less restrictive splinting during the day, splinting continued at night, joint protection, assistive devices, physical agent modalities Active ROM and/or passive ROM with gentle stretch, proper positioning Increased functional activities to tolerance, isometric exercises
III. Chronic active	Minimal inflammation, less pain and tenderness, increased activity tolerance, low endurance	Decrease pain and inflammation Increase ROM Increase strength and endurance	Joint protection, splinting as needed, assistive devices as needed, physical agent modalities as needed Active ROM and/or passive ROM with stretch at end range Resistive exercises (isometric or isotonic if no risk of oversteering joints), cardiovascular exercises, increased functional activities
IV. Chronic inactive	No inflammation, pain and stiffness from disuse, low endurance	Decrease pain Increase or maintain ROM Increase strength and endurance	Joint protection, splinting as needed, assistive devices as needed, physical agent modalities as needed Active ROM and/or passive ROM with stretch at end range Resistive exercises (isometric or isotonic if no risk of oversteering joints), cardiovascular exercises, increased functional activities

ROM, range of motion.

intervention methods. Because therapy intervention will most likely be intermittent throughout the client's course of disease, the client's ability to follow through with and self-manage interventions at home will greatly influence the ultimate success of treatment.

Table 38-6 outlines some common symptoms, general objectives, and OT interventions typically appropriate for each stage of inflammatory disease; it can be used as a starting point for planning treatment.^{11,64} Nina was in the subacute stage of her RA flare-up. All six general objectives listed previously were important to address in her OT program.

OT Practice Notes

As always, the occupational therapist's clinical judgment of each client's unique status is crucial for tailoring programs appropriately.

Occupational Therapy Intervention

Treatment methods useful in the remediation of clinical or functional problems include rest, physical agent modalities (PAMs), therapeutic exercise and activity, splinting, occupational performance training, and client education. It is important to foster the client's self-efficacy in his or her ability to follow through with treatment at home given the influences of the home contexts because building the client's confidence will probably lead to the desired behavior. Asking the client a question such as "How certain are you that you can perform this activity at home as well as you did in the clinic?" can provide feedback on the need for further training and practice.⁵⁸ The interventions chosen should reflect the individual client's needs and choices whenever appropriate. General treatment precautions related to arthritis are listed in Box 38-3.

Sleep and Rest

Rest should be considered an active means of reducing inflammation and pain. Rest and relaxation can effectively break the vicious cycle of pain, stress, and depression by

■ Box 38-3

Treatment Precautions Related to Arthritis

- Respect pain.
- Avoid fatigue.
- Avoid placing stress on inflamed or unstable joints.
- Use resistive exercise or activity with caution.
- Be aware of sensory impairments.
- Be cautious with fragile skin resulting from systemic disease or pharmacologic side effects.

allowing the body time to heal itself. Rest can be either systemic or local. Whole-body general rest, including recuperative sleep, is necessary for health. However, individuals with arthritis are at risk for sleep problems because of pain and depression.⁸³ During periods of active systemic inflammatory disease, at least 8 to 10 hours of sleep at night and half-hour to 1-hour morning and afternoon rest periods are recommended.^{9,83} The amount of systemic rest needed varies by individual, from complete bedrest to an extra nap during the day. Localized rest of joints with symptoms of RA and OA may include wearing a splint, avoiding or modifying activity, or positioning during the day or at night to prevent joint stress.²³ Repetitive joint loading or motion with activity should be alternated with rest. The effectiveness of rest will be seen as an improved energy level with less joint swelling, pain, and fatigue.

Nina required both general rest for her body and localized rest for her inflamed wrists and hands. It was important to help her realize the physiologic need for rest during recovery from her flare-up. This assurance permitted her to feel less guilty about tasks left undone and enabled her to understand that taking care of herself in the short term would allow her to return to activity in the long term.

Physical Agent Modalities

PAMs may be helpful in relieving pain or in maintaining or improving ROM. Although modality use alone has not been shown to provide sustained benefits in rheumatic disease, clients do report less pain and stiffness from a clinical standpoint.^{9,11} The most commonly used PAMs are superficial heat and cold agents. Benefits of heat in clients with arthritis include increased blood flow, pain relief, and increased tissue elasticity, with a negative effect of increasing inflammation also possible.^{16,44} Benefits of cold include reduced inflammation and decreased pain threshold, with possible negative effects of increased tissue viscosity and decreased tissue elasticity causing more joint stiffness.^{16,44} Heat can be delivered through hot packs, paraffin, fluid therapy, hydrotherapy in a heated pool, and even a warm shower or bath; cold can be delivered through ice packs or gel packs. When selecting the proper

modality, the therapist must consider the activity and stage of the disease process. Acutely inflamed joints may be exacerbated by heat, whereas ice may be more helpful in reducing pain and inflammation. In the subacute or chronic stages, heat or cold may be equally effective.¹⁶ Nina preferred the use of heat and found it helpful in loosening her joints and lessening her pain. Even though she was in the subacute phase, some inflammation was still present; therefore, her response to heat was closely monitored so that it did not worsen her inflammation. She was educated in the safe use of warm baths and microwave packs at home.

There are some medical conditions associated with rheumatic disease that contraindicate the use of thermal agents. For example, use of cold is contraindicated in clients with Raynaud's phenomenon, a vasospastic disorder of the digits.^{16,44} Clients with RA often have unstable vascular reactions to heat and cold that cause greater than normal heat retention with heat agents or increased coldness and stiffness with cold exposure.⁴⁴ Careful monitoring of client responses to PAMs is crucial. Client preference and ease of home application should also be considered before choosing an agent to use. Home paraffin units, microwave packs, and continuous low-level heat wraps are increasingly accessible and affordable in community stores and thus provide clients with more options.⁶⁶ Safety should always be a primary concern. Clients and significant others should be carefully instructed in proper application techniques to prevent burns or other tissue damage. Before using any modality, the therapist must fully understand tissue responses and related precautions and be competent in safe delivery of the agent. This typically requires specific education beyond entry-level preparation. Therapists must also adhere to any state licensure or training requirements.

Therapeutic Exercise

The purpose of exercise in the treatment of arthritis is to keep muscles and joints functioning as normally as possible by maintaining muscle strength, preventing disuse atrophy, and maintaining or improving ROM.¹⁰² Regular physical activity can also be helpful in alleviating depression.¹⁰⁰ It is helpful to find out what exercises the client may already be performing and whether these exercises were suggested by a professional or a well-meaning family member or friend; many self-initiated exercises can be harmful to a person with arthritis. There is no universal exercise program suitable for all clients with arthritis. Exercise programs should be designed with regard to individual client needs and tolerances. As a good rule of thumb, pain lasting greater than 1 or 2 hours after completion of exercise signals a need to modify or decrease an exercise.^{64,102} General guidelines for exercise in clients with arthritis are to avoid undue joint stress, avoid pain and joint swelling, and work within the client's comfortable ROM.^{11,56,102} The client should be

taught to perform exercises slowly, smoothly, and with proper technique. The client must also understand the rationale behind the prescribed exercises.¹⁰² Exercises to maintain ROM should be performed at least once daily, even during a flare. For RA each major joint should be taken through its full comfortable ROM. This includes the neck and possibly the jaw if symptomatic. The stiffest joints require the most attention. The type of ROM exercise selected depends on the disease activity and location of the joint. Active ROM is typically preferred, with assisted or passive ROM if pain or weakness precludes it. In cases of active synovitis, active ROM can exert more stress on a joint than gentle passive ROM, so passive ROM exercises may be safer.⁶⁴ Performing shoulder exercises is often easier in a supine position, which eliminates the effects of gravity. The number of repetitions should be weighed against the potential inflammatory response. On good days, 10 repetitions may be appropriate; on bad days, 3 or 4 repetitions within a smaller arc of motion may be indicated.¹⁰² If the goal of exercise is to increase joint mobility, active or passive stretch can be incorporated. This is appropriate for the subacute or chronic phases of disease but never for the acute phase.⁶⁴ Box 38-4 presents general active ROM exercises for RA.

Exercises for strengthening can be dynamic (isotonic) or static (isometric) and should be aimed toward recovery of function.^{26,64,100} Strengthening must be approached

cautiously so that pain is not increased, deforming forces are not created, and joint stability is not compromised. Grip-strengthening exercises, even those using light putty, can impart large forces to unstable hand joints.¹⁷ Additionally, this type of dynamic exercise may aggravate joints or pose a risk for potential deformity and in general should be avoided in clients with rheumatoid hand involvement.¹¹ Resistive exercise of any kind should never be performed during periods of acute flare or inflammation but may be used at other stages. Isometric exercises are usually the least painful for clients with RA because they eliminate joint motion and can be as effective or more effective in improving muscle strength and endurance.⁶⁴ Isometric contractions are generally held for 6 to 12 seconds.²⁶ Programs to maintain strength vary depending on the client's overall activity level. Clients who are sedentary may require a daily program, whereas clients who are active may need to perform only specific exercises once a week.⁶⁴ Gradual progression of repetitions or resistance is recommended.¹⁰⁰

Exercises to promote general health and fitness are recommended for all adults as part of a healthy lifestyle and should be encouraged in clients with arthritis. Current evidence supports the benefits of aerobic and conditioning exercise for people with hip and knee OA, as well as aerobic and strength training in adults with stable RA.¹⁰⁰ Stationary bicycling, walking, and low-impact aerobic dancing, once thought to cause joint damage, have been found to increase

□ Box 38-4

Range-of-Motion Exercises for Rheumatoid Arthritis

Instructions

1. Start with 5 of each exercise, 1 or 2 times each day.
2. Progress to 10 of each exercise, 1 or 2 times each day.
3. Do all exercises slowly and smoothly.
4. If in a flare, cut down on exercises but do not discontinue them entirely.

Jaw

1. Open your mouth wide and then close it.
2. With your mouth open, move your jaw from side to side.
3. Bring your lower jaw forward and then relax.

Neck

4. Look up toward ceiling and then look down to the floor.
5. Bend your head toward one shoulder and then bend your head toward the other shoulder.
6. Slide your chin forward and then relax.
7. Slide your chin toward the back of your neck and then relax.

Shoulders and Elbows

8. Shrug your shoulders up and down.
9. With your hands on your shoulders, make circles clockwise and then counter-clockwise.

10. With your hands behind your head (or if unable, on your shoulders), bring your elbows together in front of you and then spread your elbows apart.
11. Touch your shoulders with your hands and then straighten your elbows.

Forearms and Wrists

12. With your elbows partially bent and kept at your sides, turn your palms up and then down.
13. Lift your hands backward, letting your fingers curl, and then bend your hands down, letting your fingers straighten.

Fingers

14. Make fists and then open your hands and straighten your fingers.
15. Touch your thumb tips to the tips of each finger.
16. With your palms on your thigh or a table, move your thumbs away from your fingers and then slide each finger toward your thumbs.

flexibility, strength, endurance, and cardiovascular fitness without aggravation of symptoms. T'ai chi has been reported to have positive effects on self-efficacy, quality of life, general health status, pain, stiffness, and physical functioning in older adults with lower extremity OA^{41,84} and is being used for clients with RA as well.

Whether for ROM, strengthening, or overall conditioning, the occupational therapist should work closely with the client to help ensure that any exercise program can be successfully integrated into the client's typical daily routine with a proper balance of rest and activity. Exercises should ideally be done when the client feels most limber and has the least pain. Community land- and water-based exercise classes specifically designed for people with arthritis are available through the Arthritis Foundation. They offer the added benefits of social interaction and peer support and have been shown to be safe and effective in increasing fitness and strength and decreasing pain and difficulty in daily functioning.^{13,88,92}

Daily upper body active ROM exercises with gentle stretch and isometric exercises for the shoulders and elbows were prescribed to improve Nina's motion and strength. It was decided that the best time to perform these exercises was after her morning shower, when she felt less stiff and least fatigued. The therapist recommended that Nina become involved in an Arthritis Foundation exercise class, once her flare subsided, to build her endurance and cardiovascular conditioning. She was interested in joining and planned to attend classes on the days that she worked fewer hours.

Therapeutic Activity

Performance of therapeutic activities offers many benefits, both physical and psychologic. Discussing current and past hobbies or having the client complete an interest survey can help the therapist determine activities that may be most appropriate for the client. New activities may be suggested or previously enjoyed activities reintroduced. A carefully chosen and graded activity can be an effective means of encouraging ROM and strength. When selecting therapeutic activities, the therapist should apply the same principles as with exercise.⁶⁴ Activities should be nonresistive, avoid patterns of deformity, and not overstress joints; instead, they should offer enough repetition of movement to help improve ROM and strength. The effect of the activity on all joints should be considered.

It is typically recommended that clients with RA not engage in activities that require use of the hand in prolonged static positions. However, sometimes the psychologic benefits of doing activities that one enjoys outweigh the risks involved, especially if the risks can be minimized. Examples of activities that are often frowned on include knitting and crocheting. These activities are truly contraindicated only if there is active MCP synovitis, a developing swan neck deformity, or thumb CMC joint involvement.⁶⁴ Potential problems may be averted by having the client wear

a hand or thumb splint to support the vulnerable joints while performing the activity. Additionally, educating the client to incorporate frequent rest breaks and stretching exercises for the intrinsic muscles will help limit risks (see Chapter 29 for additional information regarding therapeutic exercise and activity).^{27,64}

Splinting

Indications

Splinting is often an integral component of the treatment of arthritis. Splints can be used for numerous reasons, with the fundamental goal of maximizing function. It is important for the therapist to understand the pathomechanics of the disease process when prescribing an appropriate and feasible splinting plan. Inappropriate use of splints can be harmful. Indications for splinting in clients with arthritis include reducing inflammation, decreasing pain, supporting unstable joints, properly positioning joints, limiting undesired motion, and increasing ROM. Although it is generally agreed that splinting has a place in the acute phase of RA, there are few documented or well-established protocols for splinting in later stages.³⁴ Table 38-7 summarizes the potential splinting indications on the basis of progression of the joint destruction in RA.^{11,64}

Ultimately, the individual needs of each client must be determined carefully. What are the primary goals for splinting? What benefits will a splint provide? What limitations will a splint impose? Which joints are involved and should be incorporated into a splint design? What effect will splinting have on unsplinted joints? Is the client receptive to splinting? What splints has the client tried or worn before? When should the splint be worn? These factors should be considered when deciding on an appropriate splinting plan.

Considerations

There are some special considerations for splinting in clients with RA. Because the added weight of a splint puts additional stress on the upper extremity and may cause problems with pain and fatigue, a splint should be as lightweight as possible. Forces are also transferred from splinted to adjacent unsplinted joints. For example, a thumb splint leaving the wrist and IP joints free may cause these joints to become more symptomatic. Skin tolerance can be an issue because skin is often more fragile as a result of the RA disease process and effects of medication. The presence of sensory impairments may also require closer monitoring for signs of pressure. Finally, splint straps may need to be modified to allow increased ease and decreased joint stress during donning and doffing of splints.

Options

If splinting is indicated, the therapist must then determine which type of splint will work best. The growing array of commercial products has led to a greater number of choices. Should the splint be rigid, semirigid, or soft? This will often be decided by the splint's proposed purpose and the client's

■ **TABLE 38-7** | Splinting Indications by Classification of Progression of Rheumatoid Arthritis

Stage	Symptoms/Radiographic Changes	Splinting Indications
Stage I: Early	No destructive changes; possible osteoporosis	Resting splints to decrease acute inflammation, decrease pain, protect joints
Stage II: Moderate	Osteoporosis with or without slight subchondral bone destruction, slight cartilage destruction, no joint deformities, limited joint mobility possible, muscle atrophy, extra-articular soft tissue lesions possible	Day splints to provide comfort Night splints to relieve pain and/or protect joints against potential deformity Splints to increase ROM
Stage III: Severe	Cartilage and bone destruction, joint deformity, extensive muscle atrophy, extra-articular soft tissue lesions possible	Day splints to improve function (decrease pain, provide stability, limit undesired motion, properly position joints) Night splints to provide positioning and comfort
Stage IV: Terminal	Criteria for stage III, with fibrous and bony ankylosis	Day splints to improve function (decrease pain, provide stability, limit undesired motion, properly position joints) Night splints to provide positioning and comfort

ROM, range of motion.

preference. Rigid splints provide maximal immobilization or stability, soft splints allow more freedom of motion, and semirigid splints combine elements of both. Should the splint be prefabricated or custom-made? This decision is based on many splint- and client-related factors, including splint availability, cost to purchase or fabricate, durability, weight, ease of care, ease of donning and doffing, cosmetic appearance, and extent of the client's existing deformity.

Providing the client with choices will enhance splint use and client satisfaction. Studies have shown that the following additional factors may encourage splint wear: flexibility of the splinting regimen and vigorous client education regarding the splint's purpose and wearing schedule, individualized splint prescriptions based on the client's comfort and preference, strong family support, positive attitudes and behaviors exhibited by health care providers, and benefits that are immediately obvious to the client.^{20,33,37,69,71,90} Rapport, trust, sensitivity to clients' learning styles, splint trial evaluations, and providing clients with the opportunity to voice their concerns and frustrations can also enhance the collaborative process and splinting outcome.²⁴ The therapist can recommend splinting, but ultimately the client will decide whether the splint's benefits outweigh the limitations that it imposes.

Commonly Used Splints for Arthritis

A resting hand splint is useful for the treatment of acute synovitis of the wrist and hand. Its primary function is to provide localized rest to the involved joints. It can also serve to relieve pain, decrease muscle spasm, and protect joints vulnerable to contracture or deformity from synovitis. Joints are rested in positions that place the least internal pressure on them and are opposite that of potential

deformity.¹¹ The recommended joint positions during rest are slight wrist extension (0 to 20 degrees) and ulnar deviation (10 to 20 degrees), MCP flexion (20 to 30 degrees), slight PIP and DIP flexion (10 to 30 degrees), and slight thumb extension and abduction at the CMC joint with slight flexion of the MCP and IP joints.^{34,64,104} However, the client's comfort should always take precedence, and joints should never be forced into the ideal position. The splint is worn continually for the duration of the flare-up and removed at least once a day for skin hygiene and gentle ROM exercises. Splint use should continue full-time for at least 2 weeks after the flare subsides, with a gradual decrease in wearing time to allow the joints to recover.^{34,64} In the later stages of disease, the splint is often used at night only to increase comfort and protect against deforming positions. If bilateral splints are needed, clients may alternate splints or wear the splint on the most symptomatic hand.

Commercial splints, such as those made from wire-foam or a malleable metal frame covered by soft padding (Figure 38-13), may be used if the limited adjustments that they allow can provide the client with a proper fit. This is often not possible in clients with established joint deformities. A custom-fabricated thermoplastic splint will allow a precise individualized fit. Joints that are asymptomatic may not need to be included in the splint. Modified resting splints with the uninvolved joints left free may lessen joint stiffness related to splint wear, allow some degree of hand function while the splint is worn, and improve splint wear and comfort.

Although the benefits of resting hand splints are recognized by health care professionals, studies have shown that client adherence to splint wear is moderate at best.^{1,33} In a study comparing the use of soft and hard resting splints in

FIGURE 38-13 Prefabricated resting hand splint.

FIGURE 38-14 Custom-fabricated thermoplastic wrist splint.
(Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, Calif.)

clients with RA, pain was significantly decreased with splint wear, with 57% preferring the soft splint, 33% the hard splint, and 10% no splint at all. The rate of compliance was greater for the soft splint than for the hard splint.²⁰

A wrist splint is often used to provide wrist stability, decrease pain, and improve function. Supports may be custom-fabricated (Figure 38-14) or prefabricated. Because they are intended to provide support while allowing functional use of the hand, fit and comfort are crucial. A variety of commercial splints made from many materials that offer a full range of soft to rigid support are available. Aside from support, clients with arthritis frequently report a benefit from the neutral warmth that many fabrics provide. Studies have shown conflicting results of different splint styles in grip strength, dexterity, pain reduction, hand function, comfort, security during performance of tasks, effects of

FIGURE 38-15 Prefabricated wrist and metacarpophalangeal joint soft support.

stiffness, or muscle atrophy related to wearing of wrist splints in clients with RA.^{71,90} In a study of splint preference, most clients were able to identify their preferred splint within only a few minutes of wear when given three styles to try.⁸⁹ These studies illustrate the importance of offering a wide variety of splints for each client to try. When the MCP joints are symptomatic, a splint can be used to support them along with the wrist (Figure 38-15).

MCP ulnar deviation splints may be beneficial in providing relief of pain, stability, alignment, and reduced stress on painful, subluxed, or deviated joints. They may slow the progression of deformity, but they will not prevent or correct it.^{63,73} Splints can be fabricated or obtained commercially, with support ranging from soft to rigid (Figure 38-16). Despite the variety of splint designs and materials,

MCP ulnar deviation splints are reported to be infrequently prescribed and used by clients.⁷⁵ Immobilization of the MCP joints can impede functional use of the hand or increase pain and stress on adjacent PIP joints.^{63,73} Bulky or volar-based splints can also interfere with palmar sensation or impair the ability to grasp objects. However, some clients benefit from the pain relief and improved digital alignment. High client satisfaction rates have been reported for a custom dorsal-based design.⁷⁵ Soft splints are commercially available or can be custom-fabricated.³⁶ The client's preference for use and selection of an MCP ulnar deviation support should be the primary factor in decision making.^{40,63}

A swan neck splint, also known as a PIP hyperextension block, is used to restrict unwanted PIP hyperextension motion. Swan neck deformities often cause difficulty in hand closure because the PIP tendons and ligaments can catch during motion and the finger flexors have less of a mechanical advantage to initiate flexion when the PIP joint is in a hyperextended position. By blocking the PIP joint in slight flexion, the client can flex the PIP joint more efficiently, thus improving hand function. Swan neck splints can be custom-fabricated from thermoplastics for short-term or trial use. For long-term use or for use on adjacent fingers, commercial products made of metal or polypropylene are often recommended because they are more durable, less bulky, more easily cleaned, and more cosmetically appealing (Figure 38-17). Swan neck splints or splints of similar design can also be used to provide lateral stability to unstable IP joints of the fingers or thumb.^{11,40}

Flexible boutonnière deformities may benefit from boutonnière splints to block the PIP joint in extension and leave the DIP joint free to flex. These can be fabricated by the therapist or custom-ordered from the same companies that manufacture swan neck splints. As a result of the direct pressure that they exert over the dorsum of the PIP joint, the skin must be monitored closely. Clients may reject wearing these splints during the day if limiting PIP flexion impedes function. Night splinting with the PIP joint in maximal extension can be used in an attempt to maintain ROM.¹¹

Thumb splinting can provide positioning opposite that of the developing deformity in early stages of disease and a more stable and pain-free pinch for function in later stages.¹¹ Hand-based short thumb spica splints or opponens splints leave the wrist and IP joints free and can be used for problems at the MCP or CMC joints. Splinting for the CMC joint may sometimes necessitate inclusion of the wrist or MCP joints, but both hand-based and forearm-based (long thumb spica) types have been found to be effective.^{40,93,98} Several thermoplastic splint designs exist, as do numerous prefabricated splints made from a variety of materials. Depending on the client's symptoms and stage of disease, a soft support (Figure 38-18, A) may suffice or the client may require a rigid support (see Fig. 38-18, B) to counteract the stressors applied to joints during functional use. In a study comparing a short neoprene thumb spica and a custom thermoplastic hand-based splint for OA of the CMC joint,

FIGURE 38-17 Splints for swan neck deformity: custom-fabricated thermoplastic, commercial custom-sized metal, and prefabricated polypropylene.

(Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, Calif.)

A

B

(Courtesy Occupational Therapy Department, Rancho Los Amigos National Rehabilitation Center, Downey, Calif.)

both splints improved pain and function and reduced subluxation. The thermoplastic splint reduced subluxation more, but the neoprene splint provided better pain relief and was preferred by clients.⁹⁹ A systematic review found fair evidence of the effectiveness of splinting in relieving pain and improving function in OA of the CMC joint, no evidence of a particular splint superiority, and varying patient preferences.³¹

Dynamic splints and serial static splints may be used to regain ROM lost by shortening of periarticular structures or to maximize motion after surgical procedures such as joint arthroplasty. If the joint space is preserved (as determined by radiographs), there is a soft end-feel, and no more than minimal inflammation is present, gentle splinting may be indicated. The program should be monitored closely for adverse signs of increased pain and swelling. Static splints are often better tolerated than dynamic ones because they apply lesser amounts of force on the joint.⁴⁰

Finally, silicone-lined digital sleeves and pads (Figure 38-19) may be helpful in protecting painful nodes or nodules from external trauma.

The splinting program for Nina focused on decreasing her inflammation and pain and protecting her vulnerable joints. Because she had no established deformity, prefabricated splints were a viable option, one that she preferred. Bilateral lightweight resting hand splints were selected for use at night. To afford her some ability to function, semi-rigid wrist splints were prescribed for use during the day. She was taught to monitor her symptoms and intermittently use the resting hand splints as needed if daytime activity led to increased pain or inflammation. Splint straps were modified by attaching loops to one end so that she could more easily manage them (see Chapter 30 for additional information).

Occupational Performance Training

An effective means of maintaining functional motion and strength with arthritis is to have clients perform daily occupations.⁶⁴ During active stages of the disease, occupations may be limited to just a few, such as feeding and hygiene. As the client's condition improves, usual life activities should be resumed because this will help promote physical status and psychologic well-being. An important but sometimes neglected aspect of ADL training is sexual counseling. Given the pain, fatigue, and ROM limitations resulting from arthritis or movement restrictions imposed post-operatively after joint replacement, an open discussion of issues and illustrations of more comfortable and safe positions for intercourse may prove helpful for clients and their partners. Excellent resources for sexual functioning with disabilities are available (see Chapter 12 for additional information).^{25,79,82}

Analysis of activity demands and activity contexts is a critical component in helping clients maintain, restore, or enhance their engagement in desired activities and occupations. Environmental modifications, alternative methods, or assistive devices often make a difference by increasing clients' independence, ease, and safety in completing meaningful occupations with less pain and stress on their joints. Creative problem solving with the client as an active participant can lead to solutions for unique challenges. Understanding the client's perspective, the meaning of roles, and the cultural and physical environment will allow the therapist to propose more effective intervention.⁷

Assistive Devices

Numerous assistive devices can be fabricated or purchased commercially. The therapist should be familiar with the types of devices available and sources where they can be obtained at minimal expense. Many devices that were previously available exclusively from medical suppliers can now be found in retail stores at much less cost. Commonly used in arthritis interventions are extended-handle devices (e.g., dressing sticks, sock aids, shoe horns, bath sponges, hair-brushes, toilet aids; Figure 38-20, *A*), to compensate for loss of proximal ROM and strength, and devices with built-up handles (e.g., eating utensils, button aids, writing implements; see Figure 38-20, *B*), to compensate for limited hand function (Table 38-8). The therapist should carefully consider the client's goals, factors, activity demands, and contexts when suggesting assistive devices.⁶⁴ Most relevant to clients with arthritis are the following: Is the client receptive to using a device? Will the device successfully reduce pain, joint stress, energy demands, or time expenditure? Is the device easy to use? Is the device acceptable to the client in terms of appearance, cost, and maintenance needs? Is the device compatible with the physical environment and others in the environment? Is the device likely to cause any negative effects?

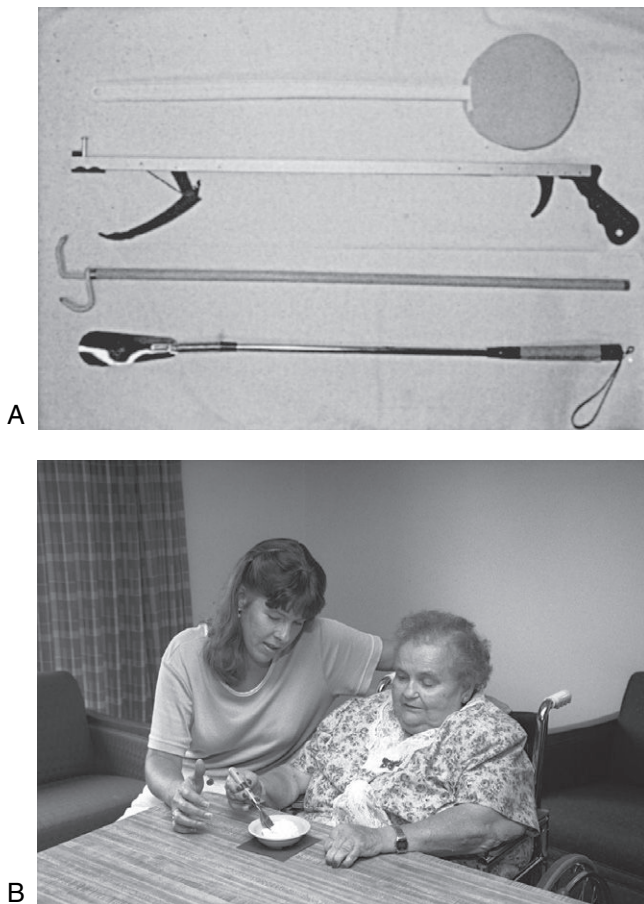

FIGURE 38-20 A, Extended-handle devices. B, Built-up handle. (A, From Harris ED, Budd RC, Genovese MC, et al: *Kelley's textbook of rheumatology*, ed 7, Philadelphia, Pa, 2005, Saunders; B, from Byers-Connon S, Lohman H, Padilla RL: *Occupational therapy for elders: strategies for the COTA*, ed 2, St Louis, Mo, 2004, Mosby.)

Having sample equipment on hand for the client to try can be helpful in finding the best device for each client. In some cases it may be necessary to modify existing devices before the client can use them successfully. For example, the handle of a dressing stick may be built up for a client with limited grasp. Surprisingly little research has been done on assistive devices for clients with arthritis and on the characteristics of device users and nonusers, but clinical experience shows that clients are less likely to use devices that they perceive as not helpful, too complicated, too expensive, or too bothersome to others sharing the environment.^{78,91} A study of device use in frail elderly clients, including some with arthritis, demonstrated that they were willing to use the devices but required assistance in identifying sources for devices.^{60,61} Some clients may need to use assistive devices only during a flare or on more symptomatic days. On good days, it may be appropriate to encourage clients to perform tasks without them to promote strength and mobility.

■ **TABLE 38-8** | Commonly Used Assistive Devices for Arthritis

Activity	Assistive Devices
Dressing	Dressing stick, shoe horn, sock aid, button hook, zipper pull, elastic shoelaces
Bathing	Hand-held shower hose, bath bench, grab bars, long-handled sponge
Toileting	Raised toilet seat, grab bars, extended perineal hygiene aid
Hygiene and grooming	Built-up or extended-handle toothbrush, suction denture brush, extended-handle hairbrush or comb, suction nail brush, mounted nail clipper
Feeding	Built-up or extended-handle utensils, lightweight T-handled mug
Meal preparation	Electric can and jar openers, adapted cutting board, utensils with built-up handles, ergonomic right-angled knives, rolling utility cart, knob turner for stove, reacher
Miscellaneous	Doorknob levers, built-up or extended key holder, extended-handle dust pan, built-up pen, loop or spring-loaded scissors, speaker phone

Client and Family Education

Providing clients with as much information as possible regarding their conditions and treatment is a crucial component of OT and should be integrated throughout all phases of the program. Whether it is the client's first visit or one of many therapy encounters, educational needs should always be explored. The client's estimation of the therapist's credibility, the quality of the therapeutic relationship, and whether the client's experience confirms the therapist's statements are important factors tied to success in changing the client's knowledge and beliefs.⁵⁸ Client education has been shown to empower clients and lead to positive changes in pain reduction, psychologic status, disease management, self-efficacy, and overall health promotion.^{18,39,57,59,62}

Ethical Considerations

Information should be presented at a level appropriate for each client and significant other, along with sensitivity to learning styles; socioeconomic status; educational level; cultural implications; and personal values, beliefs, and feelings.

Rather than focusing exclusively on providing basic information and generic skills, encouraging client self-reflection and transformation of client perspectives has been suggested as a helpful part of rehabilitation.³⁰ Repetition, reinforcement, and real-life application to the client's situation are other keys to education. By focusing on the client's symptoms and concerns, the therapist can capitalize on "teachable moments" to provide present-oriented and problem-focused learning activities.¹⁴ It may be helpful to provide both verbal and written instructions. The following are some important educational aspects to cover: disease process, symptom management, joint protection and fatigue management, and community resources.

Disease Process

Does the client understand the type of arthritis, basic underlying pathology, medications, and medication side effects? Does the client understand that prolonged synovitis in RA can lead to irreversible joint damage and potential disability? Does the client feel comfortable in discussing questions with the physician, nurse, or other treating clinicians? Does the client know of available resources to learn more?

Symptom Management

Does the client know how to monitor for signs and symptoms of inflammation? Does the client understand that pain lasting for more than 1 or 2 hours after an activity signals a need to modify or cease doing that task? Does the client understand the rationale behind, demonstrate appropriate use of, and appropriately integrate rest, exercise, splinting, and PAMs into a daily routine? Do family members understand the client's abilities and when they should or should not assist the client with activities? Does the client know to take a cautious approach to nontraditional arthritis remedies to avoid falling prey to medical quackery?

Joint Protection and Fatigue Management

Does the client understand the rationale and general principles of joint protection and fatigue management? More importantly, does the client successfully integrate them into daily activities? It can be challenging not just to help the client understand the potential implications but also to translate learning into action. The purpose of joint protection is to reduce internal and external joint stress, pain, and inflammation in the involved joints and preserve the integrity of joint structures during the performance of daily activities.⁶⁴ Although it has not been proven that use of joint protection techniques prevents deterioration, knowledge of the disease process and pathomechanics of deformity and clinical experience suggest that joint protection is a sound idea.^{27,67} Studies have shown that clients who experience pain relief or improved function may be more receptive to changing their behavior.^{27,38,68} Fatigue management, a more contemporary term for energy conservation, is aimed toward saving and expending energy wisely (Box 38-5).

Organizing the environment, pacing activity, and resting can successfully moderate fatigue.²⁶ Instruction of principles should be based on teaching key concepts rather than general rules and should be specifically applied to each client's lifestyle and pattern of occupation with the aim of achieving occupational balance.^{64,80,87} Practice in the therapy setting can help with carryover because following these principles often necessitates a change in lifelong habits. General principles for joint protection and fatigue management are especially helpful for clients with RA or clients with OA involving the hands, hips, or knees.^{23,27,64}

Joint protection and fatigue management principles are as follows (more detailed information can be found in the sources just cited):

- Respect pain. Pain is a signal from the body that something is wrong. Clients often feel that they can ignore and work through pain, but the result is often more pain. If pain is present from an acute episode of inflammation, rest and avoidance of activity are indicated so that the pain and inflammation are not worsened. In chronic stages, pain that lasts for more than 1 or 2 hours after completion of an activity indicates that the activity should be modified or avoided. Clients should be encouraged to be aware of their limits and stop activities before pain occurs. Disregard of pain can lead to joint damage.
- Maintain muscle strength and joint ROM. Joints that are less stiff and have balanced strength will be less susceptible to further injury. Limited motion at one joint transmits force to another and may require exaggerated motions at other joints to accomplish a task. For example, loss of MCP motion will affect the PIP joint. Daily functioning and exercise programs should be done with all joint protection principles in mind to ensure that they are as least stressful as possible.
- Use each joint in its most stable anatomic and functional plane. This plane is the point at which resistance to motion is provided by muscle rather than ligament. Following this principle will minimize excessive stress on ligaments and allow muscle power to be used with the greatest mechanical advantage. Examples include not leaning to either side when rising from a seated position to lessen rotational forces on the knees and pinching with the pad of the thumb and the IP joint in a flexed position to minimize force on the ulnar collateral ligament.
- Avoid positions of deformity. The customary way of performing tasks may cause forces to be applied in directions of deformity. Tasks involving tight squeezing, pinching, or twisting motions are especially stressful. Opening a jar lid, turning a doorknob, cutting food with a knife, and lifting a coffee cup are all activities promoting MCP ulnar deviation. Instead, clients with hand involvement can be encouraged to open lids with

Box 38-5

Principles of Fatigue Management

Attitudes and Emotions

- Remove yourself from stressful situations.
- Refrain from concentrating on things that make you tense.
- Close your eyes and visualize pleasant places and thoughts.

Body Mechanics

- When lifting something that is low, bend your knees and lift by straightening your legs. Try to keep your back straight.
- Avoid reaching (use reachers). Avoid stretching, bending, carrying, and climbing. If you have to bend, keep your back straight.
- Incorporate good posture into your activities.
- Whenever possible, sit when working.
- To get up from a chair, slide forward to the edge of the chair. With your feet flat on the floor, lean forward and push with your palms on the arms or seat of the chair.
- Stand by straightening your legs.
- Before you get tired, stop and rest.

Work Pace

- Plan on getting 10 to 12 hours of rest daily (naps and nights).
- Work at your own pace.
- Spread tedious tasks throughout the week.
- Do the tasks that require the most energy at the times when you have the most energy.
- Alternate easy and difficult activities, and take a 10- to 15-minute rest break each hour.

Leisure Time

- Devote a portion of your day to an activity that you enjoy and find relaxing.
- Check out what is available in the community.

Work Methods

- Keep items within easy reach.
- Use good light and proper ventilation and room temperature.
- Use joint protection techniques.
- Work surfaces should be at a correct height.

Organization

- Plan ahead; do not rush or push yourself.
- Decide which jobs are absolutely necessary.
- Share the workload with family and friends.

How to Begin

- Plan ahead by charting your daily routine.
- Make a list of tasks, and spread them out in your schedule.
- Include daily rest periods and rest breaks during energy-consuming times.

Weekly Schedule

TIME	SUN	MON	TUES	WED	THURS	FRI	SAT
7:00							
8:00							
9:00							
10:00							
11:00							
12:00							
1:00							
2:00							
3:00							
4:00							
5:00							
6:00							
7:00							
8:00							
9:00							
10:00							

Check your schedule for the following factors:

- Is there 1 day in the week that is longer than the others?
- Are heavier tasks distributed through the week?
- Is there a long task that could be done in several steps?
- Will your plan allow flexibility?
- Have you devoted part of your day to a relaxing activity?
- Does your plan use the principles of energy conservation?

the palm of their hand and shoulder motion or with a jar opener; to turn a doorknob with an adapted lever; to cut food with a dagger-type grip, rolling pizza cutter, or adapted knife; and to lift coffee mugs with two hands. Static positioning should also be considered. For example, clients should be discouraged from leaning their chin on the back of the fingers because this applies considerable force to the flexed MCP joints.

- Use the strongest joints available. Using larger, inherently stronger joints reduces the stress on smaller joints. Carrying bags and purses on the shoulder or elbow lessens strain on the wrist and hand. Properly fitting backpacks or waist packs are other good alternatives, as is pushing or pulling a rolling cart instead of carrying items on the body. The palms rather than the fingers should be used to lift, push, or take weight to better distribute the forces.

FIGURE 38-21 Use of palms to push off a chair helps protect finger joints.

- Ensure correct patterns of movement. The client may adopt incorrect patterns because of pain, deformity, muscle imbalance, or habit. For example, the client may use the dorsum of the fingers to push up from a seated position. This movement places deforming forces toward MCP flexion. A more suitable pattern is to use the flat surface of the palm (Figure 38-21). In the hand, use of the long extensors during finger movement should be maintained. Finger flexion should be initiated at the DIP joints while maintaining extension at the MCP joints versus leading motion with the intrinsic muscles.
- Avoid staying in one position for long periods. Prolonged static positions can lead to joint stiffness and muscle fatigue. Positional stress is then transmitted to the joint ligaments, which may already be in a weakened state. Changing body positions and gripping postures, taking frequent breaks, and integrating active motion exercises during activities such as computer keyboarding, writing, gardening, and knitting can prevent fatigue, soreness, stiffness, and resulting poor movement patterns.
- Avoid starting an activity that cannot be stopped immediately if it becomes too stressful. This will prevent the load from going to the joint capsule and ligaments if muscles tire. Continuing a task that causes sudden or severe pain is likely to cause joint damage, and severe fatigue can cause poor movement patterns and safety risks. Realistic planning of options can help prevent these situations. For example, clients can keep a

bath bench available in case they need to rest while standing in the shower. Clients also can note the location of benches in a mall in relation to the stores where they plan to shop.

- Balance rest and activity. Chronic pain and a systemic disease such as RA can drain both physical and psychologic resources. Helping the client understand the physiologic need for proper rest can facilitate this often difficult lifestyle change. The key to increasing functional endurance is to rest before becoming overfatigued, which could mean napping or taking breaks during or between activities. Clients with arthritis often relate similar stories of feeling a need to take advantage of good days by trying to complete as many tasks as possible. These good days are more than likely followed by several bad days as their bodies try to recover. Balancing activities during the day and longer-term across the week or month can be accomplished through planning and establishing priorities.
- Reduce force and effort. Less force and effort equate to less joint stress, less pain, and less fatigue. Using built-up handles, levers, more even distribution of loads, alternative methods, and other aforementioned joint protection and fatigue management techniques can help toward this end. For example, rearranging the kitchen environment to have everything within easy reach, planning tasks and gathering all needed items, sitting down while at the sink or stove, and using assistive devices all contribute to easier meal preparation.

Community Resources

Does the client know of and use available resources? Clients should be made aware and encouraged to take advantage of them. Reading materials, exercise and educational programs, and support groups can supplement medical and therapy intervention and promote lasting positive self-management behavior. The Internet, libraries, YMCAs, and senior centers are sources of information and activity or exercise programs. The Arthritis Foundation, a national organization with many local chapters throughout the country, is an excellent resource for clients, families, and clinicians. Among other services, the Arthritis Foundation offers educational pamphlets, pool- and land-based exercise programs, self-help groups, and support groups designed exclusively for persons with arthritis. Box 38-6 highlights some programs and materials of special relevance to persons with RA and OA.

Occupational performance training was an important component of Nina's OT intervention. Her ability to continue working was addressed through a combination of modification of activities, use of assistive devices, and client education. Client education focused on her ability to better understand her disease process, manage her symptoms, and integrate joint protection and fatigue management principles into her life. Nina and the therapist reviewed her typical

Selected Arthritis Foundation Programs and Materials

Exercise Programs

- Arthritis Foundation Aquatic Program (community water exercise)
- Arthritis Foundation Exercise Program (community exercise, varying levels)
- Arthritis Today Walking Guide (tips, 12-week home walking plan)
- Tai Chi Program
- Walk with Ease (audiotape and book)

Educational Programs

- Arthritis Foundation Self-Help Program (group education)

Written Materials

- Arthritis Answers
- Arthritis in the Workplace
- Arthritis Today magazine
- Arthritis Today Drug Guide
- Arthritis Today Supplement Guide
- Complementary Therapies
- Exercise and Your Arthritis
- Gardening and Arthritis
- Living with Osteoarthritis
- Living with Rheumatoid Arthritis
- Managing Your Activities
- Managing Your Fatigue
- Managing Your Pain
- Managing Your Stress
- Nutrition and Your Arthritis
- Protect Your Joints
- Range of Motion Exercises
- Surgery and Arthritis

- RA Connect Online Community

weekly schedule and together planned one that allowed a more suitable balance of rest and activity given her patterns of fatigue and peak energy. The therapist recommended ways to improve Nina's computer workstation at home, including moving the keyboard and monitor to more appropriate heights, adjusting her chair for optimal body positioning, using a pad to support her wrists, and switching from a standard mouse to a trackball device. Assistive devices were recommended for other occupations, such as cooking and managing her home. Mutual problem solving identified solutions that allowed Nina to gradually return to her previous level of work hours. Among these solutions were having Nina do much more work from her home, where she could rest as needed, and to spread out visits to her contracted businesses over several weeks and only when needed. Planning and taking an afternoon rest before

picking up her grandchildren from school gave her the energy to take them to the park more frequently.

Summary

Arthritis is a chronic condition that can impose devastating limitations on a person's ability to engage in meaningful occupations. It is important for the therapist to understand the different disease processes and pathomechanics of the joint destruction found in OA and RA. Through a carefully crafted program based on a thorough evaluation of the physical, psychosocial, and functional barriers, OT can decrease pain, protect joints, and enable increased participation in life skills.

Threaded Case Study Nina, Part 2

Critical evaluation components in assessing Nina's previous and current functional status were the occupational profile and typical-day assessment; assessment of clinical status included pain, inflammation, stiffness, range of motion, strength, endurance, and functional mobility. The aspects of the disease process most problematic to Nina were inflammation, pain, and fatigue from a flare of her rheumatoid arthritis. Her ability to engage in her employment was affected by her motor and process performance skills; roles and routines performance patterns; physical, social, personal, temporal, and virtual contexts; object, space, body functions, and body structures activity demands; and sleep, energy, attention, joints, and muscle function client factors.

Nina benefited from splinting, exercise, heat, and occupational performance training with activity modification, assistive devices, and client education in symptom management, joint protection, fatigue management, and available resources. A collaborative approach throughout the entire therapy process was essential in promoting lasting benefits and engagement in meaningful occupations.

Review Questions

1. What are the major differences between osteoarthritis and rheumatoid arthritis?
2. What are three systemic signs of rheumatoid arthritis?
3. What are the clinical signs of joint inflammation?
4. When is resistive exercise appropriate for persons with rheumatoid arthritis?
5. What are the typical indications for splinting in arthritis?
6. What are the purposes and major principles of joint protection and fatigue management?
7. What assistive devices are commonly helpful for clients with arthritis?
8. What are the general treatment precautions related to arthritis?

Hand and Upper Extremity Injuries

39

MARY C. KASCH
J. MARTIN WALSH

■ Chapter Outline

Examination and evaluation

Observation and topographic assessment
Assessment of performance skills and client factors
Grip and pinch strength
Functional assessment

Intervention

Fractures
Nerve injuries
Tendon injuries
Complex injuries
Edema
Wound healing and scar remodeling

Pain syndromes

Joint stiffness
Cumulative trauma disorders
Strengthening activities
Purposeful and occupation-based activity

Functional capacity evaluation

Work hardening
Consultation with industry
Psychosocial effects of hand injuries
Summary

■ Key Terms

Upper quadrant

Edema

Provocative tests

Splinting

Peripheral nerve injuries

Tendon injuries

Complex regional pain syndrome

Cumulative trauma disorders

Functional capacity evaluation

Ergonomic

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Discuss the incidence and effect of upper extremity (UE) injuries in the United States and their effects on occupational performance.
2. Identify three upper quarter screening tests, and explain their significance in developing an intervention plan.
3. Discuss the importance of joint mobility in regaining the motor performance skill of hand function.
4. Describe the four categories of tests used to evaluate peripheral nerve function, and explain how the results would be used in developing an intervention plan.
5. Compare the standardized tests used to assess the motor performance skill of hand function.
6. Describe the sensory and motor innervation patterns of the three major nerves, and differentiate between the effects of proximal and distal lesions in each of the nerves and how they might affect occupational performance.

■ Learning Objectives—cont'd

7. Discuss complex regional pain syndrome and the intervention approaches that should be included in the occupational therapy (OT) intervention plan for that disorder.
8. Compare techniques used in the rehabilitation of tendon injuries.
9. Describe the significance of edema with regard to wound healing and joint mobility.
10. Discuss the role of the occupational therapist in the evaluation and rehabilitation of injured workers.

Threaded Case Study | Gerry, Part 1

Gerry is a 32-year-old man who is self-employed as a cabinetmaker. He sustained a table saw injury to his nondominant left hand while working. The thumb, index, and middle fingers of Gerry's left hand were amputated at the level of the proximal phalanges as a result of the saw injury and were subsequently replanted by a hand surgeon using microsurgical techniques. Gerry is single, lives with a roommate, and is in business with his father in a small but busy cabinet shop. Gerry is extremely active at work and during his free time. He is very social and has an extensive network of supportive friends and family.

Gerry was referred to hand therapy as an inpatient 5 days after the replantation surgeries, as soon as he was discontinued from the anticoagulation medications. The initial interview with Gerry was performed at bedside. He was to be discharged from the hospital the following day with instructions to return for outpatient hand therapy. A protective splint was fabricated on the first therapy session, and Gerry was taught about postsurgical precautions, wound care, and dressing changes. During the initial evaluation, Gerry said that he was very distressed about the potential loss of function of his left hand and that he wanted to accomplish three of his most valued occupations in the months to come. The first occupation was to return to work with his father making cabinets in the family business, the second was to resume playing softball with his league, and the third was to play golf again. The first occupation was

one he valued not only as a source of livelihood but also as a profession in which he demonstrated great skill and derived joy. The second two occupations were important to him not only as a source of relaxation but, more important, as a primary venue for social interaction with friends and family.

Gerry initiated hand therapy in the hospital during the acute phase of his recovery. He was followed in hand therapy for 15 months from the date of his injury and through several additional surgeries and throughout all phases of his rehabilitative process: the acute or immobilization phase, the intermediate or mobilization phase, and the late or strengthening phase.²³ During the initial evaluation, Gerry clearly expressed a desire to return to three specific occupations of value to him: working as a cabinetmaker, playing golf, and playing softball.

Critical Thinking Questions

1. How will the intervention plan change over the course of Gerry's recovery? What specific intervention approaches will be used during the three phases of his recovery?
2. What specific tools or instruments will be used to assess Gerry's performance skills during the different phases of his recovery?
3. What are some of the specific preparatory methods and purposeful activities that may be used in preparation for Gerry's occupation-based performance activity of golf?

Treatment of the upper extremity (UE) is important to all occupational therapists who work with persons with physical disabilities. The incidence of UE injuries is significant and accounts for about one third of acute injuries overall⁵⁶ and 26% of work-related injuries.¹⁰¹ In addition, disease and congenital anomalies contribute to UE dysfunction, and it is estimated that only about 15% of those who experience severe cerebrovascular accident recover hand function.⁵⁶

The hand is vital to human function and appearance. It flexes, extends, opposes, and grasps thousands of times daily, allowing the performance of necessary daily activities. The hand's sensibility allows feeling without looking and

provides protection from injury. The hand touches, gives comfort, and expresses emotions. Loss of hand function through injury or disease thus affects much more than the mechanical tasks that the hand performs. Hand injury may jeopardize a family's livelihood and, at the least, affects every daily activity. The occupational therapist with training in physical and psychological assessment, prosthetic evaluation, fabrication of orthoses, assessment and training in the activities of daily living (ADLs), and functional restoration is uniquely qualified to treat UE disorders.

Hand rehabilitation, or hand therapy, has grown as a specialty area of occupational therapy (OT) and physical therapy (PT). Many of the intervention techniques used

with hand-injured clients have evolved from the application of therapy and knowledge of both specialties to be used by the hand therapist. It is not the purpose of this chapter to instruct the OT student in physical agent modalities. Rather, intervention techniques that have been found to be beneficial to clients with hand injuries are presented. It is assumed that therapists best trained to provide them will provide these techniques.

As used in this chapter, *hand therapy* is a term that includes intervention of the entire upper quadrant, which includes the scapula, shoulder, and arm. Upper quadrant and UE are used interchangeably. UE rehabilitation requires advanced and specialized training by both occupational and physical therapists. A practice analysis study of the theory and knowledge that serves as the underpinning for hand therapy has been reported.³⁶ Intervention techniques, whether thermal modalities or specifically designed exercises, are used as a bridge to reach a further goal of restoring functional performance. Thus, some modalities may be used as adjunctive or enabling modalities in preparation for functional use. It is within this context that intervention techniques are presented in this chapter.

Intervention for the injured UE is a matter of timing and judgment. After trauma or surgery, a healing phase must occur in which the body performs its physiologic function of wound healing. After the initial healing phase, when cellular restoration has been accomplished, the wound enters its restorative phase. It is in this phase that hand therapy is most beneficial. Early intervention that occurs in this restorative phase is ideal and in some cases essential for optimal results.

Although sample timetables may be presented, the therapist should always coordinate the application of any intervention with the referring physician. Surgical techniques may vary, and inappropriate treatment of the client with hand injury can result in failure of a surgical procedure.

Communication among the surgeon, therapist, and client is especially vital in this setting. A comfortable environment that allows group interaction may increase client motivation and cooperation. The presence of the therapist as an instructor and evaluator is essential, but without

the client's cooperation limited gains will be achieved. Treating the psychological loss suffered by the client with a hand injury is also an integral part of the rehabilitative therapy.

In UE rehabilitation, changes have been manifested as changes in delivery of services. In some cases, therapists are not members of the approved provider panel and are no longer able to treat clients who are members of a health maintenance organization. Reimbursement patterns have altered the provision of services by limiting the number of visits authorized. Therapists are also being asked to provide outcome data that support the need for services. They also need high-quality information on which to base clinical decisions, which points to the need for evidence-based practice.⁶¹ Evidence-based practice uses the best evidence in conjunction with clinical expertise and patient values to make clinical decisions.²⁰ It is likely that outcome-based or evidence-based intervention plans with functional goals and analysis of goal achievement will become the standard for the reimbursement of OT services. In addition, client satisfaction and perception of health status have become crucial in the delivery of medical care in a consumer-based economy. Continuous quality improvement documentation is often required for participation in managed care programs. With fewer authorized visits, the therapist must be more adept in instructing the client in self-management of the condition being treated. Hand therapists and rehabilitation providers are also subject to intense scrutiny and review by multiple regulatory agencies. Insurance companies and government agencies also review patient records and billing documentation. In addition, reimbursement for therapy services relies on detailed documentation of services provided. The best way to assure compliance with all of these agencies is to perform frequent reviews of patients' medical records in the form of chart reviews.⁴² In the future, occupational therapists should anticipate a greater need to justify intervention as part of the national challenge to control medical costs. Aides, certified assistants, and other support personnel will be used increasingly, but the quality of services provided must continue to meet all professional and ethical standards. This climate of change will present unique opportunities for the occupational therapist. Clinical specialists may find new roles as consultants and trainers. Just as OT teaches the client to adapt to changes in health status, the OT profession will need to adapt to social and economic changes to remain a leader in health management.

OT Practice Notes

Hand therapy is provided in a number of intervention settings, ranging from private therapy offices to outpatient rehabilitation clinics and hospitals or even in the workplace. Reimbursement for services may come directly from the client or through private medical insurance, workers' compensation insurance, or a variety of managed care programs. Changes in reimbursement have driven changes in the marketplace and employment patterns. In the future, OT will be provided in a variety of new settings and OT intervention will continue to evolve.

Examination and Evaluation

When approaching a client who has a hand injury, the occupational therapist must gather information about the client's occupational history, including a detailed description, from the client's perspective, regarding how the hand injury may interfere with the resumption of daily rounds of

meaningful occupation. Armed with this occupational profile, the therapist and client continue the evaluation process. The therapist must be able to evaluate the nature of the injury and the limitations it has produced. First, the injured structures must be identified by consulting with the hand surgeon, reviewing operative reports and x-ray films, and discussing the injury with the client. Assessment of bone, tendon, and nerve function must be ascertained, using standardized assessment techniques whenever possible.

The client's age, occupation, and hand dominance should be taken into account in the initial evaluation. The type and extent of medical and surgical treatment that has been received and the length of time since such intervention are important in determining an intervention plan. Any further surgery or conservative intervention that is planned should also be noted. A written intervention plan should have the approval of the referring physician. Most physicians welcome observations and evaluation-based recommendations from the therapist regarding the client's care.

The purposes of hand evaluation are to identify physical limitations, such as loss of range of motion (ROM); functional limitations, such as an inability to perform daily tasks;³ substitution patterns to compensate for loss of sensibility or motor function;⁴ and abnormalities, such as joint contracture.

The movement of the arm and hand must be coordinated for maximal function. Shoulder motion is essential for positioning the hand and elbow for daily activities.²² The wrist is the key joint in the position of function.¹² Skilled hand performance depends on wrist stability. Although a mobile wrist is preferable, function is possible as long as the wrist is positioned to maximize movement of the fingers. Function also depends on arm and shoulder stability and mobility for fixing or positioning the hand for activity. The thumb is of greater importance than any other digit. Effective pinch is almost impossible without a thumb, and attempts will be made to salvage or reconstruct an injured thumb whenever possible. Within the hand the proximal interphalangeal (PIP) joint is critical for grasp and is considered to be the most important small joint.¹² Limitations in flexion or extension will result in significant functional impairment.

The hand therapy evaluation should, therefore, consist of two concurrent stages. One stage consists of assessing the client's occupational profile to help the therapist select an effective intervention that addresses the client's occupational priorities. The other stage of the hand therapy evaluation consists of assessing specific performance skills, such as coordination and strength, and client factors, such as sensory functions, neuromusculoskeletal and movement-related functions, and the functions of the hand and related structures. Evaluating both the client's occupational profile and the client's performance skills ensures that the client's priorities are addressed and makes the intervention more meaningful.

Observation and Topographic Assessment

The occupational therapist should observe the appearance of the entire UE. The position of the hand and arm at rest, and the carrying posture can yield valuable information about the dysfunction. The therapist should observe the way that the client treats the disease or injury. The therapist should note if the hand and arm are overprotected and carefully guarded or ignored and if the client carries the arm close to the body, in an awkward posture, or even covered.

The cervical and shoulder area posture should be observed for evidence of abnormalities in cervical and thoracic curvature that may reduce the potential for shoulder movement. Muscle atrophy may be evident in the scapular area if there has been significant long-term weakness or if the rotator cuff is torn. The scapula may appear asymmetrical or altered if muscle imbalances of length or strength are present.

The skin condition of the hand and arm should be noted. In particular, the therapist should note any lacerations, sutures, or evidence of recent surgery; whether the skin is dry or moist; whether scales or crusts are present; and whether the hand appears swollen or has an odor. Palmar skin is less mobile than dorsal skin normally. The therapist should determine the degree of mobility and elasticity and the adherence of scars. The therapist should also observe trophic changes in the skin. To assess the vascular system, the therapist should observe the skin color and temperature of the hand and evaluate for the presence of edema (swelling). Any contractures of the web spaces should be noted. The therapist should observe the relationship between hand and arm function as the client moves about and performs test items or tasks.

The therapist should ask the client to perform some simple bilateral ADLs, such as buttoning a button, putting on a shirt, opening a jar, and threading a needle, and observe the amount of spontaneous movement and use of the affected hand and arm. Similar screening tests can be used to determine shoulder mobility, such as reaching overhead, as well as placing the hand behind the back and behind the head.

Assessment of Performance Skills and Client Factors

A number of standardized tests can be used to determine physical limitations in the UE. Joint measurement and manual muscle testing are crucial and are described in other chapters (see [Chapters 21 and 22](#)). Special tests used by the hand therapist are described here in a general sense, but the student should consult other textbooks for detailed instructions in such areas as assessment of adverse neural tension.¹⁶

Screening the Cervical Neck and Shoulder

Screening examination of the cervical neck and shoulder regions should be included in evaluation of hand conditions to determine whether these areas are contributing to the client's symptoms or limitations in function.

Active movements of the neck should be conducted, with attention paid to complaints of UE symptoms during cervical extension or lateral flexion to the same side. Complaints during these movements may suggest nerve root irritation. Hand symptoms with opposite side bending may be a sign of adverse neural tension. Few occupational therapists are knowledgeable in the intervention of cervical conditions, and care must be taken not to aggravate an existing condition. The therapist should return the client to the referring physician with recommendations for referral to an appropriate practitioner if the results of this testing are positive.

Assessment of Movement

The effect of trauma or dysfunction on anatomic structures is the first consideration in evaluating hand function. The joints must be assessed for active and passive mobility, fixed deformities, and any tendency to assume a position of deformity. The ligaments must be assessed for laxity or contracture and their ability to maintain joint stability. Tendons must be examined for integrity, contracture, or overstretching; muscles are tested for strength and function.

Limited Movement in the Shoulder

Examples of conditions in the shoulder region leading to reduced strength, reduced ROM, or pain in the shoulder are outlined in Table 39-1. Comparing initial responses with the results of follow-up evaluation will help document a positive response to intervention. Patterns of impairments in UE ROM and strength, as well as a positive response to

provocative testing, should be reported to the referring physician if they would affect the client’s planned intervention or outcome. Therapists must not attempt to treat conditions that are beyond their scope of knowledge. Referral to an appropriate practitioner should be discussed with the physician if indicated.

Impingement Tests

The examiner passively overpressures the client’s arm into end-range elevation. This movement causes a jamming of the greater tuberosity against the anterior inferior acromial surface.⁸⁰ The test is positive if the client’s facial expression shows pain. An alternative test is described by Hawkins and Kennedy.⁴⁶ The examiner forward flexes the arm to 90 degrees then forcibly internally rotates the arm. Pain indicates a positive test result.

Drop Arm Test

The client’s arm is passively abducted by the examiner to 90 degrees with the client’s palm down. The client is then asked to lower the arm actively. Pain or inability to lower the arm smoothly with good motor control is considered a positive test result.^{66,86}

Soft-Tissue Tightness

Joints may develop dysfunction after trauma, immobilization, or disuse. Menell emphasized the importance of the small, involuntary motions of the joint, which he referred to as “joint play.”⁷⁵ Others⁶⁷ have described these as “accessory motions.” Both terms describe those movements that are involuntary and physiologic and can be performed only

■ **TABLE 39-1** | Clinical Tests for Specific Dysfunction in the Shoulder

Condition	Pattern of Impairment	Characteristic Findings/Special Tests
Adhesive capsulitis	Loss of active and passive shoulder motion with the most pronounced loss in external rotation and, to a lesser degree, abduction and internal rotation	Capsular end feel to passive motions in restricted planes of movement
Subacromial impingement	Painful arc of motion between approximately 80 and 100 degrees elevation or at end range of active elevation	In early stages, muscle tests may be strong and painless despite positive impingement test
Rotator cuff tendinitis	Painful active or resistive rotator cuff muscle use	Painful manual muscle test of scapular plane abduction or external rotation Nonpainful passive motion end ranges Tenderness at tendons of supraspinatus or infraspinatus.
Rotator cuff tear	Significant substitution of scapula with attempted arm elevation	Positive drop arm test Very weak, less than three-fifths abduction or external rotation

by someone else.⁵⁷ Examples of accessory motions are joint rotation and joint distraction. If accessory motions are limited and painful, the active motions of that joint cannot be normal. Therefore, it is necessary to restore joint play through the use of joint mobilization techniques before attempting passive or active ROM.⁷⁶

Joint mobilization may date back to the fourth century BC, when Hippocrates first described the use of spinal traction.⁵⁷ In the 1930s, an English physician, James Mennell, encouraged physicians to perform manipulation without anesthesia, a practice that is advocated today by James Cyriax,³⁰ who explored the use of manipulation of the intervertebral disks. Current theorists include Cyriax, Robert Maigne, F.M. Kaltenborn, G.D. Maitland, Stanley Paris, and John Mennell, son of the late James Mennell. Although physicians originally practiced manipulation, therapists have adapted the techniques, which are now called joint mobilization.

The techniques used to assess joint play are also used in the treatment of joint dysfunction. During assessment the evaluator determines the range of accessory motion and the presence of pain by taking up the slack only in the joint. Some practitioners advocate use of a high-velocity, low-amplitude thrust or graded oscillation to regain motion and relieve pain.⁶⁷

Guidelines must be followed in applying joint mobilization techniques, and the untrained or inexperienced practitioner should not attempt to use the techniques. Postgraduate courses are offered in joint mobilization of the extremities, and the therapist must be familiar with the orthokinematics of each joint, as well as with the techniques used.

Joint mobilization is generally indicated with restriction of accessory motions or the presence of pain caused by tightness of the joint capsule, meniscus displacement, muscle guarding, ligamentous tightness, or adherence. It is contraindicated in the presence of infection, recent fracture, neoplasm, joint inflammation, rheumatoid arthritis, osteoporosis, degenerative joint disease, and many chronic diseases.⁵⁷

Limitations in joint motion may also be caused by tightness of the extrinsic or intrinsic muscles and tendons. If the joint capsule is not tight and accessory motions are normal, the therapist should test for extrinsic and intrinsic tightness.

To test for extrinsic extensor tightness, the metacarpophalangeal (MP) joint is passively held in extension and the PIP joint is moved passively into flexion. Then the MP joint is flexed, and the PIP joint is again passively flexed. If the PIP joint can be flexed easily when the MP joint is extended but not when the MP joint is flexed, the extrinsic extensors are adherent.⁴

If there is extrinsic flexor tightness, the PIP and distal interphalangeal (DIP) joints will be positioned in flexion, with the MP joints held in extension. It will not be possible to pull the fingers into complete extension. If the wrist is

then held in flexion, the IP joints will extend more easily because slack is placed on the flexor tendons.

Tightness of the intrinsic musculature is tested by passively holding the MP joint in extension and applying pressure just distal to the PIP joint. This action is repeated with the MP joint in flexion. If there is more resistance when the MP joint is extended, intrinsic tightness is indicated.⁴

If passive motion of the PIP joint remains the same whether the MP joint is held in extension or flexion and there is limitation of PIP joint flexion in any position, tightness of the joint capsule is indicated. The therapist should assess the joint for capsular tightness if this has not already been done.

Provocative tests that are used to assess ligament, capsule, and joint instability are summarized in Table 39-2. For more detailed and comprehensive information regarding administration of these tests, the reader is referred to textbooks dedicated solely to hand therapy or to the specific topic.^{66,86}

Assessment of Peripheral Nerve Status

Nerve dysfunction can occur at any point from the nerve roots through the digital nerves in the fingers. A good understanding of the peripheral nervous system is essential for appropriate treatment of the UE. Determining the approximate location of nerve dysfunction can assist in intervention planning.

Categories of Tests

A variety of tests may be required to assess nerve function adequately. These tests can be divided into four categories: (1) modality tests for pain, heat, cold, and touch pressure; (2) functional tests to assess the quality of sensibility, or what Moberg⁷⁹ described as “tactile gnosis”; (3) objective tests that do not require active participation by the client; (4) and provocative tests that reproduce symptoms.

Examples of functional tests are stationary and moving two-point discrimination and the Moberg pick-up test; objective tests include the wrinkle test, the Ninhydrin sweat test, and nerve-conduction studies.¹⁹ Electrodiagnostic testing is the most conclusive and widely accepted method of determining nerve dysfunction.

Provocative tests are highly suggestive of a nerve lesion if results are positive but do not rule out a problem if results are negative. Tests of nerve dysfunction are summarized in Table 39-3. Instructions for administration of the most common tests are described in the following paragraphs.

Adson Maneuver

The examiner palpates the radial pulse on the arm to be tested. The client then rotates the head toward the arm being tested. The client then extends the head and holds a deep breath while the arm is being laterally rotated and extended. Disappearance or slowing of pulse rate is considered a positive test result suggesting presence of thoracic outlet syndrome.^{1,66}

TABLE 39-2 | Clinical Tests for Specific Dysfunction in the Wrist

Condition	Pattern of Impairment	Special Tests
Thumb ulnar collateral ligament (gamekeeper's or skier's thumb)	Pain and instability of the thumb MP joint	Movement greater than 35 degrees when valgus instability stress is applied to the thumb MP joint
Instability of the scaphoid	Pain in the area of the scaphoid bone (anatomic snuffbox) or "clunking" with movement of the wrist	Watson test Pain or sound associated with subluxation of the dorsal pole of the scaphoid while performing test
Instability of the distal radioulnar joint	Pain and tenderness in the wrist	"Piano keys" test Hypermobility and pain associated with pressure on the distal ulna
Lunate dislocation	Pain or instability in the central wrist	Murphy's sign Head of the third metacarpal level with the second and fourth metacarpals while making a fist
Lunotriquetral instability	Pain or instability in the central or ulnar wrist	Lunotriquetral ballottement test Crepitus; laxity or pain with isolated movement of the lunate
TFCC tear	Pain and instability in the ulnar wrist	Wrist arthrogram or MRI

TABLE 39-3 | Clinical Tests for Specific Nerve Dysfunction in the Upper Extremity

Condition	Pattern of Impairment	Characteristic Findings/Special Tests
Thoracic outlet syndrome	Nonspecific paresthesias or heaviness with sustained positioning or activity above shoulder level or behind the plane of the body	Adson test Roos test
Adverse neural tension	Nonspecific pain or paresthesias with reaching in positions that place tension on brachial plexus nerves	Positive upper limb screening test
Carpal tunnel syndrome	Pain and numbness, primarily in the thumb, index, and middle fingers Usually worse at night and may be associated with activity	Tinel's sign at the wrist Phalen's test Reverse Phalen's test Carpal compression test
Cubital tunnel syndrome	Compression of ulnar nerve at elbow	Elbow flexion test
Ulnar nerve paralysis	Paralysis of the adductor pollicis muscle	Froment's sign Jeanne's sign Wartenberg's sign

Roos Test

In this test the client maintains a position of bilateral arm abduction to 90 degrees, shoulder external rotation, and elbow flexion to 90 degrees for 3 minutes while slowly alternating between an open hand and a clenched fist. Inability to maintain this position for the full 3 minutes or onset of symptoms is considered a positive test result for thoracic outlet syndrome.^{66,88}

**Upper Limb Tension Test
(Brachial Plexus Tension Test)**

This test is designed to screen for symptoms that are produced when tension stress is placed on the brachial plexus. The maneuver described primarily stresses the median nerve and C5-C7 nerve roots. Adverse neural tension in the ulnar or radial nerves may also be tested. However, we have found that using the median nerve test as a screening device establishes a marker against which to gauge the success of intervention. Although some authors recommend using the neural tension tests for intervention as well as assessment, this has not been the practice of the authors. The occupational therapist should use this screening process to rule out or confirm the involvement of more proximal structures.

The client is positioned supine, and the examiner takes the client's arm into abduction and external rotation behind the coronal plane at the shoulder. The shoulder girdle is fixed in depression. The elbow is then passively extended with the wrist in extension and the forearm in supination. Symptoms of stretch or ache in the cubital fossa or tingling in the thumb and first three fingers indicate tension on the median nerve. Lateral flexion of the neck to the opposite side will amplify symptoms by increasing tension on the dura mater. Elbow extension ROM should be compared with the uninvolved side to indicate the degree of restriction.^{16,66}

Tinel's Sign

The test is performed by tapping gently along the course of a peripheral nerve, starting distally and moving proximally to elicit a tingling sensation in the fingertip. The point at which tapping begins to elicit a tingling sensation is noted and indicates the approximate location of nerve compression. This test is also used after nerve repair to determine the extent of sensory axon growth.⁹²

Phalen's Test and Reverse Phalen's Test

Phalen's test is performed by fully flexing the wrists with the dorsum of the hands pressing against each other. Reverse Phalen's is performed by holding the hands in the "prayer" position for 1 minute. The test results are positive if the client reports tingling in the median nerve distribution (thumb, index, middle and radial aspect of ring finger) within 1 minute.

Carpal Compression Test

The examiner places pressure over the median nerve in the carpal tunnel for up to 30 seconds. The test result is positive if tingling occurs in the median nerve distribution. The combination of wrist flexion and compression of the median nerve for 20 seconds has been found to be more sensitive than other provocative tests used alone.⁹⁶

Elbow Flexion Test

The elbow flexion test is used to screen for cubital tunnel syndrome (compression of the ulnar nerve in the cubital tunnel). The client is asked to fully flex the elbows with the wrists fully extended for a period of 3 to 5 minutes. The test result is positive if tingling is reported in the ulnar nerve distribution of the forearm and hand (ulnar ring finger and small finger).⁶⁶

**Quick Tests for Motor Function
in the Peripheral Nerves**

The ulnar nerve may be tested by asking the client to pinch with the thumb and index finger and palpating the first dorsal interosseous muscle. Another test for ulnar nerve paralysis involves asking a client to grasp a piece of paper between the thumb and index finger. When the examiner pulls away the paper, the tip of the thumb flexes because of absence of the adductor pollicis muscle (Froment's sign). If the MP joint of the thumb also extends at the same time, it is known as Jeanne's sign. Wartenberg's sign for ulnar nerve compression is positive if the client is unable to adduct the small finger when the hand is placed palm down on the table with the fingers passively abducted.

The radial nerve may be tested by asking the client to extend the wrist and fingers. Median nerve function is tested by asking the client to oppose the thumb to the fingers and flex the fingers.⁶⁶

Sensory Mapping

Detailed sensibility testing can begin with sensory mapping of the entire volar surface of the hand.¹⁹ The hand must be supported by the examiner's hand or be resting in a medium such as therapy putty to stabilize the hand during testing. The examiner draws a probe, usually the eraser end of a pencil, lightly over the skin from the area of normal sensibility to the area of abnormal sensibility. The client must immediately report the exact location where the sensation changes. This is done from proximal to distal and radial and ulnar to medial directions. The areas are carefully marked and transferred to a permanent record. Mapping should be repeated at monthly intervals during nerve regeneration.

Sympathetic Function

Recovery of sympathetic response such as sudomotor (sweating), vasomotor (temperature discrimination), pilomotor (gooseflesh), and trophic (skin texture, nail, and hair growth) may occur early but does not correlate with functional recovery.³¹ O'Riain observed that denervated skin

does not wrinkle.⁸² Therefore, nerve function may be tested by immersing the hand in water for 5 minutes and noting the presence or absence of skin wrinkling. This test may be especially helpful in diagnosing a nerve lesion in young children. The ability to sweat is also lost with a nerve lesion. A Ninhydrin test evaluates sweating of the finger.⁷⁹

The wrinkle test and the Ninhydrin test are objective tests of sympathetic function. Recovery of sweating has not been shown to correlate with the recovery of sensation, but the absence of sweating correlates with the lack of discriminatory sensation. Other signs of sympathetic dysfunction are smooth, shiny skin; nail changes; and “pencil-pointing” or tapering of the fingers.¹⁰⁵

Nerve Compression and Nerve Regeneration

Sensibility testing is performed to assess the recovery of a nerve following laceration and repair, as well as to determine the presence of a nerve compression syndrome and the return of nerve function after surgical decompression or the efficacy of conservative intervention to reduce compression. Therefore, tests such as vibratory tests may be interpreted differently, depending on the mechanism of nerve dysfunction. In the following section, tests are described and differences drawn as appropriate to assist the therapist in selecting the correct assessment technique, as well as in planning treatment based on the evaluative measures.

During the first 2 to 4 months after nerve suture, axons regenerate and travel through the hand at a rate of about 1 mm per day, or 1 inch (2.54 cm) per month. Tinel’s sign may be used to follow this regeneration. As regeneration occurs, hypoesthesias develop. Although this hypersensitivity may be uncomfortable for the client, it is a positive sign of nerve growth. An intervention program for desensitization of hypersensitive areas can be initiated as soon as the skin is healed and can tolerate gentle rubbing and immersion in textures. Desensitization is discussed further in the intervention section.

Vibration

Dellon was an early advocate of the use of 30-cycles-per-second (30-cps) and 256-cps tuning forks for assessing the return of vibratory sensation after nerve repair, as regeneration occurs and as a guideline for initiating a sensory re-education program.^{30,32} However, many clinicians found that use of a tuning fork was not discrete enough to detect sensory abnormalities.

Lundborg has described the use of commercial vibrometers to detect abnormal sensation.⁶⁴ This method was less subjective and thought to be more reliable. In a study of induced median nerve compression, Gelberman found that vibration and touch perception as measured by the Semmes-Weinstein monofilaments are altered before two-point discrimination because they measure a single nerve fiber innervating a group of receptor cells.⁴⁴ Two-point discrimination is a test of innervation density that requires overlapping sensory units and cortical integration. Thus, two-point

discrimination is altered after nerve laceration and repair but remains normal if the nerve is compressed, as long as there are links to the cortex. Bell-Krotoski has also found normal two-point values in the presence of decreased sensory function.¹⁰

Vibration and the Semmes-Weinstein test are more sensitive in picking up a gradual decrease in nerve function in the presence of nerve compression where the nerve circuitry is intact. They also correlate with decreases in the potential amplitude of sensory nerve action as measured by nerve conduction studies.⁹⁵ Therefore, Semmes-Weinstein and electrical testing are reliable and sensitive tests for early detection of carpal tunnel syndrome and other nerve compression syndromes. Semmes-Weinstein can be performed in the clinic with no discomfort to the client and is an excellent screening tool when nerve compression is suspected.

Touch Pressure

Moving touch is tested using the eraser end of a pencil. The eraser is placed in an area of normal sensibility and, with application of light pressure, is moved to the distal fingertip. The client notes when the perception of the stimulus changes. Light and heavy stimuli may be applied and noted.³⁴ Constant touch is tested by pressing with the eraser end of a pencil, first in an area with normal sensibility and then placing the eraser distally by lifting up the pencil before placement. The client responds when the stimulus is altered; again, light and heavy stimuli may be applied.³⁴

The Semmes-Weinstein monofilaments are the most accurate instruments for assessing cutaneous pressure thresholds.¹⁰ The original testing equipment consisted of 20 nylon monofilaments housed in plastic handheld rods. Many therapists today use the smaller five-pack filaments. These five monofilaments correspond to the categories of light touch sensation described later. The diameter of the monofilaments increases, and when applied correctly, they exert a force ranging from 4.5 mg to 447 g. Markings on the probes range from 1.65 to 6.65 but do not correspond to the grams of force of each rod. Normal fingertip sensibility has been found to correspond to the 2.44 and 2.83 probes.

The monofilaments must be applied perpendicularly to the skin and are applied just until the monofilament bends. The skin should not blanch when the monofilament is applied. Probes 1.65 through 2.83 are bounced three times. Probes marked 3.22 to 4.08 are applied three times with a bend in the filament, and probes marked 4.17 to 6.65 are applied once. The larger monofilaments do not bend; therefore, skin color must be observed to determine how firmly to apply the probe.

The examiner should begin with a probe in the normal range and progress through the rods in increasing diameters to find the client’s threshold for touch throughout the volar surface.¹⁰ A grid should be used to record the responses so that varying areas of touch perception can be demonstrated. Two correct responses out of three applications are necessary

for an area to be considered as having intact sensibility. It is preferable to place the monofilaments randomly rather than to concentrate on an area, to allow the nerves recovery time. When a filament is placed three times, it should be held for a second, rested for a second, and reapplied. Results can be graded from normal light touch (probes 2.83 and above) to loss of protective sensation (probes 4.56 and below). Diminished light touch and diminished protective sensation are in the range reflected by the central probes (probes 3.22 to 4.31).¹⁰

Two-Point and Moving Two-Point Discrimination

Discrimination, the second level of sensibility assessment, requires the subject to distinguish between two direct stimuli. Static or stationary two-point discrimination measures the slowly adapting fibers. The two-point discrimination test, first described by Weber in 1853, was modified and popularized by Moberg,⁷⁹ who was interested in a tool that would assess the functional level of sensation. A variety of devices have been proposed to use in measuring two-point discrimination. The bent paper clip is inexpensive but often has burrs on the metal tip. Other devices include industrial calipers* and the Disk-Criminator.^{65†} A device with parallel prongs of variable distance and blunted ends should produce replicable results.

The test is performed as follows⁹²:

1. The client's vision is occluded.
2. An area of normal sensation is tested as a reference, using blunt calipers or a bent paper clip.
3. The calipers are set 10 mm apart and are randomly applied, starting at the fingertip and moving proximally and longitudinally in line with the digital nerves, with one or two points touching. The caliper should not blanch the skin.
4. The distance is decreased until the client no longer feels two distinct points, and that distance is measured.

Between 3 and 4 seconds should be allowed between applications, and the client should have four correct responses out of five administrations. Because this test indicates sensory function, it is usually administered at the tips of the fingers. It may be used proximally to test nerve regeneration. Normal two-point discrimination at the fingertip is 6 mm or less.

Moving two-point discrimination measures the innervation density of the quickly adapting nerve fibers for touch. It is slightly more sensitive than stationary two-point discrimination. The test is performed as follows³²:

1. The client's vision is occluded.
2. An area of normal sensation is tested as a reference, using blunt calipers or a bent paper clip.

3. The fingertip is supported by the examining table or the examiner's hand.
4. The caliper, separated 5 mm to 8 mm, is moved longitudinally from proximal to distal in a linear fashion along the surface of the fingertip. One and two points are randomly alternated. The client must correctly identify the stimulus in seven out of eight responses before proceeding to a smaller value. The test is repeated down to a separation of 2 mm.

Two-point values increase with age in both sexes, with the smallest values occurring between the ages of 10 and 30 years. Women tend to have smaller values than men, and there is no significant difference between dominant and nondominant hands.⁶² (See Chapter 23 for further information on the evaluation of sensation.)

Modified Moberg Pickup Test

Recognition of common objects is the final level of sensory function. Moberg used the phrase tactile gnosis to describe the ability of the hand to perform complex functions by feel. Moberg described the pick-up test in 1958,⁷⁹ and it was later modified by Dellon.³² This test is used with either a median nerve injury or an injury to a combination of median and ulnar nerves. It takes twice as long to perform the tests with vision occluded as with vision unimpaired. The test is performed as follows:

1. Nine or 10 small objects (e.g., coins or paper clips) are placed on a table, and the client is asked to place them, one at a time, in a small container as quickly as possible, while looking at them. The client is timed.
2. The test is repeated for the opposite hand with vision.
3. The test is repeated for each hand with vision occluded.
4. The client is asked to identify each object one at a time, with and then without vision.

It is important to observe any substitution patterns that may be used when the client cannot see the objects.

Edema Assessment

Hand volume is measured to assess the presence of extracellular or intracellular edema. Volume measurement is generally used to determine the effect of intervention and activities. By measuring volume at different times of the day, the therapist can measure the effects of rest versus activity, as well as the effects of splinting or intervention designed to reduce edema.

A commercial volumeter²⁸ may be used to assess hand edema. The volumeter has been shown to be accurate to 10 ml¹⁰⁶ when used in the prescribed manner. Variables that have been shown to decrease the accuracy of the volumeter include the use of a faucet or hose that introduces air into the tank during filling, movement of the arm within the tank, inconsistent pressure on the stop rod, and the use of a volumeter in a variety of places. The same level surface

FIGURE 39-1 Volumeter is used to measure volume of both hands for comparison. Increased volume indicates the presence of edema.

should always be used.¹⁰¹ The evaluation is performed as follows (Figure 39-1):

1. A plastic volumeter is filled and allowed to empty into a large beaker until the water reaches spout level. The beaker is then emptied and dried thoroughly.
2. The client is instructed to immerse the hand in the plastic volumeter, being careful to keep the hand in the midposition.
3. The hand is lowered until it rests gently between the middle and ring fingers on the dowel rod. It is important that the hand not press onto the rod.
4. The hand remains still until no more water drips into the beaker.
5. The water is poured into a graduated cylinder. The cylinder is placed on a level surface, and a reading is made.

A method of assessing edema of an individual finger or joint is circumferential measurement using either a circumference tape* or jeweler's ring-size standards. Measurements should be made before and after intervention and especially after the application of thermal modalities or splinting. Although clients often have subjective complaints relating to swelling, objective data of circumference or volume will

*DeRoyal/LMB, DeRoyal Industries, Powell, TN.

FIGURE 39-2 Jamar dynamometer is used to evaluate grip strength in both hands.

help the therapist to assess the response of the tissues to intervention and activity. Edema control techniques are discussed later in this chapter.

Grip and Pinch Strength

UE strength is usually assessed after the healing phase of trauma. Strength testing is not indicated after recent trauma or surgery. Testing should not be performed until the client has been cleared for full-resistive activities, usually 8 to 12 weeks after injury.

A standard adjustable-handle dynamometer is recommended for assessing grip strength (Figure 39-2). The subject should be seated with the shoulder adducted and neutrally rotated, the elbow flexed at 90 degrees,⁶⁹ forearm in the neutral position, and wrist between 0 and 30 degrees extension and between 0 and 15 degrees of ulnar deviation. Three trials are taken of each hand, with the dynamometer handle set at the second position.⁷³ The examiner should hold the dynamometer lightly to prevent accidental dropping of the instrument. A mean of the three trials should be reported. The noninjured hand is used for comparison. Normative data may be used to compare

FIGURE 39-3 Pinch gauge is used to evaluate pinch strength to a variety of prehension patterns of pinch.

strength scores.^{55,72} Variables such as age will affect the strength measurements.

Pinch strength should also be tested, using a pinch gauge. The pinch gauge has been found to be the most accurate.⁷² Two-point pinch (thumb tip to index fingertip), lateral or key pinch (thumb pulp to lateral aspect of the middle phalanx of the index finger), and three-point pinch (thumb tip to tips of index and middle fingers) should be evaluated. As with the grip dynamometer, three successive trials should be obtained and compared bilaterally (Figure 39-3).⁴¹

Manual muscle testing is also used to test UE strength. Accurate assessment is especially important when the client is being prepared for tendon transfers or other reconstructive surgery. The student who wishes to study kinesiology of the UE is referred especially to Brand's work.¹⁴ Additionally, muscle testing is addressed in Chapter 22.

Maximal voluntary effort during grip, pinch, or muscle testing will be affected by pain in the hand or extremity, and the therapist should note if the client's ability to exert full force is limited by subjective complaints. Localization of the pain symptoms and consistency in noting pain will help the therapist evaluate the role that pain is playing in the recovery from injury. Pain problems are discussed in more detail later in this chapter.

Functional Assessment

Assessment of hand function or performance is important because the physical assessment does not measure the client's ingenuity and ability to compensate for loss of strength, ROM, sensation or the presence of abnormalities.²²

The physical assessment should precede the functional assessment because awareness of physical dysfunction can result in a critical analysis of functional impairment and an understanding of the reasons that the client functions as he or she does.⁷⁴

The occupational therapist should observe the effect of the hand dysfunction on the use of the hand during ADLs. In addition, some type of a standardized performance test,

such as the Jebsen Test of Hand Function⁴⁹ or the Quantitative Test of Upper Extremity Function,²² should be administered.

The Jebsen Test of Hand Function⁴⁹ was developed to provide objective measurements of standardized tasks with norms for client comparison. It is a short test that is assembled by the administrator. It is easy to administer and inexpensive. The test consists of seven subtests, which test writing a short sentence, turning over 3×5 -inch cards, picking up small objects and placing them in a container, stacking checkers, simulated eating, moving empty large cans, and moving weighted large cans. Norms are provided for dominant and nondominant hands for each subtest and further categorized by gender and age. Instructions for assembling the test, as well as specific instructions for administering it, are provided by the authors.⁴⁹ This has been found to be a good test for overall hand function.

The Quantitative Test of Upper Extremity Function described by Carroll was designed to measure ability to perform general arm and hand activities used in daily living.²² It is based on the assumption that complex UE movements used to perform ordinary ADLs can be reduced to specific patterns of grasp and prehension of the hand, supination and pronation of the forearm, flexion and extension of the elbow, and elevation of the arm.

The test consists of six parts: grasping and lifting four blocks of graduated sizes to assess grasp; grasping and lifting two pipes of graduated sizes to test cylindrical grip; grasping and placing a ball to test spherical grasp; picking up and placing four marbles of graduated sizes to test fingertip prehension or pinch; putting a small washer over a nail and putting an iron on a shelf to test placing; and pouring water from pitcher to glass and glass to glass. In addition, to assess pronation, supination, and elevation of the arm, the therapist instructs the subject to place his or her hand on top of the head, behind the head, and to the mouth and write his or her name. The test uses simple, inexpensive, and easily acquired materials. Details of materials and their arrangement, test procedures, and scoring can be found in the original source.²²

Other tests that are useful in the assessment of hand dexterity are the Crawford Small Parts Dexterity Test,²⁷ the Bennett Hand Tool Dexterity Test,¹¹ the Purdue Pegboard Test,⁹⁸ and the Minnesota Manual Dexterity Test.⁷⁸ The VALPAR Corporation* has developed a number of standardized tests that measure an individual's ability to perform work-related tasks. They provide information about the test taker's results, compared with industry performance standards. All of these tests include comparison with normal subjects working in a variety of industrial settings. This information can be used in predicting the likelihood of successful return to a specific job. The tests are especially useful when administering a work capacity evaluation. Tests

*VALPAR Assessment Systems (available from VALPAR International, Tucson, AZ, www.valparint.com).

may be purchased and come with instructions for administration of the test and the standardized norms. Melvin listed a variety of additional hand function tests.⁷⁴ Further discussion of vocational evaluation can be found in Chapter 14.

Intervention

Fractures

In treating a hand or wrist fracture, the surgeon attempts to achieve good anatomic position through either a closed (nonoperative) or open (operative) reduction. Internal fixation with Kirschner wires, metallic plates, or screws may be used to maintain the desired position. External fixation may also be used with internal fixation. The hand is usually immobilized in wrist extension and MP joint flexion, with extension of the distal joints whenever the injury allows this position. Trauma to bone may also involve trauma to tendons and nerves in the adjacent area. Intervention must be geared toward the recovery of all injured structures, and this fact may influence treatment of the fracture.

OT may be initiated during the period of immobilization, which is usually 3 to 5 weeks. Uninvolved fingers of the hand must be kept mobile through the use of active motion. Edema should be carefully monitored, and elevation is required whenever edema is present.

As soon as there is sufficient bone stability, the surgeon allows mobilization of the injured part. The surgeon should provide guidelines for the amount of resistance or force that may be applied to the fracture site. Activities that correct poor motor patterns and encourage use of the injured hand should be started as soon as the hand is pain free. Early motion will prevent the adherence of tendons and reduce edema through stimulation of the lymphatic and blood vessels.

As soon as the brace or cast is removed, the client's hand must be evaluated. If edema remains present, edema control techniques can be initiated using techniques described later in this chapter. A baseline ROM should be established, and the application of appropriate splints may begin. A splint may be used to correct abnormal joint changes that have resulted from immobilization, or it may be used to protect the finger from additional trauma to the fracture site. An example of this type of splinting would be the application of a Velcro "buddy" splint (Figure 39-4). A dorsal block splint that limits full extension of the finger may be used after a fracture or dislocation of the PIP joint. A dynamic splint may be used to achieve full ROM or to prevent the development of further abnormal joint changes at 6 to 8 weeks after fracture.

Intra-articular fractures may result in injury to the cartilage of the joint, causing additional pain and stiffness. An x-ray examination will indicate whether the joint surface has been damaged, which might limit the treatment of the joint. Joint pain and stiffness after fracture without the presence of joint damage should be alleviated by a combination of thermal modalities, restoration of joint play, or joint

FIGURE 39-4 Velcro "buddy" splint may be used to protect the finger following fracture or to encourage movement of a stiff finger. (Splint available from Smalley and Bates, Inc.)

mobilization and corrective and dynamic splinting followed by active use. Resistive exercise can be started when bony healing has been achieved.

Wrist fractures are common and may present special problems for the surgeon and therapist. Colles fractures of the distal radius are the most common injury to the wrist¹² and may result in limitations in wrist flexion and extension, as well as pronation and supination resulting from the involvement of the distal radioulnar joint. External fixators, which may be used with or without internal fixation, are now common in the reduction of distal radius fractures. The external fixator maintains the anatomic relationship between the radius and ulna by maintaining the length of the radius, often with excellent results. The therapist must carefully instruct the client in active ROM of the fingers and proper care of the pin sites while the fixator is in place. Use of splints, active motion that emphasizes wrist movement, and joint mobilization may be beneficial after removal of the fixator or cast. The Weight Well may be used to provide resistance to wrist motions (Figure 39-5).

The scaphoid is the second most commonly injured bone in the wrist¹² and is often fractured when the hand is dorsiflexed at the time of injury. Fractures to the proximal pole of the scaphoid may result in nonunion because of poor blood supply to this area. Scaphoid fractures require a prolonged period of immobilization, sometimes up to several months in a cast, with resulting stiffness and pain. Care should be taken to mobilize uninvolved joints early.

Trauma to the lunate bone of the wrist may result in avascular necrosis of the lunate or Kienböck's disease,¹² which may result from a one-time accident or repetitive trauma. Lunate fractures are usually immobilized for 6 weeks. Kienböck's disease may be treated with a bone graft, removal of the proximal carpal row, or partial wrist fusion.

Stiffness and pain are common complications of fractures. The control of edema coupled with early motion and

FIGURE 39-5 Weight Well is used for strengthening the upper extremity with progressive resistance applied to weakened musculature and is also useful in retraining prehension of pinch and grip. (Photo courtesy of Karen Schultz Johnson.)

good client instruction and support will minimize these complications, however.

Nerve Injuries

Nerve injury may be classified into the following three categories:

1. Neurapraxia is contusion of the nerve without wallerian degeneration. The nerve recovers function without intervention within a few days or weeks.
2. Axonotmesis is an injury in which nerve fibers distal to the site of injury degenerate, but the internal organization of the nerve remains intact. No surgical intervention is necessary, and recovery usually occurs within 6 months. The length of time may vary, depending on the level of injury.
3. Neurotmesis is a complete laceration of both nerve and fibrous tissues. Surgical intervention is required. Microsurgical repair of the fascicles is common. Nerve grafting may be necessary in situations in which there is a gap between nerve endings.⁹²

Peripheral nerve injuries may occur as a result of disruption of the nerve by a fractured bone, laceration, or

crush injury. Symptoms of nerve injuries include weakness or paralysis of muscles that are innervated by motor branches of the injured nerve and sensory loss to areas that are innervated by sensory branches of the injured nerve. Before evaluating the client for nerve loss, the therapist must be familiar with the muscles and areas that are innervated by the three major forearm nerves. A summary of UE peripheral neuropathic conditions can be found in Table 39-4.

Radial Nerve

The radial nerve innervates the extensor-supinator group of muscles of the forearm, including the brachioradialis, extensor carpi radialis longus, extensor carpi radialis brevis, extensor digitorum communis, extensor digiti minimi, extensor indicis, extensor carpi ulnaris, supinator, abductor pollicis longus, extensor pollicis brevis, and extensor pollicis longus. The sensory distribution of the radial nerve is a strip of the posterior upper arm and the forearm, dorsum of the thumb, and index and middle fingers and radial half of the ring finger to the PIP joints. Sensory loss of the radial nerve does not usually result in dysfunction.

Clinical signs of a high-level radial nerve injury (above the supinator) are pronation of the forearm, wrist flexion, and the thumb held in palmar abduction resulting from the unopposed action of the flexor pollicis brevis and the abductor pollicis brevis.⁸⁴ Injury to the posterior interosseous nerve spares the extensor carpi radialis longus and brevis. Posterior interosseous nerve syndrome includes normal sensation and wrist extension with loss of finger and thumb extension. Clinical signs of low-level radial nerve injury include incomplete extension of the MP joints of the fingers and thumb. The interossei extend the interphalangeal (IP) joints of the fingers, but the MP joints rest in about 30 degrees of flexion.

A dynamic or static splint, applied to the dorsum of the hand, that provides wrist extension, MP extension, and thumb extension should be provided to protect the extensor tendons from overstretching during the healing phase and to position the hand for functional use (Figure 39-6). A dynamic splint is commonly provided.

Median Nerve

The median nerve innervates the flexors of the forearm and hand and is often called the “eyes” of the hands because of its importance in sensory innervation of the volar surface of the thumb, index, and middle fingers. Median nerve loss may result from lacerations, as well as from compression syndromes of the wrist, such as carpal tunnel syndrome.

Motor distribution of the median nerve is to the pronator teres, palmaris longus, flexor carpi radialis, flexor digitorum profundus of the index and middle fingers, flexor digitorum superficialis, flexor pollicis longus, pronator quadratus, abductor pollicis brevis, opponens pollicis, superficial head of the flexor pollicis brevis, and first and second lumbricals.

■ **TABLE 39-4** | Nerve Injuries of the Upper Extremity

Nerve	Location	Affected	Test
Radial nerve (posterior cord, fibers from C5, C6, C7, C8)	Upper arm	Triceps and all distal motors Sensory to SRN	MMT Sensory test
Radial nerve	Above elbow	Brachioradialis and all distal motors Sensory to SRN	MMT Sensory
Radial nerve	At elbow	Supinator, ECRL, ECRB, and all distal motors Sensory to SRN	MMT Sensory
Posterior interosseous nerve	Forearm	ECU, ED, EDM, APL, EPL, EPB, EIP No sensory	Wrist extension—if present, indicates PIN rather than high radial nerve
Radial nerve at ECRB, radial artery, arcade of Frohse, origin of supinator	Radial tunnel syndrome	Weakness of muscles innervated by PIN No sensory loss	Palpate for pain over extensor mass Pain with wrist flexion and pronation Pain with wrist extension and supination Pain with resisted middle finger extension
Median nerve (lateral from C5, C6, C7, medial cord from C8, T1)	High lesions (elbow and above)	Paralysis/weakness of FCR, PL, all FDS, FDP I and II FPL, pronator teres and quad., opponens pollicis, APB, FPB (radial head), lumbricals I and II Sensory cutaneous branch of median nerve	MMT Sensory
Median nerve	Low (at wrist)	Weakness of thenars only	Inability to flex thumb tip and index fingertip to palm Inability to oppose thumb Poor dexterity
Median nerve under fibrous band in PT, beneath heads of pronator, arch of FDS, origin of FCR	Pronator syndrome	Weakness in thenars, but not muscles innervated by AIN Sensory in median nerve distribution in hand	Provocative tests to isolate compression site
Median nerve under origin of PT, FDS to middle	Anterior interosseous nerve syndrome	Pure motor, no sensory Forearm pain precedes paralysis Weakness of FPL, FDP I and II, PQ	Inability to flex IP joint of thumb and DIP of index Increased pain with resisted pronation Pain with forearm pressure
Median nerve at wrist	Carpal tunnel syndrome	Weakness of medial intrinsic Sensory	Provocative tests Tinel's sign Sensory

FIGURE 39-6 Low-profile radial nerve splint is carefully balanced to pull metacarpophalangeal (MP) joints into extension when the wrist is flexed and allows the MP joints to fall into slight flexion when the wrist is extended, thus preserving normal balance between two joints and preserving joint contracture.

(Splint courtesy of Judy C. Colditz, Raleigh Hand Rehabilitation Center.)

FIGURE 39-7 Thumb stabilization splint may be used with median nerve injury to protect the thumb and to improve functioning by placing the thumb in position of pinch. Normal pinch cannot be achieved with median nerve injury because of paralysis of thumb musculature.

Sensory distribution of the median nerve is to the volar surface of the thumb, index, and middle fingers; radial half of the ring finger and dorsal surface of the index and middle fingers; and radial half of the ring finger distal to the PIP joints.

Clinical signs of a high-level median nerve injury are ulnar flexion of the wrist caused by loss of the flexor carpi radialis, loss of palmar abduction, and opposition of the thumb. Active pronation is absent, but the client may appear to pronate with the assistance of gravity. In a wrist-level median nerve injury, the thenar eminence appears flat and there is a loss of thumb flexion, palmar abduction, and opposition.⁸⁴

The sensory loss associated with median nerve injury is particularly disabling because there is no sensation to the

volar aspects of the thumb and index and middle fingers and the radial side of the ring finger. When blindfolded, the client substitutes pinch to the ring and small fingers to compensate for this loss. An injury in the forearm that involves the anterior interosseus nerve does not result in sensory loss. Motor loss includes paralysis of the flexor pollicis longus, the flexor digitorum profundus of the index and middle fingers, and the pronator quadratus. The pronator teres is not affected. Pinch is affected.

Splints that position the thumb in palmar abduction and slight opposition increase functional use of the hand (Figure 39-7). If clawing of the index and middle fingers is present, a splint should be fabricated to prevent hyperextension of the MP joints. Clients report that they avoid use of the hand with a median nerve injury because of lack

of sensation rather than because of muscle paralysis. Nevertheless, the weakened or paralyzed muscles should be protected.

Ulnar Nerve

The ulnar nerve in the forearm innervates only the flexor carpi ulnaris and the median half of the flexor digitorum profundus. It travels down the volar forearm through the canal of Guyon, innervating the intrinsic muscles of the hand, including the palmaris brevis, abductor digiti minimi, opponens digiti minimi, flexor digiti minimi, dorsal and volar interossei, third and fourth lumbricals, and medial head of the flexor pollicis brevis. The sensory distribution of the ulnar nerve is the dorsal and volar surfaces of the small finger ray and the ulnar half of the dorsal and volar surface of the ring finger ray.

A high-level ulnar nerve injury results in hyperextension of the MP joints of the ring and small fingers (also called clawing) as a response to overaction of the extensor digitorum communis that is not held in check by the third and fourth lumbricals.⁸⁶ The IP joints of the ring and small fingers do not demonstrate a great flexion deformity because of the paralysis of the flexor digitorum profundus. The hypothenar muscles and interossei are absent. The wrist assumes a position of radial extension caused by the loss of the flexor carpi ulnaris. In a low-level ulnar nerve injury, the ring and small fingers claw at the MP joints and the IP joints exhibit a greater tendency toward flexion because the flexor digitorum profundus is present. Wrist extension is normal.

Clinical signs of a high-level ulnar nerve injury may include clawhand deformity (as described above) with a loss of the hypothenar and the interosseous muscles. In a low-level ulnar nerve injury, the flexor digitorum profundus and flexor carpi ulnaris are present and unopposed by the intrinsic muscles. There is a positive Froment's sign. Long-standing compression of the ulnar nerve in the canal of Guyon results in a flattening of the hypothenar area and conspicuous atrophy of the first dorsal interosseous muscle.¹²

With a low-level ulnar nerve injury a small splint may be provided to prevent hyperextension of the small and ring fingers without limiting full flexion at the MP joints. Stabilization of the MP joints will allow the extensor digitorum communis to extend the IP joints fully (Figure 39-8).

Sensory loss of the ulnar nerve results in frequent injury, especially burns, to the ulnar side of the hand. Clients must be instructed in visual protection of the anesthetic area.

Postoperative Management after Nerve Repair

After nerve repair, the hand is placed in a position that minimizes tension on the nerve. For example, after repair of the median nerve, the wrist is immobilized in a flexed position. Immobilization usually lasts for 2 to 3 weeks, after which protective stretching of the joints may begin. The therapist must exercise great care not to put excessive

FIGURE 39-8 Dynamic ulnar nerve splint blocks hyperextension of metacarpophalangeal (MP) joints that occurs with paralysis of ulnar intrinsic muscles and allows MP flexion, which maintains normal range of motion of MP joints.

(Splint courtesy of Mary Dimick, University of California–San Diego Hand Rehabilitation Center.)

traction on the newly repaired nerve. A repaired digital nerve will also be protected with flexion of the PIP joint.

Correction of a contracture may take 4 to 6 weeks. Active exercise is the preferred method of gaining full extension, although a light dynamic splint may be applied with the surgeon's supervision. Splinting to assist or substitute for weakened musculature may be necessary for an extended period during nerve regeneration. Splints should be removed as soon as possible to allow active exercise of the weakened muscles. It is important to instruct the client in correct patterns of motion, however, so that substitution is minimized.

Intervention is initially directed toward the prevention of deformity and correction of poor positioning during the acute and regenerative stages. Clients must be instructed in visual protection of the anesthetic area. ADLs should be assessed, and new methods or devices may be needed for independence. Use of the hand in the client's work should be assessed, and the client should be returned to employment with any necessary job modifications or adaptations of equipment.

Careful muscle, sensory, and functional testing should be done frequently. As the nerve regenerates, splints may be changed or eliminated. Exercises and activities should be revised to reflect the client's new gains, and adapted equipment should be discarded as soon as possible.

As motor function begins to return to the paralyzed muscles, a careful program of specific exercises should be devised to facilitate the return. Proprioceptive neuromuscular facilitation (PNF) techniques—such as hold-relax, contract-relax, quick stretch, and icing—may assist a fair-strength muscle and increase ROM. Neuromuscular electrical stimulation (NMES) can also provide an external stimulus to help strengthen the newly innervated muscle. When the muscle has reached a good rating, functional

activities should be used to complete the return to normal strength.

Sensory Re-education

Assessment of sensibility is described in some detail earlier in this chapter. This information should be used to prepare a program of sensory re-education after nerve repair.

When a nerve is repaired, regeneration is not perfect and results in fewer and smaller nerve fibers and receptors distal to the repair. The goal of sensory re-education is to maximize the functional level of sensation or tactile gnosis.

Parry first described sensory re-education in 1966,⁸⁴ and Dellon reported a highly structured sensory re-education program in 1974.³³ Dellon divided his program into early- and late-phase training, based on vibratory sensation for early phase and perception of moving and constant touch sensation for late-phase re-education. Both Parry and Dellon used the localization of stimuli and recognition of objects. Higher cortical integration was achieved by focusing attention on the stimuli through visual clues and by employing memory when vision was occluded. The clients were taught to compensate for sensory deficits by improving specific skills and generalizing them to other sensory stimuli. Daily repetition appears to be a necessary component of re-education.

Callahan outlined a program of protective sensory re-education and discriminative sensory re-education if protective sensation is present and touch sensation has returned to the fingertips.¹⁹ Waylett-Rendall also described a sensory re-education program using crafts and functional activities, as well as desensitization techniques.¹⁰⁰ All programs emphasize a variety of stimuli used in a repetitive manner to bombard the sensory receptors. A sequence of eyes-closed, eyes-open, eyes-closed is used to provide feedback during the training process. Sessions are limited in length to prevent fatigue and frustration. To prevent further trauma, objects must not be potentially harmful to the insensate areas. A home program should be provided to reinforce learning that occurs in the clinical setting.

Researchers have found that sensory re-education can result in improved functional sensibility in motivated clients.^{19,32,105} Objective measurement of sensation after re-education must be performed and then accurately compared with initial testing to assess the success of the program.

Tendon Transfers

If a motor nerve has not reinnervated its muscle after a minimum period of 1 year after nerve repair, the surgeon may consider tendon transfers to restore a needed motion. The rules of tendon transfer are to evaluate what is absent, what is needed for function, and what is available to transfer.⁸⁹

Some muscles, such as the extensor carpi radialis longus and the flexor digitorum sublimis to the ring finger, are commonly used for transfers because their motions are easily substituted by the extensor carpi radialis brevis and flexor digitorum profundus, respectively, to the ring finger.

The pronator teres is often used to restore wrist extension for radial nerve paralysis. The surgeon may request assistance from the therapist in evaluating motor status to determine the best motor transfer. Therapy before tendon transfer is essential if the motor being used is not of normal strength. A muscle loses a grade of strength when transferred, and a strengthening program of progressive resistive exercises, NMES, and isolated motion will help ensure success of the transfer. There must be full passive ROM of all joints before tendon transfer can be attempted.

After transfer, many clients require instruction to perceive the correct muscle during active use of the transfer. Use of surface Electromyography (EMG)-biofeedback, careful instruction, and supervised activity to note any substitution patterns during active use usually help the client to use the transfer correctly. Therapy must be initiated before the client has time to develop incorrect use patterns. NMES may be used to isolate the muscle and strengthen it postoperatively.

Tendon Injuries

Flexor Tendons

Tendon injuries may be isolated or may occur in conjunction with other injuries, especially fractures or crushes. Flexor tendons injured in the area between the distal palmar crease and the insertion of the flexor digitorum superficialis are considered the most difficult to treat because the tendons lie in their sheaths in this area beneath the fibrous pulley system and any scarring causes adhesions. This area is often referred to as zone two or “no-man’s-land.”

Primary repair of the flexor tendons within zone 2 is most frequently attempted after a clean laceration. Several methods of postoperative management have been proposed with the common goals of promoting gliding of the tendons and minimizing the formation of scar adhesions.

Controlled Mobilization of Acute Flexor Tendon Injuries: Louisville Technique

Dr. Harold Kleinert of the University of Louisville School of Medicine was an early advocate of rubber band traction after repair of flexor tendons in zone two. This technique is often referred to as the Kleinert technique. The doctor and therapist do not actively participate in moving the tendon or finger when this protocol is followed as outlined by Kutz.⁵⁹

After surgical repair, rubber bands are attached to the nails of the involved fingers, using a suture through the nail or a hook held in place with cyanoacrylate glue. A dorsal blocking splint is fabricated of low-temperature thermoplastic material, with the MP joints held in about 60 degrees of flexion. The splint is constructed so that the IP joints are able to extend fully to the splint. The rubber bands are passed through a safety pin in the palm and are attached to the distal strap of the splint. The rubber bands should be placed in sufficient tension to hold the PIP joints in 40 to

FIGURE 39-9 After flexor tendon repair, the wrist is placed in 30 degrees flexion with traction applied from the nail through a safety pin pulley in the palm and attached to the proximal strap of the splint. Metacarpophalangeal joints should be maintained in about 70 degrees flexion, allowing full passive interphalangeal joint flexion and active extension.

60 degrees of flexion without tension on the rubber bands. The client must be able to fully extend the IP joints actively within the splint, or joint contractures will develop (Figure 39-9).

The client wears the splint 24 hours a day for 3 weeks and is instructed to actively extend the fingers several times a day in the splint, allowing the rubber bands to pull the fingers into flexion. This movement of the tendon through the tendon sheath and pulley system minimizes scar adhesions while enhancing tendon nutrition and blood flow.

The dorsal blocking splint is removed at 3 weeks, and the rubber band is attached to a wristband, which is worn for 1 to 5 additional weeks, depending on the judgment of the surgeon. The primary disadvantage of this technique is that contractures of the PIP joints frequently occur as a result of excessive tension on the rubber band or incomplete IP extension within the splint.

Dynamic extension splinting of the PIP joint can be started at 5 to 6 weeks if a flexion contracture is present. To be successful, this technique requires a motivated client who thoroughly understands the program.

Controlled Passive Motion: Duran and Houser Technique

Duran and Houser suggested the use of controlled passive motion to achieve optimal results after primary repair, allowing 3 to 5 mm of tendon excursion.³⁷ They found this amount sufficient to prevent adherence of the repaired tendons. On the third postoperative day, the client begins a twice-daily exercise regimen of passive flexion and extension of six to eight motions for each tendon. Care is taken to keep the wrist flexed and the MPs in 70 degrees of flexion during passive exercise. Between exercise periods the hand is wrapped in stockinette. At 44½ weeks, the protective dorsal splint is removed and the rubber band traction is attached to a wristband. Active extension and passive flexion

are performed for an additional week and gradually increased over the next several weeks.

Early Active Motion

As methods of tendon suturing and the suture materials themselves have evolved, some clinicians have begun to prescribe active movement of the repaired tendon within days of surgery. This technique is usually performed only with the most experienced surgeons and therapists working closely together. The condition of the tendon and the technique of repair must be communicated to the therapist, and the client must be closely monitored. As the rate of rupture decreases with more sophisticated repairs, the results after tendon injury have improved.⁹³

There are several well-documented early active motion protocols, but all of the protocols share in common several important factors. First, the tendon repair strength must be sufficient to be able to withstand the forces of active mobilization, and it is generally agreed that a suture four strand repair be performed to use this intervention approach. Second, the timing and the initiation of therapy must be considered. It has been suggested that early active motion be initiated between 2 and 4 days after repair to allow inflammation to subside, thus reducing the amount of force on the tendon during active flexion. Third, the client must be able to comprehend and be compliant with the exercise program for the tendon rehabilitation to be successful and to prevent rupture of the tendon by overstressing the repair site. Finally, for this technique to be successful, the therapist and surgeon must be in good communication and be skilled in the rehabilitation of flexor tendons.

Because early active mobilization of newly repaired flexor tendons involves a somewhat higher risk of rupture if managed incorrectly, it is strongly recommended that this approach be used with the full cooperation of the surgeon. Again, this approach should not be used by an inexperienced therapist or with a poorly compliant client.

Immobilization Technique

A third postoperative program involves complete immobilization for 3 to 4 weeks after tendon repair. Good results have not been consistently achieved with immobilization, and this technique may increase the risk of tendon rupture after repair because a tendon gains tensile strength when submitted to gentle tension at the repair site. It is still the preferred method when treating young children or with a noncompliant client.⁹⁴

Many practitioners have modified the tendon protocols, using a combination of passive flexion and active extension techniques, on the basis of clinical experience. Protocols are suggested as guidelines, but they vary in actual practice.

Postacute Flexor Tendon Rehabilitation

When active flexion is begun out of the splint after any of the postoperative management techniques described previously, the client should be instructed in exercises to facilitate

FIGURE 39-10 Blocking splint can be used to isolate tendon pull-through and joint range of motion by blocking out proximal joints. This splint is being used to facilitate motion at the distal interphalangeal joint following repair of the flexor digitorum profundus tendon.

FIGURE 39-12 Plaster cylindrical splint is used to apply static stretch of proximal interphalangeal joint contracture. It is not removed by client and must be replaced frequently by therapist with careful monitoring of skin condition.

FIGURE 39-11 Manual blocking of metacarpophalangeal joint during flexion of proximal interphalangeal joint.

FIGURE 39-13 This finger splint is used to increase the extension of the proximal interphalangeal joint.
(Splint available from DeRoyal/LMB, DeRoyal Industries, Powell, TN.)

differential tendon gliding.¹⁰⁷ Wehbe has recommended three positions—hook, straight fist, and fist—to maximize isolated gliding of the flexor digitorum superficialis and the flexor digitorum profundus tendons, as well as stretching of the intrinsic musculature and gliding of the extensor mechanism.¹⁰⁸ Tendon gliding exercises should be done for 10 repetitions of each position, two or three times a day.

Isolated exercises to assist tendon gliding may also be performed using a blocking splint (Figure 39-10) or the opposite hand (Figure 39-11). The MP joints should be held in extension during blocking so that the intrinsic muscles that act on it cannot overcome the power of the repaired flexor tendons. Care should be taken not to hyperextend the PIP joints and overstretch the repaired tendons.

After 6 to 8 weeks, passive extension may be started and splinting may be necessary to correct a flexion contracture

at the PIP joint. A cylindrical plaster splint may be fabricated to apply constant static pressure on the contracture, as described by Bell-Krotoski (Figure 39-12).⁹ Static splinting may be especially effective with a flexion contracture greater than 25 degrees. A finger gutter splint may be made using $\frac{1}{16}$ -inch (0.16-cm) thermoplastic material for static extension at night, which will help maintain extension gains made during the day. Gentle dynamic traction may be applied using a commercial splint such as a spring finger extension assist (Figure 39-13) or one that is fabricated by the therapist (Figure 39-14). Dynamic flexion splinting may be necessary if the client has difficulty regaining passive flexion.

At about 8 weeks, the client may begin light resistive exercises and activities. The hand can now be used for light ADLs, but the client should continue to avoid heavy lifting

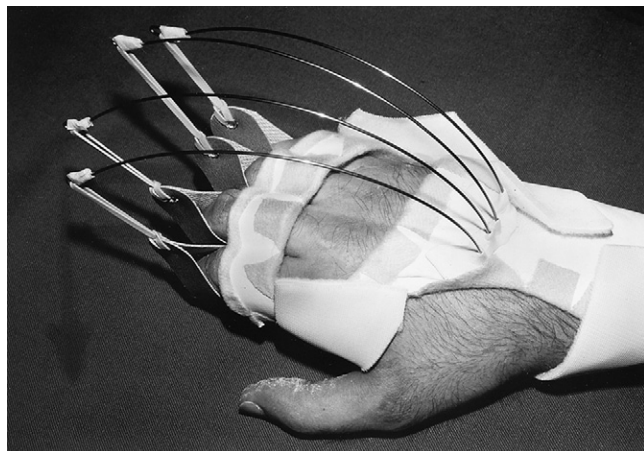

FIGURE 39-14 Dynamic outrigger splint using spring-steel outriggers with a lumbrical block can be used to assist proximal interphalangeal (PIP) joint extension, stretch against scar adhesions of extrinsic flexors, or reduce PIP joint contractures. The therapist must frequently assess proper fit and tension of rubber bands.

with the affected hand or excessive resistance. Sports activities should be discouraged. Such activities as clay work, woodworking, and macramé are excellent, however. Full resistance and normal work activities can be started 3 months after surgery.

After a hand has sustained a tendon injury, passive versus active limitations of joint motion must be evaluated. Limitations in active motion may indicate joint stiffness, muscle weakness, or scar adhesions.⁸⁵ If passive motion is greater than active motion, the therapist should consider that tendons may be caught in the scar tissue. The therapist should be able to determine if a tendon is adhering and causing a flexion contracture or if the tendon is free but the joint itself is stiff. Intervention should be based on this type of evaluation.

ROM, strength, function, and sensibility testing (if digital nerves were also injured) should be performed frequently, with splints and activities geared to progress. Although performance of ADLs is generally not a problem, the therapist should ask the client about any problems he or she may have or anticipate. Disuse and neglect of a finger, especially the index finger, are common and should be prevented.

Gains in flexion and extension may continue to be recorded for 6 months postoperatively. A finger with limber joints and minimal scarring preoperatively will function better after repair than one that is stiff and scarred and has trophic skin changes.¹³ Therefore, it is important that all joints, skin, and scars be supple and movable before reconstructive surgery is attempted. A functional to excellent result is obtained if the combined loss of extension is less than 40 degrees in the PIP and DIP joints of the index and middle fingers and less than 60 degrees in the ring and small fingers⁹⁴ and if the finger can flex to the palm.¹³

Flexor Tendon Reconstruction

If the tendon is damaged as a result of a crush injury or if the laceration cannot be cleaned up enough to allow for a primary repair, staged flexor tendon reconstruction may be performed. At the first operation, a Silastic rod is inserted beneath the pulley system and attached to the distal phalanx. Other reconstructive procedures, such as pulley reconstruction, are performed at the same time. A mesothelial cell-lined pseudosheath is formed about the rod, and a fluid similar to synovial fluid is formed in the postoperative recovery phase.⁶⁰ The second stage is performed about 4 months later, when the digit can be moved passively to the palm. A tendon graft is inserted and the Silastic rod removed. The postoperative program is carried out in the same manner as for a primary tendon repair.⁴⁸

After a two-stage tendon reconstruction or primary repair, a tenolysis may be performed if there is a substantial difference between the active and passive motion. Tenolysis is usually not performed for 6 months to 1 year after tendon repair. At the time of tenolysis surgery, scar adhesions are removed from the tendon and gliding of the tendons is assessed. Clients are often asked to move their fingers in the operating room at the time of lysis to determine the extent of scar removal.⁹⁰ Active motion is begun within the first 24 hours. Transcutaneous electrical nerve stimulation (TENS)²¹ and medications may be used to control pain.

LaSalle and Strickland have recommended a system for evaluating the results of tenolysis surgery by comparing the preoperative passive IP joint motion with the postoperative IP joint motion.⁶⁰ On the basis of this comparison, LaSalle and Strickland found that in one group of clients undergoing tenolysis 40% had an improvement in motion of 50% or better, compared with their preoperative status.

Extensor Tendons

Treatment of extensor tendon injuries requires a thorough knowledge of the extensor anatomy and biomechanics of the hand. The extensor mechanism of the hand is a highly sophisticated and complicated system. It is divided into seven zones for the fingers and five for the thumb. The level of injury will dictate the intervention regimen. Timelines for immobilization, initiation of motion, and resistive exercise depend on the level of injury and the unique healing time frames for the structures in the different zones.

There are four zones distal to the MP joint and three zones starting at the MP joint and proximal. Zones I and II consist of the structures at the DIP joint and middle phalanx, and injuries to this area are treated similarly. Zones III and IV are the areas over the PIP joint and proximal phalanx; again, these zones are treated similarly depending on the structures repaired. Zone V consists of the area over the MP joint, whereas zone VI is the area over the dorsal hand and zone VII the area over the wrist. In the thumb, zone T1 consists of the area over the DIP joint, T2 the middle phalanx, T3 the MP joint, T4 the proximal phalanx, and T5 the area over the CMC joint and wrist.

Dorsal scar adherence is the most difficult problem after injury to the extensor tendons because of the tendency of the dorsal extensor hood to adhere to the underlying structures and thus limit its normal excursion during flexion and extension. Overstretching the extensor tendon is another common occurrence and can result in an extensor lag, or lack of full active extension.

Extensor tendon injuries distal to the MP joint (zones I to IV) generally require a longer period of immobilization, usually 6 weeks. As with flexor tendon injuries, controlled mobilization is being used with increasing frequency for zones III and IV. A protocol developed by Evans called the short arc motion protocol, or SAM protocol,³⁸ allows for immediate active flexion of the PIP joint to 30 degrees followed by full passive extension. Complete immobilization for 6 weeks or longer is necessary for injuries in zones I and II.

Several abnormal finger joint changes are associated with injuries distal to the MP joints. An injury to zones I or II, when there is a traumatic disruption of the terminal extensor tendon, is called a mallet finger. This joint change is characterized by flexion of the DIP joint and the inability to actively extend this joint. A swan-neck posture is a result of the dorsal displacement of the lateral bands (part of the extensor mechanism) in zone III and results in hyperextension of the PIP joint and flexion of the DIP joint. Another abnormal joint position originating from zone III is known as the boutonnière deformity. A boutonnière deformity results when the common extensor tendon is ruptured and the lateral bands sublux volarly. This volar subluxation of the lateral bands results in flexion of the PIP joint and hyperextension of the DIP joint.

Extensor tendons in zones V, VI, and VII (proximal to the MP joints) become adherent because they are encased in paratenon and synovial sheaths and respond to injury in a way similar to flexor tendons, resulting in either incomplete extension, also known as extensor lag, or incomplete flexion caused by loss of gliding of the extensor tendon.

Evans studied the normal excursion of the extensor digitorum communis in zones V, VI, and VII to suggest guidelines for early passive motion of extensor tendons.^{38,39} She concluded that 5 mm of tendon glide after repair was safe and effective in limiting tendon adhesions and designed a postoperative splint that allows slight active flexion while providing passive extension.³⁹ The splint is worn for 3 weeks, with the initiation of active motion between the third and fourth weeks. A removable volar splint is used between exercise periods to protect the tendon for 2 additional weeks. Dynamic flexion splinting may be started at 6 weeks after surgery to regain flexion if needed.

Injuries to extensor tendons proximal to the MP joint may be immobilized for 3 weeks. After this period, the finger may be placed in a removable volar splint that is worn between exercise periods for an additional 2 weeks. Progressive ROM is begun at 3 weeks, and if full flexion

FIGURE 39-15 Proximal interphalangeal (PIP)–distal interphalangeal (DIP) splint may be used to increase flexion of both PIP and DIP joints. Tension can be adjusted with Velcro closure. The therapist should determine wearing time.

(Splint available from DeRoyal/LMB, DeRoyal Industries, Powell, TN.)

is not regained rapidly, dynamic flexion may be started at 6 weeks.

Dynamic splints may include a PIP-DIP splint, first described by Hollis and now available commercially (Figure 39-15), a web strap made of lamp wick or elastic, a fingernail hook with rubber band traction, a traction glove, or another splint.

The client begins exercising within the first 24 hours, and splints are applied as needed. Active exercise is essential, and the client must be carefully instructed in a home program. The client is encouraged to use the hand for all activities except those requiring heavy resistance.

Total Active Motion and Total Passive Motion

Total active motion (TAM) and total passive motion (TPM) are methods of recording joint ROM that are used to compare tendon excursion (active) and joint mobility (passive). They represent the measure of flexion minus extensor lag of three joints. The American Society for Surgery of the Hand has recommended TAM and TPM for use in reporting joint motion.⁴

TAM is computed by adding the sum of the angles formed by the MP, PIP, and DIP joints in flexion, minus incomplete active extension at each of the three joints. For example, MP joint flexion is 85 degrees with full extension, PIP is 100 degrees and lacks 15 degrees extension, and DIP is 65 degrees with full extension; therefore,

$$\text{TAM} = 85 + 100 + 65 - 15 = 235 \text{ degrees.}$$

TAM should be measured while the client makes a fist. It is used for a single digit and should be compared with the same digit of the opposite hand or subsequent measurements of the same digit. It should not be used to compute a percentage of loss of impairment. TPM is calculated in the same manner but measures only passive motion.

Complex Injuries

Complex injuries to the hand or injuries to multiple anatomic structures of the hand are some of the most challenging injuries for the therapist to treat. Complex injuries to the hand differ from other types of hand injuries because they involve trauma to multiple anatomic systems of the hand, resulting in a varied clinical picture. Injuries to these anatomic systems include skin, nerve, tendon, skeletal, and vascular injuries. Because of the complex nature of these injuries and because each injured structure has a unique healing time frame, precaution, and treatment approach, there is no set protocol to follow in treating these injuries.

Many of the treatment precautions established for any one of the aforementioned injuries contradict one another. Therefore, the therapist's challenge is to determine when it is safe for the client to move forward with treatment without risking injury to healing structures. "The therapist must have a thorough knowledge of anatomy, wound healing, biomechanics, and treatment guidelines of various traumatic injuries"²³ as well as a "thorough understanding of the injuries and types of repairs performed. That understanding should include location and quality of repair, types of sutures used, associated injuries, and any structures that were injured but not repaired."²³ Consequently, the therapist must maintain close communication with the treating surgeon. Types of complex hand injuries include crush injuries, amputations with or without replantation, and avulsion injuries and may be caused by motor vehicle accidents, explosions, gunshots, and machinery accidents. Gerry, the client discussed in the case study at the beginning of this chapter, sustained a complex injury to his hand. All of the anatomic structures of his hand were affected by the saw injury; his intervention plan needed to take into account the unique healing time frames and precautions for each of these anatomic structures.

Generally, and in the case of Gerry, the rehabilitation process for these types of injuries is divided into three stages: early or protective stage (first 5 to 10 days), intermediate or mobilization stage (1 to 8 weeks after surgery), and late or strengthening stage (6 to 8 weeks after surgery). The therapist and surgeon must be skilled and experienced in the rehabilitation of these injuries.

Ethical Considerations

Inexperienced therapists should not treat these clients without the supervision of a more experienced therapist or without additional training in and familiarization with treatment protocols for the various injured structures. Explore further reading for treating these types of injuries.

Edema

Although edema is a normal consequence of trauma, it must be quickly and aggressively treated to prevent permanent stiffness and disability. Within hours of trauma,

vasodilatation and local edema occur, with an increase in white blood cells in the damaged area.⁴⁰ The inflammatory response to the injury results in a decrease in bacteria to control infection.

Edema should be controlled early on through elevation, massage, compression, and active ROM. The client is instructed at the time of injury to keep the hand elevated, and a compressive dressing is used to reduce early swelling. Pitting edema appears early and can be recognized as a bloated swelling that creates a pitted appearance when pressed. Pitting may be more pronounced on the dorsal surface, where the venous and lymphatic systems provide return of fluid to the heart. Active motion is especially important to produce retrograde venous and lymphatic flow.

If the swelling continues, a serofibrinous exudate invades the area. Fibrin is deposited in the spaces surrounding the joints, tendons, and ligaments, resulting in reduced mobility, flattening of the arches of the hand, tissue atrophy, and further disuse.³⁵ Normal gliding of the tissues is eliminated, and a stiff, often painful hand is the result. Scar adhesions form and further limit tissue mobility. If untreated, these losses may become permanent.

Early recognition of persistent edema through observation and volume and circumference measurement is important. It may be necessary to use several of the suggested edema control techniques.

Elevation

Early elevation with the hand above the heart is essential. Slings tend to reduce blood flow and should be avoided. Resting the hand on pillows while seated or lying down is effective. Resting the hand on top of the head or using devices that elevate the hand with the elbow in extension has been suggested.

The client should use the hand for ADLs, within the limitations of resistance prescribed by the physician. Light ADLs that can be accomplished while the hand is in the dressing are permitted.

Manual Edema Mobilization

Manual edema mobilization (MEM) is a method of edema reduction based on methods to activate the lymphatic system. These methods include the principles of manual lymph-edema treatment (MLT) massage, medical compression bandaging, exercise, and external compression adapted to meet the specific needs of subacute and chronic postsurgical and poststroke UE edema. The goals are to stimulate the initial lymphatics to absorb excessive fluid and large molecules from the interstitium and to move this lymph centrally. "MEM is not indicated for all hand clients but can be highly effective in cases of recalcitrant subacute or chronic edema. MEM is used to prevent or reduce subacute or chronic high-protein edema as seen in postsurgical, trauma, or post-cerebrovascular accident (CVA) hand edema."⁶

MEM is an advanced skill that requires specialized training of the practitioner.

The following overview will acquaint the reader with the techniques involved in MEM:⁶

- Provide light, stroking massage of the involved area. It has been shown that more than 40 mm Hg pressure will cause collapse of the lymphatic pathways.
- Incorporate exercise before and after massage in a specific sequence, following the recommended guidelines.
- Massage, done in segments, is proximal to distal, then distal to proximal, always following movement of the therapist's hand in the proximal direction.
- Massage follows the flow of lymphatic pathways.
- Massage reroutes around the incision area.
- Recognize that this method does not cause additional inflammation.
- Include a client home self-massage program.
- Guide intervention to avoid increased edema from other intervention techniques.
- Incorporate low stretch compression bandaging and warmth to soften hardened tissues, especially at night.

Active Range of Motion

Normal blood flow is dependent on muscle activity. Active motion does not mean wiggling the fingers; instead, it means maximal available ROM, performed firmly. Casts and splints must allow mobility of uninjured parts while protecting newly injured structures. The shoulder and elbow should be moved through full available ROM several times a day. The importance of active ROM for edema control, tendon gliding, and tissue nutrition cannot be overemphasized.

Compression

Light compression using Coban wraps* of the affected area (Figure 39-16) or light compressive garments such as those made by Aris† or Jobst⁵⁰ (Figure 39-17) will help to control swelling, especially at night.

Wound Healing and Scar Remodeling

The basis of hand therapy is the histology of wound healing. Acute intervention must be planned using the foundation of tissue healing as a guide. Bones, tendons, nerves, and skin follow a progression of healing phases. Intervention must respect healing tissue to promote recovery and prevent further damage. The therapist must take care to do no harm, and that can be accomplished only with a thorough understanding of the physiology of healing.

The first phase of wound healing, the acute inflammatory phase, is initiated within hours, when the tissues are disrupted through injury or surgery, causing vasodilatation,

FIGURE 39-16 One-inch Coban is wrapped with minimal pressure from the distal end to the proximal crease of the digit. The client is instructed to be aware of vascular compression or tingling. Coban may be worn several hours a day to reduce edema. (Product available from Medical Products Division/3M, St. Paul, MN.)

FIGURE 39-17 Custom-fit Jobst garment may be used to reduce edema and reduce and prevent hypertrophic scar formation after burns or trauma. Inserts may be used with garment to increase pressure over natural curves, such as the dorsum of the wrist.

local edema, and migration of white blood cells and phagocytic cells to the area. The phagocytes remove tissue fragments and foreign bodies and are critical to healing. The inflammatory process can subside or persist indefinitely, depending on the degree of bacterial contamination.⁴⁰

*Coban (available from North Coast Medical, Morgan Hill, CA).

†Aris Isotoner gloves (available from North Coast Medical, Morgan Hill, CA).

Fibroblasts, in combination with associated capillaries, begin to invade the wound within the first 72 hours and gradually replace the phagocytes, leading to the second phase: the collagen or granulation phase, between the fifth and fourteenth days. Collagen fiber formation follows the invasion by fibroblasts, so that by the end of the second week the wound is rich with fibroblasts, a capillary network, and early collagen fibers. This increased vascularization results in the erythema (redness) of the new scar.

During the third to sixth weeks, fibroblasts are slowly replaced with scar collagen fibers, and the wound becomes stronger and more able to withstand progressive stresses, leading to the last phase of scar maturation. Tissue strength continues to increase for 3 months or longer. The collagen metabolizes and synthesizes during this period, so that new collagen replaces old while the wound remains relatively stable. Covalent bonding between collagen molecules leads to dense scar adhesions and the formation of whorl-like patterns of collagen deposits, which may be altered as the scar architecture and collagen fiber organization within the wound change over time.³⁵

Myofibroblasts, which are fibroblasts with properties similar to smooth muscle cells, are contractile and cause a shortening of the wound.

Tissues that have restored gliding have different scar architecture from those that do not develop the ability to glide. With gliding, the scar resembles the state of the tissues before injury, whereas the nongliding scar remains fixed on surrounding structures. Controlled tension on the scar has been shown to facilitate remodeling. Scar formation is also influenced by age and the quantity of scar deposited.³⁸

Wound Care and Dressings

Wounds may be described using a “three-color concept” of red, yellow, or black wounds.⁴⁰ This system simplifies wound description and intervention. Guidelines for treating the three wound types help the therapist choose the proper method of cleansing and dressing wounds. The reader is encouraged to review this material and obtain advanced education before treating wounds.

Topical intervention such as antimicrobials may be used to control bacteria. There are a variety of dressings that can be placed on a wound, including gauze that has been impregnated with petroleum, such as Xeroform gauze or Adaptic. Ointments such as Polysporin are also commonly applied. N-Terface* is a dry mesh fabric that looks and feels like the interfacing used in sewing. Because it is nonadherent, it can be used directly over wounds. Sterile dressings can be applied directly over the N-Terface without ointments or gels. The selection of materials depends on the amount of exudate and the goal of the dressing (which may include removing debris, absorbing exudate, or protecting new cells).

*N-Terface, made by Winfield Laboratories (available from North Coast Medical, Morgan Hill, CA).

The wound can be cleaned with sterile saline, with dead tissue then being gently removed with sterile swabs. Sterile saline solution can be used to soak off adherent bandages rather than pulling them off the client. The therapist should pour a small amount of saline on the area that is sticking, wait a few moments, and gently pry the dressing off. Dead skin can be debrided using iris scissors and pickups. Soft surgical scrub sponges may be used for cleaning and desensitization of the wound once it is healed and the stitches have been removed. The client also can do this procedure at home. Sterile whirlpool baths may be used for debridement, especially if the wound is infected.

Pressure

A hypertrophic scar or a scar that is randomly laid down and thickened is reduced by the application of pressure, often by means of pressure garments.^{50*} Use of an insert of neoprene[†] fabric or silicone gel sheets or molds made from Silastic elastomer^{68‡} under the pressure garment increases the conformity of the garment. Pressure should be applied for most of the 24-hour period, and with a hypertrophic burn scar this intervention should continue for 6 months to 1 year after the injury. Silicone Gel Sheets[§] have been found to reduce hypertrophic scarring when worn on a regular basis for 12 to 24 hours a day.

Massage

Gentle to firm massage of the scarred area using a thick ointment rapidly softens scar tissue and should be followed immediately with active hand use so that tendons glide against the softened scar.³⁰ Vibration to the area with a small, low-intensity vibrator will have a similar effect.^{30,51} Active exercise, using facilitation techniques and against resistance, or functional activity, should follow vibration. Massage and vibration may be started 4 weeks after injury.

Thermal heat in the form of paraffin dips, hot packs, or fluidotherapy, immediately followed by stretching while the tissue cools, provides stretch to the scar tissue. Wrapping the scarred or stiff digit into flexion with Coban during the application of heat often increases mobility in the area. Heat should not be used on insensate areas or if swelling persists.⁵²

Active Range of Motion and Electrical Stimulation

Active ROM provides an internal stretch against resistant scar, and its use cannot be overemphasized. If the client is unable to achieve active motion because of scar adhesions or weakness, the use of a battery-operated NMES may augment the motion.¹⁰⁹ Stimulation may be performed by

*Bio-Concepts, Phoenix, AZ. Cica-Care Silicone Gel Sheets (available from Smith & Nephew, Milwaukee, WI).

‡Silicone elastomers (available from Smith & Nephew, Milwaukee, WI).

§Cica-Care Silicone Gel Sheets (available from Smith & Nephew, Milwaukee, WI).

the client for several hours at home and has been shown to increase ROM and tendon excursion.⁷⁷

Some hand therapists use high-voltage direct current as an intervention to increase motor activity of denervated muscles.² Ultrasound interventions are often prescribed but may be more effective if done within the first few months after trauma. A continuous passive motion (CPM) device may be used at home to maintain passive ROM and does not promote too much tendon gliding. It should be used for several hours a day for maximal benefit.

Pain Syndromes

Pain, the subjective manifestation of trauma transmitted by the sympathetic nervous system, may interfere with normal functioning. Because pain leads to overprotection of the affected part and disuse of the extremity, it should be treated early.

Desensitization

Stimulation of the large afferent A nerve fibers leads to a reduction of pain by decreasing summation in the slowly adapting, small, unmyelinated C fibers, which carry pain sensation. The A-axons can be stimulated mechanically with pressure, rubbing, vibration, TENS, percussion, and active motion. Desensitization techniques are based on the amplification of inhibitory mechanisms.

Yerxa has described a desensitization program that “employs short periods of contact with three sensory modalities: dowel textures, immersion or contact particles, and vibration.”¹¹¹ This program allows the client to rank 10 dowel textures and 10 immersion textures on the degree of irritation produced by the stimulus. Intervention begins with a stimulus that is irritating but tolerable. The stimulus is applied for 10 minutes, three or four times a day. The vibration hierarchy is predetermined and based on cycles per second of vibration, the placement of the vibrator, and the duration of the intervention. Complete instructions for assembling the Downey Hand Center desensitization kit can be found in the literature in the references. The Downey Hand Center Hand Sensitivity Test can be used to establish a desensitization intervention program and measure progress in decreasing hypersensitivity.^{7,111}

Neuromas

Neuromas are a complication of nerve suture or amputation. A traumatic neuroma is an unorganized mass of nerve fibers that results from accidental or surgical cutting of the nerve. A neuroma in continuity occurs on a nerve that is intact.⁹⁷ Neuromas may be clinically identified by a specific, sharp pain. Stimulation of a neuroma usually causes the client to pull the hand away quickly; many clients report a burning pain that radiates up the forearm. Neuromas are disabling because any stimulation causes intense pain and the client avoids the sensitive area.

A generalized desensitization program may not work because the client never develops a tolerance for stimulation

of the neuroma. Injection of cortisone acetate may help break up the neuroma, making desensitization techniques more effective. Surgically excising the neuroma or burying the nerve endings deeper may be necessary.

Complex Regional Pain Syndrome

Complex regional pain syndrome (CRPS) is the term that replaced “reflex sympathetic dystrophy (RSD)” to describe a group of disorders that “involve pain and dysfunction of severity or duration out of proportion to those expected from the initiating event.”¹¹⁰

Complex denotes the complex nature of the pain response, which may include inflammation and autonomic, cutaneous, motor, and dystrophic changes. Regional refers to the wide distribution of symptoms beyond the area of the original lesion. Pain is the primary characteristic of this syndrome. It includes spontaneous pain, thermal changes, and at times burning pain. CRPS, type I, corresponds to RSD. Type II corresponds to causalgia, a severe, burning pain first described during the Civil War.

Diagnostic criteria for CRPS must include spontaneous pain beyond the territory of a single peripheral nerve and disproportionate to the inciting event. There is generally edema, skin blood-flow abnormality, or abnormal sudomotor activity in the area of the pain. The diagnosis is excluded by the existence of conditions that would otherwise account for the pain. The hallmarks of CRPS are pain; edema; blotchy-looking, shiny skin; and coolness of the extremity. Sensory changes may occur. Excessive sweating or dryness may occur if there is associated sympathetic dysfunction. The degree of trauma does not correlate with the severity of the pain and may occur after any injury. CRPS, type I may be triggered by a cycle of vasospasm and vasodilatation after an injury. Abnormal edema and constrictive dressings or casts may be a factor in initiating the vasospasm. A vasospasm “causes tissue anoxia and edema and therefore more pain, which continues the abnormal cycle.”⁸³ Circulation is decreased, which causes the extremity to become cool and pale.

Fibrosis after tissue anoxia and the presence of protein-rich exudates result in joint stiffness. The client may cradle the hand and prefer to keep it wrapped. There may be an exaggerated reaction to touch, especially light touch. Osteoporosis may be apparent on x-ray films by 8 weeks after trauma after active use of the hand. Burning pain associated with causalgia (CRPS, type II) is a symptom that may be alleviated by interruption of the sympathetic nerve pathways.

There are three stages of CRPS. Stage I (traumatic stage) may last up to 3 months; it is characterized by pain, pitting edema, and discoloration. Stage II (dystrophic stage) may last an additional 6 to 9 months. Pain, brawny edema, stiffness, redness, heat, and bony demineralization are usually found in this stage. The hand usually has a glossy appearance. Stage III (atrophic stage) may last several years or indefinitely. Pain usually peaks in stage II and decreases in

stage III. Thickening around the joints occurs, and fixed contractures may be present. If swelling is present, it is hard and not responsive to techniques such as elevation. The hand may be pale, dry, and cool. There may be substantial dysfunction of the limb.

CRPS is treated by decreasing sympathetic stimulation. It is most responsive in stage I. The first goal of intervention is reduction of the pain and hypersensitivity to light touch. This goal may be accomplished with application of warm (not hot), moist heat; fluidotherapy; gentle handling of the hand; acupressure; desensitization; and TENS before active ROM. Intervention that increases pain (such as passive ROM) should be avoided. Many clients respond well to gentle manual edema mobilization,⁶ which reduces the edema and reintroduces touching of the hand. Stellate ganglion blocks to eliminate the pain are effective early. They should be coordinated with therapy so that the client can perform active ROM and functional activities during the pain-free period after the blocks. Active ROM is crucial. Gravity-eliminated exercise, either in water or on a tabletop, may be more easily tolerated.

A variety of drugs may be used, including sympatholytic drugs⁵⁸ that reduce the vasoconstrictive action of the peripheral vessels. Neurontin is often effective in reducing pain and increasing temperature in the extremity. Calcium channel blockers are also effective. Carefully monitored use of narcotics may interrupt the pain cycle and allow active use of the hand. A stress-loading program that has been used effectively to reduce symptoms of RSD (CRPS, type I) has been described.¹⁰⁴ It can easily be adapted for home use.

Edema control techniques should be started immediately. Elevation, manual edema mobilization, contrast baths, and high-voltage direct current in water have been found to be effective. Surface EMG-biofeedback training for relaxation may help muscle spasms and increase blood flow, in addition to reducing anxiety.

CRPS frequently triggers shoulder pain and stiffness, resulting in shoulder-hand syndrome or adhesive capsulitis of the shoulder (“frozen shoulder”). Therefore, active ROM and functional activities should include the entire upper quadrant. Skateboard exercises are helpful in the early stages for active-assisted exercise of the shoulder. Splints that reduce joint stiffness should be used as tolerated. Splints must not cause pain or increase swelling. Reliance on immobilization splinting should be avoided because clients with CRPS prefer not to move the affected part, which ultimately makes their symptoms worse.

A tendency to develop CRPS should be suspected in any client who seems to complain excessively about pain, appears anxious, and complains of profuse sweating and temperature changes in the hand. Some clients report nausea associated with touching the hand. Clients tend to overprotect the hand. Early intervention with a structured therapy program of functional activities, group interaction, and exercises that include the hand and shoulder may

prevent the occurrence of a fully developed CRPS. This problem is best recognized early and treated with tempered aggressiveness and empathy.

Transcutaneous Electrical Nerve Stimulation

TENS is an intervention technique that is thought to stimulate the afferent A nerve fibers in the high-frequency mode and stimulate the release of morphine-like neural hormones, the enkephalins, in the low-frequency mode. Its efficacy as an intervention for pain control is well documented in medical literature. As with other electrical modalities that may be used by occupational therapists, TENS should be correlated with functional use of the hand.

TENS should be used for intervention periods not to exceed 60 minutes at a time to achieve pain control.⁵⁴ A TENS diary should be used to record the level of pain on a scale of 1 to 10 before and after intervention, as well as activities that exacerbate the pain. To prevent overuse, TENS may be tapered as the pain-free periods increase. Intervention can be continued as long as necessary to provide pain control.

Joint Stiffness

Joint stiffness has been discussed in other sections of this chapter because it is seen after almost any hand trauma or disease. In the acute phase it may also result from “internal splinting” done unconsciously by the client to avoid pain. It may be prevented by early mobilization, pain control, reduction of edema, active and passive ROM, use of a CPM device, and appropriate splinting techniques. Grades I and II joint mobilization are especially helpful in preparing for passive and active motion and providing pain relief.

Treatment of established joint stiffness is more difficult. Thermal modalities, joint mobilization, ultrasound and electrical stimulation, dynamic splinting, serial casting, and active and passive motion in preparation for functional use should all be included in the intervention regimen.

Cumulative Trauma Disorders

A number of terms are used throughout the world to describe injuries to the musculoskeletal system, including overuse syndromes, repetitive strain injuries, cervical-brachial disorders, repetitive motion injuries, and, in the United States, cumulative trauma disorders (CTDs). There were 281,800 cases of CTDs reported in private industry in the United States in 1992.⁵⁶ Women account for about two thirds of work-related repetitive motion injuries. According to statistics reported by the U.S. Department of Labor in 2008, there were 334,140 cases of injuries to the neck, shoulder, and upper extremities involving days away from work, but only 30,920 cases were attributed to repetitive motion.¹⁰² This decline in reported CTDs may be associated with recognition of the need for early prevention, ergonomic intervention, and proper work station or tool modifications.

The term *cumulative trauma disorder* should be viewed as a description of the mechanism of injury and not a diagnosis. Even when the presenting symptoms are confusing, attempts to define a specific diagnosis are necessary because “each disorder has a different cause, intervention, and prognosis.”⁸⁷ Diagnoses associated with cumulative trauma usually fall into one of three categories: tendinitis (such as lateral epicondylitis—tennis elbow or de Quervain’s tenosynovitis), nerve compression syndromes (such as carpal tunnel syndrome or cubital tunnel syndrome), or myofascial pain.

Cumulative trauma occurs when force is applied to the same muscle or muscle group, causing an inflammatory response in the tendon or muscle.⁸⁷ Muscle fatigue is an important aspect of cumulative trauma. Excessive use of the muscle or body system (overuse or overexertion) is experienced as a muscle cramp. Acute overuse is relieved by rest, but chronic fatigue is not relieved by rest. The amount of fatigue is related to the amount of force and the duration of force application.

Fatigue occurs more quickly with high force. If force is maintained, repetitions must be reduced to allow recovery. Therefore, if the force is decreased while repetitions are maintained and recovery time is adequate, harm is less likely to occur. The combination of repetitions without adequate recovery time and high force establishes an environment that is likely to lead to injury. Byl found that repetitive hand opening and closing may lead to motor control problems and the development of focal hand dystonias through a degradation of the cortical representation.¹⁸ Applying this research may help therapists develop more effective intervention programs for cumulative trauma and chronic pain.

Intervention may be divided into phases. Acute-phase intervention is geared toward decreasing the inflammation through dynamic rest. Splints are used for immobilization. Splinting alone may relieve symptoms; splinting may be combined with cortisone injections to reduce inflammation. Icing, contrast baths, ultrasound phonophoresis, iontophoresis (the movement of ions through biologic material under the influence of an electric current), and interferential and high-voltage electrical stimulation have all been found to be effective in reducing pain and decreasing inflammation. Nonsteroidal anti-inflammatory drugs are also frequently used. When splints are used, they should be removed frequently during the day for stretching of the affected musculature (e.g., the extensor group with lateral epicondylitis) to maintain or increase muscle length and to prevent joint stiffness. Painful activities should be avoided during the dynamic rest phase. Vibration is contraindicated because vibration may contribute to inflammatory problems.

As the acute symptoms decrease, the client begins the exercise phase of intervention. After slow stretching warms up the muscles, the client begins controlled progressive exercise. Resistance should be increased slowly, and the frequency, intensity, and duration of exercises should be

monitored and adjusted in response to pain and fatigue levels.¹⁷

Clients are instructed to continue stretching three times a day, especially before activity, for an indefinite time. Proper body mechanics are critical in the long-term control of inflammatory problems, so clients must become aware of what triggers their symptoms and learn early intervention if symptoms reappear. Icing, splints, stretching, and modified activities combined with correct body mechanics are usually effective. The key is that the clients learn self-management techniques and take an active role in their intervention.

Work-related risk factors for CTDs include the following:⁵

- Repetition
- High force
- Awkward joint posture
- Direct pressure
- Vibration
- Prolonged static positioning

An assessment of the job site, tools used, and hand position during work activities may be indicated with the client whose symptoms are related to job demands. Modification of the equipment used and strengthening of the dominant muscle groups and their antagonist muscles may permit continued employment and control the inflammatory problem.

Tendinitis (inflammation of the tendon) and tenosynovitis (inflammation of the tendon sheath) are frequently seen in cumulative trauma. The cycle of overuse leading to microtrauma, swelling, pain, and limitations in movement is followed by rest, disuse, and weakness. Normal activity is resumed, and the cycle begins again.

Clients usually have a combination of localized pain, swelling, pain with resisted motion of the affected musculotendinous unit, limitations in motion, weakness, and crepitation of the tendons. Symptoms are reproduced with activity or work simulation. Using functional grades to describe the associated symptoms assists in evaluation, as well as in monitoring of improvement (Table 39-5).⁵³ Although isometric grip strength may be normal, wrist and forearm strength are often decreased and out of balance. Dynamic grip strength may be more limited because tendon gliding is more likely to increase inflammation and pain. Muscle imbalance leads to positioning and substitution patterns that may result in worsening or spreading of symptoms.

Nerve compression syndromes, especially carpal tunnel syndrome, are frequently seen.⁶³ Carpal tunnel syndrome is caused by pressure on the median nerve as it travels beneath the transverse carpal ligament at the volar surface of the wrist.⁴³ The syndrome is associated with increased pressure in the carpal canal because of trauma, edema, retention of fluids as a result of pregnancy, flexor tenosynovitis, repetitive wrist motions, or static loading of the wrist.

■ **TABLE 39-5 | Functional Grading of Cumulative Trauma Disorders**

Grade	Description
Grade I	Pain after activity; resolves quickly with rest No decrease in amount or speed of work Objective findings usually absent
Grade II	Pain in one site while working Pain consistent while working but resolves when activity stops Productivity sometimes mildly affected May have objective findings
Grade III	Pain in one or more sites while working Persistent pain after cessation of activity Productivity affected and multiple breaks sometimes necessary to continue working May affect other activities away from work May have weakness, loss of control and dexterity, tingling, numbness, and other objective findings May have latent or active trigger points
Grade IV	All common uses of hand and upper extremity resulting in pain, which is present 50% to 75% of the time May be unable to work or works in limited capacity May have weakness, loss of control and dexterity, tingling, numbness, trigger points, and other objective findings
Grade V	Loss of capacity to use upper extremities because of chronic, unrelenting pain Usually unable to work Symptoms sometimes of indefinite duration

From Kasch MC: Therapist's evaluation and treatment of upper extremity trauma disorders. In Mackin EJ, et al, editors: *Rehabilitation of the hand and upper extremity*, ed 5, St. Louis, 2002, Mosby.

Symptoms are night pain that is severe enough to waken the client; tingling in the thumb and index and middle fingers; and, if advanced, wasting of the thenar musculature caused by pressure on the motor branch of the nerve. Early carpal tunnel syndrome may be recognized during a thorough nerve evaluation.

Conservative intervention is usually attempted first and includes splinting of the wrist in no more than 20 degrees extension, contrast baths to reduce edema, wearing of Iso-toner gloves, and activity analysis. A semiflexible or neoprene splint rather than a completely rigid splint may be used to provide support while allowing a small amount of flexion and extension for greater functional use in carpal tunnel syndrome.

Ultrasound phonophoresis and iontophoresis may be used to reduce inflammation, and icing techniques are

beneficial. Specific strengthening exercises of the wrist, fingers, and thumb should be given when the pain and inflammation have been controlled.

In 1988, 35,000 carpal tunnel releases were performed in the United States. In 2002, this number climbed to more than 200,000.¹⁰⁰ Most clients report a relief of numbness, but many have persistent pain. Therapy is often provided after surgical release and may include a combination of ultrasound to the scar, massage, manual edema mobilization, desensitization, dexterity activities, and strengthening.

Myofascial pain and fibrositis are also conditions of pain elicited by activation of trigger points within the muscles and resulting in pain referred to a distal area; these are frequently encountered conditions. Travell studied myofascial pain and mapped out the traditional trigger points and their referral patterns.⁹⁹ Poor posture and positioning of the body out of normal alignment are often the mechanisms of injury in myofascial pain, so careful examination of the client and his or her normal daily activities is indicated. The therapist should observe the client performing the activity rather than rely on a verbal description.

Myofascial pain should be considered if direct intervention of the painful area does not relieve the pain. Evaluation for trigger points must be done meticulously, and mapping of the trigger points and the referral areas must be documented. Because the pain is referred, the trigger point must be treated, not the referral area. The interventions used for other inflammatory problems, such as ice and ultrasound phonophoresis, can be used. In addition, specific interventions for the trigger points, such as friction massage and TENS, may relieve the pain. Activity analysis is an essential part of intervention to relieve the stresses on the affected tissues.

Elastic Therapeutic Taping

First developed in Japan in the 1970s, Kinesio Taping* has become increasingly popular with therapists in the intervention of CTDs in the United States since its introduction here in 1994. Kinesio Taping is a taping technique that uses a special elastic tape called Kinesio Flex tape. Other elastic tapes may also be used. Unlike athletic taping, which is restrictive and is used to provide stability and restrict joint motion, Kinesio Flex tape is elastic and designed to “mimic the elastic properties of muscle, skin, and fascia.”²⁶ When properly applied, the elasticity of the Kinesio tape does not restrict the movement of soft tissue but supports weakened muscles and allows for full movement of the joints.

There are many variations in Kinesio taping techniques. Depending on the problem being addressed, the tape is anchored at either the origin or insertion of a muscle and then gently stretched and taped over or around either a

*Kinesio Tape (available from North Coast Medical, Morgan Hill, CA).

shortened or elongated muscle, after which time the muscle is placed back in a neutral position. The tape is believed to affect the peripheral somatosensory receptors located in the superficial skin, which in turn affects the skin and lymphatic system, as well as muscle and joint function, as they relate to pain, proprioception, and motor control.²⁵

Goals and concepts of elastic taping include the following:^{25,26}

- Decrease pain by increasing the somatosensory system.
- Reduce inflammation and edema by stimulating the lymphatic system.
- Normalize muscle tone by reducing overstretching and overcontraction of muscles.
- Reduce muscle fatigue by supporting and enhancing the contraction of weakened muscles.
- Improve ROM by relieving pain.
- Provide support and alignment to joints by supporting weakened ligaments.
- Prevent injuries during ADLs by providing support to muscles and ligaments.

Strengthening Activities

Acute care is followed by a gradual return of motion, sensibility, and preparation to return to normal ADL and IADL routines.

The client usually cannot strengthen the injured and neglected extremity at home because of the fear of further injury and pain. Because every hand clinic has its own armamentarium of strengthening exercises and media, only a few suggestions are provided here.

Computerized Evaluation and Exercise Equipment

Baltimore Therapeutic Equipment (BTE) has made available the BTE Work Simulator (Figure 39-18),²⁹ an electromechanical device that has more than 20 interchangeable tool handles and can be used for both work evaluation and UE strengthening. Resistance can vary from no resistance to complete static resistance, with tool height and angle also adjustable. When the device is used for strengthening, the resistance is usually set low and gradually increased. Length of exercise is increased when a base level of strength has been achieved. The BTE Work Simulator allows for close simulation of real-world tasks that are easily translatable into physical demands common to manual work.

Other computerized evaluation equipment allows the therapist to record the results of assessment and print a report. The percentage of impairment can also be determined electronically. Portable systems are being developed that allow the therapist to record daily intervention and download the information into a computerized network. Outcome data from many sources can then be compared. The advancement of technology in rehabilitation will allow

FIGURE 39-18 BTE Work Simulator is an electromechanical device used to simulate real-life tasks for upper extremity evaluation and strengthening. The client's progress is monitored through a computerized printout, and the program can be modified to increase resistance and endurance.

the therapist to be more efficient and also capture important information that is not available through traditional means.

Many practitioners use real occupation-based interventions that simulate the actual work done, either in the clinic or at the work site. These methods are the most in keeping with the Occupational Therapy Practice Framework.

Weight Well

The Weight Well⁷ was developed at the Downey Community Hospital Hand Center in Downey, California, and is available commercially.* Rods with a variety of handle shapes are placed through holes in the box and have weights suspended. The rods are turned against resistance throughout the ROM to encourage full grasp and release of the injured hand, wrist flexion and extension, pinch, and pronation and supination patterns. The Weight Well can be graded for resistance and repetitions and is an excellent tool for progressive resistive exercise.

*Upper Extremity Technology Weight Well (available from Upper Extremity Technology, Glenwood Springs, CO).

Theraband

Theraband* is a 6-inch (15.2-cm) wide rubber sheet that is available by the yard and is color coded by degrees of resistance. It can be cut into any length required and used for resistive exercise for the UE. Use of Theraband is limited only by the therapist's imagination, and it can be adapted to diagonal patterns of motion, wrist exercises, follow-up intervention of tennis elbow, and other uses. The Theraband can be combined with dowel rods and other equipment to provide resistance throughout the ROM. It is inexpensive and easy to incorporate into a home intervention program.

Hand-Strengthening Equipment

Handgrips of graded resistance are available from rehabilitation supply companies and sporting goods stores. They can be purchased with various resistance levels and can be used for progressive resistive hand exercises.

The therapist is cautioned against using overly resistive spring-loaded grippers often sold in sporting goods stores. These devices may be beneficial to the seasoned athlete but are usually too resistive for the recently injured.

Therapy putty can be purchased in bulk, and the amount given to the client is geared to hand size and strength. Putty is also available in grades of resistance, and some provide chips that can be added to progressively increase resistance. It can be adapted to most finger motions and is easily incorporated into a home program.

Household items such as spring-type clothespins have been used to increase strength of grasp and pinch. Imaginative use of common objects should present a challenge to the hand therapist.

Purposeful and Occupation-Based Activity

Purposeful and occupation-based activities are an integral part of rehabilitation of the hand. Purposeful and occupation-based activities include crafts, games, dexterity activities, ADLs, and work samples. Several studies have shown that clients are more likely to choose occupationally embedded exercise and performed better using this type of exercise over rote exercise.^{81,111} Many of the intervention techniques described previously are used as preparatory methods for the hand in preparation for purposeful activity.

Activities should be started as soon as possible at whatever level the client can perform them with adaptations to compensate for limited ROM and strength. They should be used in conjunction with other interventions. The occupational therapist must continually assess the client's functional capacities and initiate changes in the intervention plan to incorporate activities as soon as possible in the restorative phase.

Vocational and leisure goals should be established at the time of initial evaluation and taken into account when

devising the intervention plan. The needs of a brick mason may be quite different from those of a mother with small children, and the environmental needs of the client must not be neglected.

Crafts should be graded from light resistance to heavy resistance and from gross dexterity to fine dexterity. Crafts that have been found to work extremely well with hand injuries include macramé, Turkish knot weaving, clay molding, leather tooling, and woodworking. All of these crafts can be adapted and graded to the client's capabilities and have been found to have a high level of client acceptance. When integrated into a program of total hand rehabilitation, they are viewed as another milestone of achievement and not as a diversion to fill up empty hours. For example, the pride of accomplishment for Gerry, who was able to complete his first simple woodworking project, is evidence that the purposeful activity of crafts belongs in hand rehabilitation.

Activities that do not have an end product but provide practice in dexterity and ADL skills also fit into the category of purposeful activities. Developmental games and activities that require pinch or grasp and release may be graded and timed to increase difficulty. ADL boards that have a variety of opening and closing devices provide practice for use of the hand at home and increase self-confidence. String and finger games are challenging coordination activities that can be done in pairs and are fun to do.

A hobby can often be adapted for use in the clinic. Fly-tying is a difficult dexterity activity but one that is frequently enjoyed by an avid fisherman. Golf clubs and fishing poles can be adapted in the clinic; in the case of Gerry, therapy with these tools allowed early return to a favorite form of relaxation.

Humor and interaction with the therapists and the other clients are vital but intangible benefits of hand therapy intervention. The intervention should be planned to promote both.

Functional Capacity Evaluation

The ultimate goal of therapy for an injured worker is to return to full employment. Many weeks or months may have elapsed between the time of the injury and the point at which the physician believes that a return to work is appropriate from a medical standpoint. Despite the fact that x-ray examinations may show full healing and restored ROM, many clients do not feel that they have the strength, dexterity, or endurance to return to their former jobs. Pain may continue to be a limiting factor, especially with heavy activities. Light duty or part-time positions may not be available, and the physician, therapist, industrial insurance carrier, and especially the client are frustrated by the lack of an objective method of evaluating an individual's physical capacity for work. Occupational therapists with training in evaluation, kinesiology, and adaptation of environmental

*Theraband (available from Smith & Nephew, Milwaukee, WI).

factors coupled with a functional approach to the client may play a key role in functional capacity evaluation.

A renewed interest in evaluation of prevocational factors has brought the OT profession full circle (see Chapter 14). Although regarded as one of the cornerstones of the profession in its early years, prevocational evaluation was neglected in many centers during the 1960s and 1970s. Since the early 1980s, however, occupational therapists have rediscovered a need that the profession is in a unique position to provide. The term *prevocational evaluation* ambiguously implied that occupational therapists were involved in assessing the vocational needs of clients they treated. The terms *functional capacity evaluation (FCE)* and *work tolerance screening (WTS)*, however, more clearly describe the process of measuring an individual's ability to perform the physical demands of work.

The results of the FCE allow the therapist, worker, physician, and vocational counselor to establish a specific, attainable employment goal using reliable data. This approach relieves the physician of the responsibility of returning the client to work without objective information about the client's ability to do a job. It also allows the client to test his or her own abilities and may result in increased self-confidence about returning to work.

Many techniques for performing a functional capacity evaluation have been proposed.^{8,46,69,70,91} Some basic steps may be followed regardless of the specific technique adopted. The client should be evaluated for grip and pinch strength, sensation, and ROM. Edema and pain must also be assessed and reassessed during the course of the evaluation.

The GULHEMP (general physique, UE, lower extremity, hearing, eyesight, mentality, and personality) Work Capacity Evaluation Worksheet⁶⁹ may be used as a general method of determining functional abilities. The GULHEMP Physical Development Analysis Worksheet⁶⁹ may be used to evaluate the job.

Job analysis may also be provided by a rehabilitation counselor and through information provided by the client. The therapist should consult the Dictionary of Occupational Titles (DOT)¹⁰² to obtain information about the worker traits required for the expected job. This dictionary contains 12,900 job descriptions and 20,000 job titles. If sufficient information about the job is not available through these methods, an onsite job analysis by the therapist may be necessary. Once the physical demand characteristics of work have been documented, it is possible to evaluate the client's ability to perform them. The U.S. Department of Labor sponsors the Occupational Information Network online (<http://online.onetcenter.org>), which includes job titles, job accommodations, and the ability to search for job information using several criteria.

Schultz-Johnson described an FCE adapted for UE injuries based on the physical demands established by the U.S. Department of Labor.⁹¹ After evaluation, the therapist may recommend a work therapy program.⁹¹ Work therapy can include simulated job tasks to increase job performance.

Matheson has written several manuals and articles that describe work capacity evaluation (WCE).^{69,70} This 8- to 10-day work assessment includes evaluation of the client's feasibility for employment (worker characteristics, such as safety and dependability), employability, work tolerances (e.g., strength, endurance, and the effect of pain on work performance), the physical demand characteristics of the job, and the worker's ability to "dependably sustain performance in response to broadly defined work demands."⁷⁰

Tests with well-accepted reliability—such as the Purdue Pegboard Test,⁹⁸ the Crawford Small Parts Dexterity Test,²⁷ the Minnesota Manual Dexterity Test,⁷⁸ and the Jebsen Hand Dexterity Test⁴⁹—may be administered as a screening process. These tests will give the therapist valuable information through observation, whether the normal tables are used or the test is adapted to an individual worker.

Many assessments and job simulation devices are available and should be reviewed before a physical capacity evaluation program is established. To choose appropriate work samples, the therapist should determine the job market in a specific area. This can be done by consulting rehabilitation counselors and representatives from vocational schools and employment agencies in the area.

Work samples, available through organizations such as the Jewish Employment and Vocational Service,¹⁰³ or VALPAR,* may be used to test specific skills. The therapist may also develop job samples by using information on jobs in the local area. Discarded electronic assembly boards, a lawn mower motor, an automobile engine, or other items from the local hardware store may provide valuable information about the worker's ability.

Work simulation using job samples or the BTE Work Simulator assesses the worker's specific physical capacities, as well as endurance and symptoms that become cumulative with prolonged use of the injured part (called symptom response to activity, or SRA). Monitoring the client's SRA may prevent loss of time and money expended in training for an inappropriate vocational goal.

A combination of "normed" tests, job samples, job simulation, and WCE devices may provide the therapist with the best information about a worker's physical capacity. For more information about vocational evaluation and rehabilitation, the reader is encouraged to visit the website for the University of Wisconsin-Stout at www.uwstout.edu/programs/sp/vert/sp_vert.pdf.*

Work Hardening

Work hardening is the progressive use of simulated work samples to increase endurance, strength, productivity, and often feasibility. Work hardening may be performed for a period of weeks, and the progressive ongoing nature of the work usually improves physical capacity. It is an important contribution to return to work.

*Materials Development Center, Stout Vocational Rehabilitation Institute, University of Wisconsin-Stout, Menomonie, WI.

Because FCE is also performed over time, it may be difficult to identify the difference between FCE and work hardening. An FCE is generally done when the client has stopped improving with traditional therapy methods and may have been released from acute medical care. The client may be unable to return to his or her former employment, or the client's ability to do the former work may be in doubt. A physician, rehabilitation counselor, insurance adjuster, or attorney may initiate an FCE.

Work hardening or work conditioning may be initiated earlier in the rehabilitation process, perhaps by the treating physician or therapist who recognizes that an individual may have difficulty returning to the former employment. It is performed before the end of medical care and may serve as a final checkout before discontinuing intervention.

Standards for work hardening services have been developed by the Commission on Accreditation of Rehabilitation Facilities (CARF)²⁴ to ensure that injured workers are offered high-quality programs that are maximally effective in returning them to gainful employment. Roy Matheson and Associates⁷¹ offers many publications and resources to therapists interested in establishing WCE, work tolerance screening, or work hardening services.

FCE and work hardening are adjuncts to the vocational rehabilitation process. Occupational therapists are trained to observe behavior and have the skills necessary to translate that observation into useful data. FCE and work hardening should not compete with the work of rehabilitation or vocational counselors; instead, they should provide critical information about a worker's physical functioning and foster reentry into the job market.

Consultation with Industry

Occupational therapists may be asked to visit the job site to make recommendations for ergonomic adaptations, including tool modification, ergonomic furniture and accessories, and training of workers in proper positioning to reduce the incidence of CTDs. Because prevention substantially reduces the costs to industry, occupational therapists have a unique opportunity to apply their training in activity analysis and adaptation of the environment in a new setting. The Americans with Disabilities Act (ADA) mandates reasonable accommodations for workers with disabilities. Many occupational therapists have become active in helping companies comply with the requirements of the ADA. The American Occupational Therapy Association is an excellent resource for information about the ways in which therapists can be involved in these efforts in their communities (also see Chapter 15).³

Psychosocial Effects of Hand Injuries

After a hand injury, a number of psychosocial reactions may occur, including changed body image and self-image, depression, anxiety, and decreased self-worth (as

experienced by Gerry, the cabinet maker in the case study with the amputated fingers and surgical replantation), to name but a few. For traumatic hand injuries, acute stress disorder and posttraumatic stress disorder are not uncommon and can be problematic for the client, especially if they are not addressed promptly. The hand therapist is often the primary contact for the client after injury and may see the client several times per week on a one-to-one basis. The hand therapist, therefore, plays a "very important role in helping the client return to pre-injury physical and emotional functioning."¹⁵ Not only do occupational therapists who specialize in hand therapy provide the client with emotional support, but they are also critical in recognizing psychosocial issues that the client may be having; are educated in evaluating and providing intervention for these; and, when necessary because of the severity of the problem, are capable of facilitating referral to an appropriate mental health professional.

Summary

This chapter provides an overview of intervention of the UE. Evaluation procedures are discussed, as well as the basic intervention techniques. Management of both acute injuries and cumulative trauma is included, as well as information on strengthening and programs for industrial injuries. Most occupational therapists working in physical disabilities should be familiar with the basic intervention approaches described for the UE because they work with clients who have some limitation in the UEs. Specialization in hand therapy requires both advanced academic study and clinical experience. A therapist who specializes in this area of practice and who meets minimum requirements may choose to take the Hand Therapy Certification Examination and become a certified hand therapist (CHT). For more information on becoming a CHT, contact the Hand Therapy Certification Commission (www.htcc.org).⁴⁵ Links to educational resources are also available on this website. Another valuable resource is membership in the American Society of Hand Therapists (www.asht.org).

Although much of UE rehabilitation involves the use of preparatory methods such as exercise, splinting, and physical agent modalities, these interventions should be used in preparation for purposeful or occupation-based activities. The goal is always for the client to be as independent as possible and to use these preparatory methods to achieve the client's occupation-based performance goals. Purposeful activity is used whenever feasible in the hand clinic according to space and time constraints, and clients are encouraged to use their new skills in their own home or work contexts and bring back to the clinic information about the obstacles that they experience in achieving their performance goals.

Threaded Case Study | Gerry, Part 2

The case study presented at the beginning of this chapter described Gerry, a 32-year-old cabinetmaker with an acute, complex hand injury involving amputation and surgical replantation of three digits. Gerry progressed through all phases of rehabilitation over the course of 15 months, from the acute hospital stay to return to work and play activities. Based on the case presented, how would the intervention plan change over the course of Gerry's recovery, and what specific intervention approaches could his occupational therapist use?

During the acute phase, one of the therapist's goals was to promote and maintain the health of the client's unaffected joints that were vulnerable to becoming stiff from protective posturing. Another goal during the acute phase was to prevent further injury or abnormal joint changes to the left hand. ROM exercises were administered to maintain the healthy function of the client's unaffected joints such as the shoulder and elbow and a protective splint was fabricated, placing Gerry in a protective and functional position of mild wrist flexion, MP flexion, and IP extension. During this phase of recovery, education was an important component of the client's intervention plan. Gerry was taught appropriate postoperative precautions and splint wear and care; his family received education on wound care, dressing changes, and signs of infection. Gerry was given written material regarding this home program.

During the intermediate phase of his recovery, the intervention approach was to restore active and passive ROM, strength, and coordination to Gerry's hand so that he could return to his previous occupations (specifically, cabinetry, golf, and softball). The ROM activities were graded, and motion was progressively added as the tendons, nerves, and vessels healed. Strengthening exercises were added during the late phase of recovery, and at this point Gerry could safely attempt to return to his previous activities. It was at this time that purposeful and occupation-based activities were added to Gerry's therapy regimen. In addition, Gerry's areas of occupation had to be modified for the loss of mobility, strength, and coordination of the hand. Gerry was taught one-handed ADLs during the acute phase of recovery so that he could be self-sufficient until he regained the use of his left hand. Modifications to his activity demands were also implemented, such as enlarging the handles of his golf clubs to compensate for the lack of full finger ROM during the intermediate to late phases of recovery. Finally, Gerry was taught to prevent further injury to his hand through visual compensation techniques for loss of sensation, to monitor for signs of infection, and to undertake postsurgical precautions during the acute phase of his injury.

Throughout Gerry's intervention, his performance skills were reviewed to identify barriers to performance using a variety of assessment tools. A grip dynamometer, pinch meter, and manual muscle tests were used to assess grip, pinch, and muscle strength. A goniometer was used to assess ROM, and Semmes-Weinstein monofilaments were used to assess sensation. A volumeter and circumferential measurements were used to assess edema, and the Jebson Test of Hand Function was used to assess the functional use of Gerry's hand in a standardized format. The evaluation data were then interpreted and the intervention plan modified to achieve the targeted outcomes.

Once the intervention plan was established, various preparatory methods and purposeful activities were chosen to achieve Gerry's occupational goals. For the occupational performance goal of golfing, splints were used as a preparatory method during the intermediate phase of recovery to help Gerry gain passive ROM of stiff joints and increase overall flexion of the replanted digits so that he could eventually hold a golf club. Physical agent modalities such as paraffin and ultrasound were applied before performance of purposeful activity during the intermediate and late phases of recovery. Purposeful activities such as swinging a golf club in the clinic, simulating a golf swing on the BTE work simulator, and gradually increasing the physical resistive demands of this golf swing were performed. Gerry also practiced putting in the clinic with special "flexion gloves" early on so that he could hold the golf club; later, he progressed to wearing no glove but instead enlarging the handle of the golf club to facilitate a secure grip.

To address Gerry's occupational goal of returning to work as a cabinetmaker, a volunteer opportunity was arranged for him to participate in the purposeful activity of making "wooden sliding/transfer boards" and other assistive devices for the acute rehabilitation clients. Not only was this activity goal directed and directly related to his work occupation, but it also fulfilled Gerry's desire to use his talents in carpentry to help other clients in the hospital; this contributed to improving his feelings of self-worth. During the late phase of Gerry's recovery, additional occupation-based activity was initiated to address his avocational interests. During the actual performance of golfing and softball outside of the clinic, it was found that Gerry was hypersensitive in the palm over the scars. Desensitization techniques were performed as part of his home program, and he purchased gloves with gel inserts to absorb the shock of hitting the ball.

Review Questions

1. A client is seen for a hand problem and found to have limited or painful ROM of the shoulder. List three tests that should be performed.
2. Discuss three approaches to postoperative care of flexor tendon injuries, and describe how the differences among the methods would influence the initiation of OT.
3. To what does joint dysfunction refer? What are its causes?
4. Discuss the three classifications of nerve injury.
5. Define the area referred to as "no-man's land." What distinguishes injury to this area?
6. What techniques are used to evaluate the physical demand characteristics of work?
7. List three methods of applying pressure to a hypertrophic scar.

8. Which functional activities could be used for restoration of hand function following laceration and repair of the extrinsic finger flexors?
9. Which assessments should be included in a functional capacity evaluation?
10. List five tests used to assess joint integrity in the hand.
11. List three objectives of splinting as they relate to injury of the radial, median, and ulnar nerves.
12. What are the characteristics of complex regional pain syndrome, type I? What are the intervention goals?
13. Define work hardening. How can work hardening be incorporated into OT?
14. How is the presence of edema evaluated? List three methods used to reduce edema.
15. What are the primary work-related risk factors associated with cumulative trauma? How can the occupational therapist intervene to prevent the development of cumulative trauma?

Hip Fractures and Lower Extremity Joint Replacement

Chapter Outline

General medical management of fractures

Etiology of fractures

Medical management

Hip fractures

Types of hip fractures and medical management

Hip joint replacement

Etiology and medical management

Knee joint replacement

Etiology and medical management

Special considerations for lower extremity joint replacements

Psychological factors

Rehabilitation

Role of occupational therapy

Evaluation and intervention

Client education

Specific training techniques

Training procedures for persons with hip surgery

Training procedures for persons with total knee replacement

General considerations and evidence for occupational therapy intervention

Special equipment

Summary

Key Terms

Abduction brace

Weight-bearing restrictions

Posterolateral approach

Joint resurfacing

Osteoporosis

Arthroplasty

Partial joint replacement

Knee immobilizer

Osteoarthritis

Avascular necrosis

Hip precautions

Leg Lifter

Open reduction and internal fixation

Anterolateral approach

Minimally invasive technique

Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the etiology of hip fractures and lower extremity joint replacements and how these problems limit participation in areas of occupation.
2. Describe the medical management for these conditions.
3. Identify the medical precautions associated with hip fractures and lower extremity joint replacements.
4. Outline client factors, performance patterns, and performance skills that are appropriate to include in the occupational therapy evaluation.
5. Develop occupational therapy intervention goals utilizing information gained from the occupational profile and evaluation results.
6. Discuss appropriate interventions that address all areas of occupational performance.
7. Discuss the impact of hip fractures and joint replacement on occupational performance and performance patterns.

Threaded Case Study Mrs. Hernandez

Mrs. Hernandez, a 70-year-old Latina grandmother to three small children, has been experiencing increasing right hip pain over the past few years as a result of osteoarthritis and degenerative joint disease. She received a right total hip replacement that was performed using an anterior approach, minimally invasive procedure. Mrs. Hernandez is usually very active, attending swimming classes twice a week, helping her daughter care for her three children, and heading two committees at her parish church. These activities became very important to her after her husband died 5 years ago. They give her a sense of purpose and help her feel connected with others. Mrs. Hernandez lives alone in an apartment with elevator access. Her daughter and grandchildren live 15 minutes away and often visit and involve her in many of their family activities.

Mrs. Hernandez was referred for occupational therapy because her hip pain had increased to the point that it kept her from attending the swimming classes she enjoys so much. Climbing in and out of the pool had simply become too painful. Driving was especially difficult at times because she worried that she would not be able to operate the gas or brake pedal and might lose control of the car. She relied on her church friends and daughter to bring her to church each week but had to cut back on attending the meetings for the committees to which she belongs. She is hoping that the occupational therapy she receives will help her be able to drive again as soon as possible.

Critical Thinking Questions

1. When completing the occupational profile, what additional information would the occupational therapist need to gather during the evaluation to supplement the information already provided in the case scenario?
2. Identify important areas to address first when educating Mrs. Hernandez to perform her daily activities safely.
3. What prerequisite performance skills should be addressed with Mrs. Hernandez before the occupational therapist directly addresses her ability to drive again?

Hip fractures and lower extremity (LE) joint replacements are two orthopedic conditions that occur with a relatively high frequency. Persons who have been involved in sports or occupations that put great amounts of stress on the knee or hip joints may experience joint pain and degeneration as they get older. In addition, older individuals are more likely to have orthopedic problems such as osteoporosis and degenerative joint changes as a part of the aging process. LE joint problems can lead to temporary or more long-lasting disability. In both hip and knee conditions, a large weight-bearing joint is typically unstable for a period of time, which limits an individual's participation in meaningful daily occupations. For example, Mrs. Hernandez discontinued swimming and driving and limited her physical activities

with her grandchildren because of her hip pain. All of these occupations were valued aspects of her life in which she felt unable to participate. However, medical advances have made the treatment of hip fractures and LE joint problems safer and have made the conditions easier to manage.

The elderly population is most at risk for hip fractures. Reduced mobility and the presence of osteoporosis are two specific risk factors. Elderly women, in particular, develop osteoporosis to a greater degree than men and thus tend to have more hip fractures when they fall.⁴

Mobility is compromised in the elderly population because of decreased flexibility, diminished strength, reduced vision, slowed reaction time, and the use of assistive ambulatory aids such as canes and walkers. Many elderly people become more cautious when moving about and are fearful of falling. In some cases, individuals use a cane or walker improperly, which causes a fall. Not seeing a step or threshold is also a common cause for falling.

Individuals with a history of osteoarthritis or other rheumatic disease are primary candidates for LE joint replacement. Individuals who elect to undergo this surgical procedure usually have been living with increasing pain in their joints for many months or years, and their ability to perform daily tasks is already limited. By having the painful joint replaced, they hope to return to a more active and satisfying lifestyle.

Occupational therapy (OT) plays a key role in identifying and remediating the many functional problems imposed by these acute and chronic orthopedic conditions, thus sharing in the goal of returning the orthopedic client to optimal performance of safe, independent, and meaningful occupations. For example, OT can help Mrs. Hernandez identify alternative ways of participating in her daily occupations safely; the therapist must make sure to address all of the occupations that the client identifies as important.

This chapter includes a discussion of hip fractures and LE joint replacements and their medical and surgical management. The Occupational Therapy Practice Framework, Second Edition, is used to discuss evaluation and intervention for persons with these conditions. Specific areas addressed in the chapter are occupational therapy evaluation of performance skills in areas of occupation, occupational therapy interventions addressing specified occupations, the psychological implications of hospitalization and disability, and the healthcare team approach in both the acute hospital and rehabilitation settings.

General Medical Management of Fractures

In general, a fracture occurs when the bone's ability to absorb tension, compression, or shearing forces is exceeded.⁵ The healing process begins after the fracture. Osteoblasts, cells that form bone, multiply to mend the fractured area. A good blood supply is necessary to supply the cells with oxygen for proper healing. The fracture site is protected

OT Practice Notes

It is important for the occupational therapist working with clients who have orthopedic problems or diagnoses to have a good understanding of the site, type, and cause of the fracture before starting the evaluation and intervention processes. A basic understanding of fracture healing and medical management is also necessary to appreciate the risks, precautions, and complications involved. The occupational therapist is advised to consult an orthopedic manual for specific information regarding the specifics of the fracture healing process.

during the postsurgical healing process by pins, plates, and wires. In rare cases in which extra protection is needed, an external abduction brace may be used for the hip. This brace extends around the pelvis and down the thigh of the fractured hip and prevents movement, especially hip abduction, according to settings determined by the orthopedic surgeon. Other types of braces or casts may be used for fractures of other parts of the lower extremity (e.g., a knee immobilizer). It may take several months for a bone fracture to heal completely. The time needed varies with the age and health of the client, the site and configuration of the fracture, the initial displacement of the bone, and the blood supply to the fragments.

Etiology of Fractures

Trauma is the major cause of fractures. In most cases, the trauma occurs as a result of falling. Poor lighting, throw rugs, and unmarked steps are particular hazards that can lead to a fall. Osteoporosis is a common bone disease that affects people as they get older. It results in decreased bone density, most commonly in the vertebral bodies, the neck of the femur, the humerus, and the distal end of the radius. Because the bone becomes porous and therefore fragile, the affected bones are prone to fracture during a fall or other traumatic event. A pathologic fracture can occur in a bone weakened by disease or tumor, as with osteomyelitis and cancers that have metastasized to the bone.⁵

Medical and Surgical Management

The goals of fracture management are to relieve pain, maintain good position of the bone, allow fracture healing, and restore optimal function to the client. Reduction of a fracture refers to restoring the bone fragments to normal alignment.⁵ This can be done by a closed procedure (manipulation) or by an open procedure (surgery). The physician performs a closed reduction by applying force to the displaced bone, opposite to the force that produced the fracture. Depending on the nature of the fracture, the reduction is maintained in a cast, brace, traction, or skeletal fixation. With open reduction, the fracture site is exposed surgically so that the bone fragments can be aligned. The fragments are held in

Box 40-1

Weight-Bearing Restrictions

NWB (non-weight bearing) indicates that no weight at all can be placed on the extremity involved.

TTWB (toe-touch weight bearing) indicates that only the toe can be placed on the ground to provide some balance while standing—90% of the weight is still on the unaffected leg. In toe-touch weight bearing, clients are instructed to imagine that an egg is under their foot.

PWB (partial weight bearing) indicates that only 50% of the person's body weight can be placed on the affected leg.

WBAT (weight bearing at tolerance) indicates that clients are allowed to judge how much weight they are able to put on the affected leg without causing too much pain.

FWB (full weight bearing) indicates that clients should be able to put 100% of their weight on the affected leg without causing damage to the fracture site.

From Early MB: Physical dysfunction: practical skills for the occupational therapy assistant, St. Louis, 1998, Mosby.

place with internal fixation by pins, screws, a plate, nails, or a rod. Further immobilization by a cast or a brace may be necessary. Because a closed reduction or an open reduction and internal fixation (ORIF) usually must be protected from excessive forces, weight-bearing restrictions are typically indicated.⁵

There are several levels of weight-bearing restrictions. The physician indicates at which level the client should be placed and changes the restrictions as the fracture site heals and becomes stronger. The levels of weight-bearing restrictions are listed in [Box 40-1](#).⁷

Hip Fractures

Types of Hip Fractures and Medical Management

Knowledge of hip anatomy is necessary for understanding medical management of hip fractures. An anatomy and physiology reference text should be consulted for details. See [Figure 40-1](#) for an illustration of the normal hip joint.

The common fracture lines are shown in [Figure 40-2](#). The names of the fractures generally reflect the site and severity of injury and may signal the form of medical treatment that will be used. For example, a femoral neck fracture will be treated with femoral neck stabilization.¹⁷

Femoral Neck Fractures

Femoral neck fractures, which include subcapital, transcervical, and basilar fractures, are common in adults over 60 years old and occur more frequently in women. If the bone is osteoporotic, fracture may result from even a slight trauma or rotational force.¹⁰ Treatment of a displaced fracture in this area is complicated by poor blood supply, osteoporotic

bone that is not suited to hold metallic fixation, and a thin periosteum covering the bone. The type of surgical treatment used is based on the amount of displacement and the circulation in the femoral head.

The age and health of the client are considered in deciding on the surgical procedure. Generally, hip pinning (application of a compression screw and plate) is used when displacement is minimal to moderate and blood supply is intact. With a physician's approval, a client is usually able to begin limited out-of-bed activities 1 to 3 days after surgery. Per physician's orders, weight-bearing restrictions may be necessary, with the aid of a walker or crutches for at least 6 to 8 weeks while the fracture is healing. Weight bearing may be limited beyond this time if precautions are not observed or if delayed union occurs.¹⁷

With severe displacement or in the case of a femoral head with poor blood supply (avascular) or nonunion (a poorly healing fracture site where new bone does not form) and degenerative joint disease, the femoral head is surgically removed and replaced by an endoprosthesis. This joint replacement is referred to as a hemipolar arthroplasty, sometimes referred to as a hemiarthroplasty.^{12,17} Several types of

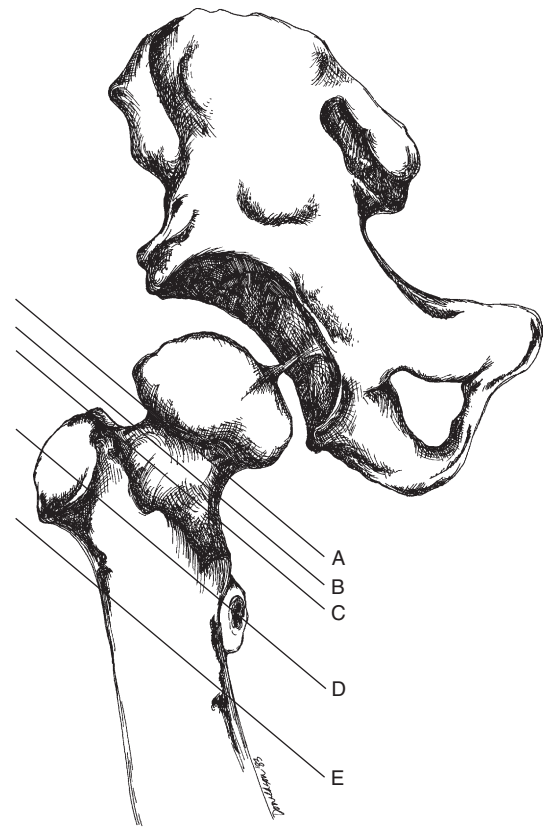

FIGURE 40-2 Levels of femoral fracture. A, Subcapital. B, Transcervical. C, Basilar. D, Intertrochanteric. E, Subtrochanteric. (Modified from Crow I: *Fracture of the hip: a self study*, *ONA J* 5:12, 1978.)

metal prostheses can be used for a hemiarthroplasty; each has its own shape and advantages. Weight-bearing restrictions are sometimes indicated. Depending on the surgical procedure used (posterolateral or anterolateral approach), specific precautions for positioning the hip must be observed to prevent dislocation. These precautions are the same as for a total hip arthroplasty or hip replacement, which will be outlined later in this chapter. Clients who have had a prosthesis implanted can usually begin limited out-of-bed activity, with a physician's approval, about 1 to 3 days after surgery.^{12,17,20}

Intertrochanteric Fractures

Fractures between the greater and lesser trochanter are extracapsular, or outside the articular capsule of the hip joint, and the blood supply is not affected. Like femoral neck fractures, intertrochanteric fractures occur mostly in women but in a slightly older age group. The fracture is usually caused by direct trauma or force over the trochanter, as in a fall. The preferred treatment for these fractures is an ORIF. A nail or compression screw with a sideplate is used. Weight-bearing restrictions must be observed according to the surgeon's orders for up to 4 months during ambulation. The client is allowed out of bed 1 to 3 days after surgery, pending the physician's approval.¹⁷

Subtrochanteric Fractures

Subtrochanteric fractures 1 to 2 inches below the lesser trochanter usually occur because of direct trauma, as in falls, motor vehicle accidents, or any other situation in which there is a direct blow to the hip area. These fractures are most often seen in persons younger than 60 years old. Skeletal traction followed by an ORIF is the usual treatment. A nail with a long sideplate or an intramedullary rod is used. An intramedullary rod is a rod inserted through the central part of the shaft of bone to help maintain proper alignment for bone healing.⁵

In all types of hip fractures, the practitioner should be aware of the coexisting conditions of soft-tissue trauma, edema, and bruising that occur around the fracture site.^{5,12,17} These conditions can greatly affect the amount of pain and discomfort that a client may experience.

Hip Joint Replacement

Etiology and Medical Management

Restoration of joint motion and management of pain by total hip replacement, or arthroplasty, is sometimes indicated, primarily in osteoarthritis, rheumatoid arthritis, and occasionally in other disease processes. Osteoarthritis or degenerative joint disease may develop spontaneously in middle age and progress as the normal aging process of joints accelerates. Degenerative changes may also develop as the result of trauma, congenital deformity, or a disease that damages articular cartilage. Weight-bearing joints such as the hip, knee, and lumbar spine are usually affected. In the hip, there is a loss of cartilage centrally on the joint surface and formation of osteophytes on the periphery of the acetabulum, producing joint incongruity. Pain originates from the bone, synovial membrane, or fibrous capsule and from muscle spasm. When movement of the hip causes pain and limited mobility, the muscles shorten, which can result in a hip position of flexion, adduction, and internal rotation that causes a painful limp.¹⁵

Mrs. Hernandez experienced a “catch” in her right hip that was a result of the loss of cartilage around the femoral head and acetabulum in her hip. Because the joint surfaces were uneven, she experienced a great deal of pain when walking. Using a cane helped to relieve some of the pressure on her hip prior to her surgery.

Rheumatoid arthritis (see Chapter 38) may involve the hip joint. Surgery is often performed early in the disease process to limit fibrotic damage to the joint and tendon structures.⁵ Other disease processes (e.g., lupus and cancer) and some medications (e.g., corticosteroids such as prednisone) can compromise the blood flow to the hip joint and lead to avascular necrosis (AVN, a condition in which bone cells die because of poor blood supply) or osteoporosis; either condition results in a painful hip.¹⁵

When conservative forms of management (e.g., cortisone injections) for the pain and decreased mobility have not been successful, a total joint replacement is considered to

restore an individual's ability to participate in daily occupations. The total joint replacement is not considered for persons who will not comply with a rehabilitation program or who will not experience significant improvement in functional ability.^{12,13} There are two mechanical components to this type of endoprosthesis. A high-density polyethylene socket is fitted into the acetabulum, and a metallic prosthesis replaces the femoral head and neck. Methylmethacrylate or acrylic cement fixes the components to the bone. Various surgical approaches are used. The specific approach is selected on the basis of the surgical skill or technique of the orthopedic surgeon, severity of the joint involvement, anatomic and biomechanical structure of the client's hip, and history of past surgery to the hip.¹⁷ With an anterolateral approach, the client will be unstable in external rotation, adduction, and extension of the operated hip and usually must observe precautions to prevent these movements for 6 to 12 weeks. Hip abduction may be prohibited as well with this surgical approach. It is important for the OT to carefully read the surgeon's postoperative orders. If a posterolateral approach is used, the client will be unstable primarily with hip flexion and must be cautioned not to move the operated hip past specific ranges of flexion (usually 90 degrees) and not to internally rotate or adduct the leg, for 6 to 12 weeks. Failure to maintain these hip precautions during muscle and soft-tissue healing may result in hip dislocation (Box 40-2).

Most surgeons do not restrict weight bearing postoperatively when cement fixation is used. However, one of the major problems with total hip replacement is the loss of fixation at the prosthesis interface with the remaining bone. The use of biologic fixation, where bony in-growth, instead of cement, secures the prosthesis, can improve fixation at the prosthesis interface. In other words, new bone grows into openings in the prosthesis, and this secures the prosthesis to the bone (Figure 40-3). The precautions following the surgery are identical to those of the anterior or posterior hip replacements, with an additional restriction on weight bearing for 6 to 8 weeks. The restrictions on weight bearing

Box 40-2

Hip Precautions

Posterolateral Approach

- No hip flexion greater than 90 degrees
- No internal rotation
- No adduction (crossing legs or feet)

Anterolateral Approach

- No external rotation
- No adduction (crossing legs or feet)
- No extension

From Early MB: *Physical dysfunction: practical skills for the occupational therapy assistant*, St. Louis, 1998, Mosby.

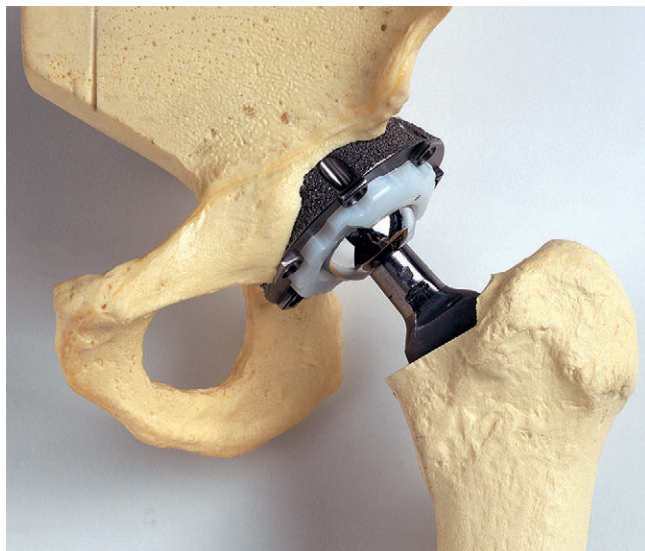

FIGURE 40-3 Hip prosthesis.

vary in terms of amount of pressure and length of time. A walking aid, usually a walker or crutches, is necessary for at least the first month while the hip is healing and muscles are becoming stronger. Clients with total joint replacements usually begin out-of-bed activity 1 to 3 days after surgery.¹²

Recently, orthopedic surgeons have used a minimally invasive technique to perform the posterolateral and anterior approaches for hip replacement. This technique reduces the amount of trauma to the tissues and allows for faster recovery. The traditional posterolateral surgical technique requires that a long (about 10 inches) incision be made and muscles detached to get to the hip joint. In the minimally invasive technique, two incisions of approximately 2 inches are needed and no detachment of muscles is required. Because no muscles are detached, the hip is more likely to remain in a stable position during the healing process. Similarly, for an anterior approach, a small vertical incision is made on the anterior surface of the hip joint with the hip placed in hyperextension. In addition to a faster recovery, this particular technique minimizes the risk of dislocation and postoperative limp.^{16,17} The minimally invasive techniques are not appropriate for all total hip replacements or arthroplasties. Persons with severe damage to the hip joint will require the traditional surgical method. Hip precautions that are identified for the posterolateral and anterolateral approaches are indicated for persons receiving a minimally invasive technique.¹⁹

To reinforce proper hip precautions and guide treatment intervention and discharge planning, the occupational therapist must know the type of surgical procedure that was performed. For example, someone with a hip replacement in which the minimally invasive technique was used may tolerate more activity after surgery than someone who underwent the traditional surgical technique.

FIGURE 40-4 Knee prosthesis.

(From Black J, Hawks J: *Medical surgical nursing: clinical management for positive outcomes*, ed 8, St. Louis, 2009, Elsevier.)

Total joint surface replacements (joint resurfacing), which are less commonly used, are a variation of the total hip replacement.¹⁵ The surface of the femur is capped by a metallic shell, and the acetabular cavity receives a plastic cup. Both are held in place by methylmethacrylate (acrylic cement). This technique preserves the femoral head and neck. With this technique, no weight-bearing restrictions apply.¹⁵

In Mrs. Hernandez's case, the orthopedic surgeon decided to perform the total hip replacement using the anterior approach, minimally invasive procedure because she was in relatively good health, physically fit, and the joint degeneration was not severe enough to require a traditional surgical procedure.

Knee Joint Replacement

Etiology and Medical Management

The reason for a total knee replacement is similar to that for the total hip replacement, except that the degenerative changes occur in the knee joint. Knee degeneration is often due to osteoarthritis or degenerative joint disease, trauma or injury to the knee, or other rheumatic conditions. Surgical knee replacement is designed to alleviate pain, increase motion, and maintain alignment and stability of the knee joint when conservative treatment has failed. The process involves cutting away the damaged bone (as little bone as possible) and attaching a prosthesis for the new joint.²² Various types of prostheses are used, depending on the severity and region of knee damage (Figures 40-4 and 40-5). Total knee replacement, or total knee arthroplasty (TKA), is indicated when two or more compartments of the knee

FIGURE 40-5 Total knee replacement. The metal aspects of the prosthesis cover the distal portion of the femur and the end of the tibia. There is a polyethylene plastic-bearing surface (plastic) between the metallic aspects of the two surfaces. The patella is replaced by a polyethylene button. The medial collateral ligament (MCL), lateral collateral ligament (LCL), and cruciate ligaments (CL) are retained.

(From Early MB: *Physical dysfunction: practical skills for the occupational therapy assistant*, St. Louis, 1998, Mosby; modified from Calliet R: *Knee pain and instability*, ed 3, Philadelphia, 1992, FA Davis.)

are damaged. A partial or unicompartmental knee arthroplasty (UKA) is indicated if there is medial or lateral compartmental damage between the femur and tibia. The UKA is often placed with a minimally invasive technique, which allows greater knee flexion (up to 90 degrees) more quickly after surgery.¹⁸ Because fewer ligaments are cut, increased stability is obtained immediately.¹⁴ In addition, various prosthetic devices are chosen based on the medical condition and activities performed by the client.¹¹ A fixed platform prosthesis allows only flexion and extension of the knee, but a rotating platform prosthesis allows the slight rotation normally available at the knee. The rotating platform is typically used for younger, more active people, or for women, as they typically have more rotation available at the knee than men.⁸

The prosthesis can be cemented to the bone with acrylic cement or not cemented. With a cemented prosthesis, clients are usually able to bear weight as tolerated on the operated leg. With a noncemented prosthesis, initial weight bearing is usually avoided. Clients may start out-of-bed activities 1 to 3 days after surgery, pending the physician's orders. Clients sometimes use a knee immobilizer (Figure 40-6) to support the knee when moving in and out of the bed and ambulating. The client should avoid rotation at the knee for up to 12 weeks after surgery. There is usually no restriction on bending the knee. In fact, maintaining the mobility of the knee is important to ensure adequate mobility during healing.^{3,12,17} Some clients describe postsurgical pain that is more significant following TKA as compared to a total hip replacement, but this can be managed with

FIGURE 40-6 A knee immobilizer is used to support and stabilize the knee joint during mobility.

(From Ignatavicius D, Workman ML: *Medical-surgical nursing: patient-centered collaborative care*, ed 6, St. Louis, 2010, Elsevier.)

medications, use of superficial cold modalities, and proper positioning during transitional movements.

Occupational therapists can reinforce the use of a knee immobilizer or encourage an appropriate amount of knee flexion during intervention sessions when the surgical technique that was used is clearly understood.

Special Considerations for Lower Extremity Joint Replacements

Individuals with joint changes that result in increasing pain may have multiple joint involvement (i.e., both knees or hips). Some clients opt to have both joints replaced during the same hospitalization, either during the same surgery or with procedures 3 to 7 days apart. This can complicate the rehabilitation process because the client will not be able to rely on the nonoperated leg when walking, moving from seated to standing positions, and performing daily occupations.

It is important to be aware of complications or special procedures that occurred during surgery and to inquire about additional precautions and risks. Common complications include dislocation, degeneration of parts, fracture of bone next to implanted parts, loosening of parts, and infection of the hip or knee joint after surgery. A special procedure for individuals at high risk for a hip dislocation after surgery involves using an abduction brace to immobilize the hip joint.⁵

Emphasis in rehabilitation is on maintaining or increasing joint motion, slowly increasing the strength of surrounding musculature, decreasing swelling, and increasing the client's independence and participation in areas of

occupation, particularly activities of daily living (ADLs). The occupational therapist's role in this process is primarily in educating the client who has undergone joint replacement or fixation of a fracture about adaptive techniques for ADLs and instrumental activities of daily living (IADLs) with limited mobility while maintaining any joint precautions for movement or weight bearing.

Psychological Factors

Psychological issues are critical in the overall intervention for the orthopedic client. Many clients in this population are faced with a chronic disability (e.g., rheumatoid arthritis), a life-threatening disease (e.g., cancer), or consequences of the aging process. The loss or potential loss of mobility and physical ability that limits participation in areas of occupation is a major concern for most of these clients. Adjusting to loss is stressful and requires an enormous amount of physical and emotional energy.¹⁰ An awareness of and a sensitivity toward the psychosocial challenges of the person with an orthopedic problem are critical for the delivery of optimal client care.

Clients with a chronic orthopedic disability often experience one or all of the following: disease of a body part, fear, anxiety, change in body image, decreased functional ability, joint deformity, and pain. Interventions for a client with a chronic orthopedic disability must address these issues and provide the support needed for the grieving process to take place. Without an opportunity to confront these issues, the client is likely to become depressed, filled with guilt and anxiety, and paralyzed with fear. These emotions inhibit the client's progress and further damage the client's self-image. Occupational therapists can help clients acknowledge and express some of these feelings, an experience that ultimately enhances the intervention process. One way to ease anxiety and fear is to make sure that the client understands the intervention and procedures he or she is receiving, as well as the likelihood of a positive prognosis. Taking time to answer questions and provide additional information can be crucial for successful adjustment.

The elderly client experiencing disability deals with additional issues specific to the aging process: fear of dependence and relocation trauma. With the onset of a disability late in life, the client may be forced to let go of independence and self-sufficiency.¹⁰ This can be a devastating experience for some clients, and prolonged grieving may be necessary before adjustment. Others may use dependence for secondary gain, remaining in the hospital for extra attention or manipulating their support systems to avoid taking responsibility for themselves and others. When individuals are removed from their familiar environment, confusion, disorientation, and emotional lability may result. Decorating the client's room with familiar items and using a calendar can help to reduce the traumatic effects of relocation.

Learning to cope and adjust to the changes resulting from chronic disability or the aging process is a critical

aspect of recovery. Practitioners must realize that the client has relinquished a great deal of functional independence as a result of disease or disability. The occupational therapist must address the psychosocial issues resulting from this loss while focusing on maximizing the client's ability to participate in areas of occupation that are meaningful.¹⁰

Mrs. Hernandez may experience all or many of the aforementioned feelings and issues. The occupational therapist must provide her with educational resources and opportunities to ask questions regarding her problems and recovery. Mrs. Hernandez may be unaware of the adaptive aids available that would improve her performance skills. Access to these resources may provide the impetus for a more positive perspective on aging and remaining active and independent. It is important for the occupational therapist to help Mrs. Hernandez develop strategies and coping skills to deal with the psychosocial aspects of having hip surgery. Individual or group intervention should provide Mrs. Hernandez with the opportunity to share her feelings and explore ways to resume her occupational routines; these might include interacting with her grandchildren, swimming, and participating in church activities. The occupational therapist can assist Mrs. Hernandez in finding a more accessible pool (e.g., one with ramp access) for swimming and alternative temporary transportation to get to church so that she need not rely on her friends and family.

An important area of ADL that is often overlooked is sexual activity. Persons with a hip fracture or LE joint replacement will have difficulty performing sexual activities in their usual manner (see Chapter 12). It is recommended that such persons refrain from sexual activity for 6 weeks so that they maintain the movement precautions applicable to their condition.¹² Clients of all ages and both genders may have questions regarding the level of sexual activity that is allowed. The occupational therapist must create an environment in which the client feels comfortable enough to ask personal questions. The therapist can do this by being open-minded and realizing that sexual activity is important and meaningful. The therapist may need to suggest ways for the client to position the operated leg during sexual activity to maintain precautions. Side-lying on the nonoperated side is one option. Abduction precautions can be maintained via pillows between the knees. To prevent excessive external rotation at the hips while in the supine position, the client can place pillows under the knees. Clients with knee replacements or weight-bearing precautions should refrain from kneeling.¹² Written information with diagrams can be helpful when addressing such a personal issue. The client can read this information privately or with his or her partner.

Rehabilitation

Good communication and clear role delineation among members of the healthcare team are essential for an effective and efficient therapy program. The healthcare team usually

consists of a primary physician, nursing staff, an occupational therapist or assistant, a physical therapist or assistant, a dietician, a pharmacist, and a social worker or case coordinator. Many facilities have a protocol or critical pathway that outlines each team member's responsibilities and a time frame for accomplishing assigned tasks related to the client's rehabilitation. Regular team meetings, to discuss each client's ongoing progress, and discharge plans are necessary for coordinating individual intervention programs. Members from each service usually attend each meeting to provide information and consultation.

The role of the physician is to inform the team of the client's medical status. This includes information regarding previous medical history, diagnosis of the present problem, and a complete account of the surgical procedure performed. Information provided may include the type of appliance inserted, the anatomic approach, and any movement or weight-bearing precautions that could endanger the client. The physician is also responsible for ordering specific medications and therapies and directing pain-management approaches. The physician should approve any change or progression in therapy or change in the client's medication regimen.

The nursing staff is responsible for the physical care of the client during hospitalization, including care and monitoring of the surgical incision. The orthopedic nurse must have a thorough understanding of the surgical procedures and movement precautions for each client. Proper positioning using pillows and wedges is carried out by the nurse, especially in the first few days after surgery. As the client's therapy program progresses, the client starts to take more responsibility for proper positioning and physical care. The nurse works closely with the occupational and physical therapists to carry through self-care and mobility skills that the client has already learned in therapy.

The physical therapist is responsible for evaluation and intervention in the areas of musculoskeletal status, lower extremity sensation, pain, skin integrity, and mobility (especially gait). In many cases involving total joint replacement and surgical repair of hip fracture, physical therapy is initiated on the first day after surgery. Adhering to the prescribed precautions of the protocol, the physical therapist obtains baseline information, including range of motion (ROM), strength of all extremities, muscle tone, and mobility. A treatment program that includes therapeutic exercises, ROM activities, transfer training, and progressive gait activities is established. The physical therapist is responsible for recommending the appropriate assistive device to be used during ambulation. As the client's ambulation status advances, instruction in stair climbing, managing curbs, and outside ambulation is given.¹²

The dietician consults with each client to ensure that adequate and appropriate nutrition is received to aid the healing process. The pharmacist monitors the client's drug therapy and provides information and assistance with pain management.

The role of the case coordinator is to ensure that each client is being discharged to the appropriate living situation or facility and often to ensure the availability of durable medical equipment recommended by physical and occupational therapy staff. The case coordinator is usually a registered nurse or social worker with a thorough knowledge of available community resources and nursing care facilities. However, occupational therapists have served in the position of case coordinator. Occupational therapists typically have access to community resources for equipment and living accommodations because those are areas that are addressed in the occupational therapy intervention plan. With input from the healthcare team, the case coordinator makes the arrangements for ongoing therapy after acute hospitalization, for admission to a rehabilitation facility or skilled nursing facility for further intensive therapy if needed, or for home healthcare as appropriate. The case coordinator works closely with the healthcare team and is instrumental in coordinating the discharge plans of the interdisciplinary team.

Role of Occupational Therapy

After a lower extremity joint replacement or surgical repair of a fractured hip, OT typically begins when the client is ready to start getting out of bed, usually 1 to 3 days after surgery. The actual time varies, depending on the age and general health of the client and on surgical events or medical complications involved. Before any physical assessment, it is important to introduce and explain the role of OT and complete an occupational profile. This profile involves gathering information regarding the client's occupational history, prior functional status in ADLs and IADLs, descriptions of performance contexts (e.g., home environment and social support available), and the client's goals. The goal of OT is for the client to maximize performance skills in daily occupations, with all movement precautions observed during activities. The role of the occupational therapist and assistant is to teach the client ways and means of performing daily occupations safely.¹⁰

Evaluation and Intervention

The role of the occupational therapist and occupational therapy assistant can be clearly defined with cases of lower extremity joint replacement and hip fractures. The occupational therapist is responsible for performing any necessary assessments. In addition to an occupational profile, an assessment of the psychosocial issues related to the surgery and the surgery's impact on the client's lifestyle is completed via interview. A baseline physical evaluation is necessary for determining whether any physical limitations not related to surgery might prevent functional independence. Performance skills and client factors such as upper extremity (UE) ROM, muscle strength, sensation, and coordination and status of cognitive skills are assessed before a functional evaluation is made. Evaluation of basic activities of daily

living, instrumental activities of daily living, and functional mobility is necessary for clinical reasoning and holistic intervention planning. During evaluation it is also important to observe and document any signs of pain and fear at rest or during movement.

OT involves an intervention program of functional activities that gradually enables a person to regain abilities and skills to facilitate greater participation in identified areas of meaningful occupation. The therapist introduces and trains clients in the use of assistive devices, proper transfer techniques, and ADL and IADL techniques while maintaining hip and weight-bearing precautions. Specific training techniques are discussed later in the chapter. An OT assistant may play a large role in this training. Both the occupational therapist and the OT assistant are involved in treatment planning, documentation, and discharge planning (including the recommendation of equipment and home exercise programs).

Client Education

Although hip fractures are never a planned occurrence, lower extremity joint replacements are usually planned and scheduled to be performed on a specific date. Occupational therapists often provide education classes for individuals at risk for fractures and those planning joint replacement. For the person who may be at risk for falling, attending a class on fall prevention is a wise recommendation. Topics may include home modifications (e.g., removal of throw rugs, telephone cords, and clutter), safe transfer techniques, use of public transportation, and community mobility tips. The person who is having an elective total joint replacement may benefit from a class offered before surgery that explains the surgical procedures and precautions, introduces assistive devices, describes the therapy process, and describes the typical recovery period.

Specific Training Techniques

Some common assistive devices are useful for many people with hip fractures or joint replacements (Figure 40-7). Helpful assistive devices or adaptive aids include a dressing stick, sock aid, long-handled sponge, long-handled shoe-horn, reacher, elastic shoelaces, leg lifter, elevated toilet or commode seat, three-in-one commode, and shower chair or bench. Walker bags are helpful for people using walkers who need to carry small items from one place to another. The OT clinic should have samples of these devices that are available for client use during the intervention process.

Training Procedures for Persons with Hip Surgery

The training procedures outlined in the following sections apply to hip fractures and the different types of hip joint replacement unless otherwise noted. The positions of hip instability for the specific types of surgical procedures for hip replacement are important to remember. For the posterolateral approach (traditional or minimally invasive),

FIGURE 40-7 Assistive devices for ADLs. From top to bottom: reacher, sock aid, long-handled sponge, dressing stick, long-handled shoe horn, and leg lifter.

positions of instability include adduction, internal rotation, and flexion greater than 90 degrees precautions. For the anterolateral approach (traditional or minimally invasive), positions of instability include adduction, external rotation, and excessive hyperextension.

Bed Mobility

The supine position with an abduction wedge or pillow in place is recommended in bed. If a client sleeps in the side-lying position, sleeping on the operated side is recommended if tolerable. When sleeping on the nonoperated side, the client must keep the legs abducted with the abduction wedge or larger pillows supporting the operated leg to prevent hip adduction and rotation. The client is instructed in getting out of bed on both sides, although initially it may be easier to observe precautions by moving toward the non-operated leg. Careful instruction is given to avoid adduction past midline. It is important to determine the type and height of the client's bed at home. When getting in and out of bed initially, the client may use a leg lifter to help the operated leg move from one surface to another. Some clients have an overhead trapeze bar placed on the bed to assist with bed mobility. It is important to wean the client away from using this device because he or she will most likely not have one at home.

The best procedure for moving from the supine position to sitting on the edge of the bed is to have clients support the upper body by propping up on their elbows, then moving the lower extremities toward the side of the bed in small increments, and following with the trunk and upper extremities. The client should gradually turn in this manner until he or she can lower the legs out of the bed and push the trunk into the sitting position. Extending the hip and knee of the operated leg assists in maintaining hip precautions.

Transfers

It is always helpful for the client to observe the proper technique for transfers before attempting the movement.

OT Practice Notes

One way to help therapists understand the impact of maintaining the proper hip position during the healing process is for the therapist to tape a goniometer to his or her own hip when positioned at 90 degrees and attempt to do the transfers listed below. Therapists will soon discover the difficulty of maintaining the proper hip position during functional activities!

Chair

A firmly based chair with armrests is recommended. To move from standing to sitting, the client is instructed to back up to the chair, extend the operated leg forward, reach back for the armrests, and slowly lower to the sitting position. For the person with a posterolateral approach, care should be taken not to lean forward when sitting down (Figure 40-8). To stand, the client extends the operated leg and pushes up from the armrests. Once standing, the client can reach for an ambulatory aid, such as a walker if it is being used. Because of the hip flexion precaution for the posterolateral approach, the client should sit on the front part of the chair and lean back (see Figure 40-8, C). Firm cushions or blankets may be used to increase the height of chair seats and may be especially helpful if the client is tall. Low chairs, soft chairs, reclining chairs, and rocking chairs should be avoided.¹

Commode Chair

Three-in-one commode chairs with armrests can be used in the hospital and at home. For the person with a posterolateral approach, the height and angle can be adjusted so that the front legs are one notch lower than the back legs; thus, with the client seated, the precautionary hip angle of flexion is not exceeded. A person with an anterolateral approach may have enough hip mobility to use a standard toilet seat safely at the time of discharge. All clients should wipe between the legs in a sitting position or from behind in a standing position and use caution to avoid forward flexion of the hip greater than 90 degrees, or rotation of the hip. The client is to stand up and step to turn to face the toilet when flushing so as to avoid hip rotation.¹

Shower Stall

Nonskid strips or stickers are recommended in all shower stalls and tubs. When the client is entering the shower stall, the walker or crutches go first, then the operated leg, and then the nonoperated leg. A shower chair with adjustable

legs or a stool and grab bars are strongly encouraged to be installed to prevent losing balance and to maintain weight-bearing precautions. An alternate method to enter the shower stall is to back up to the edge or rim of the shower while using the walker for balance, then stepping into the shower while looking down at the feet and shower rim for safety.

Tub Shower (Without Shower Doors)

The client is prohibited from taking a bath sitting on the floor of the tub. This action puts the client at severe risk of causing damage to the impaired joint as well as other types of injuries. In addition, a tub chair or tub transfer bench is strongly recommended to preserve hip precautions. The client is instructed to back up to the tub chair or bench using the walker or crutches for support. Then the client should reach for the backrest, extend the operated leg, and slowly lower to a seated position. The legs can then be lifted into the tub as the client leans back, using a leg lifter or bath towel if needed to support the operated leg. A handheld shower is helpful in directing the water for an effective and comfortable bath. Sponge bathing at the sink is an alternative activity,¹ although use of a long-handled sponge or reacher is recommended to avoid hip flexion when bathing the lower extremities.

Car

Bucket seats in small cars should be avoided. Bench-type seats are recommended. The client is instructed to have a helper move the front passenger seat back as far as it will go and recline the back support in order to observe the hip flexion precaution. Then the client is instructed to back up to the seat, hold onto a stable part of the car, extend the operated leg, and slowly sit in the car. Remembering to lean back, the client then slides the buttocks toward the driver's seat. The upper body and LEs move as one unit to turn to face the forward direction. Firm pillows in the seat may be necessary to increase the height of the seat. Prolonged sitting in the car should be avoided. If transferring to the front passenger seat is a problem, transferring to the back seat of a four-door car is an alternative. The client backs to the seat, extends the operated leg, and slowly sits in the car. Then he or she slides back so that the operated leg is resting on the seat fully supported. Clients should not return to driving until given permission by their surgeon, even if the operated leg is not the leg used for operating the controls.

Lower-Body Dressing

The client is instructed to sit in a chair with arms or on the edge of the bed for dressing activities. The client is instructed to avoid hip flexion, adduction and rotation, or crossing the legs to dress. The client must refrain from crossing the operated extremity over the nonoperated extremity at either the ankles or the knees. Assistive devices may be necessary for observing precautions (see Figure 40-7). To maintain hip precautions, the client uses a reacher or dressing stick to put

FIGURE 40-8 Chair transfer technique. **A**, Client extends operated leg and reaches for armrests. **B** and **C**, Bearing some weight on arms, the client sits down slowly, maintaining some extension of the operated leg.

on and remove pants and shoes. For pants and underwear, the operated leg is dressed first by using the reacher or dressing stick to bring the pants over the foot and up to the knee. A sock aid is used to don socks or knee-high nylons, and a reacher or dressing stick is used to doff them. A reacher, elastic laces, and a long-handled shoehorn can also be

provided.¹ It is also prudent for the occupational therapist or occupational therapy assistant to discuss clothing choices with the client for ease of dressing. Slip-on shoes with a nonslip sole, for example, may be easier to put on with appropriate adaptive equipment than sneakers with elastic laces.

Lower-Body Bathing

The section on transfers describes the proper method of getting in and out of the shower or tub. Sponge bathing at the sink is indicated until the physician designates that it is safe for the client to shower, which is typically 7 to 10 days postsurgery, after the margins of the incision are healed. A long-handled bath sponge or back brush is used to reach the lower legs and feet safely. Soap-on-a-rope is used to prevent the soap from dropping, and a towel is wrapped on a reacher to dry the lower legs.¹ Once showering is approved, a handheld shower head is recommended to direct the water and provide a more comfortable shower.

Hair Shampoo

Until able to shower, the client is instructed to obtain assistance for shampooing hair. The client can have a helper wash the hair while the client is supine, using pillows for back support and a bucket or bowl to catch the water poured from a pitcher to rinse the hair. Another method involves having the client sit in a chair with the back to the sink. The client leans backward to position the head over the sink while the helper washes the hair. The client can also visit a hair salon until he or she is able to perform hair washing independently. If unable to obtain any assistance, the client may shampoo the hair while standing at the kitchen sink with a handheld sprayer, observing hip precautions at all times. Because bending forward at the kitchen sink can be performed with less than 90 degrees of hip flexion, most clients can observe the proper hip precautions using this method.

Homemaking

The client should initially refrain from heavy housework, such as vacuuming, lifting, and bed making. Kitchen activities can be initiated in therapy, with suggestions made to keep commonly used items at countertop level or within easy reach. The client can carry items by using an apron with large pockets, sliding items along the countertop, using a utility cart, attaching a small basket or bag to a walker, or wearing a fanny pack around the waist. Reachers are provided to grasp items in low cupboards or retrieve items from the floor. Items in the refrigerator should be kept on the higher shelves, with only light items that can be obtained with the reacher on lower shelves. For cooking activities, it is recommended that the client use the stovetop or microwave oven rather than placing items in the stove, as it is difficult to maintain hip precautions when reaching in or out of the oven. Washing dishes should be done at the sink or using the top level only of an automatic dishwasher. The occupational therapy practitioner should also instruct the client in relevant energy conservation techniques for instrumental activities of daily living.

Caregiver Training

A family member, friend, or caregiver should be present for OT intervention sessions so that any questions may be answered. Appropriate supervision recommendations and instruction regarding activity precautions are given at this time. So that they fully understand the impact of following the hip precautions, caregivers should be encouraged to practice doing the adapted activities as well. Instructional booklets on hip fractures and total hip and knee surgery may be purchased from the American Occupational Therapy Association to supplement training.¹

Training Procedures for Persons with Total Knee Replacement

Procedures for ADL and IADL training for persons with total knee replacement are similar to those described for someone with a hip replacement. However, hip flexion and adduction are allowed, and knee flexion is encouraged. Positions of knee instability include internal and external rotation at the hip and knee flexion greater than comfortable ROM permits.

Bed Mobility

The supine position is recommended when the client is in bed, with the entire leg slightly elevated via balanced suspension (the weight of the elevated leg is balanced by weights on the opposite end of the pulley system used to support the leg) or pillows, with or without a knee immobilizer. This will help to reduce edema and prevent knee flexion contractures. It is recommended that a person not sleep on the operated side. As in hip replacement, a pillow or wedge can be placed between the legs if this is necessary for side-lying and if the person lies on the nonoperated side. A continuous passive motion (CPM) machine may be used for several hours a day following surgery to facilitate recovery and increased range of motion,⁹ and the client must use this in a supine position. However, use of the CPM machine is often discontinued prior to returning home, when more normal activities are resumed. To enter or exit the bed, clients can move freely and specific techniques can be identified according to client preferences. There are no restrictions that dictate bed mobility procedures.

Transfers

In general, the client can bend at the hip as much as he or she is able. Because of decreased knee flexion, the client may need to use the same techniques for commode and car transfers as have been described for hip replacements. Use of grab bars or a shower chair or bench is recommended, especially for transferring to the tub shower, as well as for the individual with decreased standing endurance or an inability to bend the knee enough to sit on the floor of the tub.² As an alternative to use of a tub chair or bench, the client may stand beside the tub, in a parallel position facing one of the short walls of the tub. By leaning with the upper

extremities on the short wall, clients can extend the hip behind them to side-step into the tub. This method decreases the amount of knee flexion required for this transfer.

Lower Extremity Dressing and Bathing

The dressing of lower extremities presents a problem only if the client is unable to reach his or her toes, which is usually done by leaning forward at the hips or raising the feet on a footstool. If necessary, techniques described for the hip replacement can be used. The client should practice donning and doffing the knee immobilizer. The client should be cautioned to prevent torque or rotation at the knee joint when dressing by not twisting the body or leg while bearing weight on the operated leg. Clients can take a sponge bath in the initial stages of recovery and typically are not approved to shower until the margins of the incision have healed.²

Homemaking and Caregiver Training

Homemaking and caregiver training is the same as that for hip replacement. Energy conservation remains important, although hip movement is not restricted. Care should be taken when standing for extended periods of time to avoid prolonged static positioning of the knee, as a pain management technique.

General Considerations and Evidence for Occupational Therapy Intervention

In addition to the ADL and IADL strategies previously specified, the occupational therapist should be sure to address all areas of occupation that may be difficult for the client as well as those that may pose a safety risk. Occupations such as care of a pet, navigating through a cafeteria for meals, traveling in vehicles other than cars, and attending religious activities or other community activities that require specific transfers (i.e., to a church pew) are all examples of activities that may be part of a client's typical performance pattern and should be addressed by OT. The occupational therapist can assist the client in approaching meaningful occupations safely, observing any movement precautions that are required and suggesting and demonstrating alternative methods and assistive devices.

A limited number of studies have examined OT intervention for LE joint replacements and hip fractures. According to a small Swedish study of clients who had incurred hip fractures, clients reported a significant decline in their ability to perform hobbies and social activities that they had participated in before their hip fracture. The clients cited these activities as more important than self-care activities.

Occupational therapists were able to address these occupations in their interventions²¹ (see Chapter 16). Another study supports the hypothesis that hip fractures affected social interaction over other areas of occupation.⁶ By designing an intervention that targets the client's prior performance patterns and psychosocial needs, the occupational therapist can play a key role in contributing to the client's

psychosocial adjustment to physical limitations and maximizing the client's return to participation in meaningful activities.

For Mrs. Hernandez, in addition to ADL and IADL training, OT intervention will include car transfers, ways to sit safely in a church pew, and methods for engaging in activities with her grandchildren without damaging her newly replaced hip. The occupational therapist will also discuss community mobility and recommend that Mrs. Hernandez obtain clearance from her surgeon before returning to driving. Before attempting car transfers, the OT will train Mrs. Hernandez on basic transfers first (e.g., bed, shower/tub) and be sure that she understands and can follow her hip precautions. Because Mrs. Hernandez's daughter lives nearby and is very involved in her mother's life, she should be provided with caregiver training so that she can help reinforce safe mobility and hip precautions.

Special Equipment

The OT practitioner should be familiar with the following equipment that is commonly used in the treatment of hip fracture and total hip replacement:

Hemovac. During surgery, a plastic drainage tube is inserted at the surgical site to assist with postoperative drainage of blood. It has an area for collection of drainage and may be connected to a portable suction machine. The unit should not be disconnected for any activity because this may create a blockage in the system. The Hemovac is usually left in place for 2 days after surgery.

Abduction wedge. Large and small triangular foam wedges (Figure 40-9) are used when the client is supine to maintain the LEs in the abducted position.

Balanced suspension. This is fabricated and set up by an orthopedic technician and can be used for about 3 days after surgery. It balances the weight of the

FIGURE 40-9 Abduction wedge.

elevated leg by weights placed at the opposite end of the pulley system. Its purpose is to support the affected LE in the first few postoperative days. The client's leg can be taken out of the device for exercise only.¹⁷

Reclining wheelchair. A wheelchair with an adjustable backrest that allows a reclining position is used for clients who have hip flexion precautions while sitting.

Commode chairs. The use of a commode chair instead of the regular toilet aids in safe transfers and allows the client to observe necessary hip flexion precautions.

Sequential compression devices (SCDs). SCDs are used postoperatively to reduce the risk of deep vein thrombosis. They are inflatable, external leggings that provide intermittent pneumatic compression of the legs.⁵

Antiembolus hose. These are thigh-high hosiery that are worn 24 hours a day and removed only during bathing. Their purpose is to assist circulation, prevent edema, and thus reduce the risk of deep-vein thrombosis.⁵

Client-controlled administration IV. Patient-controlled analgesia (PCA) is delivered through an IV; patient-controlled epidural analgesia (PCEA) is delivered

through an epidural line). A prescribed amount of medication is programmed by the physician and nursing staff to allow the client to self-administer pain medication by pushing a button to inject a safe amount. When dosages have reached a limit, the machine will not administer medication even if the button is pushed.

Incentive spirometer. This portable breathing apparatus is used to encourage deep breathing and prevent the development of postoperative pneumonia.

Continuous passive motion (CPM) machine. This mechanical device supports a joint and can be set to move slowly through a designated range of motion to promote controlled movement in the operated joint.

Summary

Hip fractures and LE joint replacement are orthopedic conditions in which OT intervention may speed the client's return to optimal participation in daily activities safely and comfortably. OT evaluation and intervention begins with obtaining the client's occupational profile and an assessment of the psychosocial issues related to the surgery and the surgery's potential impact on the client's lifestyle. Awareness of and a sensitivity to the psychosocial challenges of the

Threaded Case Study | Mrs. Hernandez, Part 2

After reading the chapter, the occupational therapist can plan an effective intervention. Mrs. Hernandez's occupational profile revealed that she has many roles that she finds meaningful: grandmother, church member, and swimmer. She also seems to value being independent: She not only does things with her daughter and her family but also has interests and activities in which she participates on her own. Supporting contextual factors include an accessible home, a daughter nearby who involves her in many activities with her children, church friends who can offer some assistance, and strong spiritual beliefs that can help her through recovery from surgery. Nonsupportive contextual factors include an inaccessible swimming pool and the fact that she lives alone. Additional information that would be useful to obtain from Mrs. Hernandez for the occupational profile includes but is not limited to specific information about the arrangement of furniture and other items in her home, how willing is her daughter to assist her with her needs, prior surgeries or conditions that would impact the current plan of care, and equipment or home modifications already established. This will aid the OT in planning for discharge and specific equipment recommendations.

Client factors that must be assessed before training Mrs. Hernandez to perform her daily activities safely, including driving, are strength, ROM, sensation, cognition, coordination, and pain. These factors will impact the extent to which she will be able to engage in and learn the prerequisite performance skills needed to optimize her independence in ADL and IADL.

The OT must first be sure that Mrs. Hernandez understands the hip precautions and is able to recall them. Then the OT must address her ability to move herself in and out of bed and perform toileting functions while observing the hip precautions. These prerequisite skills will prepare her for more advanced skills like dressing, bathing, driving, and home management activities. Because she lives alone, she needs to be able to complete all of her ADLs and IADLs independently. The therapist should be sure to address the prerequisite skills first and progress Mrs. Hernandez to more complex ADL tasks that increase her confidence to return home and resume her typical occupations and performance patterns.

Because driving allows Mrs. Hernandez to get to her swimming classes, church meetings, and her daughter's home, this is placed as first in the list of problems, and she verbalizes that this issue is most important. Mrs. Hernandez should have demonstrated relative independence in different types of transfers, especially car transfers, before she considers driving again. It is important that she obtain medical clearance from her physician or surgeon before resuming driving activities. The OT can assist her in identifying other community mobility resources available to her until her return to driving.

By using the ADL and IADL strategies presented in the chapter and reinforcing healthful behaviors such as joint protection, Mrs. Hernandez can return to optimal participation in occupations that she finds meaningful.

person with an orthopedic problem are critical for the delivery of optimal occupational therapy.

The protocol for other areas of OT intervention is determined by the surgical procedure performed and by the precautions prescribed by the physician. Clients who have weight-bearing precautions must be trained to observe these during all ADL and IADL routines. A simulation of the home environment or a home assessment is helpful in preparing the client for potential problems that may arise after discharge. Areas to assess include the entry, stairs, bathroom, bedroom, sitting surfaces, and kitchen. Recommendations to remove throw rugs and slippery floor coverings and obstacles are made because the client will most likely be going home using an assistive device for ambulation. A kitchen stool or utility cart may be indicated. It is important to assess and instruct the client and caregiver regarding ADLs and IADLs with adaptive equipment, as well as any movement precautions. Home therapy may be indicated after a hospital stay to ensure safety and independence in daily occupations if these goals were not met during hospitalization.

Preoperative teaching programs are invaluable in aiding client adjustment. The class familiarizes the client with the hospital, nursing, physical therapy, OT, and discharge planning. Procedures and equipment, concerns regarding hospitalization, discharge, and therapy are addressed. Participation in this type of class has been shown to relieve anxiety and fear, empower the client during the hospitalization, and decrease the hospital length of stay.

Review Questions

1. Explain the difference in precautions for the anterolateral and posterolateral approaches for a hip replacement.
2. When a client is transferring from one surface to another, what is the general procedure to follow to ensure the safety and protection of the involved side?
3. List the most common types of adaptive equipment used during rehabilitation of hip fractures and LE joint replacements, and describe their purpose.
4. Describe how the case coordinator and occupational therapist can work together to ensure a safe discharge for the client.
5. List two specific suggestions for performing sexual activities for someone with a hip replacement.
6. What information should be obtained when completing the occupational profile?
7. Identify two factors that affect fracture healing.
8. Identify two ways an occupational therapist can address the psychosocial adjustment to LE joint replacement and hip fracture.
9. Why are weight-bearing precautions observed with an ORIF?
10. Compare rehabilitation techniques between clients with a hip replacement and clients with a knee replacement.
11. What are the benefits of conducting client education preoperative classes for persons who are at risk for falls or who are planning a joint replacement?
12. How might a person's rehabilitation program be affected by bilateral joint replacements?

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Define neutral spine.
2. Demonstrate how a neutral spine is integrated into a variety of activities of daily living and instrumental activities of daily living.
3. Demonstrate use of the "golfer's lift" in performing an activity of daily living.
4. Identify the basic concepts of body mechanics.
5. Demonstrate the relationship between anatomy and body mechanics.
6. Articulate normal back anatomy in terms that a client can comprehend.
7. Identify the occupational therapist's role in evaluation and intervention.
8. Recognize the psychosocial effect of low back pain.

Threaded Case Study

Pilar, Part 1

Pilar is 45 years old and a homemaker and lives with her husband and four children aged 4, 6, 10, and 14 years. She complains of lower back pain primarily on her right side, with the pain increasing as she does housework and cooks. Pilar was referred to occupational therapy for reduction of her pain during activities. During her occupational profile, pain is noted during activities requiring bending, such as removing clothing from the washing machine and dryer, cleaning the bathtub, making the bed, and taking items from the oven. As a result, she often asks her husband and children to help at home. She avoids preparing any meals that require baking and no longer makes cookies or brownies for her children. She is very concerned that she is not being a good mother or wife because it is difficult to cook and care for her family. In the morning she has increased pain in the lower part of her back.

Initial analysis of her occupational performance in a kitchen setting indicates that she bends at the waist repeatedly while retrieving items from the refrigerator, lower cabinets, and dishwasher. While performing these occupations, she reports an increase in pain from 2 to 7 on a scale of 10. Activities that require reaching, such as reaching into the washer and dryer, resulted in reports of increased pain. It was also noted that she was bending at the waist when she reached into the dryer. When her self-care activities were assessed, it was found that she had pain while donning socks, shoes, and pants. In addition, she experiences pain while washing her face and brushing her teeth. While performing all of the self-care activities for which she reported pain, she demonstrated bending at the waist. She habitually sleeps on her right side in a fetal position, with her left leg rotating over her right. At bedtime her pain is 5 of 10 and on occasion increases to 7 of 10 when she awakens.

Pilar's occupational therapy intervention plan will focus on client education. Education will include incorporation of information obtained from physical therapy with respect to pelvic positioning during activities and using that information in daily activities. Education will also involve demonstration of daily activities incorporating various movement techniques, positioning, and body mechanics to decrease her lower back pain. All of Pilar's newly learned back safety strategies must become habitual so that she can transfer them into future occupations.

Critical Thinking Questions

1. How is back anatomy and physiology related to Pilar's motor performance?
2. Can the evaluator identify movement patterns that result in pain during performance of daily occupations?
3. How can Pilar's movements be modified through interventions for pain-free occupations?

Low back pain (LBP) is a complaint that often causes the individual to seek help from the medical system. Four of five adults will experience significant LBP sometime during their lives. After the common cold, LBP is the most frequent cause of lost workdays in adults younger than 45 years. Most cases of LBP are not serious and respond to simple treatments such as rest or anti-inflammatory drugs. Common causes of LBP include poor conditioning, improper use of the back, obesity, smoking, age, and simple wear and tear over time. Osteoporosis, arthritis, fractures of the spine, and protruding disks are the most common causes of structural problems in the low back region. Before consulting a physician or occupational therapist, patients often seek help from chiropractors, massage therapists, acupuncturists, and proponents of the latest fads (e.g., magnets) to reduce the pain.

Spinal Anatomy

The occupational therapist must understand both normal anatomy and the pathology underlying numerous back problems. To educate the patient regarding the rationale for proper body mechanics, the occupational therapist must also understand how the anatomy and pathology are related to movement and daily occupations. Furthermore, the occupational therapist must be able to convey this information in a way that is accessible to clients with varying degrees of knowledge about anatomy and back pathology.

Vertebral Column

The structures that compose the vertebral column are the vertebrae and intervertebral disks. Each vertebra contains the vertebral body, which is the weight-bearing component, and the vertebral arch, which arises from the back of the vertebral body (Figure 41-1). The vertebral arch is composed of two pedicles (one on each side) that extend into the lamina. The laminae join together to form the vertebral foramina, which make up the vertebral canal in which the spinal cord resides. From the pedicle and joining of laminae are three bony projections called processes. These lateral processes join to form joints with adjacent vertebrae superiorly and inferiorly (Figure 41-2). Between the joint of these adjacent vertebrae is the intervertebral foramen, from which the spinal nerves enter and exit. At the back of the spinal arch is the spinous process, where muscles attach. The low back region is composed of five lumbar vertebrae.

Between the vertebrae are intervertebral disks. The intervertebral disks are composed of fibrocartilage and a central mass of pulpy tissue, the nucleus pulposus (Figure 41-3).

Under pressure, the disk bulges. The disks work as shock absorbers and are relieved of pressure only when the body is supine. Being the nonrigid part of the column, they provide flexibility for movement. When a person is standing with a neutral spine, the disk is under uniform pressure. Movements such as bending, twisting, and reaching result in extension of the spine, and pressure on the disk may

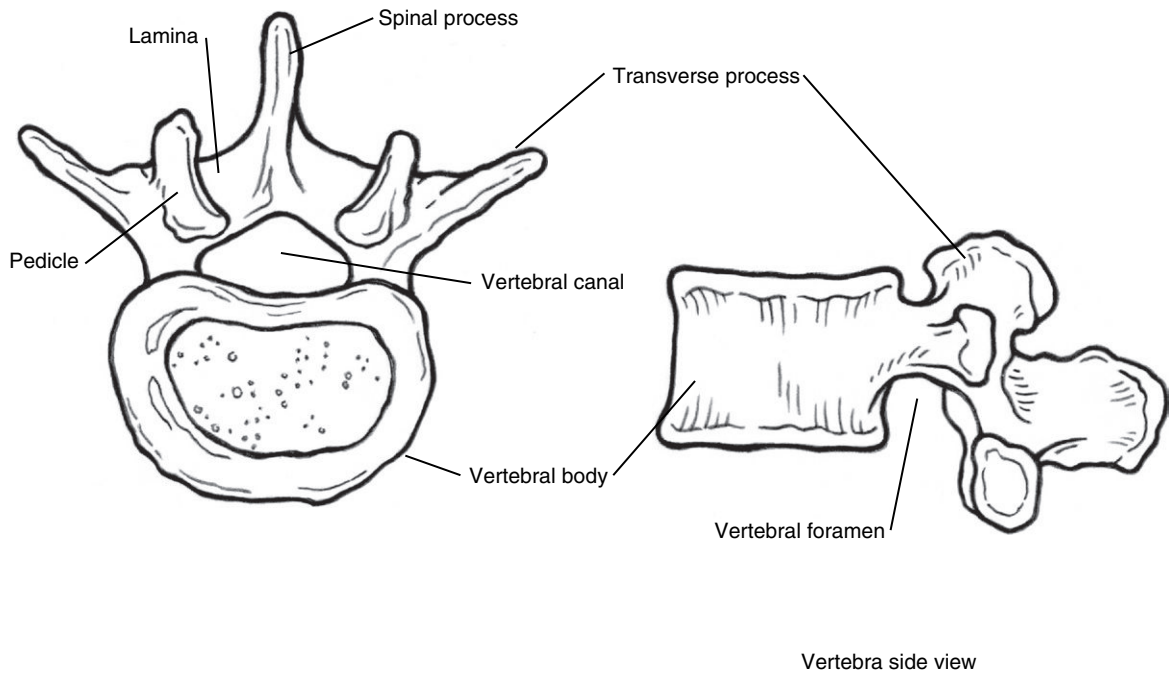

FIGURE 41-1 Vertebra from above and side view.

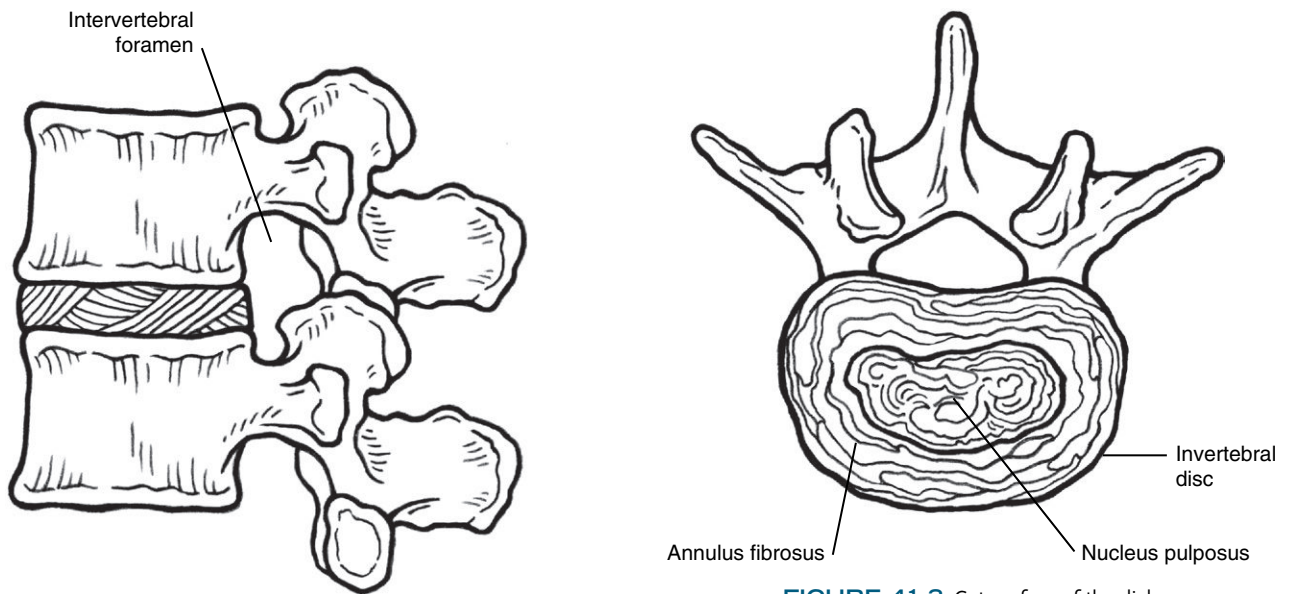

FIGURE 41-2 Two vertebrae in articulation. The spinal nerve exits via the intervertebral foramen.

FIGURE 41-3 Cut surface of the disk.

increase in one part of the back, whereas in another part of the back it may be under stretch (Figure 41-4).

Anterior and posterior longitudinal ligaments extend the length of the vertebral column and are attached to the vertebral bodies and intervertebral disks. These ligaments check excessive movement of the column. The sacrum is the lower fused portion of the vertebral column and is attached to the pelvis. Movement of the pelvis changes the lordosis, or curve of the lower part of the spine.

Muscles of the lumbar spine include the intertransversarii and interspinalis, which are small intersegmental muscles that connect the transverse process to the spinous process of adjacent vertebrae. The lumbar multifidus, lumbar longissimus, and iliocostalis make up the lumbar muscles. These muscles are primarily extensors for the spine, but the lumbar longissimus and iliocostalis can also assist in lateral flexion. In addition, muscles of the abdominal wall contribute to stabilization of the spine, including the transversus

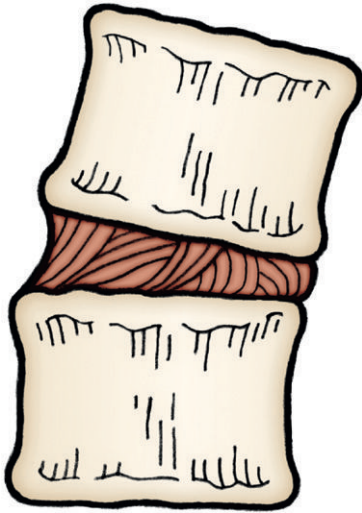

FIGURE 41-4 The same disk may be under compression and extension at the same time.

abdominis and obliquus internus abdominis, by providing a corseting effect. For further information on interaction of the back and abdominal muscles during specific movements, the reader is advised to do additional reading in this area.

Incidence of Low Back Pain

LBP resolves within 6 weeks in 90% of clients. It resolves in 12 weeks in another 5%.¹ “Less than 1% of back pain is due to ‘serious’ spinal disease (e.g., tumor, infection). Less than 1% of back pain stems from inflammatory disease, and less than 5% is true nerve root pain.”¹ Typically, back pain is a result of poor physical fitness, obesity, reduced muscle strength and endurance, or use of poor body mechanics. Actual changes in the structure or mechanics of the lower part of the back may result in problems, including the following:

- Sciatic (nerve root) pain. The nerve is entrapped by a herniated disk.
- Spinal stenosis. Narrowing of the intervertebral foramen decreases the space where the spinal nerve exits or enters the spine.
- Facet joint pain. Inflammation or changes in the spinal joints cause facet joint pain.
- Spondylosis. This is a stress fracture of the dorsal to the transverse process.
- Spondylolisthesis. One vertebra slips on another.
- Herniated nucleus pulposus. Stress may tear fibers of the disk and result in an outward bulge of the enclosed nucleus pulposus. This bulge may press on spinal nerves and cause various symptoms, including nerve entrapment.
- Compression/stress fractures. These fractures are usually a result of osteoporosis and occur in the vertebrae.²

Rehabilitation

The best intervention for a client with LBP is a team approach using the skills of not only an occupational therapist but also a physician, physical therapist, caseworker, and psychologist. Depending on the circumstances of the client, other team members, such as the vocational counselor, social worker, discharge planner, nutritionist, and nurse, could be vital to successful intervention outcomes. These members may be part of the rehabilitation team, pain team, managed care group, and so forth.

The main member of this team, however, is the client. The client’s goals and desired outcome should direct the way in which the team approaches care. Each member must be aware of the context or contexts that will influence the client’s performance. This will affect the way that the client may or may not participate or take responsibility for his or her performance outcome.

Much has been written about workers and the effects of job satisfaction and limitations resulting from back pain. However, Waddell “asserts upon extensive review of the literature that ‘social class’ is probably the strongest personal predictor of incurring back trouble. This is in part due to heavy manual labor and in part due to ‘social disadvantages’ such as poor health care or lifestyle.”⁵ People who experience more anxiety with loss of work and the resulting financial implications frequently require the assistance of a psychologist. However, both these issues—decreased job satisfaction and anxiety—may surface during the patient’s occupational profile and should be addressed by all members of the team.

Physician

The physician is responsible for the initial work-up (or evaluation) of the client. Although the evaluation process varies according to the type of physician, the examination usually includes a thorough medical history, current symptoms and complaints, functional limitations, posture, gait, strength, reflexes and sensation, and past interventions for this problem. A diagnosis is usually made at this time, or the physician may order additional tests, such as nerve conduction tests, computed tomography scans, magnetic resonance imaging, and blood work. After arriving at a diagnosis, the physician often prescribes medication and determines restrictions in activity and exercise guidelines. To re-evaluate progress or lack thereof, the physician will typically see the patient in 1 or 2 weeks for a follow-up visit. If the symptoms have not decreased by that time, the client may be referred to physical therapy (PT).

During the client’s course of treatment, the skilled services of psychology, vocational counseling, and social work may be required. A low back injury may affect many areas of the client’s life significantly, including personal interactions, work, and finances; these consequences can increase the client’s stress and affect the outcome of treatment.

OT Practice Notes

Unfortunately, intervention for clients with low back pain is often not regarded or recognized as an appropriate role for occupational therapy because of the medical focus being on physical symptoms rather than performance outcomes. Working with and educating physicians and physical therapists in the ways that occupational therapy can assist these clients is vital not only for quality intervention for the client but also for program development in this area of practice.

Physical Therapy

The client is usually referred to PT to address pain, spasms, limited flexibility, and posture. The PT evaluation generally includes a review of the mechanism of injury, date of injury, progression of symptoms, medical history, recent tests and procedures, medications, past treatment history, previous level of functioning, and the client's goal for therapy. A subjective history of activities of daily living (ADLs) and sleep disturbances is reviewed. An objective examination will include analysis of posture, gait, active range of motion (ROM) of the spine, active ROM of the extremities, pelvic symmetry, signs of nerve tension, strength, reflexes and sensation, leg length, and palpation of soft tissue. On the basis of the data collected, the physical therapist develops a treatment plan that includes pain and spasm control, exercises, determination of the pelvic basis for daily activities, and patient education. The goals of PT are to reduce symptoms and increase strength and flexibility to achieve a functional pain-free outcome for the client.

A number of different theories are used by physical therapists. Two popular approaches are the McKenzie extension exercises and the Williams flexion exercises,¹ but there are many others. For the purpose of this chapter, the dynamic lumbar stabilization (DLS) approach will be considered. Regardless of the approach or program used by the physical therapists with whom you work, additional knowledge of the theory and program is necessary to provide effective team communication and a satisfactory client outcome.⁴

Dynamic Lumbar Stabilization

DLS incorporates many PT theories, including flexion, extension, and body mechanics of the lower part of the back. DLS involves integration of the muscle groups that control movement of the spine and the abdominal muscles that support the back. The abdominal muscles act as a corset to support the lumbar area. These muscles can flex the lumbar spine by acting on the superficial portion of the dorsolumbar fascia. They can also extend the lumbar spine by acting on the deep portions of the fascia, which form the interspinal ligaments. Control of lordosis in flexion and extension is extremely important. Because repetitive loads applied to the lumbar intervertebral joint can lead to

progressive tearing, fatigue, and ongoing disk prolapse, the client must learn to balance muscular function and flexibility to control the stresses involved in movement.

Each client must be able to identify his or her own "neutral position." A neutral spine does not mean an absence of or no lordosis or curve of the lower part of the spine but rather refers to the most comfortable spinal position for the individual to complete movement patterns and then integrate this neutral position into daily occupations. The neutral position for each client is the condition in which the vertebrae and disks are under equal pressure.

To find the neutral position (called "finding neutral"), the client should stand with the knees slightly bent and the weight distributed evenly. Using the abdominal muscles to tilt the pelvis, the client should flex and extend the lumbar spine until the balanced position of optimal function and stability is attained (Figure 41-5). The abdominal muscles should be contracted to maintain this position, much as a corset would. This position or stabilization should be maintained and integrated into performance of the client's occupations. Some individuals experience no pain while in a greater degree of extension or with a greater curve in the lower back region, whereas others prefer a neutral position of flexion and have more of a flattened abdomen.

Clients who prefer a neutral position in extension find that extension of the back is beneficial in relieving pain generated from flexion, which is a result of impingement of the nerve as a result of narrowing of the foramen by arthritis or a disk problem. The focus is on extension exercises and low back positioning with a greater low back curve. This takes the pressure off the disk and places it on the facet joints, which allows the nucleus pulposus to migrate anteriorly away from the area of impingement. The neutral-with-flexion position is most commonly used with patients who have a posterior spine problem such as facet pain. Positioning the spine in flexion acts to reduce facet joint compression and places the pressure on the disk and vertebra body.

As a team member, the physical therapist will communicate the appropriate pelvic position for the client to the rest of the team. On the basis of the physical therapist's recommendations for pelvic positioning, the occupational therapist will work with the client to incorporate the proper movement into daily occupations (Figure 41-6).

Occupational Therapy

The occupational therapist will work with the client to develop an occupational profile. This is achieved by using an occupational self-report questionnaire and interview process. Filling out a questionnaire before the actual interview allows the client to begin to identify problem areas of occupation and stimulates conversation during the occupational profile. However, depending on the treatment setting, the client may regard the use of a questionnaire and subsequent review of the same material with the therapist as redundant and a waste of time. To develop a thorough

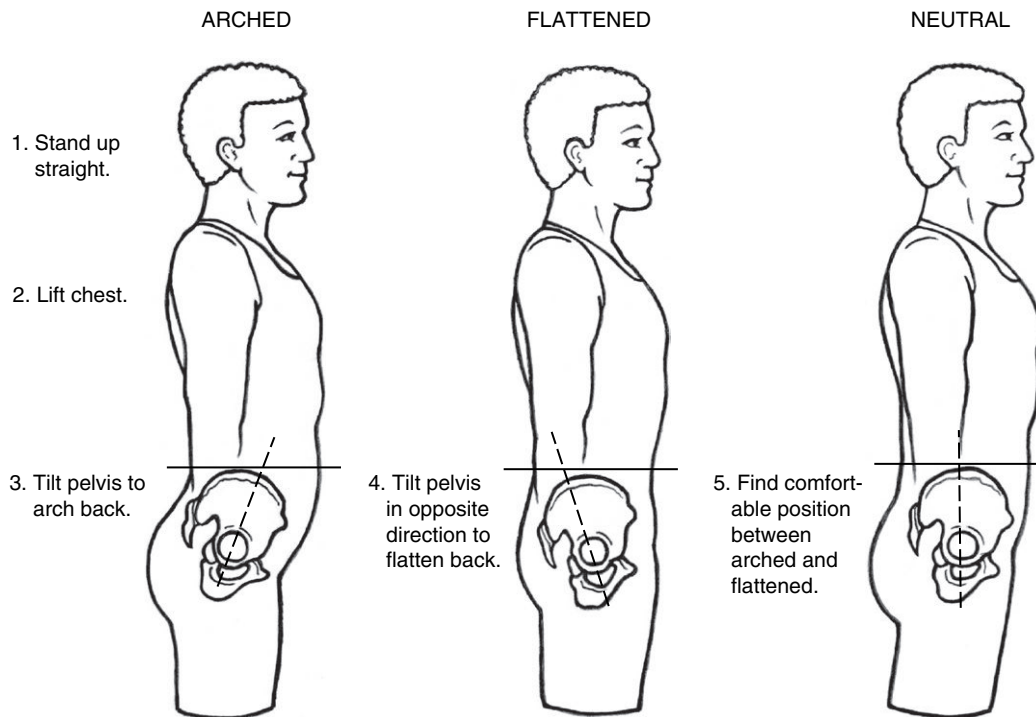

FIGURE 41-5 Finding the neutral position.

(Redrawn from Moore J, Long K, Von Korff M, et al: *The back pain help book*, Cambridge, Mass, 1999, Perseus Books Group.)

occupational profile, performance areas that have been affected by back pain should be identified. Analysis of occupational performance can best be determined by actual performance. To structure the evaluation within the clinic setting, an obstacle course consisting of various ADLs and instrumental activities of daily living (IADLs) may be used to assess various performance skills within predetermined occupations (Figure 41-7). In addition, occupations identified as being problematic during the interview should be assessed in the same way.

Assessment of performance in specific problematic areas of occupation will help in formulating the intervention plan and outcomes. A combination of intervention methods will provide the best outcomes for the client. For the intervention plan to succeed, the therapist should discuss with the client anatomy, pathology, back stabilization, ergonomics, body mechanics, and pacing. The plan must incorporate education and demonstration of back protection techniques while the client is engaged in actual occupations. The most important part of this process is to have the client understand, practice, demonstrate, and then incorporate the learned information into current and new occupations. The education received and incorporated into performance of occupations by the client must become a habit to ensure pain-free living. The client's outcomes will include reduction of pain, use of back stabilization techniques, use of adaptive equipment, and incorporation of body mechanics and ergonomics into client-specific areas of occupation, as well as the ability to adapt this learning to new occupations to prevent future problems.

Occupational Therapy Interventions

On the basis of the client's evaluation, the therapist develops an intervention plan that may use any or all of the following:

- Education regarding normal back anatomy and the physiology of back movement as they relate to performance of occupations
- Use of neutral-spine back stabilization in occupational performance to reduce pain
- Education in basic body mechanics
- Training in the use of adaptive equipment to modify tasks
- Task analysis and use of ergonomic design to modify the environment
- Training in the use of energy conservation to maintain participation in occupation
- Use of occupations to increase strength and endurance
- Education in strategies for pain management, stress reduction, and coping.

Client Education

As described and reiterated throughout this chapter, client education seems to be the key to success for a client with LBP. Knowledge of basic anatomy and physiology helps the client understand what is occurring when movement while engaging in an occupation results in pain. This knowledge is the foundation on which to build the rest of the intervention plan and ultimately select the appropriate interventions. Education can be provided in both group and individual settings.

Back Client ADL Referral/Follow-up

Name: _____ Phone: _____

Dx: _____ Onset Date: _____

- Client is very familiar with back stabilization concepts, demonstrating excellent body mechanics.
- Client has had ADL training from OT within the past 2 years.
- Client is not appropriate for an ADL evaluation. If so, explain:

P.T. _____

If any of the above is checked, STOP. If not, complete rest of this form.

Recommend emphasis in training the following ADLs:

Symptom irritability: Minimal/none Moderate Severe

MUST avoid the following lumbar positions: Flexion Extension
 Both No precaution

Ability to squat: Full ¾ ½ ¼ Unable

Knee pathology? Yes No

If yes, explain: _____

Hamstring flexibility: <45 <45-70 >70

ADL training: Indoor Outdoor

Comments: _____

OT Practice Notes

Information individualized to each client's needs is ideal. Many books, videos, card systems, and computerized educational systems are available from vendors. In addition, charts and models of anatomy are available to assist the client in understanding anatomy and physiology.

Back Stabilization and Neutral Spine

Before starting each activity, the occupational therapist should work with the client to identify his or her proper lower back position. It is important to monitor and cue the client as needed during the activity to maintain the proper position (see [Figure 41-5](#)).

In addition to a neutral spine, the client will need to learn and integrate a number of positions into activities to

FIGURE 41-8 **A**, Squat. Squat and lift with both arms held against the upper part of the trunk. Tighten the stomach muscles without holding your breath. Use smooth movements to avoid jerking. **B**, Diagonal lift. Squat down and bring the item close for lifting. **C**, Golfer's lift. When reaching into the cart, lift the opposite leg to keep the back straight.

help in lifting and movement. These positions include the squat, diagonal lift, and golfer's lift. The client's ability to perform a squat requires an absence of any knee or hip pathology. While performing a squat, the client keeps the back straight while maintaining a neutral spine (Figure 41-8, A). A diagonal lift requires the lift to be performed with one foot in front of the other and the legs shoulder length apart (see Figure 41-8, B). A golfer's lift requires bending at the hips while raising one leg behind (see Figure 41-8, C). Using a team method, the physical therapist identifies the client's ability to squat, as well as the type of neutral spine. Proper analysis of specific ADLs and the best position for commencement of activities requires a thorough understanding of the client's particular type of neutral spine, either flexion or extension.

Body Mechanics

Thorough knowledge of the concepts of body mechanics by the client is critical for the use of back stabilization. These concepts include maintaining a straight back, bending from the hip, avoiding twisting, maintaining good posture, carrying objects close to the body, lifting with the legs to promote safe performance, and using a wide base of support. Another key concept that is incorporated into activities is reducing back stress while standing. Using a small stool or opening a cabinet door and resting the foot inside the cabinet base usually accomplishes this goal. Instruction in avoiding any twisting of the back during activities is also essential, as will be noted in many habitual activities, such as flushing the toilet. In these instances the client must be instructed to turn as a unit while maintaining a neutral spine.

Adaptive Equipment

Adaptive equipment is often useful. The most frequently recommended pieces of equipment for persons with LBP include long-handled sponges or brushes, reachers, long-handled shoehorns, sock aids, elevated commodes or toilet seats, hand-held shower sprayers, and footstools.

Ergonomics

Much has been done to create environments that better fit the individual needs of a person with LBP. For example, office chairs that permit height, back angle, and back height adjustments allow the user to fit the chair. A chair for desktop work must provide back support and maintain the hips and knees at 90 degrees with the feet flat on the floor or a footrest. The back of the chair should not be so far back that it cuts into the back of the legs or causes forward bending of the back and straining with the arms. The rest of the body position should allow the client to complete the desktop activity with proper positioning of the neck and upper extremities.

An analysis of the client's work tasks should be completed and modifications made. In addition, the worker needs to change positions and take breaks. Occupational therapists and other specialists in ergonomics are available to provide consultation, as well as work site assessment and recommendations to employers, or to give the client information that allows him or her to complete a task analysis independently in the relevant environment. The Internet and office supply companies offer a great deal of information, in addition to products for the consumer.

Energy Conservation

Given their busy lives, clients may not realize that vacuuming, dusting, cleaning bathrooms, and preparing dinner for guests may be more than they—or their backs—can tolerate. Teaching clients the principles of energy conservation can help alleviate or minimize problems in this area. These principles include planning ahead, pacing oneself, setting priorities, eliminating unnecessary tasks, balancing activity with rest, and learning one's activity tolerance.

Planning ahead, for example, might involve preparing portions of a meal ahead of time for company and freezing them so that they may be reheated. Pacing requires examination of the required task, the time frame for completion, and the individual's ability to complete the task without resulting dysfunction. An example of pacing might include the recommendation that the client finish dusting a room in the morning and then vacuum in the afternoon instead of completing both tasks in one session. The principle of setting priorities might be illustrated by the client going out to dinner with company rather than preparing a large meal (cooking, serving, and cleaning); the former affords the client greater opportunity to enjoy the evening. The principle of eliminating unnecessary tasks might involve using paper towels for guests instead of cloth towels, which creates extra laundry. One example of balancing rest with an

activity is to use a stool and sit while preparing food, thus resting the back while completing a task. Similarly, the therapist might suggest that the client complete grocery shopping in the morning and read in the afternoon to rest after the morning task. The key to success in incorporating energy conservation into one's daily occupational life is for the client to be aware of his or her individual activity tolerance, including specific knowledge regarding triggers of fatigue and the amount of rest necessary for recovery.

Occupations to Increase Strength and Endurance

Once the principles of energy conservation have been taught and incorporated into several of the client's occupations, it is important to build on that knowledge and enable the client to increase strength and endurance for engagement in more favored occupations. Given the opportunity to prepare a meal nightly, the client can soon develop the endurance to prepare a meal for guests. Sitting at a computer to write a letter while maintaining a neutral spine strengthens the abdominal muscles; it also increases the ability to sit in the car for a ride.

Strategies for Stress Reduction and Coping

Numerous methods can be used to promote stress reduction and coping, including relaxation techniques, deep breathing, meditation, prayer, and guided imagery. Avoiding frustration, managing angry feelings and negative thoughts, and most important, participating in meaningful daily occupations can help the client avoid stress that results in pain. In addition to the services provided by occupational therapists and other professionals, the local bookstore offers many self-help books addressing LBP.

The following sections describe specific areas of occupation that may be identified during the occupational profile and the type of back position that can be used to reduce back stress. It is important to begin by analyzing each occupation by using an approach such as the one described in the next section.

Analysis of Occupations

After the client has completed the occupational profile and identified specific problem areas, ask yourself the following questions:

- What is the normal movement in this activity? Analyze the activity.
- What separate movements make up this activity?
- Which movements could trigger pain in this client?

Now plan for the way in which this intervention will be provided:

- How can this activity be properly performed to avoid the position that causes pain?
- Could the environment be changed or adapted?

Threaded Case Study | Pilar, Part 2

While observing Pilar getting vegetables from the refrigerator, the therapist notices that once Pilar opens the refrigerator, she bends at the waist, reaches and pulls the vegetable drawer open with one arm, and then reaches into the drawer to grab a bag of carrots (Figure 41-9, A).

What Is the Normal Movement in Performing the Activity for Most Individuals?

From observation, you note that most individuals bend at the waist to reach the vegetable drawer and then pull the drawer open to remove the vegetables.

What Separate Movements Occur during This Activity?

Bending, reaching, pulling, and pushing are involved.

What Movements Could Position This Client for Pain?

Bending, reaching, pulling, and pushing with the arms while the back is in a bent position could result in pain. We know, however, based on normal anatomy that bending at the waist increases pressure at the anterior portion of the vertebral body and disk, along with increased stretch at the back of the disk.

As the arms extend and reach forward, more weight is pulling forward on the already compressed anterior portion of the disk.

How Can This Activity Be Properly Performed to Avoid the Position That Causes Pain?

Pilar should squat and keep her back straight while positioned close to the drawer. Next, she should pull the drawer open, remove the carrots, and hold them close to her body. During all of these movements, the structures in the back remain in a neutral spine position (Figure 41-9, B).

Could the Environment Be Changed or Adapted?

The carrots could be placed on a higher shelf. Pilar might also consider purchasing one of the newer refrigerator models that have the least used portion—the freezer—positioned on the bottom, thus reducing the frequency of the need to bend.

The interventions described may sound as though they require many more movements, but in reality the movements are the same, just done properly. With practice, the new movement patterns will become a habit and replace the old painful movements.

FIGURE 41-9 A, Incorrect way to reach into a drawer. B, Squat with the knees apart to reach the lower shelves and drawers.

Activities of Daily Living, Instrumental Activities of Daily Living, and Other Areas of Occupation

This section reviews specific areas of occupation that may be identified during the occupational profile and the type of back position that can be used to reduce back stress.

Bathing

For a person with LBP, a shower is usually better than a bath because it is easier to maintain a neutral spine while standing. It is also more difficult to get in and out of the tub safely.

One tip to make showering easier on the back is to keep all items within easy reach in the shower. Many types of

FIGURE 41-10 Dressing. Lie on your back to place socks or slacks over your feet, or bend your leg up while keeping your back straight.

OT Practice Notes

Back schools have been developed (by the various health care professionals mentioned) over the years to deliver information similar to that presented in this chapter. This is a cost-effective way to deliver these services. Many health maintenance organizations or therapy groups deliver services this way to decrease cost and prevent overuse and possible duplication of services. The theory is that this type of information can meet the client's needs when delivered in a group setting. One therapist for six clients per hour is more cost-effective than 1 hour for each client and the accompanying paperwork. The group teaching session offers the added advantage of peer support and opportunities for discussions that might not occur during an individual session. However, with an individualized program, the therapist can better determine the unique occupational needs of the client and more closely assess the learning that has occurred.

racks that allow the client to place items below the showerhead are available for purchase. Long-handled scrub brushes or sponges allow washing of the back, legs, and feet without bending and twisting. A hand-held shower attachment also allows control of water flow and decreases unnecessary movements. With significant back pain, a shower chair can

be used. A simple plastic lawn chair outfitted with nonskid safety feet will work well. If a client must use a tub, he or she could sit in a plastic chair and use a hand-held shower attachment. When sitting in the tub, the client should always use a bath mat to reduce the chance of slipping and drain the water before attempting to get out.

Dressing

The client should sit while dressing and keep the back straight or should lie flat on the bed while pulling clothing up. Clients should refrain from getting dressed while bending forward. To don and doff socks and shoes, the client should sit and bring the foot to rest on the knee. Clients who do not have good external rotation of the hip may place their feet on a stool while donning and doffing socks and shoes (Figure 41-10). Slip-on shoes are easier to use than lace-up shoes. A long-handled shoehorn is useful to assist in donning shoes that require tying. Similarly, the client can thread a belt through the belt loops before donning slacks to keep from twisting the back. Loose-fitting clothing is easier to put on than tight clothing. Back protection techniques should be used for both dressing and undressing.

Functional Mobility

Use of a “logroll” to roll in bed requires movement of the body as a whole unit (Figure 41-11, A). To sit up or lie down, the client bends the knees and pushes up with the

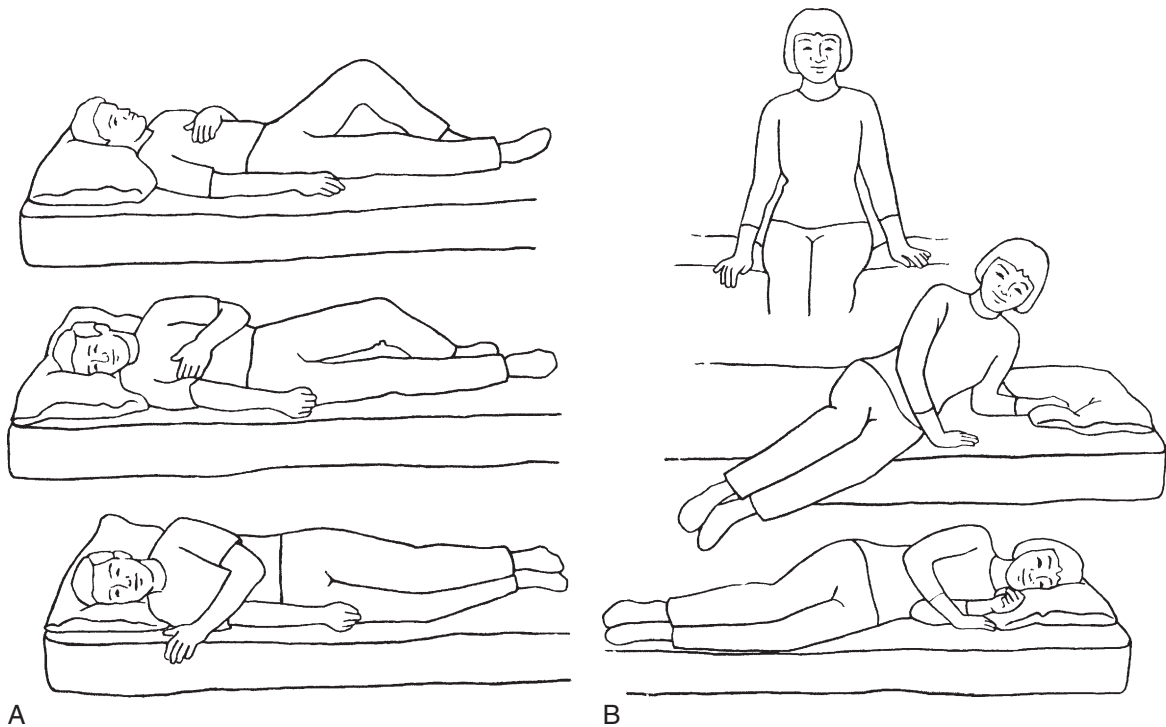

FIGURE 41-11 **A**, Logroll. Lying on your back, bend your left knee and place your left arm across your chest. Roll all in one movement to the right. Reverse for rolling to the left. Always move as one unit. **B**, Movement in and out of bed. Lower your body to lie down on one side by raising your legs and lowering your head at the same time. Use your arms to assist in moving without twisting. Bend both knees to roll onto your back if desired. To sit up, start by lying on your side, and use the same movements in reverse. Keep your trunk aligned with your legs.

arms while coming to a sitting position (see [Figure 41-11, B](#)). To lie down, the client brings the legs up and uses the arms to lower the body to the bedside. For both movements, the client is instructed to lie down and bring the legs up while using the arms to lower the body to the bedside. During both movements, the client must keep the back straight and tighten the abdominal muscles to support the back.

When getting on and off a toilet, the client must lower the body while maintaining a straight back and neutral spine. Supporting the hands on the thighs is helpful. Grab bars at the side of the toilet are also useful. However, grab bars must be secured properly and designed exclusively for this purpose; clients sometimes jeopardize their safety by using towel bars or tissue holders, which may cause further injury. In addition, clients sometimes grab a countertop on one side and the tub on the other, which results in twisting of the back or lateral flexion.

It is recommended that the client use a firm-armed chair that is supportive and not too low (rather than a soft couch). The client can use the chair arms to push up to a standing position ([Figure 41-12](#)). To reduce stiffness, the client should not sit longer than 15 or 20 minutes.

Personal Hygiene

Activities at a bathroom sink can be difficult because most sinks are designed to accommodate both children and adults; this low positioning forces most adults to bend

FIGURE 41-12 Stand to sit and sit to stand. To sit, bend your knees to lower your body onto the front edge of the chair and then scoot back on the seat. To stand, reverse the sequence by placing one foot forward and scoot to the front of the seat. Use a rocking motion to stand up.

forward, which places increased stress on the back structures. While brushing the teeth, shaving, or washing the face, the client should place a foot inside the base cabinet to reduce strain on the lower part of the back and bend

FIGURE 41-13 Shaving. Stay upright with one foot on the ledge of the cabinet under the sink.

(Courtesy Visual Health Information, Tacoma, Wash.)

from the hips while keeping the back straight (Figure 41-13). Alternatively, the client may bend forward and bear weight through one knee while extending a straight leg back for balance and support and maintaining a neutral spine position. To apply cosmetics, the client should use a hand-held mirror or a mirror that attaches to the wall so that the height can be adjusted.

Sexual Activity

Sexual activities require positions that place the lower part of the back in the neutral position. Clients with back pain may be most comfortable taking a passive position on their back. Positioning pillows under the buttocks or upper part of the back may help reduce arching of the back. A rolled towel under the lower back region may also help maintain a neutral back position. In addition, the client is advised to start slowly and gradually work up to more vigorous movements. Stretching and warming up muscles may enable greater activity. Taking a warm shower or bath before sexual activity may also relax muscles and help reduce pain. A bit of planning will allow enjoyment of sexual activity (Figure 41-14).

Sleep

We spend a third of our lives in bed, so it is important to consider the effects that being supine have on our backs. A firm, supportive mattress is important. The pillow should support the neck and head without causing the neck to flex.

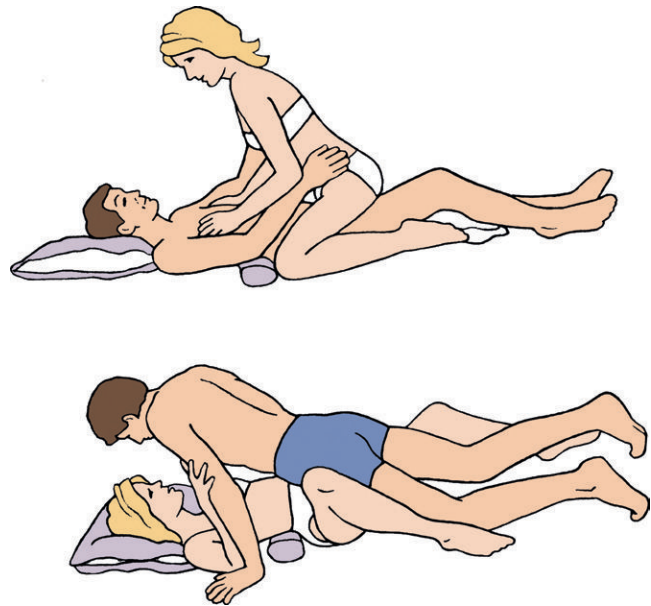

FIGURE 41-14 Sex positions. Communicate with your partner to find the position that is most comfortable for you. Plan ahead, and use pillows and rolls for support as needed.

Many types of formed foam pillows are helpful. While sleeping on the back, the client should place a pillow under the knees to reduce strain on the lower part of the back and help maintain a balanced lower back position (Figure 41-15, A). While lying on the side, the client should place a pillow between the knees to keep the top leg from moving out of alignment and twisting the lower part of the back (see Figure 41-15, B). For some individuals, sleeping on the stomach is appropriate (see Figure 41-15, C). In this position, pillows would not be appropriate, but a small pillow under the feet to bend the ankles and knees will take stress off the lower back region.³ For additional information on sleep and rest please refer to Chapter 13.

Toileting

When cleaning after toileting, the client should reach between the legs to avoid twisting the back. When turning to flush the toilet, the client should turn all the way around and face the toilet to flush it rather than twisting and reaching. During an acute episode of back pain, a toilet can be used by straddling the seat and facing the back of the toilet. This affords a wider base of support and also provides use of the toilet tank when coming to a standing position.

Child Care

Handling children requires special precautions for individuals with back pain. Sudden movements can increase the client's pain and interfere with the ability to handle the child safely. Clients should use a changing table or elevated surface when dressing the child. Bathing can be performed in a kitchen sink or in a portable tub on an elevated surface. Many contemporary cribs have drop-down rails so that the

FIGURE 41-15 **A**, Sleeping on the side. Place a pillow between your knees. Use cervical support under your neck and a roll around your waist as needed. **B**, Sleeping on the back. Place a pillow under your knees. A pillow with cervical support and a roll around the waist are also helpful. **C**, Sleeping on the stomach. If this is the only desirable sleep position, place a pillow under the lower part of your legs and under your stomach or chest as needed.

FIGURE 41-16 Child care, in and out of a car. Stand close and keep your back straight. Bend your knees to put the baby in or take the baby out of the car seat.

client does not need to extend his or her arms to lift the child over the crib.

Always remind the client to bend at the hips and keep the back straight during all of these tasks. To lift a child from the ground, the client should squat down and bring the child close before standing up. As the child gets older, the client should ask the child to stand or sit on a chair or couch before being lifted. This decreases the distance that the child must be lifted and eliminates the need for the client to bend forward. To place a child in a car seat, the client should stand close to the car seat and keep the back straight (Figure 41-16).

Computer Use

Much has been written about the use of computers and their effect on the body. It is important to position work so that the client is facing forward and ensure that the body is in good alignment. The keyboard and monitor should be directly in front of the client. The top of the monitor should be approximately at eye level. Clients are instructed to use a proper work height and seat height with the feet flat on the floor, wrists in a neutral position with the forearms

parallel to the floor, and the elbows at a 90-degree angle. If the client is using a laptop computer, the same guidelines should be used. Clients are taught to look at the screen by lowering their eyes rather than flexing their necks. In addition, clients are encouraged to stretch, take breaks, and change positions often. Document holders can assist in proper placement to prevent the need to twist the body. (See the previous section on ergonomics and Chapter 14 for additional information on seating.)

Driving

When getting in and out of a car, the client should sit on the seat and turn the body as a unit to keep from twisting. In some cars, this may require adjusting the seat to get in and out; the client should sit with the knees no higher than the hips. A small, rolled-up towel positioned in the lumbar area may be helpful. Most cars now allow adjustments in seat height, seat angle, seat position, and steering wheel angle. When riding for extended periods, the client should schedule rest breaks to change positions. For drivers with back pain, use of cruise control allows more frequent changes in position.

FIGURE 41-17 Laundry, unloading the wash. To unload small items at bottom of the washer, lift your leg opposite the arm used for reaching.

Home Establishment and Management

The client should organize all work spaces so that the equipment and materials needed for specific tasks are within the work area. For example, if the client is planning to bake cookies, flour, sugar, baking spices, bowls, and measuring cups should all be within reach. The mixer (if used regularly) should be on the counter to obviate the need for lifting and reaching. Work areas should allow flexion of the elbows and no bending or straining of the lower back region. Routinely used items in cabinets should be at reach overhead, and the client should not be required to extend the back or neck to retrieve them. Items in lower cabinets should allow easy access with a partial squat. Cabinets can be modified with slide-out shelves/drawers that allow easier access. Items that are used less frequently can be stored in hard-to-reach cabinets. To prepare meals, the client must work at a proper work space. The ideal height for most individuals allows comfortable work with the elbows bent at 90 degrees and above and below extension of the arms without extension of the back and neck or bending. The kitchen set-up should feature work areas in which the items needed for a particular task are within easy reach.

To remove clothing from the washer when doing laundry, the client should use a golfer's lift to reach inside the machine (Figure 41-17). To place clothes in the dryer, the client is instructed to squat down and then load the dryer. To retrieve clothes, the client repeats the squat, removes the clothes, and places them in a basket that is positioned nearby. When carrying the basket, the client should hold it close to the body; the same is true while lifting the basket when coming from a squat to a standing position.

For ironing, it is recommended that the client raise the ironing board to the proper height, thus allowing the client to have the elbow flexed at 90 degrees, as well as providing adequate extension of the elbow to avoid twisting of the lower part of the back. While ironing, the client is instructed

to rest one foot on a low stool to help reduce low back strain. Ironing can also be completed while sitting if the ironing board is lowered beforehand. Because of the adjustability of an ironing board, this surface can be used for many other activities, such as folding clothes and wrapping packages.

A long-handled brush or sponge is recommended to clean the bottom of a tub. Using a hand-held sprayer and a spray cleaner is easier than scrubbing and rinsing the surfaces. While vacuuming, clients should move their feet and legs rather than reach or bend forward. They are also cautioned to avoid twisting; when vacuuming under a table or chair, they should bend at the hips and knees to keep the back in a balanced position.

When mowing the lawn, the client should face forward and align the hips with the mower. The client should keep the back straight, the spine in a neutral position, and the abdominal muscles tight; take frequent breaks; and refrain from twisting. When using a shovel, the client should bend at the hips and knees rather than at the waist and keep the shovel and its load close to the body. The preferred method for emptying the shovel is to turn the entire body and keep the hips and shoulders in alignment while maintaining the load close to the body and facing the location to unload the shovel. None of these household activities should be attempted when the client is in an unstable condition with acute pain.

Shopping

When retrieving items from a lower shelf, the client should squat or go down on one knee while keeping the back straight. The shelf should be used as support when returning to a standing position. When items are located overhead, the client should get as close as possible and use one hand for support on the shelf. To use a shopping cart, the client should find his or her neutral spine position, which

should cause the abdominal muscles to tighten. The client should stand up straight and push the cart with the elbows at the side. The force to move the cart should come from the legs and body, not the back. Use of a cart is preferable to carrying a basket, even for small loads. Clients can place items in the child's portion of the cart rather than carry a basket in one hand, which puts uneven stress on the back. When unloading the cart, the client should use the golfer's lift to retrieve items from the bottom. While carrying packages, the client should distribute the weight evenly between both arms to reduce uneven lateral bending on one side. Better yet, the client can carry packages close to the body and use both arms.

Work

The demands of jobs vary considerably. Many employers now have someone on staff to assess workstations and determine whether modifications can be made (see Chapter 14). In many cases, however, it is up to the individual worker to modify his or her work situation. Many improvements can be made by simply using correct lifting techniques, using the proper equipment for the job, pacing the activity, and asking for help.

Leisure

When reading, clients should sit in a supported chair, not curl up on a sofa. Tabletop hobbies such as sewing and building models require attention to table height, chair position, and positioning of the work items for the upper extremities; these positioning recommendations resemble those for computers. All these modifications will reduce uneven pulling and twisting of the body.

When traveling, the client should use a pull-type suitcase on wheels, which is easier on the back. Backpacks and fanny packs with light loads can also be used. Travelers are encouraged to pack lightly and take only what is needed for the trip. Checking luggage and having someone else carry the load instead of trying to lift items overhead are also recommended.

Gardening can be challenging for clients with back problems. Raised garden beds and container gardening are good options to reduce back strain. Many carts or moving seats can be purchased that allow safer back positioning when working at ground level. Knee pads make gardening in a kneeling position more comfortable. The gardener is cautioned to work only within his or her immediate reach to avoid bending forward or twisting.

Only a few of the many possible interventions have been described here. Each client and each occupation must be analyzed, and an individual intervention should be developed for each client. ADL body mechanics cards from Visual Health Information can be used to customize each program. This is a card file system from which cards can be selected and copied to develop interventions for each client according to his or her individual needs. Also available are many preprinted booklets and computer programs that may

assist in client instruction. It is important to remember that most insurance companies do not cover adaptive equipment and that hospitals typically have large markups on vended equipment. Consequently, many clinics offer sample equipment for clients to try and provide community resources for equipment or consumer catalogs from vendors such as Sammons/Preston or North Coast Medical. Consumers should be made aware that many items once considered adaptive therapy equipment or ergonomic items are frequently available at a lower cost in discount stores.

Surgical Intervention

Recently, surgical treatment of back problems has undergone many advances. Current interventions include laminectomy, fusion, nerve decompression, disk dissection, vertebroplasty, and kyphoplasty. Surgical interventions are divided into two basic types: surgery that decompresses the nerve or stabilizes the spine to reduce pain. Surgeries that decompress the nerve open the transverse foramen and increase the space for exit of the spinal nerve and entrance to the spinal cord. Some surgeries may remove a structure, such as part of a disk or an osteophyte, which may create pressure on the nerve root. Stabilization can include the use of various pieces of hardware, such as screw, wires, rods, and bone grafts, to increase stability of the bony structures of the spine. In addition both vertebroplasty and kyphoplasty use a cement-like substance to stabilize compression/stress fractures. Kyphoplasty involves the use of a balloon that is placed in the fracture and, when inflated, helps restore height and reduce deformity before the cement is injected.²

OT Practice Notes

It is very important that the therapist understand what each of these surgeries involves and be able to articulate this information to the client. As part of the occupational therapy intervention in the hospital, education regarding the surgical procedure enables the client to understand the reason that certain precautions are required during the rehabilitation phase to maintain a healthy back.

Client precautions must be identified. Therapists should work with the physician to develop protocols or standards of care for specific surgeries. It is also important to identify the types of braces and other equipment that may be used for a specific surgery by a specific physician so that the occupational therapist can provide the expected instructions and precautions for use of the equipment in daily occupations. For example, one physician may allow a client to put a brace on while sitting at the bedside, whereas another physician may require the client to logroll into the brace and complete donning the brace before coming to a seated

position. Frequently, braces will be ordered and fitted before surgery, and patients will have them at admission.

Postoperative Occupational Therapy Evaluation and Intervention

When seeing a client for the first time postoperatively, the occupational therapist should obtain the client's history and occupational profile, as well as a description of his or her home environment to ascertain the types of modifications required for safety. During the occupational profile, ADL and IADL issues should be identified. As part of the home assessment, education in work simplification techniques, in conjunction with directive questions, helps the client identify further needs. Home modifications may include picking up rugs to prevent falls, increasing awareness of pets, and selecting a type of chair that is easy to get in and out of and that provides good support and fits the client. The therapist should also determine whether the home contains a standard toilet and shower and whether modifications are required.

Next, the therapist must educate the client in the required performance precautions for daily occupations; this should take place before even attempting to have the client get out of bed. This evaluation is somewhat contrary to customary practice in occupational therapy. In this situation, the therapist does not want to observe performance before the intervention. Instead, the primary focus is to educate and then cue the client through the process to avoid any improper positions or posture that creates stress on the surgical area. The outcome of occupational therapy intervention is to maintain a straight back, avoid twisting, and perform ADLs while safely incorporating back safety techniques and using adaptive equipment.

Postoperative Activities of Daily Living

While in the hospital, the most basic ADLs must be addressed initially. It is important to educate the client on proper positions for sleeping and have the client demonstrate the correct positions. The client will need to use the logroll for functional mobility in the bed. Proper methods are also taught for getting in and out of bed, in and out of a chair, and on and off a toilet; brushing teeth; washing the face; shaving; and dressing using the back protection techniques discussed earlier in this chapter. Clients are instructed to use adaptive equipment to prevent back stress in daily activities, including getting in and out of an automobile.

The hospital stay for these clients can be between 24 hours and 3 to 5 days, depending on the procedure and previous level of function. Most clients are discharged home. Because the client's stay is so short, it is good to provide them with resources to help them should specific occupations be overlooked during the hospital stay. Some facilities develop educational materials that include basic body mechanics information, hints on ADLs, and anatomic and surgical information. Various publications include post-surgical back "dos and don'ts." Many hospitals have computerized education programs that allow the provider

to issue information on the surgical procedure and the resulting back precautions. Most insurance plans do not cover adaptive equipment such as reachers and long-handled sponges; however, this equipment is necessary to ensure a successful postoperative outcome. Raised commodes and shower chairs are not usually covered, but many clients purchase these items and have them delivered to their homes before discharge. To prepare the client for home and occupation modifications, many hospitals provide preoperative education classes.

Summary

Providing effective occupational therapy intervention for a client with LBP requires a good understanding of back anatomy and physiology. The ability to analyze daily occupations and determine how back positions are affected by the occupation is crucial in attaining a successful outcome. Good communication between all team members is important to achieve both reduction of symptoms and integration of knowledge to support the performance of meaningful occupations.

Threaded Case Study Pilar, Part 3

When re-examining our case study, we note that Pilar has problems bending over while performing her daily activities. Because bending over causes increased pain, it is apparent that she is bending through her lumbar area. We know from our review of anatomy that when bending from the waist, pressure will increase on the anterior portion of the vertebra and disk, which could cause impingement on the nerve root and result in pain. The activities that Pilar has identified as painful will be the focus of intervention for education with respect to anatomy, and the probable cause of her pain is bending at the waist.

Once she understands how her movement affects her pain, maintenance of a neutral spine position will ensure even pressure on the vertebrae and disks. Her knowledge and use of proper body mechanics in maintaining a straight back will ensure even pressure on the lumbar structures. Learning the relationship between both mechanically correct and incorrect movement patterns and her pain will help her develop pain-free movement patterns. As Pilar is able to demonstrate correct movements and reduction of pain, she should be able to assimilate this information into other activities not identified and be in control of her pain, thereby positively affecting her engagement in daily occupations.

Review Questions

1. List four causes of LBP.
2. Identify the major components of the spine.
3. Explain the ways that back movements affect the spinal components while the client engages in an occupation.

4. Define neutral spine.
5. Identify the interventions used for patients with LBP.
6. Identify the interventions used for post-surgical patients.

Burns and Burn Rehabilitation*

SANDRA UTLEY REEVES
LISA DESHAIES

■ Chapter Outline

Incidence of burn injuries and burn-related deaths

Skin anatomy

Skin function

Mechanism of injury and burn depth

Percent total body surface area involved

Severity of injury

Phases of wound healing

Inflammatory phase

Proliferation phase

Maturation phase

Scar formation

Initial medical management

Fluid resuscitation and edema

Respiratory management

Wound care and infection control

Topical antibiotics

Biologic dressings

Biosynthetic products

Hydrotherapy

Sepsis

Surgical intervention

Vacuum-assisted closure

Nutrition

Associated problems and complications

Stress

Pain

Pain assessment

Pain management

Psychosocial factors

Burn rehabilitation

The team

Goals of rehabilitation

Phases of recovery

Acute care phase

Surgical and postoperative phase

Rehabilitation phase

Occupational therapy evaluation

Occupational therapy intervention

Acute care phase

Preventive positioning

Splinting

Activities of daily living

Therapeutic exercise and activity tolerance

Client education

Surgical and postoperative phase

Positioning and postoperative splinting

Therapeutic exercise and activity

Activities of daily living and client education

Rehabilitation phase: inpatient

Reassessment and intervention goals

Skin conditioning and scar massage

Compression therapy

Therapeutic exercise and activity

Edema management

Activities of daily living

Splinting

Client education

Rehabilitation phase: outpatient

Reassessment

Therapeutic exercise and activity

Scar management

Activities of daily living

Community re-entry

Psychologic adjustment

Discharge from treatment

Burn-related complications

Heterotopic ossification

Neuromuscular complications

Facial disfigurement

Summary

Review questions

*In this chapter, the terms *patient* and *client* are both used, with *client* being used in occupational therapy contexts.

■ Key Terms

Dermis	Compartment syndrome
Epidermis	Ischemia
Superficial burn	Escharotomy
Superficial partial-thickness burn	Xenograft
Deep partial-thickness burn	Allograft
Full-thickness burn	Autograft
Subdermal burn	Eschar
Hypertrophic scar	Scar maturation
Keloid scar	Heterotopic ossification

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Recognize and understand the characteristics of the different types of burn injury and the clinical techniques for determining wound depth and severity.
2. Understand the anatomy of the skin and its functional significance on performance skills and on both external and internal contexts.
3. Describe the phases of recovery and focus of occupational therapy intervention for each phase.
4. Identify factors that increase the potential for scar hypertrophy and contracture.
5. Comprehend the impact of ongoing patient and caregiver education on long-term compliance with treatment.
6. Understand the impact of early involvement of burn patients in their own self-care activities of daily living on resumption of role and performance patterns.
7. Acknowledge and anticipate complications characteristic of a severe burn.
8. Appreciate the impact that a severe burn has on the performance patterns, life roles, self-image, and valued context of the patient.

Threaded Case Study | Steven, Kenjii, Patrice, Part 1

Steven

Steven, a 38-year-old Caucasian father, was a truck driver when he sustained battery acid burns on 25% of his total body surface area in a rollover automobile accident in which he was pinned under his vehicle. As a result of the spilled battery acid, he incurred deep burns on the upper part of his chest and back, right arm extending from the anterior fold of his axilla, circumferential aspect of his upper arm, forearm, dorsal surface of his hand, and right index finger. He also suffered serious battery acid burns on his neck and face. Other injuries included skin lacerations on his forehead, fracture of his coccyx, right elbow sprain, and chest trauma resulting in a lacerated spleen and a collapsed upper lobe of his right lung. His medical history was significant only for sleep apnea and psoriasis on the lower part of both legs. He was right hand dominant and independent in all activities of daily living and instrumental activities of daily living before this injury.

At the time of his injury, Steven lived alone in a mobile home but shared custody of his 3-year-old son, who stayed

with him on alternate weekends. He has a high school education and had worked for 18 years as a truck driver until the time of his accident. He had also worked part-time at night as a bouncer at a local bar, a job he enjoyed because he was “paid to hang out with my friends.” His leisure interests included fishing, working out at the gym, and competitive power lifting. He had been capable of lifting 325 lb and had won three trophies at regional weight-lifting competitions the year before his injury.

Kenjii

Kenjii, a 22-year-old male rock musician of Asian descent, sustained severe burn injuries when a canister of stage pyrotechnic gunpowder caught fire. The gunpowder had been stored in the band’s dressing room, where someone apparently mistook the canister for a trash can and flipped a cigarette into it. As the gunpowder burned, it superheated the room, and Kenjii barely escaped by crawling out of the room on his hands and knees. His long hair, cotton blue jeans, T-shirt, and boots

helped protect much of his body, but his unprotected arms, hands, and face became severely burned. As a result of the depth of the burns on his hands, severe deformities developed on most of his fingers, and his interphalangeal joints had to be fused, with only active movement remaining in his metacarpophalangeal joints. Because of a genetic predisposition for scarring and the locations of his initial injury, severe scarring and disfigurement developed on much of his face, arms, and hands. Even surgical and skin graft donor sites scarred severely.

The distortion of Kenjii's facial appearance and impairment of hand function resulted in the loss of both his personal identity and the dexterity skills he had used to play the flute, guitar, and piano. Kenjii lost the factors on which he based his livelihood and personal identity. He lost his autonomy when he became financially dependent on his parents, who had not approved of his career choice as a musician.

Patrice

Patrice, an African American child, was scalded when she was 7 days old by her schizophrenic biologic mother during a psychotic episode. Her burns were located on her face, the top of her head, her left thigh, her abdomen, her left forearm, and the back of her left hand. Because of her young age, her burns had to be treated conservatively and allowed to heal initially without surgical intervention. Her hand was too tiny and her skull bones not developed enough for the use of conventional scar prevention techniques. As a consequence, tight scars developed and distorted her facial features and the growth of her hand. Her hand burn was serious but did not involve her fingers. However, despite frequent therapy sessions and the

excellent care provided by a devoted foster mother, the longitudinal force of the hand scar prevented natural growth of the bones in her middle, ring, and little fingers. There was so little growth in the bones of her little finger that as the rest of her hand continued to grow, the little finger gradually receded into her hand and essentially disappeared.

Critical Thinking Questions

1. The upper extremities and faces of each of these three clients were seriously injured. Which specific areas of occupation (including activities of daily living, instrumental activities of daily living, education, work, play, leisure, sleep and rest, and social participation) will be affected in each of them?
2. When planning occupational therapy intervention for these clients, how will understanding their preinjury occupational life and contexts influence the establishment of treatment priorities?
3. Both of the adults lost the performance skills on which they relied for their livelihood. The facial appearance of all three was distorted, a condition that would affect their self-perception and personal identity. How and when should the occupational therapist address the emotional impact of these losses?
4. As you read through the chapter, also reflect on the information presented on burn rehabilitation. How did occupational therapy intervention affect the client factors, performance skills, performance patterns, long-term performance in areas of occupations, and final contexts of each of the three clients portrayed in the case scenarios?

Increasing numbers of individuals are surviving burn injuries that in the past would have proved fatal. Over the past 40 years, advances in burn management, such as in resuscitation, early excision and grafting, and surgical critical care, have dramatically improved the percentage of survivors of severe burn injuries.¹⁴ With this improvement in survival comes an increased need for comprehensive burn rehabilitation so that when a life is saved, the quality of lifestyle and participation in meaningful occupation are also preserved.

Incidence of Burn Injuries and Burn-Related Deaths

It has been estimated that more than 0.5 million burn injuries requiring medical treatment occur each year in the United States.³ This represents a significant decline in the incidence of burn injuries since the early 1960s, when an estimated 2 million injuries occurred annually.⁴ Total fire- and burn-related deaths are currently estimated at 4000 per year. This total includes an estimated 3500 deaths from

residential fires and 500 from motor vehicle and aircraft crashes; contact with electricity, chemicals, and hot liquids or objects; and other sources of burn injury.³ Fire- and burn-related deaths in the United States continue to decline. Conversely, hospitalizations for burn injury have increased steadily over recent decades because of improved emergency care helping victims survive. Burn prevention and fire safety measures have reduced the incidence of severe burn injury to the extent that burn centers are now admitting greater numbers of patients with less severe burns and fewer large, deep burns.⁵

Since the early 1970s, advances in the medical, surgical, and rehabilitative management of individuals who sustain burns have expanded the focus of burn care professionals from simply ensuring patient survival to include regaining quality of life and the previous life context after a burn injury. Although functional recovery may be a long and arduous process, most burn survivors can expect to resume their roles, function at a level that is comparatively close to their preinjury level of independence, and continue engagement in occupation for satisfactory participation in life. However, from the date of injury through the outpatient

phase of care, a multidisciplinary team approach is necessary to effectively manage the medical, functional, and psychosocial problems encountered during recovery.

Skin Anatomy

The skin is the largest organ of the body. It varies greatly in thickness, flexibility, presence and amount of hair, degree of pigmentation, vascularity, nerve supply and sensitivity, amount of keratin, and types of glands present in different locations. Keratin is the tough protein substance present in skin and also forms the primary elements of hair, nails, and callused areas of the skin on the hands and feet. Most of the body is covered with thin, hairy skin. However, thicker, tougher, hairless skin, known as glabrous skin, covers the soles of the feet and the palmar surfaces of the hand and fingers.

Anatomically, the skin consists primarily of two layers: the dermis and the epidermis (Figure 42-1). The dermis, or corium, is composed of fibrous connective tissue made of collagen and elastin and contains numerous capillaries, lymphatics, and nerve endings. In it are the hair follicles and their smooth muscle fibers, sebaceous glands, and sweat glands and their ducts.⁸⁹

The epidermis is the outermost layer of epithelium, and it also lines the nail beds and the skin appendages, which are pockets of epithelium that extend down into the dermis and contain the hair follicles, sweat glands, and sebaceous glands. The epidermis consists of four or five layers, depending on the location and type of skin. The innermost layer of the epidermis is the stratum germinativum, where the keratinocytes that synthesize keratin are formed. Above this layer lies the stratum spinosum, in which the progressive stages of keratinization occur. The keratinocytes in this layer have a well-developed capacity for phagocytosis, which helps control infection by ingesting and breaking down bacteria and particulate debris. Melanin granules, which give the skin and hair their color, are present in the cytoplasm of certain cells in the stratum spinosum. In the next layer, the stratum granulosum, the cells making their way

toward the surface become flattened and accumulate many large keratin granules, termed keratohyalin. In this layer, cells lose their nucleus, change from viable to nonviable, and become a cornified layer composed chiefly of keratin filaments. Above this layer is the stratum lucidum, seen best in glabrous skin, which is thicker. The outermost layer, the stratum corneum, is composed of tightly packed dead keratinocytes known as squames that become the cornified, flattened skin cells that eventually separate from one another and detach from the surface of the epidermis. The time taken by a newly formed keratinocyte to pass from the deepest layer to the surface to be shed is estimated to be 45 to 75 days. This is the natural manner in which the epidermis continually renews itself.⁸⁹

Skin Function

The skin serves as an environmental barrier that protects against ultraviolet rays, chemical contamination, and bacterial invasion. It also serves as a moisture barrier to prevent excessive absorption of moisture or evaporative loss. Temperature regulation is also a function of the skin, with hair to insulate and perspiration to cool the body. The skin perceives injury or infection through tactile sensory receptors located in the dermis layer of the skin. These receptors heighten environmental awareness through perceived touch, pressure, pain, and temperature. When the skin is damaged, various systemic, physiologic, and functional problems can occur. A burn injury causes destruction of the protective environmental barrier, which results in exposed nerve endings, loss of body heat, seepage of body fluids, and exposure to bacterial invasion.

The skin also influences the development of an individual's body image and personal identity and enhances nonverbal social interaction. Along with age, gender, body type, and voice, the skin's scent, texture, and coloration and the appearance of facial features contribute strongly to a person's external context (physical) and self-concept-related internal contexts (e.g., body image, self-regard, sense of social and cultural acceptance). Because of all these factors,

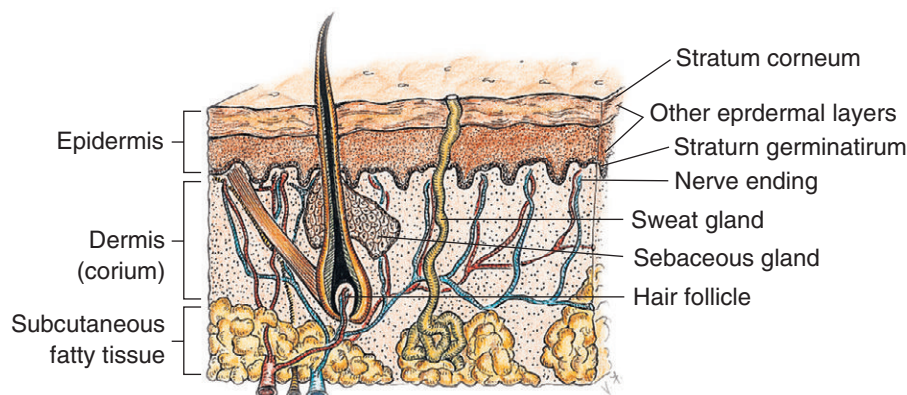

FIGURE 42-1 Cross section of the skin.

(From Potter P, Perry A: *Fundamentals of Nursing*, ed 7, St. Louis, Mo, 2009, Mosby.)

a large burn injury is considered to be one of the most physically and psychologically painful forms of trauma.

After a burn injury, many factors are taken into consideration in determining the severity of injury, potential for functional recovery, and treatment needs. Primary considerations in evaluating burn wounds are the mechanism of injury, the depth and extent of the burn, specific body areas burned, and associated or concurrent injuries such as inhalation injury and fractures. The individual's age, medical history, preinjury health, and previous life context are of equal importance in determining the impact of a serious burn injury on future occupational performance.

Mechanism of Injury and Burn Depth

Burns can be thermal, chemical, or electrical in nature and can be caused by flame, steam, hot liquids, hot surfaces, and radiation. The severity of the injury depends on the area of the body exposed and the duration and intensity of thermal exposure. Burn wounds are classified by depth, which is determined by clinical assessment of the appearance, sensitivity, and pliability of the wound.⁹³ Burn injuries were traditionally classified as first, second, third, and fourth degree. They are now classified as superficial, superficial

partial thickness, deep partial thickness, full thickness, and subdermal.⁴¹ The depth of injury is established by clinical determination of which anatomic layers of the skin are involved.⁸⁶

A superficial burn, sometimes referred to as a first-degree burn, involves only the upper layers of the epidermis. Damage through the epidermis and upper third of the dermis is referred to as a superficial partial-thickness burn. The term deep partial-thickness burn describes damage to the epidermis and upper two thirds of the dermis, and a full-thickness burn describes an injury that extends down through the entire dermis. A subdermal burn involves the fatty layer, fascia, muscle, tendon, bone, or other subdermal tissues (e.g., those seen in electrical injuries; [Table 42-1](#)).

Superficial burns are usually caused by sun exposure or brief contact with rapidly cooling, nonviscous hot fluids or surfaces (e.g., spilled coffee and a hot pan). Superficial partial-thickness burns are typically caused by prolonged sun exposure, contact with flames, or brief contact with hot viscous liquids ([Figure 42-2, A](#)). Deep partial-thickness burns are caused by longer exposure to intense heat, such as immersion in hot water or contact of the skin with flaming material. Full-thickness burns usually result from prolonged immersion scalding, contact with flaming or

A

B

FIGURE 42-2 **A**, Superficial partial-thickness burns are wet and painful with peeling epidermal blisters. **B**, The different depths of burns can be seen in the “target” appearance of this electrical burn: superficial partial-thickness burns at the periphery and deep partial-thickness and parchment-white full-thickness burns leading into charred subdermal burns in the center.

(Courtesy Edward Vergara, Gainesville, Fla.)

■ **TABLE 42-1 | Burn Wound Characteristics**

Burn Depth	Common Causes	Tissue Depth	Clinical Findings	Healing Time	Scar Potential
Superficial (first degree)	Sunburn, brief flash burns, brief exposure to hot liquids or chemicals	Superficial epidermis	Erythema, dry, no blisters, short-term moderate pain	3-7 days	No potential for hypertrophic scar or contractures
Superficial partial thickness (superficial second degree) and donor sites	Severe sunburn or radiation burn, prolonged exposure to hot liquids, brief contact with hot metal objects	Epidermis, upper dermis	Erythema, wet, blisters; significant pain	Less than 2 weeks	Minimal potential for hypertrophy or contractures if healing is not delayed by secondary infection or further trauma
Deep partial thickness (deep second degree)	Flames; firm or prolonged contact with hot metal objects; prolonged contact with hot, viscous liquids	Epidermis and much of the dermis nonviable, but survival of skin appendages from which skin may regenerate	Erythema; larger, usually broken blisters on skin with hair; on glabrous skin of the palms and soles of the feet; large, possibly intact blisters over beefy red dermis; severe pain to even light touch	Longer than 2 weeks, may convert to full thickness with onset of infection	High potential for hypertrophic scarring and contractures across joints, web spaces, and facial contours; high risk for boutonnière deformities if the dorsal surface of fingers involved
Full thickness (third degree)	Extreme heat or prolonged exposure to heat, hot objects, or chemicals for extended periods	Epidermis and dermis: nonviable skin appendages and nerve endings	Pale, nonblanching, dry, coagulated capillaries possible; no sensation to light touch except at deep partial-thickness borders	Surgical intervention required for wound closure in larger areas; possible for smaller areas to heal inward from borders over extended period	Extremely high potential for hypertrophic scarring or contractures, depending on the method used for wound closure
Subdermal	Electrical burns and severe long-duration burns (e.g., house fires, entrapment in or under a burning motor vehicle or hot exhaust system, smoking in bed or alcohol-related burns)	Full-thickness burn with damage to underlying tissue	Possible charring of nonviable surface or, with exposed fat, possible presence of small external wounds on tendons, muscles; with electrical injuries, possibility for small external wounds with significant secondary loss of subdermal tissue and peripheral nerve damage	Requires surgical intervention for wound closure; may require amputation or significant reconstruction	Similar to full-thickness burns except when amputation removes the burn site

high-temperature viscous material such as hot grease or melted tar, extended exposure to chemical agents, and contact with electrical current (Figure 42-2, B).

Superficial partial-thickness and deep partial-thickness burns generally heal without surgical intervention. However, once healed, they tend to be excessively dry, itchy, and subsequently susceptible to excoriation (i.e., abrasion or tearing of the skin surface) secondary to shear forces caused by rubbing, scratching, and other trauma. These shear forces can give rise to blisters and compromise long-term skin integrity as a result of repetitious reopening of the wound. Partial-thickness and full-thickness burns usually lead to uneven pigmentation of the healed scar. Deep partial- and full-thickness burns have a greater potential for thick, hypertrophic scar and contracture formation because of the prolonged healing period. This is especially true if a burn converts from partial thickness to full thickness because of infection or repeated trauma. Most full-thickness wounds require surgical intervention or skin grafting for wound closure. Skin graft donor sites generally heal in the same manner that superficial partial-thickness burns do, with less scarring but uneven pigmentation. In all three of the case studies, the majority of the patients' burns were deep partial-thickness injuries but with serious scar development after healing.

Percent Total Body Surface Area Involved

The extent of a burn is classified as a percentage of the total body surface area (%TBSA) burned. The two most common methods for estimating %TBSA are the “rule of nines” and the Lund and Browder chart.^{32,54,84} The rule of nines divides the body surface into areas consisting of 9%, or multiples of 9%, with the perineum making up the final 1%. The head and neck area is 9%, each upper extremity (UE) is 9%, each lower extremity (LE) is 18%, and the front and back of the trunk are each 18%. Body proportions vary in children, depending on their age, especially in the head and legs (Figure 42-3). The Lund and Browder chart⁵⁰ provides a more accurate estimate of TBSA⁶⁴ and is used in most burn centers. This chart assigns a percentage of surface area to body segments (Figure 42-4), with the calculations adjusted for different age groups. For smaller %TBSA injuries, the therapist can obtain a quick, rough estimate by using the size of the patient's palm (the hand excluding the fingers) to equal approximately 1% of the individual's TBSA. Steven's burns included his right arm and hand (8%), upper part of his chest and back (13%), anterior aspect of his neck (1%), and face (3%), for a total of 25% TBSA. Kenjii's burns included circumferential burns on his arms and the dorsal surfaces of his hands (9% each) and burns on his face and neck (5%), for a total of 23% TBSA. Neither Steven's nor Kenjii's TBSA estimates included their skin graft donor sites, which added to their total injured body surface area.

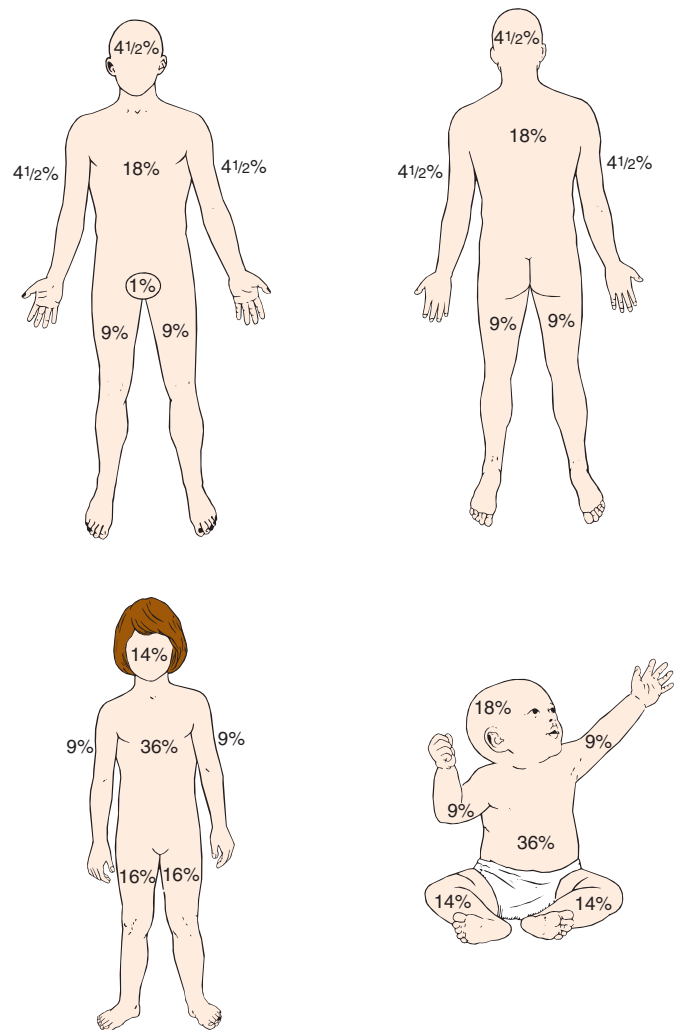

FIGURE 42-3 Rule of nines. Proportions for adults/adolescents, children, and infants are shown. Note the relatively greater surface area of the head and slightly lesser surface area of the lower extremities in young children than in adults.

(From *Mosby's Dictionary of Medicine, Nursing, & Health Professions*, ed 7, St Louis, Mo, 2009, Mosby.)

Severity of Injury

The %TBSA and depth of burn are primary indicators of the severity of injury. A burned surface area of 20% or greater was once the determining criterion for admission to a burn intensive care unit. However, depending on the burn's location, patient's age, and preinjury health, partial- or full-thickness burn wounds of less than 10% TBSA can be considered serious enough to warrant admission.

A review of national data from 1999 to 2008 found that 67% of reported burn sizes on admission were less than 10% TBSA and only 4.8% were 40% TBSA or greater.⁵ This reflects both a decrease in the number of large burn injuries and increased recognition of the importance of specialized burn care experience and facilities for treating significant burn injuries, regardless of size.

Modified Lund and Browder Chart								
Area	Age (Years)					% Partial-thickness	% Full-thickness	% Total

FIGURE 42-4 Modified Lund and Browder chart. Burn size can be determined most accurately in children by using the Lund and Browder chart, which accounts for changes in the size of body parts that occur with growth. (Modified from Lund CC, Browder NC: The estimation of areas of burns, *Surg Gynecol Obstet* 79:352, 1944.)

Deep partial- and full-thickness burns of greater than 30% TBSA usually require a prolonged period to achieve wound closure and intensive rehabilitation for functional recovery. Because of the complexity of medical treatment and rehabilitation, the severity of an injury is greater if inhalation injury occurs or if deep partial- or full-thickness burns involve the hands, face, or perineum.⁹³

Phases of Wound Healing

Wound healing takes place in three overlapping phases: the inflammatory phase, the proliferation phase, and the maturation phase.

Inflammatory Phase

The inflammatory phase usually lasts 3 to 10 days after onset. This phase is characterized by a vascular and cellular response, with neutrophils and monocytes migrating to the wound to attack bacteria, débride the wound, and initiate the healing process. The wound is typically painful, warm, and erythematous (red), and edema develops.

Proliferation Phase

The proliferation phase begins by the third day after the injury and lasts until the wound heals. It is during this phase that revascularization, re-epithelialization, and contraction of the burn wound take place. Endothelial cells bud at the end of capillaries, and they grow and create a vascular bed for new skin growth. Epithelial cells migrate over the vascular bed to form a new skin layer. Fibroblasts deposit collagen fibers, which contract to reduce wound size. During this phase the wound remains erythremic, and raised, rigid scars may develop. The tensile strength of the newly healed scars is poor and they are easily excoriated or injured.

Maturation Phase

The maturation phase generally begins by the third week after initial healing and may last 2 or more years after the initial burn injury or the date of the last reconstructive surgical procedure performed. During this phase, the fibroblasts leave and collagen remodeling takes place. The erythema fades, and the scar softens and flattens. The tensile strength of the scars increases but never recovers

A

B

(Courtesy Edward Vergara, Gainesville, Fla.)

to more than 80% of the original tensile strength of the unburned skin.⁶³

Scar Formation

After initial healing, most burn wounds have an erythematous, flat appearance. As the healing process continues, the wound's appearance may change as a result of scar hypertrophy and contraction. The long-term quality of a mature burn scar can be affected by numerous factors, some of which occur during the early phases of burn care.³⁷ The amount of time needed to achieve wound closure is a strong determinant. Age, race, and burn depth are other variables.³² Bacterial infections in the wound increase the inflammatory response, which can delay wound healing and contribute to scar formation. However, any factor that delays healing will increase the potential for scarring.

Hypertrophic scars are thick, rigid, erythematous scars that become apparent 6 to 8 weeks after wound closure.¹ Histologically, these immature scars have increased vascularity, fibroblasts, myofibroblasts, mast cells, and collagen fibers arranged in whorls or nodules that make the scar appear raised and rigid.^{10,63} Biochemical investigations have discovered increased synthesis of collagen fibers and connective tissue in hypertrophic scars. As a hypertrophic scar matures, capillaries, fibroblasts, and myofibroblasts decrease significantly, collagen fibers relax into parallel bands, and the scar becomes flatter and more pliable. The time needed for scars to mature differs markedly among individuals and depends on genetics (as with Kenjii, who has a genetic predisposition to hypertrophic scarring), the age of the patient, the location and depth of the original burn wound, the presence of chronic inflammation, wound contamination, and other factors that have been reported to influence hypertrophic scarring.^{24,85} Superficial burns that heal in less than 2 weeks will not generally form a hypertrophic scar. Deeper burns that take longer than 2 weeks to heal have a greater potential to form hypertrophic scars. Although most

hypertrophic scars mature in 12 to 24 months,²² excessive scar formation, including keloid scars, may take up to 3 years to mature (Figure 42-5). All three subjects in the case studies were of different age groups and ethnic/genetic background and had different occupational therapy (OT) interventions. Nevertheless, they all experienced serious scarring as a result of their burns.

All scars initially have increased vascularity and a red appearance. Scars that remain erythematous for longer than 2 months are more likely to develop into hypertrophic scars. They become progressively firmer and thicker and rise above the original surface level of the skin. There is a marked increase in the production of fibroblasts, myofibroblasts, collagen, and interstitial material, all with contractile properties that help draw together the borders of a wound but can also result in scar tightness. Pain and skin tightness cause most patients to become less active. These patients prefer to rest in a flexed, adducted position for comfort. This allows the new collagen fibers in the wound to link and fuse together in the contracted position. The fibers become progressively more compact and coil up into the whorls and nodules that give the scar surface the textured appearance that often leads to disfigurement. If the scar extends over one or more joints, the progressive tightness leads to a scar contracture and loss of motion. Fortunately, collagen linkage is less stable in new scars, and restructuring of an immature hypertrophic scar contracture can be influenced by sustained mechanical forces such as proper positioning, exercise, splinting, and compression. Scar hypertrophy and contracture are most active for the initial 4 to 6 months after healing.²²

Initial Medical Management

Fluid Resuscitation and Edema

Immediately after a burn injury, during the inflammatory phase, the permeability of blood vessels increases. This causes rapid leakage of protein-rich intravascular fluid into

A

B

FIGURE 42-6 A, Escharotomies performed on the dorsal surface of a hand with full-thickness burns. B, Electrical injury requiring escharotomy/fasciotomy, which will allow the muscle belly of the forearm to expand and prevent loss of blood flow to the hand. Note the distances between the edges of the incisions and the exposed tendon.

(Courtesy Edward Vergara, Gainesville, Fla.)

the surrounding extravascular tissues.⁵⁷ In larger burns, extensive loss of intravascular fluid can result in hypovolemia or burn shock because of decreased plasma and blood volumes and reduced cardiac output.³⁴ Fluid resuscitation with an intravenous fluid such as lactated Ringer solution is essential for promptly replacing venous fluid and electrolytes. The fluid volume required is determined by various formulas, such as the Parkland and modified Brook formulas,⁸ and is based on the extent of the burn and weight of the patient. The rate of fluid infusion is determined by monitoring the pulse rate, central venous pressure, hematocrit, and urinary output.

The lymphatic system, which normally carries excess tissue fluid away, often becomes overloaded, and subcutaneous edema develops. With circumferential full-thickness burns, loss of elasticity of the burned skin combined with increased edema can cause compartment syndrome, a condition in which interstitial pressure becomes severe enough to compress blood vessels, tendons, or nerves, which could result in secondary tissue damage. When blood vessels are compressed, ischemia, or restriction of circulation, could lead to tissue death in the areas of compromised circulation or even the entire distal end of the extremity. Tight burned tissue can also restrict chest expansion during respiration. Escharotomy, or incision through the necrotic burned

tissue, is performed to release the binding effect of the tight eschar (adherent dead tissue that forms on skin with deep partial- or full-thickness burns), relieve the interstitial pressure, and restore the distal circulation (Figure 42-6, A). In deeper wounds, an incision down to and through the muscle fascia, or fasciotomy, may be required to achieve adequate relief of pressure (Figure 42-6, B).

Respiratory Management

A smoke inhalation injury is a common secondary diagnosis with thermal injury and can significantly increase mortality. When the face is burned, when the burn was caused by a fire in an enclosed space, or when other objective evidence of a possible inhalation injury is present, bronchoscopy, arterial blood gas readings, and chest x-ray examinations are used to confirm the diagnosis. Intubation and mechanical ventilatory support may be required in addition to vigorous respiratory therapy. A tracheostomy is performed if the airway is difficult to maintain or if ventilatory support is prolonged.⁹⁴ This procedure, which involves surgical incision through the trachea and relocation of the ventilation tube to the neck, is more comfortable for the patient, allows oral care, and helps prevent permanent damage to the larynx or vocal cords, which may occur with extended oral intubation.

Wound Care and Infection Control

After a patent airway and fluid resuscitation have been established, attention is directed to wound care. A burn wound is dynamic, and improper treatment (e.g., lack of proper wound care, edema formation, lack of resuscitation) may actually increase the size and depth of the wound.

Wound treatment may involve a combination of surgical and nonsurgical therapy.⁴² Nonsurgical treatment involves the use of products to promote healing in a partial-thickness wound. These products are usually in the form of topical antibiotics, biologic dressings, and nonbiologic skin substitute dressings.

Topical Antibiotics

Topical antimicrobial agents have been shown to decrease wound-related infections and morbidity in burn wounds when used appropriately. The goal of topical antimicrobial therapy is to control microbial colonization, thereby preventing the development of invasive infections.

An ever-increasing variety of topical antimicrobials are used for burn wound care.⁹² Neomycin/polymyxin B/bacitracin antibiotic ointments are often used for facial and superficial burns. The ointment is applied, and the burn wound is left open. Silver sulfadiazine (Silvadene cream, Keltman Pharmaceuticals, Inc.) is a commonly used antibacterial cream applied heavily over larger burns and held in place with layers of gauze dressings. Mafenide acetate (Sulfamylon, UDL laboratories, Inc.) and papain/urea (Accuzyme, DPT Laboratories, Ltd.) topical solution and creams are used to loosen eschar and facilitate débridement through enzymatic digestion.⁶¹ Mafenide hydrochloride cream is hyperosmolar and can be painful when applied to larger areas. However, it is often used on the ears, where it can penetrate eschar to prevent chondritis, or inflammation of the ear cartilage. Mupirocin (Bactroban, GlaxoSmith-Kline Beecham) is an agent used to treat wounds infected with methicillin-resistant *Staphylococcus aureus* and *Staphylococcus pyogenes*.⁸⁷ A modified Dakin solution is a highly diluted, neutral antiseptic solution consisting of 0.025% sodium hypochlorite (household bleach [NaOCl]) and boric acid to neutralize the alkalinity. Its solvent action on dead cells hastens the separation of eschar from living tissue. Nystatin (Nilstat, Lederle Laboratories) may be used in combination with other topical agents for fungal infections caused by secondary immunosuppression. These fungal infections are often caused by long-term antibacterial use, usually originate in the gastrointestinal tract, and can be life-threatening if they infect burns covering a large surface area or invade the bloodstream.

With the improved resuscitation measures developed for burns in the 1960s, infection became the predominant cause of morbidity and mortality. Silver salts and other chemically active silver compounds have been used in various forms because of their potent antimicrobial properties and ability to reduce burn wound infection. These substances have included silver colloidal solution, which

was later replaced by silver nitrate solution, and silver sulfadiazine. Silver sulfadiazine is a water-soluble cream that is usually applied twice a day to the wound surface, as opposed to the continuous soaking required with silver nitrate. Over the past 40 years, silver sulfadiazine has become the preferred option for antimicrobial silver therapy for burns.²³

Recent major technological advances have resulted in the ability to crystallize silver in a nanocrystal form, which can release pure silver onto a wound surface in large quantities. This silver nanocrystalline delivery system is a three-ply dressing that may consist of an inner rayon/polyester core between two layers of silver-coated mesh.^{13,97} The ionic silver and silver radicals are released in high concentration when exposed to water. A layer between the wound and silver membrane maintains moisture for healing and decreases the formation of exudate.²³ The dressings, applied directly to the wound surface, promote healing by stimulating cellular dedifferentiation, followed by cellular proliferation. The dressings also have antibacterial, antifungal, and analgesic properties. These dressings have been found to be highly microbicidal against aerobic and anaerobic bacteria (including antibiotic-resistant strains), yeasts, and filamentous fungi¹³ and can remain active and in place for up to 7 days instead of having to be changed every 12 to 24 hours.

Biologic Dressings

Biologic dressings serve as temporary coverings to close a wound, prevent contamination, reduce fluid loss, and alleviate pain.⁵² Theoretically, biologic products may deliver growth factors to a wound as well. Traditional biologic dressings, such as xenografts (porcine skin) and allografts (human cadaver skin), are still widely used in burn care. Xenografts may adhere to the superficial surface film of partial-thickness burns and facilitate débridement of eschar. Human amnion has also been used as a biologic burn dressing, especially in developing countries.⁸²

Biosynthetic Products

Biosynthetic products have been used widely for burn care. Closure of wounds with these dressings may lead to less pain, faster skin regrowth, and therefore less scarring. They are used until the wound is healed over, typically in 10 to 14 days, and then the dressing peels off.

Biobrane, a biosynthetic skin substitute wound-dressing sheet (Bertek Pharmaceuticals), has been used extensively. It is constructed of an outer silicone film (the epidermal analogue) with a nylon fabric partially embedded into the film collagen. The nylon components bind to the wound surface fibrin and collagen, which results in initial adherence (dermal analogue). Small pores are present in the structure to allow drainage of exudate and increase the permeability to topical antibiotics. However, if used improperly, the dressing can enclose dead tissue in the wound and provide a medium for bacterial overgrowth and invasive wound infection.⁸²

Hydrotherapy

Once the patient's condition is sufficiently stable, hydrotherapy is usually performed at least once a day to remove loose debris and "stale" topical antibiotics. It provides thorough cleansing of both the wound and the uninvolved areas. Hydrotherapy is generally accomplished by placing the patient on a "shower trolley" covered with a sterile plastic sheet and washing and showering the wounds for 20 to 30 minutes. This nonsubmersive showering method of hydrotherapy has become the preferred method of cleansing burn wounds to prevent cross-contamination of wounds between patients and has replaced the traditional whirlpool form of hydrotherapy.^{2,27} Fresh topical agents are then reapplied to delay colonization of organisms and reduce bacterial counts in the burn wounds. During hydrotherapy the patient has usually received some form of analgesics and is unencumbered by dressings. Therefore, hydrotherapy provides an excellent opportunity for the therapist to perform assessments and range-of-motion (ROM) exercises.

Sepsis

Burn wound colonization begins at the moment of injury, with gram-negative organisms replacing normal bacterial flora. Wound cultures and biopsies are performed to monitor such growth when signs of possible serious infection are present.³⁵ A severe infection can result in sepsis, in which the infection spreads from the original site through the bloodstream, a condition known as septicemia. Septicemia initiates a systemic response that affects the flow of blood to vital organs. Bacterial infections are the most common source of sepsis, but it can also result from fungal, parasitic, and mycobacterial infections, especially if the patient is immunocompromised. Broad-spectrum antibiotic therapy is typically initiated. However, if host defenses continue to be overwhelmed, the bacterial by-products or endotoxins accumulate in the bloodstream, a condition known as toxemia, which eventually leads to septic shock, a cardiovascular response that impedes blood flow to the organ systems, and to generalized circulatory collapse. Septic shock may be characterized by ischemia, diminished urine output, tachycardia, hypotension, tachypnea, hypothermia, disorientation, and coma. Septicemia and septic shock often require multisystem supportive measures for recovery, such as the use of cardiovascular medications, hemodialysis, and mechanical ventilation.

Surgical Intervention

Although all burn wounds are treated with some type of topical antibacterial agent, when the depth and extent of the wound require more than 2 weeks for healing, surgical intervention is indicated to decrease burn morbidity and mortality. Surgical treatment of burns usually consists of excision of the nonviable burned tissue, or eschar, and placement of biologic or synthetic skin grafts.

Essentially three types of biologic grafts are available. A xenograft, or heterograft, is processed pigskin. A homograft,

FIGURE 42-7 Meshed skin grafts expand to cover a larger surface area but heal with more scarring and leave a permanent mesh pattern on the skin.

(Courtesy Edward Vergara, Gainesville, Fla.)

or allograft, is processed human cadaver skin. These grafts are used as biologic dressings to provide temporary wound coverage and pain relief. An autograft consists of permanent surgical transplantation of the upper layers or a split-thickness skin graft (STSG) of the person's own skin taken from an unburned donor site.⁷⁵ The STSG is applied to the clean, excised tissues of the burn wound graft site. Skin grafts placed as a sheet have superior appearance and quality, but to cover large surface areas rapidly, the graft may be "meshed" to allow a single sheet of skin to be expanded for coverage of a larger surface area (Figure 42-7). The meshed graft attaches to the burn surface in the same manner as a sheet graft, but the interstices, or openings in the meshed skin, must heal by re-epithelializing over granulation tissue. This leads to more scarring and a permanent mesh pattern on the skin.

Now that the size of a survivable burn has increased, the amount of available donor sites for autografting has conversely decreased. For this reason, alternatives to autografts have been developed. Examples of such alternatives are epidermal cultured skin substitutes,³³ cultured epidermal autografts,^{9,82} and dermal analogues such as Integra (Integra LifeSciences Corp.) and AlloDerm (LifeCell Corp.).⁸² A wound may be limited in size, but the defect may be so deep that survival of bone or tendon is at risk. In these instances, STSG adherence is difficult to achieve, and a full-thickness skin graft or microvascular skin flap may be indicated.⁷⁵

Vacuum-Assisted Closure

Negative pressure wound therapy, also known as vacuum-assisted closure (VAC), is a treatment in which a sealed dressing and controlled negative pressure are used to provide evacuation of wound fluid, stimulate growth of granulation tissue, and decrease bacterial colonization, especially in

deeper wounds.⁵³ Since their introduction, VAC (VAC Therapy; KCI Concepts, San Antonio, Tex) dressings have been used in a number of surgical specialties, including burn care. By assisting in the débridement of necrotic tissue and removal of soluble inflammatory substances, VAC therapy reduces the number of dressing changes required and shortens the time interval between débridement and wound closure. This has been shown to facilitate the growth of granulation tissue even in deep wounds and thus make graft adherence more successful.⁷⁹

Using a VAC device to secure a skin graft prevents fluid collection beneath the graft, ensures full contact between the wound bed and the transplanted skin, and distributes an even amount of pressure over the entire surface, regardless of the irregularity of the recipient bed. However, movement of the recipient surface could compromise the graft if it is not immobilized by proper positioning or splinting.⁸¹ During treatment the therapist must be attentive to the VAC dressings and avoid activities with the patient that could disrupt the seal around the dressing and cause an air leak.

Nutrition

Adequate nutrition is essential during wound healing because the metabolic rate of a patient with a burn injury greatly increases with corresponding increases in protein, vitamin, mineral, and calorie needs.^{51,77} Protein is especially important for wound healing and must be provided in substantial amounts. Nutritional requirements are calculated on the basis of the %TBSA and the patient's admission weight. Calorie counts and the patient's weight are closely monitored to ensure adequate nutrition. If the patient is unable to meet individual requirements through the diet, high-protein and high-calorie supplements are given either orally or through a nasogastric or gastric tube. If the gastrointestinal tract is compromised, intravenous hyperalimentation is frequently necessary for severe burns with extensive %TBSA. This solution contains sufficient amino acids, glucose, fatty acids, electrolytes, vitamins, and minerals to sustain life, maintain normal growth and development, and foster needed tissue repair. It is often infused through a central line catheter into the superior vena cava of the heart. Later, as wound closure is achieved and normal feeding resumes, nutritional demands decrease and the individual's eating habits must be normalized to prevent excessive weight gain.

Associated Problems and Complications

Stress

Traumatic events associated with severe burns include natural and intentional disasters such as tornadoes, lightning, house fires, motor vehicle accidents, acts of war or

terrorism, physical or sexual assault, and the sudden death of loved ones or friends. Burn treatment further traumatizes the patient because of associated painful medical procedures (e.g., wound care, limb amputations, multiple surgeries, and therapies). Mental health professionals are increasing their understanding of the factors associated with increased psychiatric risk and the ways in which burn patients, especially children, cope with the stress and pain triggered by traumatic events. Responses to major stress often include reliving the event, avoidance, and hypervigilance; these responses may continue long after the precipitating event. Post-traumatic stress disorder is a common psychiatric disorder after traumatic experiences, including physical injuries such as burns.^{25,26} Mood, anxiety, sleep, conduct, learning, and attention problems are often comorbid conditions, especially in children. Treatment involves pain assessment followed by specific interventions such as pain management, psychiatric consultation, and crisis intervention initiated promptly after the traumatic event. Intervention should also involve the burn survivor's family.¹⁷

Pain

Pain Assessment

Some of the most commonly used pain assessment tools include visual scales, color scales, word and faces scales, and adjective scales. A 1998 study indicated that patients prefer the faces and color scales over commonly used visual analog and adjective scales.³¹ Pain levels should be assessed during a quiet time and again immediately after any painful activity.

Pain Management

Because pain has adverse physiologic and emotional effects, pain management is an important factor to achieve better outcomes. Developmentally appropriate and culturally sensitive pain assessment, pain relief, and re-evaluation are essential in treatment. Pain control guidelines should address both background and procedural pain and associated anxiety. The occupational therapist should assist nursing staff in focused surveillance of burn pain and its successful treatment.⁵⁵

Pharmacologic treatment is primary, strengthened by new concepts from neurobiology, clinical science, and the introduction of more effective drugs offering fewer adverse side effects and decreased toxicity. Opiates remain the most common form of analgesic therapy for patients with burns, but because these patients require increased opiate dosages, optimal relief of burn pain can be difficult. Alternative pain control methods include acetaminophen as a useful analgesic for minor burns. Nonsteroidal anti-inflammatory drugs and benzodiazepines are often combined with opiates. Anti-depressants appear to enhance opiate-induced analgesia, whereas anticonvulsants are useful in the treatment of sympathetically maintained pain following burns. Ketamine has

been used extensively during burn dressing changes, but psychologic side effects, such as delirium and hallucinations, have limited its use.⁶⁰

Nonpharmacologic intervention using various hypnotic, cognitive, behavioral, and sensory treatment methods is becoming more accepted. Transcutaneous electrical nerve stimulation, topical and systemic local anesthetics, and psychologic techniques are also useful adjuncts.⁶¹ Hypnosis may be a very useful alternative when opioid pain medication proves to be dangerous or ineffective; it has received strong anecdotal support from case reports.⁵⁹ The mechanisms behind hypnotic analgesia for burn pain are poorly understood; however, patients with burn injuries are more receptive to hypnosis than the general population, possibly because of increased motivation, dissociation, and regressive behavior.⁶² Other methods of nonpharmaceutical pain reduction may be helpful. Relaxation techniques that may be of benefit include progressive relaxation, breathing exercises, guided imagery, aromatherapy, music therapy, and teaching individualized coping strategies. As with hypnosis, distraction and relaxation techniques work best with alert, motivated patients.⁵⁶

Patients with a severe burn injury naturally respond to pain by resisting painful motions or activities. Behavioral regression is also a normal response in most children (and many adults). When such regression occurs, the therapist should be supportive and continually explain beforehand what needs to be done and why in terms that the patient can understand.

Most patients are usually more interested in whether the procedure will hurt and how long it will last than in lengthy explanations or technical information. Coordinating treatments with scheduled pain medications is often helpful and highly recommended, especially if active participation is necessary. The therapist should be aware of and use techniques to minimize preventable pain (e.g., applying adequate vascular support to the LEs before standing or ambulation). The therapist must also inform the nursing staff about any noted side effects from pain medication, as well as the observed effectiveness of the currently used pain management regimen. The need for short-term breakthrough pain relief should be coordinated with the nursing staff to reduce discomfort and stress during intensive therapy procedures. If a patient's anxiety or pain is disproportionate to the treatment, antianxiety medication may be indicated both to relieve anxiety and to increase the effectiveness of pain medication. Time limits on painful treatment sessions should be predetermined with all patients who are cognizant and capable of participation. The therapist should consistently adhere to these time limits to foster trust and a sense of control for the patient. By reducing the patient's anxiety, the therapist reduces the fear factor that can exacerbate perceived pain.⁶⁸ As the wound heals, the amount of narcotic analgesia is gradually decreased, and patients usually require minimal pain medication by discharge (see Chapter 28).

Psychosocial Factors

After a burn injury there is a potential for psychologic reactions, including depression; withdrawal reactions caused by disfigurement; behavioral regression; and anxiety over the ability to resume work, family, community, and leisure roles.²⁹ The way in which a person copes with burn trauma is strongly influenced by his or her psychologic status before the injury and whether the injury was a result of accident, arson, assault, or suicide attempt. The psychologic ramifications can include guilt, anxiety, depression, regression, increased hostility, and existential crisis.⁵⁶ In the case of permanent loss of function and deformity, the patient may experience severe grief as a result of decreased physical abilities, changes in personal appearance and identity, loss of vocation, or loss of loved ones who were killed in the same accident. In the case of facial disfigurement and amputations, the patient's previous support system may also be reduced or lost as a result of abandonment by friends or significant others who cannot adjust to the physical changes in the patient.

Whether the permanent loss is social or physical, the patient may need to move through stages of grief similar to the five stages of grief in patients with a terminal diagnosis as described by Dr. Kubler-Ross in her book *On Death and Dying*.⁴⁶ The stages include the following:

- Denial and isolation. "I can't believe this happened to me ... it will be okay ... just go away!"
- Anger. The patient may express anger toward others, self, or the circumstances and be belligerent and uncooperative.
- Bargaining. Typically, this is the stage of procrastination (e.g., "I'll exercise tomorrow"). Children and teenagers are particularly adept at procrastination because they do not always understand the long-range effects of the burns.
- Depression. The patient grieves for loss of lifestyle and personal appearance and may experience guilt about surviving when a loved one did not.
- Acceptance. The patient learns to accept a new body image, physical and social limitations, and other losses. At this stage it is important to help the patient focus on remaining abilities, develop new skills, and expand or replace social support systems.

If the patient does not reach the stage of acceptance, the rehabilitation process could be severely impaired. Providing emotional support and education and helping the patient develop coping mechanisms and self-direction can promote the psychologic adjustment of patients with burn injuries. However, a severe burn injury occasionally results in a reassessment of personal values and relationships or a renewed appreciation of life. The complex interactions among pre-morbid personality style, extent of injury, and social and environmental contexts should be considered when determining how patients will adjust psychologically to a severe burn injury.⁵⁶

OT Practice Notes

OT intervention must address the psychologic aspects from the initial assessment and onset of OT intervention and continue through discharge from OT services at the end of the rehabilitation phase. Even after discharge from rehabilitation, the client may continue to need psychosocial OT intervention as he or she attempts to become actively involved in the community, resume social activities and relationships, and return or enter the paid workforce.

Burn Rehabilitation

The Team

Successful care and rehabilitation of burn survivors require a multidisciplinary team approach that begins immediately after the patient's admission to the hospital and continues through and beyond hospitalization.^{8,73} Ideally, the burn care team includes physicians, nurses, physical and occupational therapists, respiratory therapists, nutritionists, social workers, psychiatrists and psychologists, speech and language pathologists, orthotists and prosthetists, child care and recreational therapists, pastoral caregivers or clergy, interpreters or cultural support personnel, and vocational counselors. The most important members of the team, however, are the client and the client's family or support system.^{78,83}

OT Practice Notes

All health care professionals must continue to update their knowledge and professional competencies and keep abreast of the rapidly changing treatments and therapies available for treating burned patients.⁸³ Recommended ways to continue professional development include the following:

- Review professional journals such as the *Journal of Burn Care and Rehabilitation*, *Burns*, *Journal of Wound Care*, *Journal of Trauma*, and *Journal of Burns*.
- Obtain membership in burn care associations such as the American Burn Association and the International Society of Burn Injuries.
- Attend local, regional, and national association meetings. Visit regional burn centers to confer with other burn therapists.
- Visit online Websites of professional burn associations, and participate in online discussions with other burn care professionals.

Goals of Rehabilitation

The entire burn team is involved in some aspect of burn rehabilitation, whether for providing verbal support, preparing the patient for self-care tasks, reinforcing the importance of active motion, or providing patient

education. The long-term goals of OT are quite similar to the long-term goals of the entire burn team. Although specific goals may be the responsibility of various team members, everyone's efforts are focused on the same outcome. OT treatment goals should therefore be compatible with all other treatment regimens and be established in collaboration with the patient, family, and entire rehabilitation team. Inherent in this concept is the need for close communication and cooperation of all burn team members. OT should take the lead in helping all team members understand the client as a unique occupational being, along with all the relevant factors and contexts that will come into play. Role delineation between different disciplines, especially OT and physical therapy, differs among burn care facilities and may be determined by insurance reimbursement rather than by traditional roles or the specialized skills of the individual therapist. Therefore, it is especially important that all disciplines work closely together with ongoing communication so that patients benefit from the skills and viewpoints of all areas of specialization. Occupational, physical, and speech therapists who specialize in burn rehabilitation increasingly use cotreatments that promote independence in both mobility and activities of daily living (ADLs).

Phases of Recovery

Rehabilitation management of burn survivors can be divided into three overlapping phases to aid in categorizing and determining effective intervention goals. These phases of recovery are the acute care phase, the surgical and postoperative phase, and the inpatient and outpatient rehabilitation phase.

The acute care phase is usually the first 72 hours after a major burn injury. However, if the burn is superficial partial thickness and heals spontaneously in less than 2 weeks without surgical intervention, the time from injury until epithelial healing is also considered an acute care phase.⁷²

The surgical and postoperative phase follows the acute phase and continues for varying lengths of time, depending on the size of the burn injury and the presence of associated medical complications. During this period, vulnerability to wound infection, sepsis, and septic shock is especially great, and medical treatment is focused on promoting healing and minimizing infection.

The rehabilitation phase covers both inpatient and outpatient care and can extend for an indeterminate length of time. This phase follows the post-grafting period, when the patient is medically stable and most open wounds have healed. The quality of wound healing, scar formation, and need for aggressive rehabilitation make this the most challenging phase for burn patients, their families, and their therapists.

Acute Care Phase

During the acute care phase, medical management is of utmost importance for survival of the patient, and the goal of OT is primarily preventive. As the patient recovers and

wound closure progresses, the nature of OT also changes, with treatment directed at restoring function. Initially, however, when the wounds are deep partial or full thickness, the acute care rehabilitation goals are as follows:

- Provide cognitive reorientation and psychologic support.
- Reduce edema.
- Prevent loss of joint and skin mobility.
- Prevent loss of strength and activity tolerance.
- Promote occupational performance, such as independence in self-care skills.
- Provide patient and caregiver education.

Surgical and Postoperative Phase

Rehabilitation goals during the surgical and postoperative phase are focused on preserving or enhancing performance skills and patterns while supporting surgical objectives. Excision and grafting procedures usually require periods of immobilization of the areas treated to allow graft adherence. The preferred position and length of immobilization will vary by physician prerogative and burn center protocol, with the average period of immobilization being between 2 and 7 days.^{16,39,75,80} The most advantageous postoperative position usually maintains the grafted area in the position that maximizes the surface area of the grafted site. For example, a hand with a dorsal burn should be splinted with the wrist in a neutral or flexed position, the metacarpophalangeal (MP) joints flexed, and the thumb abducted and in opposition to the fifth digit to stretch the dorsal surface of the hand.

During this phase the goals of therapy include the following:

- Promote cognitive awareness by providing orientation activities when necessary, and continue psychologic support.
- Protect and preserve graft and donor sites by fabricating splints and establishing positioning techniques that support the surgeon's postoperative care orders.
- Prevent muscular atrophy and loss of activity tolerance, and reduce the risk for thrombophlebitis by providing exercise for areas that are not immobilized.
- Increase independence in self-care by teaching alternative techniques and providing adaptive equipment as needed.
- Educate and reassure the patient and family members regarding this phase of recovery.

Rehabilitation Phase

The third phase of recovery is the rehabilitation phase, which begins as wound closure occurs. Individuals with large %TBSA burns frequently enter this phase needing further surgery. However, the majority of their wounds are closed, and scar maturation is commencing. The focus of intervention during this phase is on maximizing function

and participation in occupations, promoting physical and emotional independence, and managing scar formation to prevent or correct deformity and contracture formation. Patient and family education is especially important for developing competence in wound/scar care and therapy programs in preparation for discharge.

The rehabilitation phase extends past hospital discharge and continues until maturation of all burn wounds and surgical sites is complete. Before discharge from the hospital, emphasis is placed on independence, self-management, and education. Once the client is home, emotional support and intervention must continue to help sustain the client's confidence, self-esteem, and motivation, qualities that the client needs to cope with the physical, social, and emotional consequences of a severe burn injury.

Intervention goals for this phase can be exhaustive given the potentially disabling effects of burn scars. Therefore, it is important for the therapist to incorporate the patient's personal goals from the very beginning of the rehabilitation process.

Treatment goals for the rehabilitation phase are expanded to include the following:

- Continue to provide psychologic support as the patient progresses toward physical and emotional independence and faces new challenges.
- Improve joint mobility and reduce contractures by using correct positioning, sustained passive stretching exercises, and splinting as needed.
- Restore muscle strength, coordination, and activity tolerance.
- Initiate a compression therapy and scar management program with the use of vascular support garments, custom scar compression garments, and pressure adapters to minimize scar hypertrophy, contractures, and disfigurement.
- Promote independent self-care skills or the ability to direct others to assist when needed, including appropriate positioning, exercise, and skin care. Provide instruction and opportunities to practice instrumental activities of daily living (IADLs), including vocational and home-care activities.
- Continue to provide instruction on scar development, including potential sensory and cosmetic changes, scar management techniques, and related safety precautions.
- Guide the implementation of a post-discharge plan that supports resumption of school, work, social, and leisure occupations.

Occupational Therapy Evaluation

Although medical status issues are a primary concern during acute care, whenever possible the occupational therapist should complete an initial evaluation within the first 24 to 48 hours after hospital admission. Burn etiology, medical history, and any secondary diagnoses are obtained from the medical record and team. The wounds are then visually

assessed to determine the extent and depth of injury. Any areas affecting future occupational performance and context are noted and documented.

Whenever possible, both the client and family are interviewed to establish rapport and to obtain a history of the client's previous occupational performance. This history should include preinjury body structures and body functions (i.e., hand dominance, previous injuries, and performance-limiting illnesses or conditions) and specific information on past performance skills and patterns, daily routines, and activities (including professional, educational, and domestic responsibilities). Obtaining data concerning preinjury personality traits and psychologic status is equally important. With this information, the therapist can monitor for changes in the client's behavior and cognitive functioning and choose the most appropriate interactive approach to encourage involvement of the client in goal setting and the therapy process. In the case of a severe burn requiring intubation and mechanical ventilation, this information must be obtained from family members and significant others to verify and supplement what the patient may relay nonverbally.

OT Practice Notes

Ideally, the client's history of occupational performance would be obtained before assessment of current client factors. However, the acuity of the injury, time constraints, and the need to coordinate physical assessment with pain medications, wound dressing changes, and other medical procedures may supersede completion of a detailed performance history.

Involved and uninvolved areas should be evaluated for joint mobility, strength, sensation, and functional use. However, before beginning this evaluation, the therapist should explain the purpose of OT and what the client should expect during the assessment, including the potential for discomfort. Pre-assessment instruction and ongoing encouragement help reassure clients and decrease anxiety so that they can perform at their best. Emphasis is placed on the ultimate long-term goal of resuming engagement in meaningful occupations and participation in life contexts.

The initial clinical evaluation should address all areas of potential OT intervention, including assessment of wound location and severity, presence and severity of edema, passive range of motion (PROM) and active range of motion (AROM), muscle strength, gross and fine motor coordination, changes in sensation, and level of cognitive awareness. Ideally, these assessments take place during a dressing change or hydrotherapy, when the involved areas are exposed and unencumbered.

During the initial evaluation, distinctions are made among superficial, superficial partial, and deep partial-thickness burns, as well as full-thickness burns, on the basis

of appearance and presence of sensation. The therapist must view the wounds as soon as possible after the injury, before the development of burn eschar. Eschar causes deep partial-thickness burns to closely resemble full-thickness burns and makes accurate evaluation of depth difficult. Attention should also be directed to burned joint surface areas and the presence of any circumferential burns. ROM assessment should be performed to evaluate joint mobility, and general strength should be tested before significant edema develops or restrictive dressings are applied.

Instructing the client regarding the types of movements and the number of repetitions expected while gently guiding the individual through the specific motion can help ensure achievement of full range. When possible, a goniometer should be used for assessing ROM to accurately document baseline deficits and future changes in recorded measurements. If pain, edema, tight eschar, or bulky dressings limit full ROM, such information should also be documented. Pre-existing conditions that may alter expected AROM should be investigated during the patient and family interview. Although AROM is preferred, PROM should be measured if a client is unresponsive or unable to move the extremity sufficiently. When using PROM, care must be taken to not apply excessive force, especially with older clients who have degenerative joint disease or small children with hypermobile joints.

With deeper partial- or full-thickness dorsal hand burns, boutonnière precautions should be initiated until the integrity of the hand's extensor hood mechanisms can be verified. Boutonnière precautions involve avoidance of composite active or passive flexion of the fingers. Instead, isolated MP flexion is combined with interphalangeal (IP) joint extension to prevent stress and possible damage to a compromised extensor tendon mechanism. All passive proximal interphalangeal (PIP) flexion is avoided, and protective splinting is promptly initiated to maintain the PIP joints in extension.

A gross sensory screening that includes all sensory distribution areas should be performed. Such screening is especially important in individuals with electrical injury or a history of long-standing diabetes, in whom peripheral neuropathies may be present.

If the client possessed normal functional muscle strength before the injury, an initial test of gross muscle strength may not be needed if the AROM assessment reveals adequate strength to work against gravity. Manual muscle testing of major muscle groups is indicated if the burn resulted from an electrical contact injury, if the presence of severe edema might cause compartment syndrome, or if other musculoskeletal or neurologic injuries are suspected.⁹⁶ If the hand is unburned or if the burn is superficial partial thickness, a dynamometer and pinch gauge provide objective baseline measurements of grip and pinch strength.

ADL assessment begins by interviewing the client or the family to obtain the client's preinjury level of physical, cognitive, and social performance skills and patterns. When

TABLE 42-2 | Components of Evaluation for Burn Rehabilitation

Initial	Inpatient Rehabilitation	Outpatient Rehabilitation
Cause of the burn	Graft adherence	Skin or scar condition
%TBSA	Skin or scar condition	Compression garment fit
Depth of the burn	Contracture concerns	Volumetrics if needed
Area(s) involved	Edema (if present)	ADL performance level
Age, hand dominance	ADL performance level	Work skills
Functional status	Work skills	Active and passive ROM, TAM
Occupation	Active and passive ROM, TAM	Strength and activity tolerance
ROM and strength	Strength and activity tolerance	Developmental level (child)
Mobility and activity tolerance	Developmental level (child)	Psychologic status
Developmental level (child)	Psychologic status	Social support
Psychologic status	Social support	Leisure activities
Social support	Leisure activities	Compression garment needs
Leisure activities	Compression garment needs	Home management
	Home management	Home care understanding

ADL, activity of daily living; ROM, range of motion; TAM, total active motion; TBSA, total body surface area.

the burn injury is severe, the ADL assessment is postponed until the client is medically stable and able to participate in the pursuit of more advanced occupational goals. Clients with less severe burns and those who are not mechanically ventilated should be assessed for basic ADL skills, such as feeding, basic grooming, and donning and doffing of hospital gowns. Any compensatory actions or awkward movements used to complete the activity should be noted. Any abnormal patterns should be investigated and discussed to determine whether they were present before the burn injury.

After completion of the initial evaluation (Table 42-2), short- and long-term goals should be established with the client's collaboration. The client's previous context and lifestyle, personal long-term goals, and current priorities should be taken into account when establishing OT intervention goals. All short-term goals should be specific and realistic and have an established time frame for completion. After goals are agreed on, the intervention plan can be formulated. The OT intervention plan should be practical and should complement and support the goals of the other team members.

Two fundamental principles must be kept in mind when working in burn rehabilitation: (1) the main factor hindering post-burn functional recovery is the formation of scar contractures and hypertrophic scarring, and (2) severe scars and contractures are often preventable with prompt therapeutic intervention.⁶⁹ Therefore, most burn rehabilitation intervention techniques and objectives are directed at prevention, as well as restoration.

Occupational Therapy Intervention

Acute Care Phase

Preventive Positioning

The purpose of preventive positioning is to reduce edema and maintain the involved extremities in an antideformity position (Table 42-3). Proper positioning is critical because the position of greatest comfort for the patient is usually the position of contracture.⁴⁷ The typical position of comfort consists of adduction and flexion of the UEs, flexion of the hips and knees, and plantar flexion of the ankles. The toes are generally pulled dorsally. Acutely burned hands are held by edema in a dysfunctional position consisting of wrist flexion, MP extension, IP flexion, and thumb adduction. This position, often called the "clawhand" or "intrinsic minus" position, can lead to severe dysfunction if not prevented during active scar formation.

Positioning needs are determined during the initial wound assessment by evaluating the surface areas burned and the presence of edema, considering the posture that the individual tends to assume, and assessing whether that posture would limit function if allowed. For example, if the burn injury involves the shoulder, chest, and axillae, the client's UEs should be elevated and positioned in approximately 90 degrees of shoulder abduction, 45 degrees of external rotation, and 60 degrees of horizontal adduction by using pillow inclines and arm boards or supporting the arms with sheepskin slings suspended from an overhead traction rig (Figure 42-8). Achieving full shoulder flexion

■ **TABLE 42-3** | Antideformity Positioning for Specific Areas of the Body Following Burn Injury

Body Area	Antideformity Position	Equipment and Technique
Neck	Neutral to slight extension	No pillow; soft collar, neck conformer, or triple-component neck splint
Chest and abdomen	Trunk extension, shoulder retraction	Lower the top of the bed, towel roll beneath the thoracic spine, clavicle straps
Axilla	Shoulder abduction of 90 to 100 degrees	Arm boards, airplane splint, clavicle straps, overhead traction
Elbow and forearm	Elbow extension, forearm neutral	Pillows, arm boards, conformer splints, dynamic splints
Wrist and hand	Wrist extension to 30 degrees, thumb abducted and extended, MP flexion of 50 to 70 degrees, IP extension	Elevate with pillows, volar burn hand splint
Hip and thigh	Neutral extension, hips in 10 to 15 degrees of abduction	Trochanter rolls, pillow between the knees, wedges
Knee and lower leg	Knee extension; anterior burn: slight flexion	Knee conformer, casts, elevation when sitting, dynamic splints
Ankle and foot	Neutral to 0 to 5 degrees of dorsiflexion	Custom splint, cast, AFO
Ears and face	Prevent pressure	No pillows; headgear

AFO, ankle-foot orthosis; IP, interphalangeal; MP, metacarpophalangeal.

FIGURE 42-8 Shoulder positioning using slings and overhead traction rigging. Lightweight loads allow active movement but encourage abduction as the patient relaxes.

and abduction with frequent exercise and activity is critical to prevent axillary contractures and subsequent loss of overhead reach as wound healing progresses. Once positioning needs are determined, illustrated guidelines should be posted at the bedside so that the nursing staff and team can assist in ongoing correct positioning (Figure 42-9).

After admission, positioning is initiated primarily to reduce edema formation.⁶⁶ Elevation of the entire extremity above heart level can reduce the severity of distal edema formation, especially when paired with AROM exercises. As

edema decreases and wound closure progresses, positioning goals should be directed toward prevention of skin tightness over joint surfaces (see Table 42-3).

Splinting

Splinting is initiated to maintain correct positioning and protect compromised tissues. It is not necessary for splints to be worn at all times to prevent contractures. When a splint is used during the acute phase, it is generally static in design and applied when at rest, with activity and exercise being emphasized during waking hours. Volar hand splints are indicated if a burned hand has chronic edema, active motion is limited, or unsupervised movement is contraindicated because of deep dorsal burns or other traumatic injury. The typical volar hand splint provides approximately 15 to 30 degrees of wrist extension, 50 to 70 degrees of MP joint flexion, full IP joint extension, and combined thumb abduction and extension (Figure 42-10).^{22,70} Elbows or knees should be splinted at approximately 5 degrees of flexion to avoid joint hyperextension and subsequent pain.

When checking the fit of any splint, the therapist should consider potential pressure points and ensure correct placement. Splints fabricated shortly after injury require daily assessment and may require alterations to accommodate any significant changes in edema. Hand splints are secured in place with a figure-of-eight wrap of gauze bandage and elastic wraps, with the fingertips being exposed so that circulation can be monitored. Folded 4 × 4-inch gauze sponges are used over the proximal phalanges and under the

FIGURE 42-9 Highly visible bedside posters are beneficial as reminders to the client, staff, and visitors regarding positioning, exercises, and splinting instructions.

FIGURE 42-10 Post-burn hand splint secured over compression bandages in a figure-8 pattern to apply the wraps.

wrap to keep the fingers extended and secured in the splint. Detachable straps, though convenient for later use, may be inappropriate for use with acute burn splints because of infection control concerns and the potential for constriction during fluctuations in distal edema.

When the external ear has sustained a partial- or full-thickness burn, protection is desirable to prevent further

damage caused by pressure from pillows, dressings, or endotracheal tubing. An ear protection splint should be fitted at the earliest opportunity and worn until the external ear burns have healed. The splint can be fabricated from two thermoplastic ear cups or cushioned oxygen masks secured in place with a dressing or a three-point stabilizing strapping technique.^{21,43}

Activities of Daily Living

A client's ability to perform self-care is often limited during the acute care phase because of his or her current medical condition. The need for artificial ventilation, multiple lines, catheters, and other supportive equipment interferes with independence in ADLs, and clients are dependent on nursing staff for self-care.

While the client is maintained on the ventilator and orally intubated, ADL activity may be limited to self-suctioning of the oral cavity and, if no facial burns have occurred, basic facial hygiene. After extubation, oral care is often the next ADL attempted. When the client is medically cleared to take fluid or food by mouth, the occupational therapist should assess self-feeding abilities. Airway damage, accompanied by compromised speech and swallowing ability, often results from an extended period of intubation or direct damage during the burn injury. In these cases, the occupational therapist works in concert with the speech pathologist on common goals that promote effective communication skills and independent self-feeding. Burns involving the UEs and associated pain, dressings, and edema may interfere with self-feeding motions and make temporary use of adaptive equipment necessary. This equipment may include built-up or extended handles on utensils, a plate guard, or an insulated travel mug with a lid and straw. Hair grooming and shaving are other self-care activities to initiate early, depending on the client's strength and activity tolerance.

In the acute phase, ADL tasks should be selected that are valued by the client and have a high probability of success even though temporary adaptations may be necessary. Modifications in the client's environment, equipment, or previous performance patterns may be necessary to support independence. However, eventual discontinuation of adaptive techniques and devices is a long-term goal of therapy and should be presented to the client as a sign of progress during the course of therapy. A goal shared by both the client and therapist alike should be independence in all ADLs using previous performance patterns, completed within an appropriate length of time and with minimal adaptations.

Therapeutic Exercise and Activity Tolerance

Sitting tolerance, transfers, and ambulation activities are initiated as soon as the client is medically cleared to get out of bed and bear weight on his or her LEs. If the client has burns on the LEs, elastic wraps should be applied before the client sits up and the feet become dependent. A

figure-of-eight pattern should be used from the base of the toes, over and including the heel, to at least the knees, and up to the groin as needed. When the client is sitting in a chair, the LEs should be kept elevated. Any time spent dangling the feet or standing statically should be limited to prevent distal venous congestion and unnecessary discomfort.

In addition to functional activities, active exercise is a primary component in every burn treatment plan. The exercise techniques used during acute care are not unique to the injury. Active, active assisted, or passive exercises are used, depending on the client's condition. The focus of exercise in acute care is to preserve ROM and functional strength, build cardiopulmonary endurance, and decrease edema.

Strengthening activities are introduced into the acute care intervention program as soon as the patient's condition allows. Such activities range from simple active movement to resistive activities, as tolerated, to counteract the deconditioning effects of hospitalization. Exercise after a severe burn injury was once thought to overstress an already hypermetabolic client. However, research and experience have shown that graded, progressive exercise is beneficial in recovering from acute burns.⁴⁰

Client Education

Although client education is the responsibility of all burn team members, success of the OT intervention program depends on the client's recognition of long-term activity demands, contextual needs, and role responsibilities. Initial educational objectives should focus on developing an understanding of the stages of burn recovery, the need for and importance of independent activity and motion, and pain and stress management techniques. Meeting these goals promotes motivation, active participation, and engagement in occupation, which are so essential for successful treatment outcomes.³⁰

Surgical and Postoperative Phase

Positioning and Postoperative Splinting

Excision and grafting procedures usually require a period of postoperative immobilization to allow adherence and vascularization of the grafted skin.²¹ It is beneficial for the occupational therapist to discuss postoperative positioning needs with the surgeon before surgery so that splints and positioning devices can be prefabricated and applied in the operating room immediately after the surgical procedure. A wide variety of materials and protocols are available. All have the common purposes of immobilizing the grafted area, preventing edema, and assisting in wound healing.⁷²

Postoperative positioning may follow standard positioning techniques or may be unique and designed exclusively for the specific surgical procedure. Although standard burn splints position the extremity in the antideformity position, preoperative or postoperative splints should hold the extremity in the position that promotes the greatest surface

FIGURE 42-11 Thermoplastic total-contact ankle dorsiflexion splint to prevent plantar flexion contracture.

area for graft placement. For dorsal hand grafts, the wrist is positioned in neutral, the MP joints in flexion, and the thumb in abduction to maximize the dorsal grafted surface area. Another example is that in which an axillary advancement flap is performed; the shoulder is abducted only 45 degrees. Gaining prior knowledge of the surgical procedure and determining potential postoperative complications enable the therapist to establish effective positioning and splinting procedures.

Although postoperative immobilization is often achieved through the use of bulky restrictive dressings and standard positioning equipment, splints are frequently needed to maintain the position. Most splints are typically made with plaster bandages or thermoplastic material (Figure 42-11). If a wet dressing will cover the graft site, a perforated or open-weave splinting material may be preferred to permit continuous drainage and prevent graft maceration.²¹ In some instances, movement of adjacent joints may disrupt graft adherence even though the graft does not cover the joint surface. In these cases, the splint design should incorporate immobilization of those joints in a functional position. A postoperative thermoplastic splint can generally be made by using a drape-and-trim technique.²¹ Most postoperative splints are molded into positions for temporary use and are discontinued once graft adherence is ensured. However, if the splints are made of thermoplastic material, they can later be remolded into the antideformity position.

Therapeutic Exercise and Activity

Throughout the postoperative phase of care, active and resistive exercise of the uninvolved extremities should be continued when possible to prevent loss of ROM and strength. Immediately after excision and grafting procedures, exercises for adjacent body areas are usually discontinued for a short time. Although the time varies among burn centers, the average period of immobilization is 3 to 5 days for most STSGs and 7 to 10 days for cultured

epithelial grafts.^{16,30,39,75} Exercises can be resumed as soon as graft adherence is confirmed. Before resuming exercises, the occupational therapist should view the grafts and adjacent areas to determine graft integrity and whether any tendons are exposed or subcutaneous tissues are compromised.

Gentle AROM is the treatment of choice to avoid shearing of the new grafts. If the client exhibited normal ROM before surgery and was immobilized for only 3 to 5 days, baseline ROM should be expected within 3 days after resumption of activity. Active exercise of a body area with a donor site is generally permitted after 2 to 3 days if no active bleeding is present. Donor sites on the LEs are treated similar to burns on the LEs; therefore, standard treatment involves elevation and wrapping with elastic bandage.

Ambulation following excision and grafting of the LEs is not usually resumed until 5 to 7 days after surgery. With the physician's consent, the client is encouraged and assisted to ambulate for short distances and then slowly increase the distance. Before ambulation, double elastic bandage wraps should be applied over a fluff gauze dressing to prevent shearing of the graft or vascular pooling. Use of an elastic bandage, elevation, and a stance that discourages static positioning is particularly important for protecting grafts on the LEs. When the client is able to walk, exercise on a stationary cycle ergometer is beneficial for increasing activity tolerance.

Activities of Daily Living and Client Education

Self-care and leisure-promoting activities should be continued and increased in a way that is commensurate with the demands of the activity, the client's physical abilities, and the client's tolerance of activity. Self-care is often difficult during this phase because of the immobilization positions necessary to ensure graft adherence. If a UE is immobilized, creative ADL adaptations may be needed to allow clients continued involvement in their care and control over their environment. Though only temporary, simple techniques such as universal cuffs strapped over splints or extended-handle utensils help preserve newly reacquired independence and foster confidence and feelings of self-actualization. Continued psychosocial support and burn care education are also essential to ensure understanding of post-surgical precautions and procedures.

Rehabilitation Phase: Inpatient

The rehabilitation phase generally begins when a severely burned patient no longer needs the intensive wound care provided by the burn unit. Most of the wounds are now closed, and the patient may move to a step-down unit or transfer to a rehabilitation setting. Here, patients are expected to assume a more active role in establishing treatment goals, demonstrate more independence in their care, and fully participate in their therapy. An upgraded exercise program, a variety of self-help and rehabilitation equipment, and new techniques are introduced to help increase ROM, strength, activity tolerance, and independence in

higher-level ADLs and IADLs. Intervention and patient education focus on work, recreation, and the self-care skills necessary to help prepare clients for returning to normal daily activity routines, including resumption of previous performance patterns and roles. Potential roadblocks to resuming participation in occupation in previous personal contexts, including community re-entry concerns and psychologic adjustments, are anticipated and addressed during this phase.

Reassessment and Intervention Goals

As wound closure occurs, scar formation develops, and clients frequently report increased skin tightness that restricts certain functional movements and inhibits completion of ADLs. Intervention techniques to counteract the effects of scar development include skin conditioning, scar massage, compression therapy, therapeutic exercise preceded by slow, gentle sustained stretching, and splinting.

During the inpatient rehabilitation phase, OT evaluation should emphasize a thorough ongoing assessment of performance skills. Active and passive goniometric measurements should be taken to document any limitations caused by joint restrictions or scar tightness. Joint-specific measurements can be used to document individual joint restriction, but if skin tightness affects several joints in the same extremity, the total active motion measurements or total passive motion measurements of all the joints in a combined movement pattern should be documented. If the injury is unilateral, measurements taken from the unaffected side can be used to establish normal values for the injured extremity. Muscle strength can be measured by manual muscle testing (MMT). However, if MMT is used, caution is required when the therapist applies resistance to avoid shearing of newly healed skin. Other components of the evaluation should include muscular and cardiopulmonary endurance, performance of self-care and home management activities, skin integrity, presence of edema, and scar development indicating the need for scar compression garments (see Table 42-2).

Treatment goals during inpatient rehabilitation are to increase ROM, strength, and activity tolerance to achieve independence in self-care; begin skin conditioning; aid in psychologic adjustment; and provide patient and caregiver education, including familiarizing the client with the care necessary for discharge from the hospital. Although these goals are continued and progressively increased during the outpatient rehabilitation phase, other goals are added as the client prepares for reintegration into the home and community.

Skin Conditioning and Scar Massage

Skin-conditioning techniques are used to improve scar integrity and durability against minor trauma caused by pressure or shearing forces, decrease hypersensitivity, and moisturize dry, newly healed skin. These techniques should

be used for any burned areas or surgical sites that took longer than 2 weeks to heal. Lubrication and massage with a water-based cream or lotion should be performed three to four times a day or whenever the skin feels excessively dry, tight, or itchy. This action provides needed lubrication for skin that is dry because of damaged sweat and sebaceous glands. Massage is beneficial for desensitizing well-healed but hypersensitive grafted areas or burn scars and for softening tight scar bands during sustained stretching exercises. When massaging a scar band, the therapist should be sure that the scar is fully stretched and premoisturized to reduce shearing forces and prevent splitting of immature or unstable, problematic scar tissue. Massage should be performed in a circular motion, with more pressure applied gradually as tolerated over time. Because of damaged or lost skin pigment, burn survivors are at a greater risk for sunburn. Precautions, including the use of sunblock and avoidance of prolonged sun exposure, are taught before the client is discharged.

Compression Therapy

Compression therapy should be initiated early in the inpatient rehabilitation phase, as soon as most of the larger wounds are closed. Temporary interim pressure bandages or garments assist in general skin desensitization, edema control, and early scar compression. The type of

compression chosen and the degree of compression gradient applied depend on how much pressure and shear force that the client's newly healed skin can initially tolerate; both are upgraded as the integrity of the skin improves. Selection of an interim compression bandage or garments is based on the degree and consistency of pressure that it applies, the ease of application, and the potential for damage from shear forces during application.¹⁵ Elastic bandage wraps, self-adherent elastic wraps, tubular elastic support bandages, pre-sized elastic pressure garments, and commercial or custom-made elastic garments are all commonly used (Figure 42-12).^{7,22} Approximately 5 to 7 days after removal of the postoperative dressings, temporary compression dressings or garments can usually be applied. Tubular elastic bandages, pre-sized or ready-made temporary elastic garments, Spandex "bicycle pants," and Isotoner-style gloves can be worn over light dressings. When patients have small open areas requiring minimal gauze dressings, a standard knee- or thigh-high nylon stocking can be applied over the dressings before the donning of tubular bandages or garments to reduce shearing forces and prevent displacement of the dressings. Temporary compression dressings and garments are taken off only for bathing, dressing changes, skin care, and garment laundering. Independent donning and doffing of interim garments are incorporated into the client's ADL training.

FIGURE 42-12 Early compression techniques: tubular elastic dressings, ready-made gloves and chin strap, custom-fabricated foam collar, and padded clavicular strap to preserve the neck and axillary contours.

Therapeutic Exercise and Activity

Newly healed skin tends to blister as a result of shearing forces or to split as a result of overstretching, especially when the skin is dry. Every therapy session should therefore begin with massage of the scars with a moisturizing lotion to prepare the dry or tight skin for increased motion. Whenever possible, clients should learn to perform their own skin care independently before their scheduled therapy. Once the scars are moisturized and lubricated, stretching is performed to increase the flexibility and fluidity of movement. Stretches should be slow and sustained, and forceful dynamic stretching should be avoided, with attention given to the position of adjacent joints during the stretching motion.

Massage with additional moisturizers during stretching exercises helps relieve itching and discomfort. Stretching in front of a mirror provides positive visual feedback for the patient and is helpful in correcting abnormal posturing. The therapist and client should see blanching of the scar as confirmation of an effective stretch.

AROM exercises, strengthening, and tasks to increase activity tolerance should follow stretching exercises. During the rehabilitation phase, emphasis is placed on flexibility exercises using complex motions that require the movement

of several joints simultaneously. An activity that requires hand manipulation skills while reaching overhead is an example of a complex motion for a burn injury that involves the shoulder, elbow, and hand. Most ADLs require complex motions, and exercise programs should emphasize not just individual joint ROM but also combined joint mobility in functional patterns of movement (Figure 42-13).

For clients recovering from severe hand and UE burns, intervention activities may include a variety of exercise and activity treatment media. Strengthening activities may involve the use of cuff weights, dumbbells, resistive exercise bands, or work simulation equipment. Activities for hand strengthening and coordination may include using exercise putty, hand manipulation boards, work simulators and work samples, crafts, and meaningful activities such as typing on a computer, dialing a cell phone, and playing cards or board games with visitors.

Edema Management

During the rehabilitation phase, edema often continues because of decreased function, dependent positioning without adequate external compression, or circumferential scarring of the extremity with associated lymphatic damage.

FIGURE 42-13 Combined joint motions to obtain the greatest total active motion are often the same functional patterns of movement used when performing activities of daily living.

FIGURE 42-14 Application of self-adherent elastic wrap to newly healed hands and feet provides external compression for the treatment of edema and early scarring.

When edema is present, motion is limited and painful; if the edema becomes chronic, it may lead to fibrosis.⁴⁸ To treat edema of an extremity, elevation, progressive compression, and activity are recommended.

Self-adherent elastic bandage material (Coban or Co-Wrap) is often used as an early form of compression for the digits, hands, and feet. It is applied in a spiral fashion, from distal to proximal, with the previous lap overlapped by a half overlap starting on each digit and continuing in this manner across the hand or foot and onto the wrist or ankle. Strips are also applied to each web space (Figure 42-14). The distal tips of digits are left open to monitor color, which should be rosy and not blanched or bluish. The rest of the extremity is wrapped with an elastic bandage or other form of temporary compression garment. The wrapped hand should be used during ADLs and other functional motions and elevated just above heart level when the client is resting. For edema of the LEs, use of a double layer of elastic wrap when ambulating, elevation when resting, active ankle exercises, and avoidance of static standing are recommended. Intermittent compression pump therapy is often used to treat chronic edema of the distal ends of extremities. Whenever compression therapy is used to treat edema of the hands or feet, before and after circumferential or volumetric measurements are recommended to monitor the effectiveness of the treatment (Figure 42-15).

Activities of Daily Living

As patients approach discharge from the hospital, the therapist must stress the importance of independent self-care. Eating, dressing, grooming, and bathing skills should be emphasized as part of the normal daily routine to increase independence and activity tolerance. When problems occur, the therapist must determine whether the dysfunction originates from a physical limitation, scar contracture, pain, edema, or an assumed abnormal postural reaction. Early identification of abnormal movements helps patients

FIGURE 42-15 In the treatment of extremity edema, sequential circumferences and volumetric measurements are methods to monitor and document treatment efficacy.

understand and relearn normal movement patterns before the abnormal patterns become habitual.

Practicing ADLs with personal care items and supplies from home helps foster self-confidence in functional performance skills before hospital discharge. Clients with major burn injuries may initially require adaptations to support independence. However, when assessing the need for adaptive self-care, the therapist should differentiate between a physical limitation that can be rehabilitated and permanent loss of function.

In addition to basic ADL and self-care tasks, IADL tasks such as home management responsibilities should be practiced before discharge. Fear of items associated with the injury, such as hot water, the stove, or an electric iron, can hinder functional recovery. For clients injured during a home activity, the therapist should arrange counseling, support, and practice of the skills or activity in the clinic. Prevention techniques taught as part of the inpatient treatment program should also be part of the home program.⁹⁸

Splinting

Splinting in the rehabilitation stage is used to limit or reverse potentially disabling or disfiguring contracture formations, increase ROM, distribute pressure over problem

FIGURE 42-16 A bivalved dynamic splint is used over a pre-sized intermediate scar compression glove. The splint is worn part-time to facilitate increased metacarpophalangeal and proximal interphalangeal joint flexion.

areas, or assist in function (Figure 42-16). Static splints, dynamic splints, and casting may be used,^{11,44,73} depending on the location and severity of the contracture. Regardless of the purpose of the splint, every effort should be made to ensure that its purpose and method of application are fully understood. Splinting at nighttime and during rest periods is preferred because it allows functional use of the extremity during waking hours and provides treatment of contractures while the client is unoccupied. However, splints must fit comfortably, and corrective splinting should not cause discomfort that interferes with the client’s rest. Although most clinicians agree about the value of splinting based on the strong rationale for splint use to provide counterforce to contracting scars or to lengthen scars when they limit joint motion, decision making on specifically when and how to splint remains controversial because of lack of strong clinical evidence.⁷¹ The therapist must continually weigh the risk-to-benefit ratio and consider timing, design, and duration of splinting relative to each client’s functional needs.

Client Education

Client and caregiver education becomes increasingly important during the predischarge phase to aid the transition from hospital to home. Increased understanding is needed in the areas of wound healing, the importance of preserving independence in ADLs and IADLs, the need for continued activity and exercise, the causes and effects of scar contracture, and scar management techniques and principles. Before discharge from the hospital or transfer to an inpatient rehabilitation facility, the client and family should receive a comprehensive home care education review (Table 42-4).⁴⁵ To reinforce learning, information should be presented through a variety of methods, such as verbal instruction, printed handouts, demonstrations, and educational videos. Most importantly, opportunities should be provided for the client and caregivers to practice wound care, garment and splint application, and all exercises under staff

■ **TABLE 42-4** | Home Program Outline

Item	Information Needed
Wound care, positioning	Dressing change technique, precautions, elevation
Skin and scar care	Lubricant frequency, sun protection, trauma precautions
Self-care	Techniques and equipment needed
Splints and orthotics	Donning techniques, schedule, precautions
*Pressure garments	Purpose, washing, reordering, donning techniques
Exercises	Frequency, techniques for specific areas

*Custom-made garments are available from Jobst Institute, Charlotte, NC (800) 221-7573; Barton Carey, Perrysburg, OH (800) 421-0444; Bio-Concepts, Phoenix, AZ (800) 421-5647; Medical-Z, Seattle, WA (800) 368-7478.

supervision in the weeks preceding discharge. Only with a detailed understanding of home care techniques and potential outcomes can clients be expected to assume responsibility for their own care and recovery.⁹⁸

Rehabilitation Phase: Outpatient

Reassessment

Reassessment procedures take on greater significance after discharge. ROM, strength, activity tolerance, ADLs and IADLs, and skin and scar status must be assessed frequently to ensure early identification of specific problem areas. In addition to these rehabilitation components, the effectiveness of compression garments, the fit and need for continuation of certain splints, home care activities, emotional

coping skills, and resumption of engagement in preburn occupations to support participation in contexts or life situations should also be closely monitored.

Reassessment of activity tolerance and work skills is indicated to help determine whether clients are ready to return to school or work or be referred for vocational rehabilitation. Driving evaluation and prevocational assessment by using simulated work activities or work sample testing may also be indicated for the more severely injured burn survivor. Vocational counseling and exploration should be undertaken in the later stages of recovery if residual dysfunction necessitates a change in the work environment or vocational role.

Therapeutic Exercise and Activity

Inpatient rehabilitation techniques, equipment, and therapeutic activities continue to be appropriate during outpatient therapy. However, progressive grading of exercise and the frequency, intensity, and duration of activity is necessary to successfully regain or improve the client's strength, activity tolerance, and performance skills and patterns, as well as abilities in performance in areas of occupation. Sequencing the order of intervention activities is necessary to prevent injury, minimize client discomfort, and prevent excessive fatigue. Skin lubrication, massage, and stretching should precede progressive strengthening exercises and activities.⁴⁹ Before being discharged, clients should learn how to prepare for exercise and activity by performing their own skin lubrication, massage, and stretching. Doing their own pretreatment skin care and stretching will allow outpatients to maximize actual therapy time and develop habits that promote consistent follow through with their home activities and independent exercise program.

Scar Management

A primary objective of most burn rehabilitation techniques is prevention or treatment of hypertrophic scars and scar contractures. For effective treatment of scar problems, scar characteristics must be monitored so that one can recognize when maturation occurs. Active scars are erythematous, raised, and rigid. As they mature, scars become less vascular in color, with flatter and more pliable contours and a smoother texture. Scar maturation usually takes from 12 to 18 months after injury, depending on the length of time that the original burn takes to heal. However, it is important to remember that each patient heals differently. Some scars mature in less than 1 year, whereas others may take more than 2 years.⁷³

A rating scale has been designed that allows serial assessment of scar pigment, vascularity, pliability, and height.⁸⁸ Although the ratings are somewhat subjective and time-consuming, the scale is a useful clinical tool. However, use of digital photography is a time-efficient and objective method of documenting changes in scar appearance; copies of the images can easily be inserted into the medical record.

FIGURE 42-17 The fit of custom-made compression garments must be regularly reassessed to ensure adequate compression for effective scar management.

Wearing intermediate pressure garments prepares the skin for the later fitting of custom-made compression garments. Use of compression garments is indicated for all donor sites, graft sites, and burn wounds that take more than 2 weeks to heal spontaneously.^{18,19} The occupational therapist is often responsible for the measurement, ordering, and fitting of these garments. The occupational therapist must frequently make special on-the-spot modifications during a clinic visit or fabricate underlying conformers to ensure uniform pressure. All custom-made garments are measured and ordered according to the specific instructions of the manufacturer. Most compression garment manufacturers offer a variety of design options, including special zippers or Velcro closures, silicone lining, custom inserts, and assorted colors.

Ideally, clients should be fitted with custom-made compression garments no later than 3 weeks after wound healing; otherwise, wearing of interim garments is continued until custom garments can be applied. It may be necessary to order garments on a piecemeal basis because different areas of the client may be ready for compression treatment at different points in time. Custom-made compression garments are constructed to provide gradient pressure, starting at 35 mm Hg distally (Figure 42-17). They should be worn 23 hours a day and be removed only for bathing, massage, skin care, or sexual activity. Face masks and gloves may also be removed for meals. Compression therapy should be applied to the burned area for approximately 12 to 18 months or until scar maturation is complete. Donor sites may also require compression garments, depending on the thickness of the donor skin taken and whether healing occurred in less than 2 weeks.

Once proper fit is established, it is recommended that the client possess a minimum of two sets of garments at any time to allow both around-the-clock compression therapy and laundering. Because of the elastic construction of the fabric, clients should hand-wash the garments with mild

soap and allow them to air-dry unless otherwise advised by the manufacturer. To prolong the life of the garments, washing machines, dryers, direct heat, strong detergents, or bleach should not be used. If they are properly cared for, most garments will last approximately 2 to 3 months before replacements are needed. Children may need replacements more frequently as a result of their growth and active lifestyle. Toddlers undergoing toilet training and incontinent adults may need extra garments and design options that make independent toileting easier. Adults employed indoors are usually able to return to work and previous activities without interference from the garments. However, some individuals who work outside in warmer climates may find compression garments to be too hot in the summer months and may need to change their work setting until compression therapy is no longer required.

To be effective, compression garments must exert equal pressure over the entire burned surface area. Because of body contours, bony prominences, and postural adjustments, flexible inserts or pressure-adapting conformers are often needed under the garments to distribute the pressure more evenly. Areas commonly requiring pressure adapters are the supraclavicular region of the upper part of the chest, the areas between and under the breasts of women or obese men, the nasolabial folds, the midface and chin, the areas between the scapulae and over the axillary folds, the gluteal fold, the perineum, and the web spaces of the hands and feet.

Pressure inserts and conformers are now made from a variety of materials; the choice is based on the area to be treated and the need for flexibility when applied. As with the garments, the fit of a conformer should be monitored at regular intervals for effectiveness and signs of deterioration and be replaced as needed to maintain exact contouring. Silicone gel pads, Silastic elastomer, Otoform-K, Plastazote, and Velfoam are useful for hand scars. One-sixteenth-inch Aquaplast and Silastic elastomer work well on face scars; closed-cell foams, prosthetic foam elastomer, silicone gel pads, Plastazote, Otoform-K, and Velfoam are also useful for other body areas. In addition, Velfoam and silicone gel pads are effective at the flexion creases of the knees, elbows, and anterior aspect of the ankle to equalize pressure and prevent discomfort during activities.

It is important to note that although the use of pressure garments and silicone gel is commonplace, their effectiveness is not well established. A 2009 meta-analysis examining the effectiveness of pressure garment therapy for the prevention of abnormal scarring after burn injury found sparse evidence that was insufficient to support its widespread use.⁶ A systematic review of silicone gel sheeting reported weak evidence of its benefits in preventing or treating abnormal scarring.⁵⁸

Activities of Daily Living

In addition to continued exercise, skin care, and scar management, the outpatient intervention plan should be directed at increasing independence in home care while also

FIGURE 42-18 A scar contracture occurs when tight scars limit free motion of a joint.

emphasizing resumption of prior life roles and context, including returning to previous work, school, social, and leisure activities. Scar contracture is often the primary cause of dysfunction (Figure 42-18). Therefore, activities performed during therapy should not only promote strength, activity tolerance, and functional ROM to counteract the effects of scarring but also preserve independence in performance of occupations related to clients' personal contexts and interests.

Community Re-entry

Returning to school or work becomes a primary objective during outpatient rehabilitation. However, most recovering burn survivors are capable of resuming normal daily routines and performance patterns long before their scars completely mature.

Returning to previous community settings (e.g., school, work, and social settings) and becoming reacquainted with friends and coworkers can be a difficult process for burn survivors who have cosmetic disfigurement, loss of functional performance, or restrictions in activity. A community re-entry program should be implemented before the client returns to school or work. Correspondence sent to the community setting before the client's return helps educate employers, teachers, and peers about burn injuries and what the client has experienced. This correspondence should explain the purpose of compression garments, splints, exercise, and skin care precautions; digital photos are helpful. The goal of a re-entry program is to reduce restrictions in the client's activities and ease the transition of returning to previous areas of occupation.⁴⁹

Children may have a more difficult time reintegrating into their previous roles as students and playmates. Many burn centers offer school re-entry programs to assist children in the emotional and physical challenges of returning to their school environment.⁴⁹ With prior parental permission, predischarge plans are made to send written information to the child's teacher, classmates, and (when

available) a community-based therapist working in the school system to acquaint them with the child's changed appearance and special needs. A videotaped message recorded by the child to his or her classmates explaining what happened can be very effective, especially when delivered by a family member or health care professional, who can then answer the children's questions. The tape can show the child both with and, if appropriate, without compression garments to help satisfy classmates' curiosity and concerns before the burned child returns to the classroom. Such preparations ease resumption of the student role for the child and can help improve acceptance by other children, who may misunderstand the cause of the disfigurement and the need for splints, adapted equipment, and scar compression garments. Informed classmates often serve as advocates for the burned child by passing information to students in other grades or on the bus and providing support when misinformed students reveal their ignorance or fear by teasing or taunting the burned child. Regional burn summer camps, often sponsored by local firefighter organizations or burn centers, also help children adjust by placing them in settings where they can socialize with peers who have also been burned.

Preparing a burn patient for return to work does not have to be a long-term process. Burn rehabilitation and work skills training have many similarities; therefore, it is possible to design treatment activities that simulate not only functional activities but also various work skills. Strength, activity tolerance, and flexibility, often identified as work tolerances, are obvious goals of burn rehabilitation. Physical demands of jobs, as described in the *Dictionary of Occupational Titles*,⁹⁰ are also components of functional skills; lifting, stooping, pushing, pulling, handling, and manipulating are a few examples. A job analysis interview, performed as part of the activity needs analysis, will provide the type of information needed to integrate activities into the intervention plan, which should not only improve functional ability but also provide reconditioning for returning to work.

Preparing the client for community re-entry after a burn injury also requires attention to two other types of tolerance: skin and temperature. Most clients will still need to wear compression garments and inserts, avoid prolonged sun exposure, and perform skin care while they are at school or work. Skin-conditioning activities and exercises performed while wearing garments will improve skin tolerance for friction and shear force demands (Figure 42-19). Education regarding the body's response to variations in temperature and precautions for dealing with extremes of temperature are necessary for the patient to plan for anticipated temperature tolerance problems. A systematic review of the literature reported that an average of 66% of patients returned to work following their burn, with the time taken to return to work ranging from 4.7 to 24 months. The extent and severity of the burn were the most significant barriers; others were longer hospital stays and the number

FIGURE 42-19 Valpar whole-body range-of-motion equipment is useful to increase strength and active range of motion of the upper extremities, as well as to improve activity tolerance.

(Valpar Component Work Samples, Valpar International Corporation.)

of operative procedures.⁶⁷ (See Chapters 14 and 15 for further information.)

Psychologic Adjustment

During outpatient rehabilitation, clients may undergo numerous physical and emotional changes. Once discharged from the hospital, they must face the overwhelming task of becoming responsible and self-reliant while dealing with the stress associated with developing scars and a changing self-image. They may not participate fully in therapy or adequately follow through with home care activities because of the physical and emotional effects of the injury. Apathy, avoidance of pain, scar tightness, and hypersensitivity all contribute to noncompliance and subsequent dysfunction after injury. Clients may experience symptoms of post-traumatic stress disorder, nightmares, and changes in appetite with subsequent weight gain or loss. They may become reclusive or disengage from previous relationships. Depression may occur even before discharge.^{12,65,69}

In addition to established treatments such as counseling, support, and training in pain management and relaxation

techniques, visits from a recovered burn survivor to a new patient are often of great benefit. Attending a burn support group can also help the burn survivor and family members in psychologic adjustment. Research has shown that burn survivors at different stages of recovery tend to provide positive support to one another. Group discussions among burn survivors promote acceptance of what they have already experienced and realistic expectations of what they still need to accomplish.¹²

Discharge from Treatment

The outpatient therapy program should be re-evaluated periodically to determine whether the frequency of treatment, program progression, or professional or educational status should be changed (e.g., return to work or school).⁴⁹ When clients have resumed their preinjury activities, outpatient therapy may be discontinued. Because burn scar maturation may take more than 18 months, a schedule of follow-up care, with appointments every 2 to 3 months, is needed until wearing of compression garments is discontinued. However, for children, annual burn clinic visits are recommended, even after discontinuation of compression garments, until full physical maturity is reached to ensure that growth is not impeded by scar inflexibility (see this chapter's case study).

Burn-Related Complications

Heterotopic Ossification

Heterotopic ossification (HO) is formation of bone in locations that normally do not contain bone tissue.^{28,91} The underlying cause of HO is not yet fully understood. It typically develops either in the soft tissue around the joint or in the joint capsule and ligaments, and it often forms a bony bridge across the joint, thereby resulting in a fused joint.³⁸ Although HO is frequently found in the posterior aspect of the elbow, it may occur in other joint areas such as the shoulder, wrist, hand, hip, knee, and ankle. It may occur in either extremity or bilaterally, even if the extremities were not burned. Signs that HO may be present usually appear during the latter stages of hospitalization, with the patient experiencing increased pain at a certain point in the joint's ROM. The pain is fairly localized and severe, and loss of ROM is usually rapid, with development of a hard, unyielding feel at the joint's end of available ROM. Inflammatory signs, such as redness or swelling, are not easily discernible within healing burn wounds. Once HO has been detected, frequent AROM exercise of the joint should be carried out within the pain-free range to preserve as much joint motion as possible.²⁰ Use of dynamic splints or forceful passive stretching of the involved joint should be discontinued. If the condition does not resolve with time, surgical intervention may be necessary to resect the limiting bony tissue, followed by therapy to preserve the regained ROM.

Neuromuscular Complications

Peripheral neuropathic conditions are the most common neurologic disorder observed in burn patients. They usually occur with high-voltage electrical burns or burns involving greater than 20% TBSA.³⁶ Peripheral nerve damage may be caused by infections, metabolic abnormalities, or neurotoxicities. A peripheral neuropathic condition is generally manifested as symmetric distal weakness, with or without sensory symptoms. Most conditions improve with time; however, patients often complain of fatigue and decreased activity tolerance that may last for months.³⁶

In addition to peripheral neuropathic conditions, localized compression or stretch injuries of nerves are encountered during burn recovery. Causes of localized nerve injury include improper or prolonged positioning in bed or on the operating room table, tourniquet injury, and extreme edema. Common injury sites are the brachial plexus and ulnar and peroneal nerves. Prolonged frog leg positioning can cause a stretch injury, whereas prolonged side lying can cause a compression injury of the peroneal nerve.³⁶ The ulnar nerve is subject to a compression injury if the client rests on a firm surface with the elbows flexed and the forearms pronated. The brachial plexus is susceptible to stretch or compression injury if inappropriate shoulder-positioning techniques are used. To implement more effective prevention and intervention techniques, therapists should be aware of the causes and symptoms of various nerve injuries.

Contact with high-voltage electrical current often produces permanent damage to peripheral nerves as a result of thermal damage at the entrance and exit sites of the electrical current. Damage also occurs to peripheral nerves as a result of secondary compression of the blood supply caused by swelling of surrounding tissues. Delayed neurologic complications are caused by direct thermal damage, which results in demyelination and subsequent nerve cell death, or by vascular compromise of the brain or spinal cord. This generalized damage may be manifested as paralysis, cognitive impairment, aphasia, seizures, balance problems, or other neurologic symptoms. The therapist should be attentive to any developing symptoms of sensory or motor dysfunction in a client who was initially neurologically intact.⁹⁵

Facial Disfigurement

Facial scars can be devastating, both functionally and psychologically. Tight or hypertrophic scars not only distort the smooth contours of the cheeks and forehead but can also flatten the nasal contours, evert the eyelids and lips, and constrict the optic and oral commissures. Vision, speech, feeding, and dental hygiene can be adversely affected by oral and eye contractures. Facial disfigurement is also damaging to an individual's self-image and inhibits social re-entry. A significant amount of communication and social interaction depends on nonverbal facial expressions and eye contact. Severe facial burn scars not only distort the face and restrict

expression but also undermine the patient's self-esteem when he or she is met by social rejection.

Two main compression therapy methods are used to prevent or manage hypertrophic facial scars. An elastic face mask can be worn with underlying flexible thermoplastic conformers. The other option is a rigid, total-contact transparent facial orthosis.⁷⁴ Each has advantages and disadvantages.

Because face masks are made of elastic fabric, generally enclose the entire head and neck, and use flexible conformers, they provide uniform multidirectional compression during movement or changes in position. However, because they occlude the face, they are cosmetically and socially less acceptable. The effectiveness of the compression is based on subjective feedback from the patient and observations made by the therapist during outpatient clinic visits. Most underlying conformers are easy to modify or replace to provide effective distribution of pressure over facial concavities and contours.

Conventional fabrication of a transparent, rigid facial orthosis is an involved and often expensive process. First, a cast is made of the patient's face with dental alginate over the surface of the face, and then the alginate is reinforced with a layer of fast-setting plaster strips. The patient must lie still and breathe through straws or small openings left in the alginate, which can be difficult for claustrophobic adults or small children. For this reason, some patients are unable to cooperate with this procedure unless they are under anesthesia. After the cast is removed from the patient, the breathing and neck openings are closed with more plaster strips and the facial cast filled with plaster of paris. The resulting exact duplicate plaster model is polished smooth of scars and defects by hand. Additional plaster is carved off as needed to increase pressure on specific scarred areas of the face. Clear, high-temperature thermoplastic is then heated, stretched over the model, and either vacuum-molded to the model or manually stretched and molded by hand. The edges are finished, elastic straps are applied, and the orthosis is fitted to the patient. Because the material is clear, the rigid face mask has the advantage of allowing the therapist to view the face and objectively evaluate the amount of pressure exerted on the scars. By noting the presence of scar blanching under the clear mask, precise adjustments can be made as needed. The clear mask allows the face to be seen but has the disadvantage of exerting primarily unilateral compression, which may be compromised by speech, facial expressions, or side-lying positions. The mask does not allow perspiration to evaporate and must be removed and wiped clean regularly, especially in warmer climates.

Recently, computer-aided design and manufacturing systems have been developed to efficiently and economically fabricate transparent face masks.⁷⁶ A software system integrates shape capture, mask design, and model fabrication with a linear scan noncontact laser imager for the

acquisition of facial topography. The computer then integrates with a milling machine to fabricate a positive model out of urethane foam. The foam model is modified through use of the computer program and lined with a layer of polypropylene to smooth the foam texture. The model is then sprayed with silicone and the mold released and used basically in the same manner as the plaster model described previously. The rest of the fabrication process also works in a similar way. The advantage of computerized imaging and model fabrication is the speed of fabrication of the model and the ability to obtain a model without having to take a direct cast of the patient's face.

With either method, frequent alterations are necessary to achieve and maintain adequate compression of all facial scars (Figure 42-20). The choice of method is based on the preferences of the patient and physician. However, a combination of both types may be advantageous: the patient wears a clear, rigid face mask in social settings and a fabric mask with conformers at home. Appropriate skin care education is also important. Massage with lotion twice a day will aid in scar desensitization and provide the necessary lubrication. Facial massage and exercises are performed at least four times a day to help stretch tight facial skin, maintain eyelid and mouth flexibility, and preserve the nostril openings.

Just as with any compression therapy technique, patient compliance is essential for effectiveness of the treatment. The patient is instructed to wear the face mask at all times except while eating, bathing, or engaging in sexual activity. The patient should carry written verification from the burn physician verifying the medical necessity for the mask. Regardless, patients should always remove their masks before entering any public facility to avoid provoking suspicion that they are prepared to commit robbery or violence. This is especially important when entering banks, convenience stores, or government facilities, even if the patient is well known to the employees.

Individuals wearing either type of mask will initially experience acute feelings of self-consciousness and may avoid going out in public. Parents may have difficulty putting the mask on their children and may experience feelings of guilt if the child rebels. Supportive intervention from family members and therapists is an important way to successfully manage these social and personal issues.

Consistent follow-through is especially critical in preventing or correcting facial scarring and disfigurement. Before applying the mask, the therapist must provide early education, ongoing encouragement, and continual support to ensure that the client wears the facial orthosis. Once the scars are mature and compression therapy is no longer needed, the client should be instructed in the use of special camouflaging cosmetics such as Covermark by Lydia O'Leary, which will cover minor flaws in texture and correct uneven pigmentation.

FIGURE 42-20 Close-up view of a transparent rigid facial orthosis. The mask contours and strap system are modified to adjust the amount of pressure over specific scarred areas (note the blanching of the scars on the lower lip and lateral aspect of the chin).

Summary

A serious thermal injury is one of the most devastating physical and psychologic injuries that a person can endure, especially if appropriate treatment is not received in a timely and comprehensive manner. Successful burn care requires a coordinated, multidisciplinary team approach beginning from the date of injury and continuing until scar maturation is complete.

Advancements in medical and surgical burn care have made it possible to expect not only independence in

self-care but also early resumption of occupations, including return to school, work, leisure, and social activities. Even when functional recovery is possible, pain, disfigurement, and adverse psychologic reactions (e.g., post-traumatic stress, apathy, and depression) can contribute to postinjury dysfunction. In addition to progressive physical rehabilitation, ongoing client education is crucial. A comprehensive OT program that includes client education must be initiated early and incorporate information about the physical, psychologic, and social components of burn injury to facilitate the client's cooperation and adjustment to the injury.

Threaded Case Study | Steven, Part 2

Interventions and Final Outcome

Steven's airway and respiration were compromised because of facial swelling, pharyngeal edema, and pulmonary contusions in his right lung from the crush injury, along with subsequent intubation, mechanical ventilation, and tracheostomy to maintain a patent airway. He required a mesh STSG for his right UE and a sheet STSG for his face, with donor sites being the anterior aspect of his thighs and upper part of his chest. He was extubated on the 19th day after the injury, and his tracheostomy was discontinued 6 days later. He was discharged home 28 days after his injury. At discharge, Steven was eating a regular diet but still had unhealed areas on his face and lips.

Evaluation and Goals

Because of the emergency nature of his injuries, Steven required intubation, mechanical ventilation, and heavily sedating medications for pain management. The initial absence of his family further delayed determination of his occupational profile, context, and personal priorities until well after his initial evaluation. His original evaluation instead concentrated on body functions and structures, including assessment of burn severity and location of burned surface areas; cognitive and emotional status; communication abilities; active ROM, strength, and coordination; presence and degree of edema; and screening for changes in neurologic function or sensation.

Steven's performance skills were initially impaired by an acute decline in mental status and by significant edema of the face and UEs. As Steven became more alert and able to participate in treatment, peripheral nerve damage of his right median nerve was noted on OT reassessment, with a subsequent decrease in strength and sensation in his right hand. After Steven became cognizant, treatment goals were discussed and prioritized according to his preinjury life context and personal preferences.

Acute phase treatment goals were as follows:

- Reduce facial and extremity edema.
- Improve cognitive awareness, involve the client in goal setting, and promote engagement in occupation.
- Preserve functional mobility, strength, and coordination of the neck and both UEs.
- Regain independence in basic ADLs.

A goal was added during the postoperative phase:

- Protect and immobilize surgical graft sites to maximize graft take.

Goals of increased focus in the rehabilitation phase were as follows:

- Minimize hypertrophic scarring and disfigurement.
- Preserve facial function (i.e., prevent ectropion of the eyes, oral microstomia, loss of the nasal passages).
- Regain independence in ADLs, and increase activity tolerance.
- Develop coping strategies to address the pain and facial disfigurement (added later after irreversible facial scarring occurred) and to prevent social isolation. The long-term goals of treatment were to return Steven's performance skills and patterns and performance in ADLs and other areas of occupation to his preinjury level of independence by 4 months after the injury. Acceptance of permanent

losses (e.g., vocations, physical identity, abandonment by previous friends unable to cope with his change in personal appearance) and establishment of a new set of personal contexts incorporating these changes would typically take a year or longer.

The following treatment interventions were initiated in the acute care phase:

- Positioning guidelines were established: elevation of the head of the patient's bed 20 degrees or more and elevation of both UEs on pillow inclines with the right UE abducted to 90 degrees. Illustrated positioning recommendations were posted at Steven's bedside. As the wounds healed, retrograde massage was provided to assist in reduction of the edema in his hands.
- Cognitive reorientation and client education activities were integrated into Steven's earliest treatment sessions. Emotional support was provided as he became more aware of the severity of his injuries, and nonpharmaceutical methods of pain management were incorporated into exercise and activity treatment sessions as needed to reduce anxiety and discomfort.
- PROM exercises were provided when Steven was not alert enough to participate. Later, as he became more cognizant, an active assistive exercise program was provided to promote reduction of edema and return of functional use of his extremities and face. His exercise program was posted bedside and included right arm and facial stretching exercises. Therapeutic activities of interest were encouraged to increase motivation, activity tolerance, and fine motor coordination. Steven particularly enjoyed working out on the stationary bicycle.
- After he was fully cognizant, extubated, and allowed food by mouth, he began to practice basic oral and facial ADLs while sitting supported in bed or in a bedside chair. Sponge handles were initially applied to his eating utensils and toothbrush and removed after the hand edema subsided and his right grip strength improved. Safety-related training was practiced to prevent further injury to the insensate areas of his right hand.

The following treatment interventions were begun in the postoperative phase:

- A right postoperative elbow extension splint was fabricated and worn over dressings full-time postoperatively for 5 days until his grafts adhered. The splint was then worn part-time at night until full AROM was regained.

The following treatment interventions were initiated during the rehabilitation phase:

- After Steven was orally extubated, he was measured and fitted with a microstomia prevention appliance (MPA) mouth splint that he wore initially when sleeping, but MPA use was later increased to include daytime periods because of increased oral tightness. He was measured for a manufactured elastic face mask, chin strap, and sleeve. A temporary right compressive sleeve was fabricated and applied. On arrival, the garments were fitted and underlying conformers provided to be worn under the elastic face mask and sleeve. Fabrication of a clear acrylic face mask was initiated before discharge and applied on an outpatient basis. After discharge, Steven continued to receive OT services for right UE exercise, scar management, and monitoring of fit of the compression garments and acrylic face mask.

- Because of the severity of the acid burns and a genetic predisposition to scarring, his scars continued to contract, which resulted in anterior axilla web tightness and facial distortion. The tight anterior axilla was treated with moist heat, manual massage, and slow, sustained stretching. Facial exercises were intensified, with an emphasis on client participation. Horizontal stretch exercises of the healed eyelids and midface using skin traction were performed by Steven. Oral stretch exercises, initiated by the therapist during the acute phase with the use of plastic thermometer covers, were continued. However, in this phase the mouth exercises were performed more aggressively with acrylic straws for horizontal stretching of the oral commissure and stacked tongue depressor sticks between the teeth for vertical stretching of cheek and jaw tightness.
- Practice of ADLs was continued, with progression in performance of self-care tasks, sitting on the edge of the bed, and later standing at the sink to increase general strength and activity tolerance while becoming more independent in self-care tasks.
- Relaxation techniques were taught to help Steven cope with discomfort during therapy. Emotional support was provided to help in counteracting grief over loss of his facial appearance, employment, and previous social contacts. The OT staff assisted in coping strategies and community re-entry planning. Steven was also referred for professional counseling while still an inpatient.

Outcomes

Despite compression therapy, mouth splinting, and facial exercises, Steven's facial scars continued to contract, which caused eye, nasal, and oral constriction; lip eversion; eyelid ectropion; and flattening of his facial features. About 2 months after discharge, Steven abandoned use of the acrylic face mask because the frequent long-distance trips for adjustment of the mask could not keep pace with his rapidly changing facial contours. Instead, Steven preferred using the elastic fabric face masks and flexible conformers. He continued nighttime use of his MPA for approximately 1 year after discharge to prevent further constriction of his mouth, but he continued to have webbing at each oral commissure. Steven's right arm graft sites and burn scars responded well to exercise and the consistent use of elastic compression sleeves, with resulting full AROM, a supple flattened texture, and an appearance that was acceptable to him. The scars on the upper part of his shoulders did not receive compression therapy because of his preference to use a sleeve rather than a full vest, but these scars, though having a slightly raised texture, were also acceptable to him. He continued to use sunblock lotion to protect his scars from sunburn and hyperpigmentation, especially after he began to work outside.

Over the next 6 years, Steven underwent 21 surgical revisions for treatment of recurrent facial and neck contractures caused by scarring from the severe acid burn and needed an unusually extended period to achieve facial scar maturation

(more than 3 years). He eventually regained full right-hand strength, but the impaired sensation in his thumb and forefinger required approximately 38 months to completely resolve. Although he could never return to competitive lifting, Steven returned to working out and could lift up to 280 lb; however, he continued to experience chronic low back pain. He was referred to a pain clinic, where degenerative disk disease was diagnosed in the L4 and L5 vertebrae, and he had to further restrict his lifting activities.

Because of limited field of vision caused by his distorted eyelids and right eye blurring, Steven could not return to working as a professional truck driver. To support himself, he started a part-time business providing lawn care services for private homes and local businesses. In the winter months, he expanded his business to provide pressure-washing services for sidewalks and trailers. After living with his sister's family for 3 years, Steven was financially able to return to his own home.

Although multiple surgical procedures and the use of facial compression therapy provided some improvement, Steven's facial appearance still remained unacceptable according to the social standards of the general public. His attempts to re-enter previous social circles resulted in mixed responses and in some instances led to physical altercations. Steven and his 3-year-old son had maintained contact by telephone throughout his hospitalization. During OT treatment sessions before discharge, the child had gradually been introduced to Steven's changed facial features, first with photos, then with the elastic or the clear face mask in place, and later without either mask. His son continues to remain fully accepting of his father despite his altered appearance; at age 10, Steven's son still takes personal offense when people ridicule his father.

Steven's Personal Long-Term Goals

"Because of my eyes, I'll never be able to work as a truck driver again, and because of my back, I can't power lift anymore, but I'd like to build up my lawn service. I'm still going to outpatient therapy near home. My skin is still so fragile and sometimes splits when bumped because it's thin and tight.

"Emotionally, I'm doing okay. I have my ups and downs. I can go out to eat at a restaurant now because I've learned to accept how I look. Sometimes, my appearance startles people, but usually if people see that I'm comfortable with myself, that makes them more comfortable, too. I don't like it when people stare at me and then look away without giving me a chance to nod or speak. It's rude. Children are more honest. They're just being curious. If I wave or smile, they're usually okay and wave back. My son's classmates accept me. I even go on field trips with them. I'd really like to be able to breathe better through my nose, and I wish my eyes didn't water so much. It makes me look like I'm crying. The doctors want me to come back in for a procedure to fix the tight skin on my neck."

However, after 6 years, Steven says, "I'm taking a break from surgery for a while."

Threaded Case Study | Kenjii, Part 2

Interventions and Final Outcome

OT interventions included the following:

- Prevention and reduction of scar contractures and promotion of strength, mobility, and coordination, especially in his hands and face. This involved the use of exercise, splinting, and massage to stretch out developing scar contractures. Scar management techniques were used, such as fitting and modifying compression garments and conformers for the hypertrophic burn and donor site scars on his face, UEs, and torso.
- Teaching of relaxation techniques and other nonpharmaceutical methods of pain management.
- Building of activity tolerance with therapeutic activities and independence in ADLs by teaching alternative methods of accomplishing tasks and by providing adaptive aids as needed. Initially, by learning to perform self-care tasks with adaptive aids, he eventually required only adaptive techniques to perform most tasks without the use of adaptive aids (except for using a button hook to fasten tight blue jeans, a performance routine of value to him).
- Exploration of new performance skills and occupations incorporating past values and current interests through therapeutic activities and promotion of the development of a new life context. Various adaptive techniques explored to pursue alternative outlets for his musical interests resulted in poor satisfaction for Kenjii, who was unable to resolve his decreased performance in an area in which he had once excelled. While exploring alternative interests, Kenji was noted to be skilled in creative art media and had a talent for mathematics.
- Psychologic support to assist in the grieving process and promote eventual acceptance of permanently lost skills,

body image, and lifestyle. During his extended stay, Kenjii voiced his grief to the extent of expressing suicidal ideation. He received counseling, but the occupational therapist also offered support and tried to develop and emphasize the retained skills and talents that survived his burn injury.

Final Outcome

Almost 30 years after his burn injury, contact was made with Kenjii via the Internet to find him teaching mathematics at a university. He was completing work toward a doctorate degree and happily married to someone he described as his “soul mate.” Kenjii said that he did not attempt to resume playing any of the musical instruments on which he was once was so proficient. “I knew I would never play as I once did, and the perfectionist in me could not accept less, so I chose to leave that part of my life behind.” However, the creative skills that he demonstrated so many years ago in OT activities have been well combined with his desire for perfection. Despite permanent ROM limitations in his hands, he has become an accomplished artist in a variety of media. He had undergone numerous reconstructive surgeries in the years immediately after his burn injury, but he no longer seeks to change his appearance. He states that he long ago came to accept his appearance. He is very comfortable with his public role as an educator and is very popular with his students. He often relays his burn experience in class—initially to satisfy his students’ curiosity but also to share his journey to acceptance and renewed life satisfaction. He still credits OT for “empowering” him and helping him “survive the tough times by offering hope.”

Frequent reassessment of the client’s physical abilities, ability to engage in areas of occupation, emotional status, and social needs is also required to ensure effective intervention and optimal recovery of the client.

The occupational therapist is an integral member of the burn team who provides intervention activities such as preventive positioning, therapeutic exercise and activity, training in ADLs and other areas of occupation, preventive and corrective splinting, skin conditioning and scar management techniques, client and family education, and emotional support to promote psychosocial adjustment. A basic OT concept that is crucial in burn care—or when working with any condition—is the importance of holistic treatment, or treatment of the whole person. As a profession, OT has not only focused on recovery of functional performance skills and patterns but has also always recognized the primacy of engagement in occupation and the need to preserve the client’s participation in various contexts to support a meaningful lifestyle.

Review Questions

1. Name the two layers of the skin. In which layer are the nerves and sebaceous glands located?
2. Which factors are considered in determining burn severity?
3. What is an escharotomy and why is it performed? How does it differ from a fasciotomy?
4. Describe two factors that affect the quality of burn wound healing and promote excessive scar formation.
5. During the acute care phase, which factors may limit full ROM?
6. What is a boutonnière deformity, and what are boutonnière precautions?
7. What are the two basic principles underlying most burn rehabilitation treatment techniques?
8. What is the primary objective for positioning during acute care?
9. What are the indications for initiating splints during the acute care phase?

Threaded Case Study | Patrice, Part 2

Interventions and Final Outcome

Patrice required long-term therapy and multiple surgeries to counteract the effects of the restricting scars that continued to cause problems as she grew. After the fontanelle of her skull closed, she was fitted with an elastic face mask and underlying conformer in an attempt to reduce the hypertrophic scarring and contracting scars that were pulling her nose to the side. However, neither she nor her adoptive mother (her previous foster mother) could tolerate the mask. Therefore, a series of acrylic face masks were fabricated until her scars matured. She eventually required surgical intervention to release a scar that was causing facial asymmetry and nasal distortion. As an adolescent, Patrice required surgical release of the abdominal scar to allow unrestricted growth of her left breast.

To prevent hypertrophic scarring, her hand was initially placed in a “sandwich” splint consisting of dorsal and volar thermoplastic splinting material lined with a thick layer of conforming padding. The splint provided compression to the scars and prevented the development of thick scarring and dorsal contractures of the fingers. However, this measure did not affect the longitudinal constricting force of the scar. Despite frequent therapy sessions and the excellent care provided by her devoted mother, the scar could not stretch fast enough to keep pace with the rapid growth of her hand. A skin graft was eventually applied to the dorsum of Patrice’s hand, but the graft also could not stretch fast enough. As mentioned previously, this binding effect of the scar resulted in restriction of the natural growth of her fingers. This same scarring required ongoing therapy to preserve the function of her index, long, and ring fingers.

Although the bones of Patrice’s little finger did not develop, the skin of this finger grew and resulted in a button of accumulated skin tissue where the finger should have been. The scar on the back of her hand continued to restrict MP flexion and use of her long and middle digits. When Patrice was a toddler, the tight scar on the dorsal surface of her hand was excised; the resulting defect was repaired with skin from the extra fifth digit, which was filleted and transposed onto the dorsal surface of the hand as a skin flap. The volar, glabrous skin had an unusual appearance on the dorsum of her hand but was able to keep pace with the growth of her hand, thereby allowing unimpaired hand development and improved function.

Twenty years later, Patrice related how her life has been affected by serious burns received at such an early age:

“I can remember some of the surgeries to my face and hand. I remember how I hated the face masks, but I liked the glove because the therapist always let me pick the colors.”

“I still can’t use any of the fingers of my left hand except my thumb and index finger, but I don’t feel like I’m handicapped. I’m right-handed, of course. I can do anything I really want to now, but in elementary school, I couldn’t play on the monkey bars because I couldn’t hold on with my left hand. I remember that this was something that I really wanted to do, and it made me feel left out. Because I had to stay out of the sun, I wasn’t allowed to go to recess outside or gym until middle school.”

“I finished high school with a grade point average of 3.5. I went to college for 2 years on a grant with plans to go to medical school, but now I’m working at Wal-Mart. I’d like to return to college later this year, but I don’t know exactly what degree I want to go for—something in the medical profession, maybe a nurse or EMT. When I’m not working, I like to go out with my friends, go jogging, type on my computer, read, and watch TV; I also like to draw.”

“The bald areas on my head don’t bother me too much. My doctor wanted to do surgery to stretch my scalp and cut out some of the bald skin, but I didn’t want to. The rest of my hair is very thick, and I can pull it back into a ponytail and hide most of the bald spots. I like wigs. I just bought a new blonde one. I don’t wear them because of the bald areas; I just do it for fun.”

“I’m a little quiet and shy around new people, but after I get to know someone, I’m not a bit shy anymore. I have a boyfriend now. We met at work. We’ve been dating a few months now.”

“My face is OK. The appearance of my hand bothers me more than my face. People seem to notice it more. Sometimes I feel like I’m being watched. People stare; I guess they’re curious. I wish they would just ask me instead of staring, but I just ignore it. I don’t address it directly. If they ask, then I’ll tell them about being burned.”

“I still wonder—I guess I always will—why this happened to me....”

10. When a splint is indicated in the acute phase, what is the preferred wearing schedule and why?
11. When should client education about burn injury and rehabilitation begin?
12. What would cause a patient to require temporary adaptations for self-care during the acute phase?
13. Why are patients immobilized postoperatively? On average, how soon after grafting can gentle AROM exercises be resumed?
14. How soon postoperatively can an intermediate compression dressing or garment be applied?
15. What are the two main compression therapy options for treatment of facial scars?
16. Why are skin-conditioning activities used in burn rehabilitation? What are examples of skin-conditioning techniques?
17. What is the average length of time required for scar maturation?
18. What are possible causes of limitations in ADLs during the rehabilitation phase?
19. What information should be included in predischarge education and home program review?

20. What is the primary cause of dysfunction after a burn injury?

Amputations and Prosthetics

43

DENISE D. KEENAN,
JENNIFER S. GLOVER

■ Chapter Outline

Section 1: General Considerations of Upper and Lower Limb Amputations

Causes and incidence of amputation

Surgical management

Client social, cultural, personal, and spiritual contexts

Psychosocial contexts influencing adjustment to amputation

Postsurgical physical client factors and performance skills

Skin

Sensation

Bone

Wound healing

Section 2: Upper Limb Amputations

Body-powered prostheses

Candidates for prostheses

Levels of amputation and functional losses in the upper limb

Component parts of the upper limb body-powered prosthesis

Upper limb preprosthetic program

Prosthetic information and prescription

Prosthetic program

Summary

Electric-powered prostheses

Candidates for prostheses

Hybrid prostheses

Preprosthetic therapy

Prosthetic program

Summary

Section 3: Lower Limb Amputations

Levels of lower limb amputation

Causes of lower limb amputation

Postsurgery residual limb care

Lower extremity equipment and prostheses

Participation in areas of occupation

Client factors

Performance skills

Performance patterns

Psychosocial repercussions

Context and activity demands

Additional considerations for elderly clients

■ Key Terms

Preprosthetic phase

Prosthetic phase

Residual limb

Postprosthetic phase

Socket

Neuroma

Phantom limb

Phantom sensations

Terminal device

Separation of controls

Myoelectric prosthesis

Hybrid prosthesis

Above-knee amputation

Below-knee amputation

Syme's amputation

Residual limb support

Pylon

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

Sections 1 and 2

1. List the common reasons for amputation.
2. Discuss the role of the occupational therapist in rehabilitation after limb amputation.
3. List the goals of amputation surgery.
4. Name two types of surgical procedures.
5. Name four factors that can interfere with prosthetic training.
6. Define neuroma, phantom limb, and phantom pain.
7. Describe the typical psychological consequences of amputation surgery.
8. Describe how the occupational therapist facilitates adjustment to amputation.
9. Describe the role of the occupational therapist in the rehabilitation of the individual with an upper limb amputation.
10. Discuss the impact of the residual limb status on the success of fitting and operating an upper limb prosthesis.
11. Name the five components common to all body-powered prostheses.
12. List the motions used to operate the body-powered prosthesis.
13. Describe at least two techniques for donning the body-powered prosthesis.
14. Describe the importance of prepositioning the terminal device.

15. List the two phases of training in the use of an upper limb prosthesis.
16. Explain why it is optimal to introduce postprosthetic training on three levels.
17. Describe the basic operation of an electric prosthesis.
18. Discuss the primary function of any prosthesis in different daily tasks.

Section 3

19. List the types and causes of lower extremity (LE) amputation (also known as lower limb amputation).
20. Describe the types of equipment that may be used by a person who has had a lower limb amputation.
21. Describe how lower limb amputation may affect a person's occupational performance.
22. Identify the effects that lower limb amputation may have on client factors, performance skills, and performance patterns.
23. Discuss the potential psychosocial repercussions of lower limb amputation.
24. Describe the role of the occupational therapist in working with a person who has had a lower limb amputation.
25. Explain how context and activity demands can be altered to improve a client's ability to participate in a given occupation.
26. Discuss additional concerns that may be present for an older person who has had a lower limb amputation.

■ **SECTION 1: | General Considerations of Upper and Lower Limb Amputations**

DENISE D. KEENAN

Limb loss can result from disease, injury, or congenital causes. Individuals born with congenital limb deficiencies or whose amputations occur early in life usually grow and develop sensorimotor skills and self-image without the limb. The person who undergoes an amputation in adolescence or adulthood is confronted with the task of adjusting to the loss of a well-integrated part of the body scheme and self-image. These two populations present different problems for the rehabilitation worker.^{6,64,65}

Among orthotists and prosthetists, terminology related to amputation has changed in the past few years to allow consistent communication with rehabilitation workers throughout the world. The International Society of Prosthetics and Orthotics (ISPO), the American Association of

Orthotics and Prosthetics (AAOP), and national and international prosthetics and orthotics related bodies have agreed to follow the recommendations of the International Standards Organization regarding Prosthetics and Orthotics terminology. The term used for arms and legs and portions thereof is "limb."⁷⁶

The primary responsibility of the occupational therapist in the rehabilitation program consists of formulation and execution of the preprosthetic program and prosthetic training. During the **preprosthetic phase**, the treatment plan involves preparing the limb for a prosthesis; during the **prosthetic phase**, treatment involves increasing tolerance and function with the prosthesis. The rehabilitation program involves an individualized intervention plan that helps the client with physical and psychological adjustments. This program is designed so that the client may learn to accept the new body image and to function as independently as possible.^{6,64,65}

Causes and Incidence of Amputation

Most amputations may result from trauma; peripheral vascular disease (PVD); peripheral vasospastic disease; chronic infection; chemical, thermal, or electrical injury; or malignant tumor. Elective upper limb amputations may occur as a result of a severe or complete brachial plexus injury⁹ or other medical conditions that limit the neuromuscular function of the limb.

Calculation of the number of individuals with limb amputations worldwide is difficult to complete because many countries do not keep records of these data. The U.S. National Limb Loss Information Center estimated 1.7 million Americans with upper limb loss in 2007, based on an unpublished study out of John Hopkins University. This number is projected to reach 3.6 million by 2050. Lower limb loss (80%) is more prevalent than upper limb loss (10%) or multiple limb loss (10%). Upper limb loss due to trauma is increased during times of active warfare.^{47a} The incidence of amputation remains fairly constant between the ages of 1 and 15. From 21 to 64 years of age, however, a gradual increase in incidence occurs because of work-related injuries and highway accidents. Approximately 75% of upper limb amputations in adults are caused by trauma,^{1,34,43,43a} as was the case for Roberto.

Previously, the level of amputation of the upper limb was referred to by its relationship to the elbow joint. For example, the terms above-elbow (AE) amputation and below-elbow (BE) amputation were universally used to clarify the level. This terminology has changed to reference the anatomy of the body when describing the level of limb loss. Terms now used include trans-radial, trans-humeral, and partial hand. See Figure 43-1.

The major cause of lower limb amputation is PVD, often associated with smoking and diabetes.^{36,39,56} Between 1988 and 1996, 82% of all lower limb amputations occurred as a result of vascular problems.¹⁵ Despite major improvements in noninvasive diagnosis, revascularization, and wound-healing techniques, 2% to 5% of individuals without diabetes but with PVD and 6% to 25% of those with both PVD and diabetes undergo amputation.^{28,29,41,45,68} Perioperative mortality rates of persons with lower limb amputation have been variously reported as between 7% and 13% and are usually associated with other medical problems, such as cardiac disease and stroke.^{22,28,29}

The second leading cause of lower limb amputation, accounting for approximately 17% of amputations, is trauma,¹⁵ usually the result of motor vehicle accidents or gunshots. Individuals with traumatic amputation are usually young adults and more frequently are men.^{20,27} Improved imaging techniques, more effective chemotherapy, and better limb salvage procedures have reduced the incidence of amputation from osteogenic sarcoma. Tumor resection followed by limb reconstruction frequently provides an extremity that is as functional as a prosthesis and does not appear to affect the 5-year survival rate.^{30,38,61,67,75}

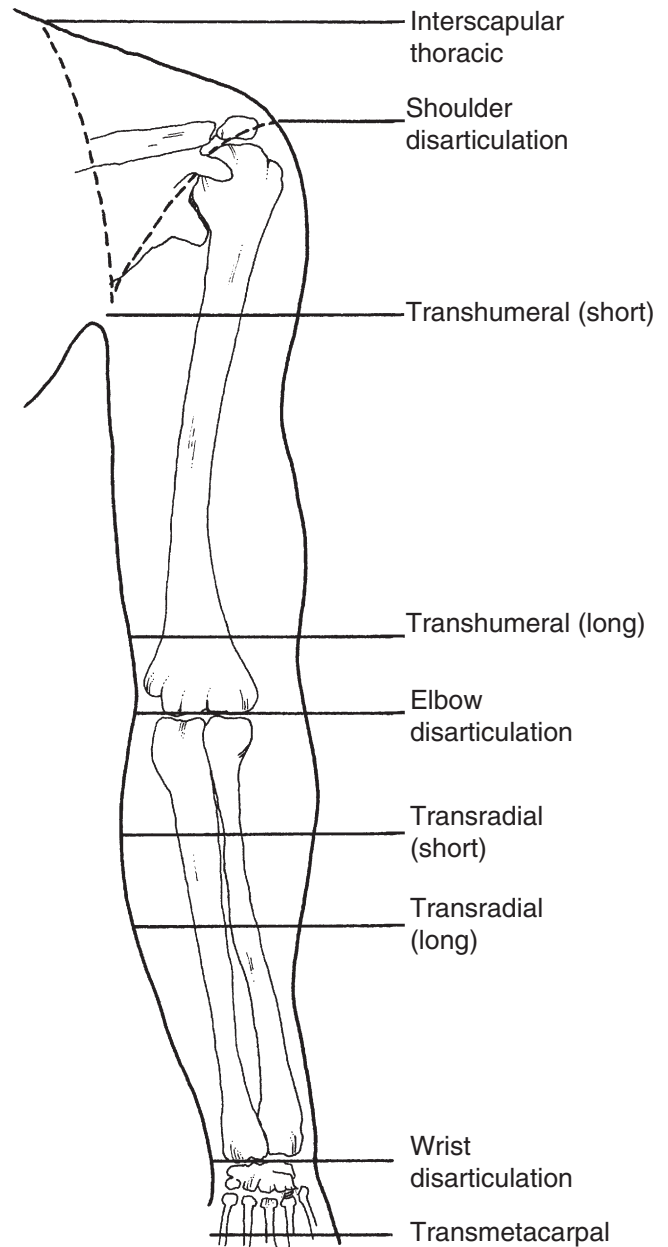

FIGURE 43-1 Levels of upper limb amputation.

Surgical Management

The surgeon is an important team member. Before performing surgery, the surgeon should consult with the health care team to maximize the functional outcome. The surgeon attempts to preserve as much length as possible and to provide a residual limb that has good soft tissue coverage and vascularization. Preservation of limb length directly affects the type of prosthesis that the limb can support; thus the surgeon and the prosthetist ideally communicate before surgical amputation or closure is performed. Conservation of residual limb length and uncomplicated wound healing

are important. During and after surgery, the primary goal is to form a residual limb that maintains maximal function of the remaining tissue and allows maximal use of the prosthesis.^{6,34,64}

Blood vessels and nerves are severed and are allowed to retract so that residual limb pain is minimized during prosthetic use. Bone beveling is a surgical procedure that smooths the rough edges and prevents the development of spurs (small projections of bone beyond the natural surface) on the remaining bone. Muscles are sutured to the bones distally by a surgical process called myodesis. The muscles involved in the function of the amputated limb are correspondingly affected by the loss.⁵¹

Surgical techniques vary with the level and cause of amputation.^{63,64} A closed or open surgical procedure may be performed. The open method allows drainage as the surgical site heals and minimizes the possibility of infection. The closed method reduces the period of hospitalization but also reduces free drainage and increases the risk of infection.⁶⁴ The specific type of amputation performed is left to the discretion of the surgeon and is often determined by the status of the limb at the time of amputation. The surgery may be ablative (removal of devitalized tissues) only or reconstructive. In either case, the surgeon must remove the part of the limb that has to be eliminated and allow for primary or secondary wound healing. When the surgeon reconstructs a **residual limb** (sometimes referred to as a stump), this is done to achieve optimal prosthetic fitting and function. The residual limb that results should be strong and resilient.⁶⁴

Client Social, Cultural, Personal, and Spiritual Contexts

Profound psychological shock and disbelief are likely to accompany amputation, particularly for those who experience a sudden trauma that causes or necessitates amputation.^{17,32,34} Seeing the residual limb for the first time can cause shock, panic, despair, self-pity, suicidal impulses, and even rage.⁴⁹ Feelings of hopelessness, despondency, bitterness, and anger may ensue. Some individuals may mourn not only the lost limb but also the possible loss of a job or the ability to participate in favorite sports or activities.

The person may feel lonely, isolated, and an object of pity. Concerns about the future, body image and function, the responses of family and friends, and employment all affect the person's emotional status.⁴⁹ Reactions to amputation may be less severe in individuals who have had a chance to adjust before the surgery is performed.^{17,32,34} Older persons may demonstrate postoperative confusion, whereas younger persons may have a sense of mutilation, emasculation, or castration.^{17,32}

The person's personality; age; cultural background; and psychological, social, economic, and vocational resources influence the reaction to amputation. Ultimately, the

individual must come to terms with the consequences of limb loss and the perception of diminished attractiveness. The person confronts discomfort, inconvenience, economic expense, loss of function, increased energy expenditure, and possible curtailment of favorite occupations. He or she may need to change employment because of social discrimination and to cope with resultant medical problems.¹⁷ Roberto expressed a strong desire to return to work. He recognized that his work capabilities had always been in the manual labor category. Roberto accepted consultation with a vocational counselor to assist him in the goal of returning to gainful employment as quickly as possible. He accepted the fact that some jobs identified by the counselor may be unfamiliar to him.

Cultural factors are important in the reaction to amputation. In some social, cultural, or religious groups, amputation may be considered a means of punishment or atonement. Such beliefs and the general aversion of society to amputation can cause the affected person to adopt the same viewpoint or to perpetuate his or her own preexisting viewpoint. Similar attitudes can result in self-hatred and self-deprecation, which may affect the person's reaction and adjustment to the disability.¹⁷

Depression and a sense of futility are considered a normal part of the adjustment process.¹⁷ If depression is severe and prolonged, psychological or psychiatric referral is indicated. Medication may be necessary to reduce depression.¹⁷ The preexisting personality of the person determines the severity and duration of the reaction, and ultimately the adjustment to the amputation and to prosthetic use.^{16,17} Roberto acknowledged his depression, reported that it was decreasing (6 months after the amputation), and said that he was actively involved in planning his life and attaining his goals for the future.

Psychosocial Contexts Influencing Adjustment to Amputation

Psychosocial adjustment depends on various factors: the individual's character and essence, the quality of the social support systems available, the sociocultural reactions to amputation, and the team's management of rehabilitation.¹⁷ Social, personal, and spiritual contexts may be significantly altered for those who have experienced amputation. Through the interview with Roberto, the therapist identifies successful adaptation and coping strategies already in place and does not note a significant change in his spiritual self.

The process of adjustment to amputation is analogous to the grieving process. The client experiences identifiable stages of denial, anger, depression, coping, and acceptance.¹⁷ Some clients move through these stages and ultimately adapt to the loss. The cause of the amputation may contribute significantly to the person's response. For example, if the amputation was caused by negligence on the part of the affected person or others, self-blame, guilt, or anger at others may be noted.

During any phase, clients may react with hostility toward themselves and the medical team. Often, overt solicitousness and friendliness may mask such hostility. Caregivers should make allowances for such behavior rather than respond in kind. Positive reinforcement through involvement in the rehabilitation process and contact with people who experienced similar amputations may help the client solve the problem of returning to former life roles.¹⁷

The client may be afraid to return to family, social, vocational, and sexual roles. Frequent discussions of fears and solutions to real or imagined problems (if possible, with a similar, successfully rehabilitated client) are important for facilitating adjustment.¹⁷

After a mourning period, the client may minimize the significance of the amputation and actually joke about it. When this phase of adjustment has subsided, the client begins seriously to consider the future. At this point, the therapist may discuss social, vocational, and educational plans with the client.¹⁷

Loss of a portion of the body necessitates revision and acceptance of the body image. Problems with acceptance of the change in body image may cause difficulties in prosthetic training.^{64,65} Fostering acceptance of the prosthesis is a crucial way to promote the client's adjustment. Establishing a training program that presents the prosthesis in a manner that meets the client's needs and goals has a beneficial effect in integrating the prosthesis into the body scheme. The prosthesis must become part of the self before it can be used most effectively. The prosthesis contributes to what society regards as a normal appearance, which may in turn help the client continue to identify with able-bodied individuals. Thus, the client may reconnect more quickly with his or her former image, leaving the door open for reconfiguration of that image to include the newly changed body.^{17,64,65}

Long-term adjustment depends on the person's basic personality structure; sense of accomplishment; and place in the family, community, and world. Generally, individuals who have had an amputation may dream of themselves as not being amputated. This image may be so vivid that persons with lower extremity amputation fall as they get up at night and attempt to walk to the bathroom without a prosthesis.⁴⁹

Rehabilitation team members can help the client understand the importance of the prosthetic training program.

Use of new prosthetic technology that addresses different lifestyles promotes participation in meaningful occupation and enhances normal appearance. The person's preferred body image should be stressed.

Postsurgical Physical Client Factors and Performance Skills

Several factors and potential problems can affect the outcome of rehabilitation. Length of the residual limb, skin integrity, edema, sensation, pain, time for healing, infection, and allergic reaction to the prosthesis are among the physical factors that affect rehabilitation potential.³⁷

Skin

Skin complications account for most postsurgical problems. These complications may occur in the preprosthetic or the prosthetic phase. Delayed healing and extensive skin grafting are complications in the preprosthetic phase. Skin breakdown, ulcers, infected sebaceous cysts, and allergic reactions can occur in the prosthetic phase. Residual limb edema can occur in either phase. Delayed healing of the incision site is one of the earliest preprosthetic complications, resulting in postponed prosthetic fitting. Necrotic areas may develop, requiring surgical intervention.⁷

To achieve a residual limb length suitable for prosthetic use, the surgeon may perform extensive skin grafting. If the skin graft adheres to bone, the area may ulcerate, requiring medical attention.⁷ Daily gentle massage by the individual, family members, or the therapist decreases the likelihood of skin graft adherence to bone and the associated complications.

Immediately after surgery, the residual limb is normally edematous as a result of fluid that collects within the soft tissues, especially in its distal portion. Compression wrapping, that is, wearing a prosthetic sock or a rigid dressing, helps decrease the edema.^{8,23,34}

During the **postprosthetic phase**, an ill-fitting **socket** or wrinkles in the prosthetic sock may cause skin breakdown or scar adhesions.²⁴ Residual limb ulceration is associated with ischemia and pressure exerted by the prosthesis on the limb. The physician should see the client in this case, and the prosthesis should not be worn until the area heals. The prosthetist should also examine the prosthesis to determine whether the socket requires adjustment. If problems persist, surgical revision of the limb may be necessary before rehabilitation can continue.⁵¹

Torque forces between the socket and the residual limb cause a predisposition to the development of sebaceous cysts. Treatment involves the application of moist heat. When the cyst becomes infected, drainage ensues and enucleation of the cyst wall may be required.⁷

Development of residual limb edema during the postprosthetic phase usually indicates an ill-fitting socket. Proximal tightness of the socket may result in distal edema, which may require a new, well-fitted socket.⁷

OT Practice Note

The client needs to receive reassurance and understanding from the entire rehabilitation team, with the focus of occupational therapy intervention on facilitation of engagement in occupation to increase participation in contexts.⁴⁹

Sensation

Loss of sensory feedback from the amputated limb is a major problem for clients. This loss of sensation is especially significant for the person with an upper limb amputation because sensory feedback from the hand, so essential for function, is lost. Residual limb hyperesthesia, neuroma, and phantom sensations are problems that interfere with functional use of the limb with or without the prosthesis.

Residual limb hyperesthesia, or an overly sensitive limb, limits functional use and causes discomfort. Desensitization consists of texture stimulation, tapping, and massage, all of which help to decrease the discomfort.^{6,24} Sympathetic nerve blocks may be used medically to manage residual limb hypersensitivity.⁵⁵

The residual limb may have areas of absent or impaired sensation requiring education and special attention when the prosthesis is worn. The person must rely on visual and proprioceptive feedback because sensation is functionally lost when the prosthesis is on the residual limb. The client must adjust to new sensations, such as the pressure of the residual limb inside the socket and the feel of the harness system, if used.⁶⁴

Neuroma

Severed peripheral nerves may form neuromas in the residual limb.^{39,44} A **neuroma** is a small ball of nerve tissue that develops when growing axons attempt to reach the distal end of the residual limb. As the axons grow, they turn back on themselves, producing a ball of nerve tissue. If the neuroma adheres to scar tissue or skin subject to repetitive pressure, it can be painful when pressed. Diagnosis is made by palpating the neuroma.⁸ Most neuromas occur 1 to 2 inches (2.5 to 5 cm) proximal to the end of the residual limb and are not troublesome.⁷

So that pain will not interfere with prosthetic wear, the neuroma must be well surrounded by soft tissue. During surgery, the surgeon identifies the major nerves, pulls them down under some tension, cuts them clearly and sharply, and allows them to retract into soft tissue of the residual limb. Neuromas that form close to scar tissue or bone generally cause pain.^{39,44}

Treatment for painful neuroma involves local anesthetic injections or ultrasound. Both treatments should be followed by massage and stretching. Surgical intervention may be necessary. Surgical options are to (1) redirect the nerve more proximally into a padded area, (2) tie the nerve ending into a proximal wound bed to protect it, or (3) tie two nerve ends to each other to prevent neuroma development. In addition, the residual limb socket may be fabricated or modified to accommodate the neuroma.^{6,71,72}

Phantom Limb

Most individuals who have had an amputation experience **phantom limb**. In its simplest form, the phantom is the sensation of the limb that is no longer there. The phantom usually occurs initially immediately after surgery. The distal

part of the limb is most frequently felt, although sometimes the person feels the whole extremity. Sensation is influenced by external stimuli such as bandaging or rigid dressing. It may dissipate over time, or the person may experience the phantom sensation throughout life. Phantom sensation that is not painful does not usually interfere with prosthetic rehabilitation. The client should be assured that the feeling is quite normal.^{63,72}

Education, supportive counseling, and early use of the residual limb with a preparatory or permanent prosthesis are effective measures for dealing with phantom limb.⁶⁴ In many cases it is best not to dwell on the discussion of phantom limb, but rather to focus on prosthetic training and the return to a former lifestyle.

Phantom Sensation

Phantom sensations are different from phantom limb in that they are detailed sensations of the limb. Individuals may describe these as cramping, squeezing, relaxed, numb, tingling, painful, moving, stuck, shooting, burning, cold, hot, or achy. Phantom sensations are described as constant or intermittent. Some individuals report a variety of sensations occurring simultaneously, especially in the hand itself. For example, they may feel the second through fifth digits cramped tightly into flexion and may describe the absence of thumb sensation, as was the case with Roberto. Alternatively, an individual may describe a painful wrist that feels stuck in one position, although the phantom forearm rotates easily with no pain. Pain is one phantom sensation. The therapist must be careful when describing or questioning the client about phantom sensations to avoid using the term “phantom pain.” This phrase is most often interpreted by clients as the absence of true pain; their psychological responses to this concept may include fear, anger, distrust in the practitioner’s knowledge or support, or confusion. Pain may diminish over time or may remain a permanent and sometimes disabling condition.

No treatment protocol has been established for the pain associated with phantom sensation. Isometric exercises of the phantom and residual limb initiated 5 to 7 days after the amputation and performed several times throughout the day may help to minimize pain. Active movement of muscles associated with the phantom limb can be beneficial, especially when the sensations are described as stuck, cramped, or tight. Mirror therapy has been eliciting some positive results in decreasing the pain of the phantom limb.^{64a,64b} Biofeedback, transcutaneous electrical nerve stimulation (TENS), ultrasound, progressive relaxation exercises, and controlled breathing exercises may reduce the pain. Activities such as massaging, tapping, and applying pressure to the residual limb may be beneficial. A physician may treat the pain by prescribing oral medications, injecting anesthetics into a specific soft tissue area, or performing sympathetic nerve blocks. Surgical revision of the residual limb is sometimes necessary to alleviate the pain.^{6,13,71} An individual may take nonpharmaceutical oral supplements

to decrease the pain. A client's excessive concern with phantom sensations requires the intervention of the team. The therapist can allay the client's fears about these phenomena by offering support, information, reassurance, and contact with other prosthesis wearers.

Bone

The formation of bone spurs is another complication that may occur during the preprosthetic phase. Because most bone spurs are not palpable, an X-ray examination is necessary to confirm their presence or absence. Bone spurs that cause pain or result in persistent drainage require surgical excision.

Wound Healing

For clients with LE amputation, delayed wound healing and excessive skin grafting are potential complications during the preprosthetic phase.

Many factors may affect normal wound healing. Postoperative infection from external or internal sources is a major concern. Clients with wounds contaminated from injury, infected foot ulcers, or wounds with other causes are at greater risk for infection. Research indicates that smoking is a major deterrent to wound healing because it diminishes or restricts circulation to the distal extremities. One study reported that individuals who smoke are approximately 2.5 times more likely to have higher rates of infection and reamputation than nonsmokers.^{15,37} Evidence suggests that failure of limb revascularization may negatively influence healing at below-knee levels. Other factors that influence wound healing include the severity of the vascular problems, diabetes, renal disease, and other medical conditions such as cardiac disease.^{14,39,68,70}

SECTION 2: Upper Limb Amputations

DENISE D. KEENAN

Body-Powered Prostheses

Candidates for Prostheses

Information regarding prostheses and the rehabilitation program should be provided before the amputation, if possible, because subsequent pain medication and anxiety may interfere with the client's ability to process new information. Team discussion is vital for determining whether to generate a prosthetic prescription and, if so, which components to include, or, alternatively, whether a prosthesis is inappropriate. The client's age, medical status, amputation level, skin coverage, skin condition, cognitive status, and desire for a prosthesis are important factors in making the decision.

Levels of Amputation and Functional Losses in the Upper Limb

The higher the level of amputation, the greater is the functional loss of the limb. Greater functional loss necessitates a more complex prosthesis and more extensive training in operation and use of the prosthesis (see Figure 43-1).²⁷ Table 43-1 provides an outline of progressively higher upper limb amputations, associated loss of function, and appropriate components required for a functional body-powered prosthesis.^{22,27} Partial hand amputations are commonly seen. When surgical replantation is not feasible, the focus is placed on reconstruction of the remaining hand. Successful fit of a partial hand prosthesis can preserve the general function of the hand or provide improved cosmesis (Figure 43-2).

Threaded Case Study | Roberto, Part 1

Roberto is 41 years old and married. He has three children and lives at home in a small community. He sustained a transhumeral amputation of his nondominant left upper limb as the result of an automobile injury 6 months ago. The residual limb is well healed, with good shrinkage. He does not describe pain in the residual limb. He had no postoperative medical complications. Roberto reports that he is performing most of his activities of daily living (ADLs) independently, using the right arm, except for bilateral activities such as cutting meat, buttoning his shirt, picking up his 2-year-old child, applying deodorant, carrying large objects, and tying his shoes. He is observed to have difficulty problem solving and identifying different strategies that would be beneficial if he is trying to complete an activity using two hands. Several instrumental activities of daily living (IADLs) challenge him, including home maintenance, car maintenance, and safely caring for his children on his own. Roberto expresses sadness about the change in his body and how it will affect his ability to work. He is concerned that his 14-year-old son will be embarrassed by his visibly weakened body, or that his daughter will be less interested in sitting with him and showing him affection. He knows that he and his wife will cope with this change, but he is worried about their financial security.

Roberto has lived in poverty all his life. His previous jobs included work as a janitor and as a field hand. Roberto says that it is important to him to return to work, but that he does not feel that he can perform the types of jobs in which he engaged before the injury. He identifies primarily with the role of caretaker for his family. Because his formal education concluded at the sixth grade level, and his communication skills have always been limited, Roberto feels that he is capable of performing only manual labor jobs. He reads basic vocabulary necessary for everyday life at home, at work, and in the community (e.g., signs, newspaper headlines). He wants to be able to provide for his family financially, and the ability to work is important to him. When employed, Roberto describes himself as a strong and steady worker. There is no hesitation in his declaration that he will find work and do it well, but he becomes tearful when he discusses this subject and states that he fears failing in this capacity. He is presently unable to work as a janitor, and this is the employment that he desires. He states that this type of work offers adequate pay and the health insurance benefits that will benefit him and his family. It is the type of work that he can perform without advanced education, and jobs are usually available in his community. His avocational interests include watching television, playing cards, woodcarving, and playing with his children.

Roberto is currently receiving state aid, and a prosthesis was funded through this source. Occupational therapy services have been authorized for him. He was referred to occupational therapy for prosthetic training and vocational evaluation.

At initial occupational therapy evaluation, Roberto states that he is accepting the prosthesis and that his depression about the loss of his arm is decreasing. He wants to wear the prosthesis and return to some type of employment. Motor skills were treated with progressive resistive exercises to increase the strength of the shoulder rotators and adductors and manual resistive exercises to strengthen control movements. The names and functions of all parts of the prosthesis were reviewed, and Roberto practiced putting on and removing the prosthesis smoothly and efficiently to enhance his process skills. Control training included practice in elbow flexion, elbow locking, elbow and wrist rotation, and terminal device (TD) opening and closing in sequence. Training in grasp and release of objects of various weights, textures, sizes, and shapes in a variety of positions (cans, wood cylinders, pencils, cabinet handles, doorknobs) was completed. Roberto describes phantom sensations in the residual arm that are not painful but are difficult to ignore. He has difficulty opening the TD because he perceives that the flexor muscle group is cramped. ADL bilateral activities that were addressed included the following: fastening trousers, handling a wallet, tying shoes, cleaning fingernails, applying deodorant, tying a necktie, buttoning a shirt, using the phone, cutting food, planting seeds in a pot, and playing cards. Work simulation activities included cleaning the floor, emptying trash, assembling electronic parts, and using hand tools.

At the completion of five occupational therapy treatment sessions, Roberto tolerates the prosthesis throughout full daytime hours. He has worn it for 90% of his community and social outings. He is incorporating it automatically into 85% of his bilateral ADL tasks. He does become physically fatigued with constant use that lasts longer than 2 hours and must take a brief respite. Roberto is pleased with the simple household maintenance activities that he has been able to perform with the help of the prosthesis. He is anxious to return to gainful employment and has met with a vocational counselor twice. Results of his occupational therapy evaluation and treatments were shared with the state vocational rehabilitation counselor assigned to him. He is scheduled for prevocational testing, and three potential jobs have been identified as possibilities for him. Future occupational therapy visits will address job simulation activities and training for the job identified to facilitate his success at the performance requirements.

Critical Thinking Questions

1. How would Roberto's ability to perform janitorial tasks and return to work be evaluated by the occupational therapist?
2. What are the specific performance skills that Roberto is unable to demonstrate that limit his ability to work?
3. What specific interventions would be most effective for enhancing Roberto's skills in functioning with the prosthesis?

■ **TABLE 43-1** | Amputation Levels, Functional Losses, and Suggested Prosthetic Components

Level of Amputation	Loss of Function	Suggested Functional Prosthetic Components
Partial hand	Some or all grip functions	Dependent on cosmesis and functional loss
Wrist disarticulation	Hand and wrist function; about 50% of pronation and supination	Harness, control cable, socket, flexible elbow hinges
Long trans-radial	Hand and wrist function; most pronation and supination	Same as for wrist disarticulation but circular wrist unit
Short trans-radial	Hand and wrist function; all pronation and supination; half cuff, wrist unit, and terminal device	Harness, control cable, self-suspending socket or traditional socket with rigid elbow hinge, wrist unit, and terminal device extension
Elbow disarticulation	Hand and wrist function; all pronation and supination; elbow flexion and extension	Harness, dual-control cables, socket, externally locking elbow, forearm shell, wrist unit, and terminal device
Long trans-humeral	Hand and wrist function; all pronation and supination; most shoulder internal and external rotation, elbow flexion and extension	Harness, dual-control cables, socket, internally locking elbow, lift assist, turntable, forearm shell, wrist unit, and terminal device
Short trans-humeral	All of the above; shoulder internal and external rotation	Same as for long transhumeral, but socket may partially cover shoulder, restricting its function
Shoulder disarticulation	Loss of all arm and hand functions	Same as for long trans-humeral, but socket covers much of the chest wall shoulder; chest strap; shoulder unit; upper arm shell; chin-operated nudge control for elbow unit
Interscapular thoracic	Loss of all arm and hand functions; partial or complete loss of clavicle and scapula	May be same as above but with lightweight materials; when minimal function is attainable, endoskeletal cosmetic prosthesis sometimes preferred
Bilateral amputation	Dependent on levels of amputation	Appropriate to level of amputation, plus wrist flexion unit and cable-operated wrist rotator

Component Parts of the Upper Limb Body-Powered Prosthesis

Various prosthetic components are available for each level of amputation (Figure 43-3). Each prosthesis is prescribed according to the client’s needs and lifestyle and is custom made and individually fitted. The prosthesis can be a functional prosthesis or a passive prosthesis. Passive does not mean nonfunctional; the prosthesis provides postural balance and can assist the individual in securing items for the functional limb.

The first five prosthetic components described in the following sections are common to all body-powered prostheses prescribed for wrist disarticulation and higher levels. They are the socket, harness, cable, terminal device (TD), and wrist unit. Many people with upper limb amputations wear a prosthetic sock between the residual limb and the prosthesis.⁶²

Prosthetic Sock

A prosthetic sock of knit wool, cotton, or Orlon Lycra is worn between the prosthesis and the limb (Figure 43-4). Silipos makes Silo-Line, which assists in minimizing

hypertrophic scarring and may be worn as the prosthetic sock or covered with an additional sock. The function of the prosthetic sock is to absorb perspiration and protect against irritation that can result from direct contact of the skin with the socket. The sock compensates for volume change in the residual limb and contributes to fit and comfort in the socket.^{62,74}

Socket

The socket is the fundamental component to which the remaining components are attached. A cast molding of the residual limb is used to construct the socket to optimize fit, comfort, and function. It fits snugly over the limb and extends as far as the wrist unit with a trans-radial prosthesis or to the elbow unit with a trans-humeral prosthesis. It should cover enough of the residual limb to be stable but not so much that it unnecessarily restricts movement. Uneven pressure distribution may lead to skin problems.^{62,72}

The length of the residual limb determines whether a socket is of single- or double-wall construction. The single wall is most commonly used with a wrist disarticulation or

FIGURE 43-3 Component parts of standard trans-humeral prosthesis.

FIGURE 43-4 Prosthetic sock worn under the prosthesis.

elbow disarticulation level of amputation. The single-wall socket requires no shaping over the residual limb. Most sockets have a double wall. This construction involves an inner socket with an outer shape created in foam or wax, covered with an outer shell that is laminated to it. The two shells, inner and outer, become one. The outer wall provides a structurally cosmetic surface. The inner wall maintains

total contact with the skin surface of the residual limb to distribute socket pressure evenly. Recently, flexible frame-type sockets have been favored. The inner socket is flexible and is covered with a rigid outer frame that carries the hardware. This type of socket allows for volume and contour changes that occur when muscles contract and relax. Wearers report that this type of socket is cooler than conventional alternatives.³ The Utah Dynamic Socket has a unique socket design that provides mediolateral and rotational stability through shaping of the shoulder region.³

Harness and Control System

The prosthetic control system functions through the interaction of a Dacron harness and stainless-steel cable. The figure-of-eight harness is commonly used, although others are available. The harness is worn across the back and shoulders or around the chest and fastens to the socket to secure the prosthesis. When the amputation level is higher, the harnessing system becomes more complex.

Loss of muscle power and range of motion (ROM) may necessitate variations in the harness design. A properly fitted harness is important for both comfort and function.^{58,62,72}

A flexible stainless-steel cable, contained in Teflon housing, attaches to the harness on one end via a T-bar or hanger fitting and attaches to a functional component of the prosthesis on the other end. Spectra fiber, an extremely strong material, has been used recently instead of the stainless-steel cable because it glides through the housing with less friction. A trans-radial prosthesis uses one cable to operate the TD, which is connected by a ball swivel. A trans-humeral prosthesis uses a second cable to lock and unlock the elbow unit. Specific upper body movements create tension on the cables, thereby operating the prosthesis. A properly fitted control system maximizes prosthetic control while minimizing body movements and exertion.^{2,58,72}

Terminal Device

The **terminal device**, the most distal component, functions to stabilize or hold an object. When choosing the most appropriate TD for a prosthesis, team members consider the client's age and life roles.

Two styles of TDs are commonly prescribed: the hook and the hand. Many TDs and prosthetic hands have the same shaft size at their base, which allows them to be interchangeable. Hooks are of two basic designs: canted or lyre shaped.¹⁸ They may be voluntary opening (VO) or voluntary closing (VC).⁴⁶

The VO TD opens when the wearer exerts tension on the control cable that connects to the "thumb" of the TD. When tension is released, rubber bands or springs close the fingers of the TD. The number of rubber bands or springs determines the holding force of the TD.

VC TDs close by tension applied to the control cable. The tension may also lock the TD and maintain the grasp on the object. The VC TD automatically opens by spring operation when the cable is relaxed. The VO TD was

FIGURE 43-5 Hosmer-Dorrance hook terminal devices are available in a variety of materials, shapes, and sizes that can be matched to the particular functional needs of a child or adult. (Courtesy Hosmer-Dorrance Corp., Campbell, CA.)

commonly prescribed in the past. Since World War II, more modern alternatives have become available (Figure 43-5).^{2,3,10}

VO TDs have several options to better suit the wearer's lifestyle. The option chosen depends on the desired durability, weight, or grip of the TD.

Stainless-steel TDs are prescribed for activities requiring a durable TD, such as yard work or construction. Aluminum TDs are recommended for lighter work and to reduce the total weight of the prosthesis for a person with a higher-level amputation. Most TDs have a neoprene lining or a serrated grid between their fingers. The neoprene lining increases the holding friction and minimizes damage when holding objects. Neoprene is a high-density rubber that wears out faster than the stainless-steel grid and disintegrates if it comes in excessive contact with some chemical solutions. The TD must be sent back to the manufacturer for neoprene replacement.

A variation of the standard VO TD is the heavy duty model. This model is made of stainless steel and has a serrated grid between its fingers. The heavy duty model is designed to hold tools, nails, and long-handled instruments such as a broom or shovel.

A prosthetic hand is also available as a TD. It attaches to the wrist unit and is passively operated or cable operated. The passive hand has cosmetic and lightweight appeal, but it is also functional because it is used to push, pull, and stabilize objects. The same control cable that operates the hook activates the functional prosthetic hand. It comes in VO and VC styles. As with the hook-style TD, the VO hand is preferred and prescribed more often than the VC hand. A flesh-colored rubber glove fits over the prosthetic hand for protection and a more realistic appearance.⁶²

The client's lifestyle and activities determine the most appropriate TDs. It is important to provide the wearer with certain information regarding the differences between hook- and hand-style TDs. The hook TD is lighter and provides better visibility when grasping objects. It is more durable and functional than prosthetic hands. Hook VO TDs are mechanically simpler than both VC TDs

and functional prosthetic hands. Prosthetic hands are more cosmetically appealing than prosthetic hook TDs. However, the cosmetic glove that covers the hand stains easily, wears out quickly, and disintegrates if it comes in contact with certain cleaning solutions and chemicals. Many individuals with amputations choose an interchangeable hand for social occasions in addition to a hook TD for daily activities.¹⁸

Wrist Unit

The wrist unit connects the TD to the forearm socket and serves as the unit for interchange and to pronate and supinate the TD for prepositioning purposes. The wearer rotates the TD by turning it with the sound hand, by pushing the TD against an object or surface, or by stabilizing the TD between the knees and using the arm to rotate it. With bilateral amputations, TD rotation in the wrist unit may be accomplished by cable operation. Five basic types of wrist units are available, and the unit for a particular patient must be chosen according to its ability to meet the person's needs in daily living and vocational activities: the friction-held unit, the locking unit, the wrist flexion unit, the oval unit, and the ball-and-socket unit.

Friction-held wrist units hold the TD in place by friction provided by a rubber washer or setscrews. Tightening the washer or screws increases friction. Friction is sufficient to hold the TD against moderate loads. Friction-held units are mechanically simple but are not as strong as locking units.

The locking wrist unit allows the TD to be manually positioned and locked into place. The quick-disconnect locking wrist unit is most common. An adapter is permanently attached to the base of the TD. The unit has a button on its side that locks, unlocks, and ejects the TD. Inserting the TD into the wrist unit locks it into place. Another style of TD with the same adapter type on its base may be locked into place. Friction and locking wrist units allow the TD to be rotated up and down but not deviated in toward the body.

The wrist flexion unit allows the TD to be manually flexed and locked into position. It is generally used on the dominant side of a person with bilateral amputations to facilitate midline activities close to the body, such as dressing and toileting.^{2,46,62,72,74}

The oval unit, which conforms to the shape of the wrist, is used on the wrist disarticulation prosthesis. It is thinner than the other wrist units, so the prosthesis may more closely match the length of the sound arm.

A ball-and-socket wrist unit is also available (Figure 43-6). This unit is unique in that it allows prepositioning in multiple wrist positions. It has constant friction, and the magnitude of the loading is adjustable.¹⁸

The socket, harness, control system, TD, and wrist unit are components common to all body-powered prostheses. Remaining body-powered prosthetic components maximize function at specific levels of amputation. These components are the elbow hinges for trans-radial prostheses, elbow units for trans-humeral prostheses, and shoulder units designed for shoulder prostheses.

Trans-Radial Hinges

A trans-radial prosthesis employs two hinges, one on each side of the elbow, that attach to the socket below the elbow and to a pad or cuff above the elbow. These hinges stabilize and align the trans-radial prosthesis on the residual limb. When properly aligned, the hinges help distribute the stress of the prosthesis on the limb.

Two hinge styles, flexible and rigid, are available for the prosthesis. Flexible hinges are used on wrist amputation and long trans-radial prostheses. They usually are made of Dacron and connect the socket to a triceps pad positioned over the triceps muscle. The flexibility permits some forearm rotation, decreasing the need to rotate the TD manually in the wrist.

FIGURE 43-6 Ball-and-socket wrist unit.
(Courtesy Otto Bock HealthCare, Minneapolis, MN.)

Medium to short trans-radial prostheses may have a socket that covers most of the residual limb below the elbow and rigid or flexible hinges to provide stability. Rigid hinges usually are made of steel and attached to a laminated Dacron biceps half-cuff positioned behind the arm, which is sturdier and provides more support than the triceps pad. They are used less frequently now and have been replaced by a design using a self-suspending socket, where supercondylar flares mimic some of the function of the hinges and triceps pad. Team members consider the amount of residual function and the length of the limb when choosing the appropriate hinge style for the trans-radial prosthesis.⁴⁶

Elbow Units for Trans-Humeral Prostheses

A prosthetic elbow unit is prescribed for the person who has had an amputation through the level of the elbow or higher. The elbow unit allows 5 to 135 degrees of elbow flexion and locks in various positions. The two main types of elbow units are internally and externally locking units. The more durable internally locking unit is prescribed for a person who has had an amputation 2 inches or more above the elbow. This unit connects the trans-humeral socket to the prosthetic forearm. The locking mechanism is contained within the unit and attaches to a control cable. A lift assist, which consists of a tightly coiled spring attached to the elbow unit and forearm shell, helps reduce the amount of energy required to lift the forearm shell. The lift assist also allows a slight bounce in the forearm when walking with the elbow unlocked, which enhances the appearance of a natural arm swing.

A friction-held turntable positioned on top of the elbow unit allows the prosthetic forearm to be rotated manually toward or away from the body. Lateral and medial aspects of a trans-humeral prosthesis are shown in Figure 43-7. The internally locking unit is 2 inches long and therefore does

A

not fit on a person who has had an amputation close to the elbow.

Correspondingly, the externally locking elbow unit is prescribed for a person who has an elbow disarticulation or an amputation within 2 inches above the elbow. This unit, which consists of a pair of hinges positioned on either side of the prosthesis, attaches the socket to the forearm. The cable attaches to one of the hinges, which locks and unlocks the unit.

Shoulder Units

A person with an amputation at the shoulder requires a prosthesis with a shoulder unit in addition to the TD, wrist unit, forearm shell, elbow unit, socket, harness, and cables. Because of the high level of amputation, however, shoulder and back movements are not sufficient to use a cable-operated shoulder unit. Thus, most shoulder units are manually operated and friction held. The TD and elbow units may still be cable operated.

Two shoulder unit styles that are often prescribed are the flexion-abduction unit and the locking shoulder joint. The flexion-abduction (or double-axis) unit provides manual prosthetic positioning in flexion and abduction and is friction held (Figure 43-8).¹⁸ The locking unit allows the prosthesis to be locked in various degrees of shoulder flexion. This feature is helpful because the prosthesis is heavy and the friction style may not be strong enough.

With an interscapular thoracic amputation, all or a portion of the scapula and clavicle is removed with the arm. If standard prosthetic components were used, the prosthesis might be too heavy for practical use. Therefore, an endoskeletal prosthesis, made from lightweight materials such as a single aluminum alloy surrounded by a soft foam shape, is often prescribed to decrease its weight. The system provides its own style of prosthetic joints, which will not withstand heavy duty usage. An endoskeletal prosthesis with a lightweight cosmetic cover is commonly prescribed as an aesthetic prosthesis with limited functional value.

Upper Limb Preprosthetic Program

The preprosthetic program begins when the decision to perform an amputation is made, or when a client is evaluated after a traumatic amputation.³⁴ Education regarding prosthesis options, relaxation techniques, the phantom limb phenomenon, and general conditioning may begin in some cases before the surgical amputation. During the period between amputation and fitting of the prosthesis, the client participates in a program designed to prepare the residual limb for a prosthesis, facilitate adjustment to his or her loss, and achieve maximal independence in self-care.^{50,72} The occupational therapist is the primary person who will be coordinating this program. It is also important for the team to assist the client in securing the financial resources necessary to complete rehabilitation and obtain a prosthesis if desired.

FIGURE 43-8 Hosmer-Dorrance flexion/abduction shoulder joint, shown attached to a shoulder disarticulation-type prosthesis, provides passive mechanical range of motion in flexion to 90 degrees and abduction to 135 degrees. An extension stop is provided to restrict extension.

(From Hunter JM, Mackin EJ, Callahan AD: *Rehabilitation of the hand: surgery and therapy*, ed 4, St Louis, 1995, Mosby.)

Preprosthetic Evaluation

To establish an individualized intervention plan, the therapist must complete a thorough evaluation, which includes assessments of the client’s medical history; body functions (mental, sensory, movement, skin); motor skills (posture, coordination, strength and effort, energy); process skills (adaptation, organizing space and objects); activities of daily living (ADLs); instrumental activities of daily living (IADLs); education; work; leisure; and rest and sleep and social participation.¹ The therapist will also consider the

Box 43-1

Interventions for Body Functions, Body Structures, and Performance Skills

- Improve body image, self-image, psychosocial adjustment.
- Promote independent function during ADLs and IADLs.
- Promote wound healing.
- Improve desensitization of the limb.
- Establish pain management practices.
- Promote residual limb shaping and shrinking.
- Promote proper skin hygiene.
- Promote care of insensate skin.
- Maintain and restore passive and active range of motion.
- Maintain and restore upper body strength and endurance.
- Improve understanding of prosthetic components and options.
- Recommend appropriate prosthetic components.

values, beliefs, and spirituality of the person. A statement of the client's goals is important for orienting treatment toward meeting these goals and for determining the client's understanding of the program and prosthesis functions.⁶ The interview portion of Roberto's evaluation was essential in establishing his desires, goals, and concerns and is necessary in developing the most appropriate intervention for him.

Preprosthetic Treatment

The intervention plan is based on evaluation results. Most plans include the interventions for body functions, body structures, and performance skills that are listed in Box 43-1.

Depending on the level of amputation, medical conditions, and ADL status, the decision is made whether to complete the preprosthetic program on an inpatient or outpatient basis. In most cases in which the client has undergone a unilateral amputation, therapy services are offered on an outpatient basis. When an individual loses a dominant hand, which is often the case with unilateral amputation, minimal training in one-handed activity completion may take place. The focus of this training is on problem-solving approaches to task completion with new hand dominance and on encouraging the client to practice completing activities independently. A person with bilateral limb amputations may need to be admitted to a facility because of the significant amount of therapy and assistance required. In the case of bilateral upper limb loss, the client has significant issues with functional independence to address, as well as emotional issues related to a severe life change that affects emotions, finances, life goals, body image, and relationships. The complexity of the issues is best addressed in an inpatient setting. A client who has had both upper limbs amputated will appreciate being introduced to other persons who are using one or two prostheses to function. The team closely monitors the residual limbs

and reports problems to the physician. If the client is followed on an outpatient basis, frequent medical visits may be necessary to monitor progress. Early fit of a prosthesis has been shown to significantly enhance functional prosthetic use.⁵³ Fitting clients with a preparatory prosthesis before they become "one-handed" facilitates their success with prosthetic function.

Body Image, Self-Image, Psychosocial Adjustment

Facilitating the client's engagement in occupations in response to altered activity demands and restoring family, occupational, and social relationships are the primary focus of occupational therapy intervention. The therapist helps the client integrate the physical loss into his or her life. It is essential that the therapist validate the client's right to be in control of his or her life. The person's values, beliefs, spirituality, and well-being direct the occupational therapist's interventions. Roberto's strong work ethic and goal of returning to work as quickly as possible to fulfill his role identity must be honored. It is not uncommon for individuals who have undergone an amputation to experience a physical shock to their body, as well as an emotional shock to their spirit. Fear, confusion, anger or frustration, emotional swings, introspectiveness, and dependence are common responses following loss. Allow the client to experience and express these feelings during therapy sessions, and promote recognition by family members and the client of the common nature of these feelings.¹

Assist the client in describing which of his or her features are pleasing. Encourage the client to continue with useful habits to maintain a normal routine. Give positive feedback for every accomplishment reported or observed.

Once the person's level of social participation before the amputation is explored, facilitate opportunities to engage in similar events. The client may be encouraged to participate in one event monthly or weekly, initially in the company of a family member or friend. Introduce the client to others who have suffered a similar limb loss to allow communication with a peer. Provide adaptive equipment that allows the client to resume leisure activities and increase his or her participation in life. Some clients are uncomfortable with the changes in fashion and clothing style that are recommended to ease the dressing process. Recommend a tailoring service, or help the client identify a family member, friend, or neighbor who would be willing to modify some of the clothing.

Activities of Daily Living

During the preprosthetic period, the client with a unilateral amputation is encouraged to use the sound arm to perform ADLs. If the dominant arm was amputated, training may be required for the nondominant limb to assume the dominant role. In the author's experience, most clients change dominance to the sound extremity automatically as a result of the adaptive process, and minimal intervention is necessary for this to occur. Some clients need support and a few

sessions of practice performing meaningful activities with the nondominant hand to understand and accept their ability to perform and create new habits. The focus of performance is on problem-solving techniques and adaptations that will allow clients to modify multiple activities in their daily lives. Some adaptive equipment is appropriate for increasing independence with bilateral activities. Practice in writing and activities requiring dexterity and coordination may be helpful in the retraining process.^{50,62,72} The importance of early fitting of a prosthesis cannot be minimized. Early fit programs are very successful in helping the client with an amputation to incorporate the new extremity more rapidly into his or her daily activities.²

In the case of bilateral amputations, adaptive equipment should be introduced as soon as possible to increase the client's level of independence. The equipment may include a utensil cuff secured by elastic or Velcro to the residual limb to aid in eating, writing, and hygiene; a dressing tree with hooks to hold articles of clothing in a position conducive to donning them, to improve dressing independence; and loops added to items such as socks and towels. Individuals with bilateral amputations can learn to complete activities using foot skills, such as holding items between the toes in a functional pinch for dressing, eating, and turning pages, and using the toes to push buttons on a keyboard or telephone pad.

Wound Healing

When the surgical dressing is removed, the residual limb is massaged to discourage scar adhesions, increase circulation, aid in desensitization, and reduce swelling. Massage of the limb also helps the client overcome fear of touching or moving the residual limb. Massage over the incision site begins once the incision has stabilized.⁶ Initially, light massage over healed areas is performed, followed by deeper pressures, as tolerated by the client. If skin grafts have been placed, the therapist must confer with the surgeon to determine tissue status before performing any scar remodeling techniques.

Desensitization

The person's residual limb may be hypersensitive after surgery, requiring a technique known as desensitization. By overstimulating a hypersensitive peripheral area with nonharmful stimuli, the central nervous system learns to accept these stimuli as nonharmful and to minimize aversive responses to them. Massage is one method of desensitization. Other methods are tapping, vibration, constant pressure, and rubbing of various textures on the limb, such as terry cloth, silk, and cotton. The therapist introduces the tissue to soft, lightweight, smooth textures and progresses to rough, hard, uneven, heavier textures as the client is able to tolerate them. A therapist with a thorough understanding of nerve anatomy and hierarchy of response to stimuli should be consulted, and the intervening therapist must understand this information before subjecting the client's

tissues to a desensitization program. As the techniques are performed, the therapist teaches them to the client and his or her family members or caregivers to facilitate completion at home.^{6,24}

Wrapping

Shrinking and shaping the residual limb are necessary to form a tapered limb that will tolerate a snug-fitting socket. Compression using an elastic bandage, a tubular bandage, or a shrinker sock applied to the residual limb aids in the shrinking and shaping process. When an elastic bandage is applied to the limb, a figure-of-eight method is used—not a circumferential method in which the bandage is wrapped around the limb spirally. Care must be taken to apply the bandage smoothly, evenly, and not too tightly from the distal to the proximal end of the residual limb. Care must also be taken to avoid wrapping skin-grafted areas too tightly or without an inner nonadherent dressing applied, so that the graft is not compromised. A limb that is wrapped incorrectly may take longer to shrink and shape. A limb with a trans-radial amputation should be wrapped up to or above the elbow. A limb with a trans-humeral amputation should be wrapped up to or above the shoulder. Short trans-humeral amputations usually must be wrapped around the chest to help stabilize the wrap.^{62,72} The elastic bandage should be changed several times a day and the skin checked between wrappings. Several compression wraps are required, so that the limb can be wrapped in a clean bandage at all times, except when bathing. Wraps should be washed often with a mild soap, rinsed well, and allowed to dry thoroughly while lying flat. For longer life, bandages should not be wrung out after washing.⁶

Shrinker socks generally are preferred over elastic bandage wrapping because the client can more independently don the sock, and because changing the sock is much quicker than changing the wrap. Compression tubing sewed closed or with a knot tied at one end is commonly used. The tubing may be attached to a chest strap if necessary. Occupational therapists collaborate with prosthetists to identify options available or recommended for the client's limb.

Circumference Measurements

Circumference measurements of the residual limb are taken often and in the same area to determine when the person is ready to be casted for a prosthesis. The therapist uses a tape measure to establish baseline and subsequent measurements (Figure 43-9). When edema is gone and circumference measurements have stabilized, the limb is ready to be casted.

Skin Hygiene

Instruction in proper residual limb hygiene is an important aspect of the preprosthetic program. The limb should be washed daily using a mild soap, rinsed thoroughly, and patted dry. The limb should dry completely before the wrap or sock is reapplied.⁵

FIGURE 43-9 Measuring residual limb circumference.

Insensate Skin

The client with an upper limb amputation requires instruction regarding the care and safety of a residual limb that lacks all or partial sensation. The client is taught to inspect the limb when removing the wrap and washing the limb. Problems should be reported to the therapist or physician. The client also learns to visually track a sensory-impaired residual limb when completing activities, such as wearing protective clothing while engaged in yard work or recreational activities, adjusting the position of the limb when seated in a chair and reading to prevent stretch or compression injury to the tissues, and refraining from using the limb for sensory input, such as testing water temperature.

Upper Extremity Range of Motion, Strength, and Endurance

Motor skills are promoted once medical approval is provided. The client begins exercises designed to maintain and increase range of motion (ROM) and to strengthen upper quadrant and trunk muscles. Depending on the level of amputation, the client performs specific exercises that mimic the movements required to operate the prosthesis. The therapist manually positions and holds the residual limb in the desired posture and asks the client to resist the hold, facilitating increased strength of the appropriate muscles. In the case of a trans-radial amputation, it is important to strengthen the muscles of the shoulder, elbow, and scapula. Pronation and supination movements are also important for long trans-radial amputations. Trans-humeral amputation strengthening may include a movement combining shoulder depression, extension, and abduction that mimics the operation of the body-powered prosthesis. Isometric exercises enable the client to engage in a strengthening program without equipment. Exercises may be completed with rubber tubing, elastic band, or strap-on weights. It may be appropriate to guide the client in the modified use of home or gym equipment to complete exercises. Chest expansion capability is important for higher-level amputations, and when the harness wraps around the chest. A tape measure positioned

FIGURE 43-10 Home program of upper limb strengthening to prepare the arm for prosthesis. Resistance tubing is being used for resistive exercise.

around the chest helps in the documentation of increased chest expansion.

The occupational therapist prepares a home program containing exercises for general strengthening and body conditioning, as well as specific movements taught during therapy. (Figure 43-10).

Prosthetic Information and Prescription

During the preprosthetic period, the client consults with a prosthetist to learn information about the benefits and limitations of a variety of prostheses. The prosthetist generally provides information regarding specific prosthetic options, and the therapist promotes the client's understanding of the options as they relate to the client's performance in areas of occupation. Through collaboration and evaluation, the therapist understands the values, beliefs, and spirituality of the client. What do the amputation and the prosthesis mean to the client at this stage, and what are the client's future goals? Roberto verbalized his desires for return to gainful and fulfilling employment to provide for his family. In selecting prosthetic components, the therapist must consider whether the client's primary desire is function or cosmetics, and which style is most appropriate for the client's needs and choices. Prosthetic components can be introduced in several ways: through slides, videotapes, photographs, interaction with a person with a similar amputation wearing a prosthesis, practice in handling a prosthesis, and a collaborative visit to the prosthetist.

Prosthetic Program

The amount of training each client needs depends on how quickly he or she is able to understand the body structures and mechanics required to operate the prosthesis and on

the client's current motor, sensory, cognitive, and emotional regulation skills. These affect the cueing needed by the client to include the prosthesis in an activity and the carry-over of motor skill between activities. When a long period has elapsed between the amputation and fit of the prosthesis, the client may require more cueing because he or she has become adept at one-handed activities. Some clients arrive at therapy already able to operate their prosthesis, whereas others require extensive training.

Ideally, the prosthetist and the therapist coordinate fitting of the prosthesis and initiation of therapy. The therapist may arrange to be present for the final fitting session with the prosthetist and the client. Communication between the wearer, therapist, and prosthetist is essential to ensure that the prosthesis fits and functions optimally. It is common that the prosthesis requires adjustments, and the therapist initiates consultation with the prosthetist when these needs become evident.

The prosthesis will not be as functional as a normal arm, and training for the client with a unilateral amputation should stress that the prosthesis functions primarily as an assist or helper to the sound arm. If the prosthesis is presented in this manner, the wearer may experience less difficulty when incorporating it into daily occupations. In training the person with bilateral amputations to function with prostheses, the likelihood of success with one prosthesis is high, as the wearer instantly recognizes the benefit of the prosthesis to independent function.

The prosthetic program begins after the final fitting of the prosthesis. This final fitting may be done with a preparatory prosthesis rather than a definitive prosthesis, incomplete in its cosmetic form. The occupational therapy intervention is occupation-based and includes purposeful activity and preparatory methods to facilitate therapeutic goals. These include the following:

- Promote positive body image and self-image
- Establish successful adaptation and problem-solving skills
- Promote proper residual limb and prosthetic sock hygiene
- Promote recognition of prosthesis terminology and function
- Promote proper care of the prosthesis
- Establish a prosthesis-wearing schedule and routines
- Promote control of the prosthesis (control training)
- Promote use of the prosthesis in activity (use training)
- Promote independent ADL and IADL function with the prosthesis (functional training)
- Promote driving modifications and ability
- Recommend a home activity program
- Restore upper extremity muscle strength necessary for operation of the prosthesis
- Prevent repetitive use injury of the sound arm
- Promote vocational re-entry
- Establish follow-up care
- Promote social routines and community integration

Prosthesis checkout, control training, use, and functional training are individualized according to the client's level of amputation.

Body Image and Self-image

The interview process reveals the client's lifestyle, habits, routines, rituals, primary roles, and social and personal relationships. The occupational therapist is the professional who investigates and responds to the spiritual essence of the client. Expanding the interview with questions about the client's interests, social activities, style of dress and appearance, and self-concept is necessary to establish the client's preinjury behaviors and skills. The therapist observes the client's body language. Is the residual limb hidden? Does the client use the residual hand and arm to communicate? Is the client visually attentive and engaged in the interview or intervention? What does this tell you about the client's self-image and body image? Provide opportunities for the client to verbalize his or her accomplishments and skills. Ask the client to describe those parts of the body with which he or she is most pleased. Create therapy sessions that facilitate the client's ability to style hair, apply jewelry, fasten a tie, apply makeup, resume general physical activity and recreation, drive independently, and manage a briefcase or personal electronic equipment.

Residual Limb and Prosthetic Sock Hygiene

The client is instructed in residual limb hygiene and care of the prosthetic sock in the early phase of prosthetic training. The residual limb and armpit should be inspected, washed, and patted dry, and deodorant should be applied daily. If the client wears a prosthetic sock, he or she should own several so that a clean one may be worn daily to decrease the incidence of skin problems. The socks should be hand washed, gently squeezed, and placed on a flat surface to dry in their original dimensions. Wearing an undergarment under the harness is often recommended because it will absorb perspiration and protect the axilla and back from irritation. It may be necessary to change prosthetic socks and undergarments twice daily in hot weather.^{72,74} To minimize sweating, educate the client in the application of antiperspirant to the portion of the extremity within the socket.

Prosthesis Terminology and Function

The wearer should learn the terminology and function of each prosthetic component. This task allows the client to communicate with the rehabilitation team, using terminology understood by all, regarding operation of the prosthesis and difficulties with or repairs needed to the prosthesis.^{5,72,74}

Care of the Prosthesis

Instructions regarding care of the prosthesis are provided and reviewed. Generally, the prosthetist educates the person in this area and the therapist reviews the

information with the wearer. The socket should be cleaned daily. Cleaning at night is recommended to allow the prosthesis to dry completely. Wearing the prosthesis when the socket is wet may lead to skin problems. Components should be cleaned and maintained according to the manufacturer's or prosthetist's specifications. Daily inspection of the prosthesis will help prevent unnecessary problems.⁵

Prosthesis-Wearing Schedule

A prosthesis-wearing schedule is established and reviewed during the first training session. The client initially wears the prosthesis 15 to 30 minutes three times a day. The skin must be closely monitored, and wearing time is increased only if the skin remains in good condition. If there are no skin problems, the three scheduled wearing periods may be increased by 30 minutes each day. By the end of the first week, the client may be wearing the prosthesis all day, as was the case with Roberto. If skin problems occur, the therapist, prosthetist, or physician must be notified. The prosthesis should not be worn until the skin problem has cleared. Restarting the initial wearing schedule may be necessary to decrease the risk of additional skin problems.⁵

As the person's wearing tolerance increases, the number of rubber bands on the TD can be increased. Each rubber band added to the TD increases the pinch force by approximately 1 pound. It is best to wait several days after adding one rubber band before adding another to allow the residual limb's skin and strength to acclimate. If the addition of a rubber band substantially increases limb pain or skin irritation, it should be removed until the pain diminishes and skin tolerance increases.

Checkout of the Prosthesis

When the prosthesis is received, team members check it to ensure that it meets prescription requirements, is functioning efficiently, and is mechanically sound. The prosthesis is checked for fit and function against specific mechanical standards developed from actual tests on prostheses worn by individuals. Tests performed are comparative ROM with the prosthesis on and off; control system function and efficiency; TD opening in various arm positions; amount of socket slippage on the residual limb under various degrees of load or tension; compression fit and comfort; and force required to flex the forearm or open/close the TD.^{2,58,72} Communication between the wearer, therapist, and prosthetist is essential to ensure an efficiently operating and comfortable prosthesis. The following methods and standards for prosthesis checkout were adapted primarily from Wellerson.⁷² Step-by-step instructions for prosthetic checkout are available in Wellerson⁷² and Santschi.⁵⁸ The prosthesis checkout is primarily performed by the prosthetist. Understanding the process allows the occupational therapist to recognize fit problems that interfere with a client's engagement in activities.

Trans-radial Prosthesis

The therapist measures elbow flexion with the trans-radial prosthesis on and off the wearer. ROM should not differ by more than 10 degrees, except when there are joint or muscle limitations. Pronation and supination of a wrist disarticulation or a long trans-radial residual limb with the prosthesis on should not be less than 50% of the rotation possible without the prosthesis.

With the elbow flexed at 90 degrees, the client should be able to open the TD fully. The TD is also opened near the mouth (elbow fully flexed) and again near the zipper of the trousers (elbow extended). From 70% to 100% of TD opening should be achieved in these two positions.

Trans-humeral and Shoulder Prosthesis

With the trans-humeral prosthesis on and the elbow locked, the client is instructed to move the residual limb (humerus) into shoulder flexion, extension, abduction, and internal and external rotation. The ROM of each of these is measured. Minimal standards for shoulder ROM with the prosthesis on are as follows: 90-degree flexion, 30-degree extension, 90-degree abduction, and 45-degree rotation. The previous part of the checkout is not applicable for the shoulder prosthesis.

With the elbow unlocked, the client is instructed to flex the shoulder slowly, which flexes the mechanical elbow. Elbow ROM should be about 10 to 135 degrees. The therapist measures the amount of shoulder flexion, which should not exceed 45 degrees, that is required to fully flex the mechanical elbow. The client should also be able to abduct the prosthesis to 60 degrees without locking of the elbow.

The client flexes the elbow to 90 degrees, locks the elbow, and then activates the TD. Full TD opening should be attained in this position. The TD is then opened in full elbow flexion with elbow locked (Figure 43-11) and extension with elbow locked (TD at fly of trousers). At least 50% of full TD opening should be obtained.

With the elbow unlocked, the client is asked to walk and practice swinging the prosthesis without locking the elbow. This action mimics a normal arm swing during gait.

The client flexes the elbow to 90 degrees, locks the elbow, abducts the residual limb to 60 degrees, and then rotates the humerus. The client should be able to control the prosthesis during this motion. The socket should not slip around the residual limb, and the client should not feel pain or discomfort during these maneuvers. When the prosthesis is removed, the residual limb should not appear discolored or irritated.

Prosthesis checkout also includes technical inspection of the prosthesis to determine correct length, fit, and mechanical function of all parts. Various forms have been devised to record all information for complete checkout of the prosthesis. The initial checkout is performed before prosthetic training begins, and the final checkout is done after prosthetic revisions and adjustments and during or after training.^{5,58}

FIGURE 43-11 Trans-humeral prosthesis checkout: opening terminal device at mouth with elbow locked in full flexion.

Donning and Doffing the Prosthesis

Two common methods of donning and doffing the body-powered prosthesis are the coat method and the sweater method. Either method can be used by a person with unilateral or bilateral amputations. The method used depends on the client's ease of use. Whichever the method, the harness and cables must not be kinked or twisted around the prosthesis before starting. When the prosthesis is removed, it should be placed on a surface so it is ready for the person to don again.

Coat Method

The coat method is similar to placing one arm in the coat sleeve and manipulating the coat to a position where the other arm can reach the sleeve. The coat method has two variants. In the first method, the person places the prosthesis on a table or bed and pushes the residual limb between the control cable and the Y-strap from the medial side into the socket. By raising the residual limb or leaning sideways, the person places the harness across the shoulder on the amputated side and dangles the harness down the back. The sound hand reaches around the back and slips into the axilla loop. The person then slips into the harness as if putting on a coat. The shoulders are shrugged to shift the harness forward and into the correct position.

The second approach works by placing the axilla loop of the harness on the sound arm first. For example, if the client has a trans-humeral amputation, it might be easier to lock the elbow at 90 degrees; position the axilla loop on the sound arm above the elbow; grasp the prosthetic forearm; and raise the prosthesis over the head, allowing the harness to position itself across the back. By raising the residual limb, the person positions it in the socket (Figure 43-12).

FIGURE 43-12 Coat method of donning prosthesis.

To remove the prosthesis, the person uses the TD to slip the axilla loop off the sound side and then slips the shoulder strap off the amputated side. The harness is slipped off like a coat.^{2,58,72}

The person with bilateral amputations can use the coat method by placing the prostheses face up on a surface, placing the longer residual limb into the socket, and elevating the prosthesis, allowing the other prosthesis to hang across the back. The person then leans to the side and places the shorter limb in the prosthesis.^{58,74} To remove the prosthesis, the person shrugs the harness off the shoulders and removes the prosthesis from the shorter side first. Before removing the prosthesis on the longer side, the person should position the prostheses somewhere convenient for the next donning.

Sweater Method

The sweater method (Figure 43-13) is equivalent to entering both sleeves at the same time and then raising both arms up, out, and up to don the sweater. To apply a unilateral prosthesis using the sweater method, the person places the prosthesis on a surface face up, positions the residual limb in the socket under the Y-strap, and places the opposite arm in the harness. The person then raises both arms above the head, allowing the axilla loop to slide down to the axilla and the harness to be properly positioned across the back and on the shoulders. To remove the prosthesis, the person raises both arms above the head and grasps and removes the prosthesis with the sound arm, while allowing the axilla loop to slide off the arm.⁵⁸

A person with bilateral amputations dons the prostheses using the sweater method by placing the prostheses on a surface, face up. With the longer limb stabilizing the socket, the shorter residual limb is then positioned under the

A

B

FIGURE 43-13 Sweater method of donning prosthesis.

FIGURE 43-14 Control training in front of mirror.

harness and in the socket. The longer limb is positioned similarly under the harness in the socket, and the arms are raised, allowing the harness to flip over the head and across the back and shoulders. The person removes the prostheses by shrugging the shoulders to bring the harness up, grasping it with one TD, and pulling it over the head, while allowing the residual limbs to come out of their sockets.

Control Training

Control training may be accomplished in front of a mirror to help the client learn the minimal motions necessary to operate the prosthesis while maintaining proper body mechanics (Figure 43-14).

Acquiring skill in the operation of the prosthesis is emphasized in control training. The therapist educates the wearer on the importance of the practice drills that will

ensure more successful function with the prosthesis in daily activities. Joint protection, energy conservation, and work simplification principles and techniques should be stressed during this phase of training. Each prosthetic component should be reviewed separately and understood before the components are combined into functional activities. Such movements as elbow flexion and TD opening are cable operated. Other movements, such as TD or elbow rotation, are passively positioned using the sound hand or an item in the environment. Emphasizing external assists from the environment is an important part of this training process. A client preparing to cut vegetables at the counter may be instructed to use the countertop to rotate the TD in the best position to stabilize the vegetable while the sound hand holds a knife.

Control Training for the Unilateral

Trans-Radial Prosthesis

Terminal Device Control

Scapula abduction and glenohumeral flexion are the motions necessary to open and close the TD. The client is instructed to operate the TD first, by flexing the humerus on the amputated side, then by scapula abduction while the humerus remains at the body's side. The therapist instructs the client to operate the TD with the arm in various positions in space, such as overhead and leaning over toward the floor.⁷⁴

Pronation and Supination

If the residual limb is long enough for flexible hinges to be prescribed on the prosthesis, pronation and supination should be practiced. The therapist asks the client to stabilize the elbow at 90 degrees and to pronate and supinate the

forearm. If rigid hinges were prescribed, the TD is manually rotated in the wrist unit to achieve pronation and supination. Using the opposite hand or stabilizing the TD between the knees and turning the forearm or shoulder accomplishes manual TD rotation.

Exchanging Terminal Devices

The client learns to exchange the TD in the wrist unit if more than one TD is prescribed. Cable slack is necessary to release the cable from the TD. To obtain enough slack in the cable, it may be necessary to place an item between the fingers of the hook or hand. The TD is then removed according to the specifications of the prescribed wrist unit. When the TD has been removed, another TD style may then be positioned in the wrist unit and the cable attached to it.

To complete control training with a below elbow (BE) prosthesis, the therapist instructs the client to repeat the motions required to position and operate the TD until they are performed in one continuous smooth and natural sequence in both sitting and standing positions.⁷² Once control training is completed, use training may begin to improve the client's application of the prosthesis in a variety of the person's customary daily occupations.

Control Training for the Unilateral Trans-Humeral Prosthesis

Most trans-humeral prostheses operate through the use of a dual-control cable system. When tension is applied on the cable attached to the elbow unit, it locks and unlocks. When the elbow unit is unlocked, tension on the second cable attached to the TD raises the prosthetic forearm (flexes the elbow). A spring assist helps reduce the amount of effort required to raise the forearm, and gravity assists in lowering it. When the elbow unit is locked, tension on the second cable is used to operate the TD. The client learns to operate each component separately.

Internal and External Rotation

Many internally locking elbow units have a manually operated turntable located between the elbow unit and the socket that allows internal and external forearm rotation. The person operates the turntable, first with the elbow at 90 degrees, by manually rotating the forearm medially (toward the body) or laterally (away from the body).

Elbow Flexion and Extension

Flexion and extension of the mechanical elbow are the next steps in the training process. The therapist should protect the client's face when teaching elbow flexion control. This precaution is important because initially the client may have poor control over elbow flexion, which could cause the TD to hit the face.²

The therapist makes sure that the elbow unit is unlocked. Then the therapist asks the client to flex the humerus slowly and to simultaneously abduct the scapula to accomplish

FIGURE 43-15 “Down, out, and away” movement used to unlock the elbow unit.

elbow flexion, and to slowly extend the shoulder to achieve elbow extension. This movement is repeated until the client gains sufficient control to accomplish elbow flexion and extension smoothly and easily.^{2,74}

Elbow Locking

The elbow unit operation has an audible two-click cycle. Both clicks must be heard each time the unit is locked or unlocked. The same body movement both locks and unlocks the unit. The client is instructed to operate the elbow unit by moving the shoulder into a combination of hyperextension, abduction, and scapula depression. This movement places tension on the cable that attaches the harness to the elbow unit and may be difficult to master. The reminder “down, out, and away” may be repeated until the client develops a proprioceptive memory. The client is then asked to practice locking and unlocking the elbow in various ranges of elbow flexion and extension (Figure 43-15).^{2,5,74}

Terminal Device Control

The same motions of shoulder flexion and scapula abduction that flex the forearm with the elbow unlocked control the TD when the elbow is locked. The person is instructed to lock the elbow, first at 90 degrees, and to perform the motions to operate the TD. Care must be taken not to unlock the elbow by placing tension on the cable that operates the elbow unit. The sequence of elbow positioning, elbow locking, TD operation, elbow unlocking, elbow repositioning, and locking is repeated at various points in elbow ROM from full extension to full flexion.^{2,74}

The person then learns how to rotate the TD manually in the wrist unit and to exchange TDs in the same manner as described previously for the trans-radial prosthesis. Once

the trans-humeral prosthesis controls are performed in a smooth manner, use training begins.

Control Training for the Shoulder Disarticulation Prosthesis

A prosthesis prescribed for a client with a shoulder disarticulation may have different components and methods of operation than those of the trans-humeral prosthesis. The prosthesis may have a manually operated, friction-held shoulder unit that the client pre-positions using the sound arm or a table's edge. Chin-operated nudge control may be used to operate the elbow unit if the client does not have the shoulder movements needed to lock and unlock the elbow (Figure 43-16). A cable connects the nudge control to the elbow unit. The client still learns the two-click cycle and dual-cable system of operation described previously for the trans-humeral prosthesis. The elbow turntable is also available for a shoulder prosthesis.

A chest harness may be needed to secure the prosthesis on the client. It can also assist TD operation by using chest expansion to increase tension on the TD cable. Shoulder flexion and scapula abduction on the opposite side also assist in TD operation. Wrist operation is the same as explained for the trans-radial prosthesis.

Control Training for Bilateral Prostheses

A client with bilateral amputations usually receives two prostheses that are attached to one harness (Figure 43-17, A). Operating one of the prostheses may transmit tension through the harness to the other prosthesis, causing it to operate also. The client must learn to operate each prosthetic component without affecting the components on

either side. This skill is called **separation of controls**, and the client may need extensive practice to master it. Each prosthesis operates according to the level of amputation, as described in the previous sections, with special attention given to relaxing the opposite side (Figure 43-17, B).

Two components not generally used on unilateral prostheses may be prescribed on bilateral prostheses to improve the client's functional independence. These components are the wrist flexion unit and a cable-operated wrist rotation

FIGURE 43-16 Nudge control used to operate the elbow unit for shoulder disarticulation prosthesis.

A

B

FIGURE 43-17 A, Single harness for bilateral prostheses. B, Passing a pen from one prosthesis to the other to practice separation of controls.

unit. The wrist flexion unit assists in the completion of midline activities and is prescribed for both prostheses or for the dominant side. The ability to achieve midline is important for completing activities such as dressing, grooming, and eating. Depressing the unit's control button and creating tension on the TD cable operate the flexion unit. The opposite TD—a surface edge, the knee, or another surface—can depress the button. The TD cable must be medial to the flexion axis of the unit to pull the TD into flexion. A spring in the flexion unit repositions the TD in extension when the button is depressed and slack is provided in the TD cable.

Wrist rotation may be achieved in several ways. One is by using the wrist units mentioned earlier and rotating the TD by placing it between the knees or by pulling on the thumb of one hook with the other. Another method consists of use of a button on the medial side of the forearm, which controls a cable attached inside the forearm to a wrist-locking device. The wrist is locked and unlocked by pressing the button against the side of the body. When the wrist is unlocked, tension on the TD cable rotates the TD to the desired position.

Use Training

Use training begins after the client understands how to operate and control the prosthetic components. This training applies the mechanics of operation to activities. Repetition is important for the wearer to gain an understanding of how to pre-position the prosthesis and the objects, and how to use the environment to help pre-position them. Along with pre-positioning, prehension training begins.

Pre-positioning

Pre-positioning involves moving the prosthetic units in their optimal position to grasp an object or perform a given activity. All prosthetic components must be pre-positioned in a proximal-to-distal order. Thus, the client with the trans-radial prosthesis rotates the TD into the desired degree of pronation or supination to accomplish an activity. With a trans-humeral prosthesis, the client flexes and locks the elbow and rotates the turntable before pre-positioning the TD. The client with a shoulder disarticulation pre-positions the shoulder unit before the elbow and wrist components. The client with bilateral prostheses must still pre-position all components in the same fashion. The goal of pre-positioning is to allow the person to approach the object or activity as one would with a normal hand or in the most efficient manner and thereby avoid awkward body movements used to compensate for poor pre-positioning.⁵⁸

Prehension Training

The prosthesis should be regarded as an assistive arm and not as the dominant arm.⁷² Training objects are used to allow the wearer to practice TD control. The person first should use large, hard objects such as blocks, cans, and jars and progress to soft, then to crushable objects, such as

rubber balls, sponges, paper boxes, cones, and paper cups. These objects should be placed in positions that require elbow and TD pre-positioning and TD operation at various heights. The hook TD has a nonmovable and a movable finger. If a hook is used to pick up objects, the person is taught to stabilize the item with the nonmovable finger and then release the tension on the movable finger to secure the object. Prehension training should be completed using all prescribed TDs.^{72,74}

Use Training for Bilateral Prostheses

After the client understands how the components operate, he or she gains control of the prostheses by practicing passing items such as a ruler or a piece of paper back and forth between the TDs without dropping them (see Figure 43-17, B). Another activity that helps the client learn separation of controls is holding an object in one prosthesis without dropping it, while completing an activity with the other prosthesis.

Functional Training

Functional training applies the concepts of control and use of the prosthesis to completion of functional and meaningful activities. The prosthesis wearer is now introduced to completion of specific tasks important to him or her. Prehension training and methods to complete ADLs and IADLs, including vocational, leisure, and driving skills, are addressed in this phase. The key to successful functional training is teaching the client a problem-solving approach with respect to the activity being performed. The person recognizes the altered environment and learns to successfully complete activities within it.

Prehension Training

Prehension training teaches the client to use all prescribed TDs in a meaningful manner, such as using the heavy duty TD with tools and the hand to eat. Items such as a pencil sharpener, lock and key, jar and lid, and bottle opener may be used to allow practice.^{2,72} In bilateral activities, the person should be encouraged to determine the best position and appropriate use for the prosthesis and their sound arm (Figure 43-18). For details, the therapist is referred to Santschi's work on prosthetic training.⁵⁸ Movements become less cognitive and more automatic during this phase, and pre-positioning occurs naturally.

Activities of Daily Living

Functional training should progress to performance of the client's usual ADLs and IADLs. Activities should be introduced in a simple-to-complex order. Personal care and hygiene activities are performed first. The therapist must understand what activities are important to the client to accomplish. It is not unusual to begin the training process with clients who indicate that there are multiple tasks that they have not tried since their amputation. The client is encouraged assisted to analyze and perform the activities of

FIGURE 43-18 Prehension training with an electric hand.

FIGURE 43-19 Hair styling practice with bilateral partial hand prostheses.

eating, hygiene and grooming, toileting, dressing, meal preparation, care of pets, shopping, financial management, job performance, play, leisure participation, and community participation as independently as possible (Figure 43-19). Roberto was confident of his goals and was ready to progress with the prosthesis to accomplish them. Frequently, individuals find it difficult to identify what they want to accomplish because of fear that they may not be able to perform adequately with the prosthesis to accomplish their goals. When appropriate, home management skills and child care should be included as part of the client's training.⁶² The therapist may help the client analyze and accomplish a task or achieve it by means of using adaptive equipment or by encouraging repetitious practice to reach maximal speed and skill. The sound arm or longer

prosthesis should complete most of the work while the opposite side acts as a stabilizer or an assist.⁷²

Adaptation and Problem Solving

No specific manner or technique is required to accomplish most tasks. Each person must learn to approach an activity in a manner that will lead him or her to successful completion. When Roberto was asked to button his trousers, plant seeds in a pot, and clean the floor, he was allowed to approach the task in a manner that made sense to him. The therapist offers guidance and recommendations to enable completion of activities in an efficient manner. Some clients consistently approach activities with the prosthetic arm as the dominant arm and confront limitations in coordination, sensation, and mobilization. With guidance and practice, they can accomplish the activity with their sound arm as the dominant arm and use the prosthesis to assist. Pre-positioning of the prosthesis helps the client complete an activity at a more natural and rapid pace. As previously mentioned, if the client wears the prosthesis often, more practice with daily activities is experienced and the better is the functional outcome. After two or three trials with a grooming activity, the approach to completion becomes automatic and successful.

Work-Related Activities

Prevocational evaluation may be included in the rehabilitation program. The therapist assesses the client's potential for returning to a former occupation or a possible change of vocation. A visit to the worksite may be necessary to make recommendations that will enable the client to return to work in a safe and efficient environment. It may also be necessary to restrict work activities, such as restricting the amount of weight that the client may lift and carry, or restricting work on ladders. Initially, the client may be able to work only part time, improving work endurance gradually. Training and education for new jobs may be necessary (see Chapter 14).

Social Routines and Community Integration

Incorporating the prosthesis into one's lifestyle includes being in the community and participating in his or her usual social events. Clients may require encouragement to don the prosthesis when going to the grocery store or taking a walk with their young children. Roberto reported wearing his prosthesis for 90% of his social outings, although many people are uncomfortable wearing the prosthesis out of their immediate home or work setting. Many individuals report that the attention and questioning of other citizens are overwhelming and invasive, and not donning a prosthesis can minimize this attention.

Driver Training

The ability to drive increases independence and may enhance vocational opportunities. The client may be referred to an adaptive driving program, where he or she

FIGURE 43-20 Steering ring used for driving with a prosthesis.

can be evaluated and trained in using assistive devices such as a driving ring or a steering knob (Figure 43-20). The controls of the car, such as the ignition switch and turn signals, can be modified to improve safety and comfort. The amount of training and the extent of modification will vary, depending on the level of amputation.

The occupational therapist is responsible for assessing predriving skills. A predriving evaluation may consist of an assessment of visual acuity, traffic signal recognition, color vision, glare recovery, night vision, peripheral vision, depth perception, reaction time, and upper extremity (UE) function. When necessary, additional cognitive, visual, and perceptual skills are evaluated. (See Chapter 11 for more information on driving.)

After completing the predriving evaluation, the therapist is responsible for making driving recommendations. These may include treatment for deficits, referral to a driver education center for training, and installation of assistive devices. The therapist's evaluation should include a statement regarding the client's potential for safe driving. If the client is unable to drive, alternative methods of transportation should be explored.

In some states, any change in physical health status must be reported to the motor vehicle department and to the person's insurance company. Failure to do so may result in loss of the individual's automobile insurance.

Leisure Activities

The rehabilitation program includes information and training regarding leisure interests. With the client's and the rehabilitation team's joint effort and motivation, the client should be able to return to a meaningful and productive life. A wide variety of specialized prosthetic devices are available for many sports and recreational hobbies. Texas Assistive Devices and Sports & Recreation Technologies, LLC, provide prosthetic devices designed to improve the wearer's ability to participate in such activities as photography, ball games, pool, guitar playing, fishing, and skiing.⁵

Duration of Training

The average adult with a unilateral trans-radial amputation who is otherwise healthy and well adjusted will require approximately 8 hours of training (five to eight treatment sessions) to master control and use of the prosthesis for daily living. The person with a unilateral trans-humeral amputation under the same conditions will require approximately 12 hours of training. About 15 hours will be required for bilateral trans-humeral prosthetic training, whereas about 20 hours is required for bilateral trans-humeral prosthetic training. The initial training session should be about 1 hour long, and subsequent sessions may be shorter, increasing in duration commensurate with the wearer's increased prosthesis tolerance and physical endurance.^{5,34,72}

Summary

Acquired UE amputations can occur as the result of trauma, infection, neoplasm, and vascular disease. Occupational therapists play an essential role in the rehabilitation process by addressing residual limb conditioning and care, preprosthetic exercise, and prosthetic training. Desired outcomes of occupational therapy include the client's adaptation to his or her altered body; independent management of ADLs; satisfaction with independent function; and resumption of work, social, and leisure roles that support the client's health and participation.

Working with a client who has an amputation can be a real challenge. Careful assessment of the client's needs, a creative approach to therapeutic intervention, an emphasis on problem solving, and close communication with the team can make the challenge rewarding and the outcome successful.

Roberto was able to operate the body-powered prosthesis successfully early in his rehabilitation. He is considered a functional user of a prosthesis, successfully incorporating it into his lifestyle. The state insurance system provided him with the customary body-powered prosthesis, which was also the least expensive type. The therapist documented his successful operation of the prosthesis and explored the advantages and disadvantages of an electric prosthesis with Roberto, in collaboration with the prosthetist. For some clients, the electric prosthesis offers improved control and success with activity completion.

Electric-Powered Prostheses

Externally powered electric upper limb prostheses have opened a new world of freedom and function for persons with upper limb amputations. The advent of electronic microminiaturization has allowed the development of prosthetic devices with totally self-contained services of power, motor units, and electrodes.²⁵ Powered prostheses have existed for decades, but it was not until the 1960s that myoelectrically controlled prostheses were clinically introduced. The activities of the Otto Bock Company in Duderstadt, Germany, began this process by aiming for the

FIGURE 43-21 A typical electric-powered myoelectrically controlled, trans-radial prosthesis with an electromechanical hand terminal device activated by electromyographic potentials.

(From Billock JN: Upper limb prosthetic terminal devices: hands versus hooks, *Clin Prosthet Orthot* 10:59, 1986.)

development of an electromechanically driven prosthetic hand that would match the technical and cosmetic demands of a human hand.⁴⁷

Clinical use of the electric devices began in Europe because of government-supported health care systems and a large client population of persons with congenital (post-thalidomide) amputations. By the late 1970s and early 1980s, clinicians in North America had increasing but limited experience with myoelectric prostheses.¹² When funding permits, hundreds of myoelectric prostheses are prescribed for children and adults throughout the United States.

The term myoelectric prosthesis is often used interchangeably with electric prosthesis.

A **myoelectric prosthesis** uses muscle surface electricity to control the prosthetic hand function. The muscle membrane generates an electric potential at the time of contraction. The myoelectric signal is sensed, amplified, and processed by a control unit that generates a motor, which in turn drives a terminal device.¹² This terminal device is often an electromechanical hand (Figure 43-21).¹⁰ Several different types of myoelectric hands are available. The myoelectric control can be a digital control or a dynamic mode control (proportional control). Digital systems are operated at only one speed, allowing them to turn on or turn off. Proportional control means that the myoelectric signal (power) to the hand is proportionate with the level of muscle signal that the wearer generates, so the wearer's effort directly controls the speed of the hand.³ A SensorHand (Otto Bock, Minneapolis, MN), which provides automatic grasping when the object in the hand is slipping and its center of gravity is changing, is now available (Figure 43-22). The motor automatically increases pressure applied to the object being held to prevent dropping of the object.

FIGURE 43-22 The SensorHand speed.
(Courtesy Otto Bock HealthCare, Minneapolis, MN.)

Myoelectric controls require minimal physical effort for operation. Muscle groups in the forearm are most frequently used according to their physiologic function, that is, the wrist extensor muscles are used for hand opening and the wrist flexor muscles for hand closing. Surface electrodes recessed within the wall of the prosthetic socket (Figure 43-23) detect muscular contractions.

Commercially released in 2009 were two electric hands from Touch Bionics (Hilliard, OH), one of which offers a powered solution to a person with a partial hand amputation.

FIGURE 43-23 Surface electrodes, recessed within the wall of the myoelectric socket, detect muscle contractions.

Candidates for Prostheses

An electric prosthesis might be chosen because of the combination of a natural appearance and the functions of high pinch force without a high level of effort. Also, a myoelectric prosthesis requires no cables for control, so harnessing can be much more comfortable. A suspension socket may be fabricated from material such as silicone, urethane, or thermoplastic elastomers. No liner socks are worn. The client's work, home, and recreational needs and activities all must be considered. Previous experience with other prostheses may be relevant.

In the past, trans-radial amputation was the most common condition for which these prostheses were prescribed. For amputation levels above the elbow, the complexity of function and the power level required to accomplish functional movement increase considerably. At the same time, the capability of the client to operate a prosthesis by harnessing body movement via straps and cables, in the traditional body-powered manner, decreases considerably.⁶⁰ More recently, with advances in technology, myoelectric prostheses for persons with higher levels of amputation are increasingly prescribed because their functional possibilities are greater.³

The Utah Arm 3 (Motion Control, Inc., Salt Lake City, UT), released in 2004, introduced microprocessor technology into the prosthetic arm with a computer interface that allows the prosthetist to fine-tune adjustments to maximize the wearer's performance. It offers simultaneous elbow and hand control because it has two microprocessors. Roberto may experience common difficulties in unlocking the elbow unit efficiently or in operating the TD with the same control quality of the elbow unit, which individuals with trans-humeral amputations frequently experience using an electric prosthesis. This design minimizes the effort of elbow and hand control and may be appropriate for Roberto.

The task of training a client with a very short trans-humeral amputation or shoulder disarticulation to function

Box 43-2

Advantages and Disadvantages of a Myoelectric Prosthesis

Advantages

- Improved cosmesis
- Increased grip force (approximately 25 lb in an adult myoelectric hand)
- Minimal or no harnessing
- Ability to use overhead
- Minimal effort needed to control
- Control more closely, corresponding to human physiologic control

Disadvantages

- Cost of prosthesis
- Frequency of maintenance and repair
- Fragile nature of glove and necessity of frequent replacements
- Lack of sensory feedback (a body-powered prosthesis has some sense of proprioceptive feedback)
- Slowness in responsiveness of electric hand
- Increased weight

with a body-powered prosthesis is substantially more challenging than training with an electric-powered prosthesis.

Before a myoelectric prosthesis is prescribed, the client should have adequate strength and the ability to contract muscles independently. A minimum muscle signal of 5 microvolts will operate the most sensitive system. The candidate with this minimum signal should be capable of developing stronger signals for longer-term use of the prosthesis. Independent contraction of each muscle is important to produce smooth and controllable prosthetic function. As a general guideline, the prosthesis can be operated with a 10-microvolt difference between muscles, but the wearer will use the prosthesis more easily if a 20- to 30-microvolt difference can be controlled. Surface electric signals are amplified by a miniature electrode and are led to the relay system. The relay is responsible for the energy supply to the battery-operated motor in the electric hand. When alternating contractions of extensor and flexor muscles take place, the direction of the current changes in the electric motor, and the hand opens and closes accordingly.⁴⁷

Some rehabilitation professionals who work with clients who have upper limb amputations believe that electric components may be the only appropriate alternative for high-level unilateral or high-level bilateral amputations. Conversely, some rehabilitation professionals believe that body-powered prostheses are the most functional and appropriate type of prosthesis for most clients, despite the level of amputation. There are many schools of thought regarding the advantages and disadvantages of myoelectric prostheses. Box 43-2 describes some of the points that differentiate the myoelectric prosthesis from a body-powered, cable-controlled, hook-type TD prosthesis.

Hybrid Prostheses

A **hybrid prosthesis** is one that combines body power with electrical power. These designs have been created and used more and more over the past several years. Hybrid prostheses, using various components and control methods from various systems, in many cases can serve as a prosthesis that is more functional and more acceptable to the individual.¹⁰ The improved technology of electric hands has increased the cost of myoelectric prostheses. The hybrid design decreases the overall cost of the prosthesis. Some hybrid designs eliminate the cable and harness, thereby eliminating pressure on the sound side when the prosthesis is operated. One hybrid design involves the use of a body-powered elbow flexion device with a myoelectric hand.¹⁰ Another configuration might be the use of a cable elbow and hook TD with an electric wrist rotator. For a person with bilateral amputations, a powered elbow combined with a cable-hook TD offers quick elbow motion and less overall bulk of the prosthesis and dedicates all excursion of the cable to the TD. A hybrid design can decrease the overall weight of a prosthesis. It can be less expensive and less complex. All excursion of the existing cable is dedicated to one component, as opposed to multiple components. This feature requires less overall force on the part of the wearer for operating the prosthesis.

Preprosthetic Therapy

Awareness of postoperative and subsequent preprosthetic principles of care is crucial for the successful management of the client who has sustained traumatic limb loss.

Ethical Considerations

The client has little control over what is happening and must depend on the health care team to provide the best treatment possible.⁶

The rehabilitation team, which ideally includes the physician, nurse, occupational therapist, physical therapist, social worker, vocational counselor, insurance representative, and client, addresses goals described in the first section of this chapter. With an electric prosthesis, additional treatment goals are as follows:

- Identify or test potential muscle sites for prosthesis control.
- Improve muscle site control and strength (once identified).
- Obtain adequate financial sponsorship for the prosthesis and training.⁴²

Identify Potential Muscle Sites

A myoelectric prosthesis functions by detecting electromyographic (EMG) signals produced by muscles. Locating appropriate superficial muscle sites is the most important

FIGURE 43-24 Otto Bock MyoBoy system used to determine the magnitude of muscle contraction.

(Courtesy Otto Bock HealthCare, Minneapolis, MN.)

aspect of the successful operation of a myoelectric prosthesis. Physical examination of a person's arm often reveals sufficient strength in natural agonist-antagonist pairs, such as the wrist extensor and wrist flexor muscles in the person with a trans-radial amputation, and the biceps and triceps muscles in the person with a trans-humeral amputation. Individuals with a short trans-humeral amputation often have an effective pectoralis or deltoid site anteriorly and an infraspinatus or trapezius site posteriorly. It is more difficult to identify proximal muscle sites that are adequate in signal and allow the prosthetist to position electrodes within the socket and hold them securely against the skin. On occasion, trauma or nerve injuries do not allow the choice of a natural pair. If a particular site could cause tissue breakdown under the pressure of an electrode, it must be avoided. Often, healed skin or muscle grafts can tolerate the pressure well. Consult the physician when dealing with repaired tissue. If the best muscle site contractions are weak during the physical examination, the therapist and prosthetist will require a biofeedback system or myotester to identify the amount of signal generated by the muscle (Figure 43-24). When surface potentials are measured with electrodes and a myotester, it is important that all electrodes have good contact with the skin and that they are aligned along the general direction of muscle fibers. Moistening the skin slightly with water may improve the EMG signal by lowering skin resistance. EMG testing begins with the most distal portion of the remnant muscle.

The goal of this testing is to identify two muscle sites that would fit appropriately within the socket with the greatest microvolt difference between them, not necessarily the two strongest muscle site signals. Selection can be considered complete when the client can tolerate a 1-hour training session with the biofeedback system and is consistently generating sufficient signals to operate a prosthesis in basic functions such as opening and closing of the TD. The

FIGURE 43-25 Therapist instructs client to imitate desired muscle contraction on both sides.

therapist should check with the prosthetist for the minimum signal required for operating the myoelectric system chosen for the client.⁴⁸

Muscle Site Control Training

The more proximal the level of the client's amputation, the more challenging it is for the prosthetist to fit the prosthesis and for the therapist to train the person to function with the prosthesis. For the client to understand a desired muscle contraction, the therapist instructs the client to imitate the desired contraction or movement with both arms. The therapist should ask the client to raise the sound hand at the wrist (wrist extension) and imagine this motion with the phantom hand on the amputated side (Figure 43-25). The therapist often can palpate the wrist flexors and extensors on the residual limb during this exercise. The person is instructed to contract and relax each muscle group separately and on command. For this step, a myotester is particularly useful because it indicates the magnitude of the EMG signal as the client contracts the muscle, as well as the decrease in signal as the client relaxes the muscle. Many clients have difficulty relaxing a muscle completely; this causes a decrease in muscle signal separation.

The myotester can be used to train the muscles with both visual and auditory feedback. Various models are available to therapists (Figure 43-26). The goals of training at this point are to increase muscle strength and to isolate muscle contractions. As confidence and accuracy improve, visual or auditory feedback should be removed. Practicing muscle contractions without feedback teaches the client to internalize the feeling of each control movement. The advantage of creating this internalized awareness of proper muscle control is that control and strengthening practice can be continued between treatment sessions without feedback equipment.⁶⁶ The therapist must learn to recognize muscle fatigue, which is frequently a side effect in this process, and must allow sufficient time for that muscle to recover during the treatment session.

FIGURE 43-26 Myotester used for training purposes.

Ideally, the client with an amputation receives adequate training and practice in initiating these muscle contractions before receiving the completed myoelectric prosthesis from the prosthetist. Prosthetists commonly engage a client in muscle site training with the preparatory socket and prosthesis fitting. This training, which usually occurs as prosthetists strive for optimal electrode placement and socket fit, is not adequate for most clients to immediately and successfully operate a prosthesis. Anxiety and frustration often accompany training in use of a myoelectric prosthesis, and a team approach to training by the therapist and the prosthetist can minimize these responses. The client's success and effectiveness in using the prosthesis are closely related to the quality of the preprosthetic training.

Prosthetic Program

Orientation in what the prosthesis realistically can and cannot do is an important aspect of a prosthetic training program. If clients harbor unrealistic expectations about the usefulness of the prosthesis as a replacement arm, they may become dissatisfied with the ultimate functioning of the prosthesis and reject it altogether. It is imperative that the therapist be honest and positive about the function of the prosthesis. If the client understands the functional potential and limitations of the prosthesis, success can be more realistically achieved.⁴

Orientation and Education

Training with a prosthesis should begin as soon as the prosthesis is received, preferably the same day. The textbook *Comprehensive Management of the Upper Limb Amputee* is an excellent resource in the training process of a client with a myoelectric prosthesis.⁶ Prosthesis component manufacturers provide written training information and/or educational courses for therapists.

Important areas to review during initial visits are orientation to prosthesis terminology and operation, independence in donning and doffing the prosthesis, orientation to a prosthesis-wearing schedule, and care of the residual limb and prosthesis.

Orientation to Prosthesis Terminology

Given that the prosthesis is a natural extension of the person's body, it is particularly important to know the functions and names of its major parts, such as electrodes, battery, glove, and electric hand. The initial visit is an appropriate time to review the battery-charging procedure with the wearer.

Batteries are energy-storing devices, and most are rechargeable. Some control systems use a 9-volt disposable battery. The prosthetist supplying the prosthesis will instruct the client on proper installation and recharging. Rechargers are plugged into a standard electrical outlet. Most manufacturers' rechargers have some type of indicator, which alerts the person when the battery is fully charged. Some rechargers require 12 hours of charging time, whereas others may take as long as 24 hours. A fast charger, which requires only 1 or 2 hours of charging time, may be available. For best results, the batteries should be close to completely drained before recharging. The prosthesis will begin to operate more slowly when the battery is low, and some unexpected control problems could occur. Therefore, the first troubleshooting step is always to make certain that the battery is charged, or a different one must be installed.⁴⁸

Although the myoelectric hand is the most commonly prescribed electric terminal device, a specially designed gripping device, the Greifer, is frequently recommended. Designed by the Otto Bock Company, the Greifer is a universal working tool designed to handle various specialized tasks. It can be used for heavy work in industry or farming and in mechanical activities at work or home because it allows for quick handling and precise manipulation of small objects. Features of the Greifer include a 38-lb grasp, as well as parallel gripping surfaces and a manually controlled flexion joint for wrist dorsal and volar flexion (Figure 43-27).⁴⁷

Instruction manuals from the manufacturer for the battery charger and the prosthesis are often provided for the wearer's reference. These are excellent tools for the occupational therapist to use for review and education.

Independence in Donning and Doffing the Prosthesis

The client should be able to put on and remove the prosthesis independently. With proper instruction and the help of the prosthetist in suspension design, the wearer will be successful. Donning the prosthesis should be performed with the electronic components in the off position to prevent any uncontrolled movements. A client with a long trans-radial amputation usually has the advantage of not requiring a harness because a supracondylar suspension at the elbow may be used. The wearer can place his or her

A

B

FIGURE 43-27 **A**, The myoelectric Greifer is designed as a universal working tool with parallel gripping force of up to 38 pounds. **B**, i-LIMB electric hand allows power to individual digits for fine motor tasks.

residual limb directly into the socket. A pull sock is sometimes used to facilitate an intimate interface between the arm and the radial socket for a person with a short trans-radial amputation. A silicone-based skin lotion applied to the skin before donning the pull sock enables the person to remove the pull sock with less effort.

Suspension designs for the client with a trans-humeral amputation may require a pull sock for donning the prosthesis. The sock is applied to the residual limb, and the prosthesis socket is pulled over it. A weighted cord from the pull sock is fed through a hole in the bottom of the socket. The wearer then pulls the sock off the arm and through the hole in the socket, creating very close contact of the prosthesis with the limb. This is a successful application, particularly for a very short residual limb. The wearer must be sure not to start with the stocking too high on the residual limb because this will increase friction during pulling and make it harder to pull the sock out of the bottom of the socket. It may be necessary to experiment with different sock materials, powder on the skin, and various donning

techniques until the most successful materials and techniques are identified.

Good electrical contact is achieved after approximately 1 minute of donning. A wearer can moisten the skin at the electrode sites to eliminate the waiting period for skin warmth to occur. The prosthetic arm should be stored in the off position with the batteries removed. The hand should be fully opened when stored to keep the thumb web space stretched.

Prosthesis-Wearing Schedule

Initial wearing periods are no longer than 15 to 30 minutes. This limit is particularly important if scarring or insensate areas are present on the residual limb. If redness persists for longer than 20 minutes in a particular area after removal of the prosthesis, the wearer should return the prosthesis to the prosthetist for adjustments. If no skin problems exist, wearing periods can be increased in 30-minute increments two to three times a day. Some individuals have difficulty tolerating the weight of the prosthesis or the heat generated by its application. Full-time wearing should be achieved as soon as possible, which may occur as soon as 1 week later.

Care of the Residual Limb and Prosthesis

Appropriate care of the skin is vitally important. The residual limb should be washed daily with mild soap and lukewarm water. It should be rinsed thoroughly and dried thoroughly.

The prosthesis may be cleaned with soap and water by using a damp cloth. Rubbing alcohol may be used to clean the inside of the socket to prevent and minimize odors. The cosmetic glove stains easily; special care must be taken to avoid contact with ink, newspaper, mustard, carrots, grease, and dirt. Wiping with soap and water or a glove-cleansing cream obtained from the prosthetist will remove general soil but not stains. The average life of a glove is approximately 6 months. Polyvinylchloride (PVC) plastic gloves are the least expensive, most flexible, and toughest. Silicone gloves are being used more frequently because the new silicone formulas are tougher and less susceptible to the yellowing and brittleness that previously set in with age; they also allow the greatest cosmesis.¹⁰ The prosthesis itself should never be immersed in water because this will seriously damage the internal electronic components. Additionally, it is important to advise myoelectric wearers against excess vibration, sand, dirt, and extremes of heat and cold. These, too, can seriously impair the electronic components.

The prosthesis should be checked occasionally for loose screws and harness attachments, and these should be brought to the attention of the prosthetist. The covers of the prosthesis should not be opened unless the prosthetist instructs the wearer or therapist to do so.

Control Training

The first function to master is opening and closing of the TD. With practice, the wearer understands the muscle contractions required to perform these actions. Each electric

prosthesis has a unique control system based on the manufactured componentry and/or the person's musculoskeletal integrity. Fewer similarities in fit and control are noted with electric prostheses as compared with body-powered prostheses, and therapists modify training guidelines and sessions to address each individual's needs. Simple opening and closing of the terminal device are practiced. The muscles should contract as independently as possible. Next, the client practices opening the hand halfway, then stopping and relaxing so the hand does not move. This is practiced in various positions of the arm. If a proportional control system is used, the client can also practice opening and closing quickly and slowly. Often, the therapist will design a home program of specific patterns of terminal device action that the person performs, to offer more practice. Control of the TD will improve in accuracy and speed with practice and use throughout the other phases of training.

Use Training

The repetitive grasp and release of objects is introduced after control training. These activities are considered preparatory in that they prepare the person for functional activity. Simple approach, grasp, and release activities are practiced with objects of various shapes, sizes, and densities. Objects that may be presented include paper or plastic cups, blocks, cubes of sponge, empty plastic containers, small weights, large bolts, empty glass jars of various sizes, and ping-pong balls. It is important for the individual first to visualize how the object should be approached and grasped, then to pre-position the myoelectric hand. Pre-positioning involves placing the TD in the optimal position to approach an object. In approaching a glass, the hand should face in toward the midline to grasp the glass as a normal hand would (Figure 43-28). The fingers of the hand should not be positioned downward because a normal hand does not approach a glass in this position.

FIGURE 43-28 When approaching the glass, the hand is pre-positioned in midline to grasp the glass as a normal hand.

FIGURE 43-29 Person with transhumeral amputation demonstrates how excessive grasp crushes the object (plastic cup) being held.

Another important goal of training a client to grasp an object is mastering pressure control or the gripping force of the TD. This skill involves close visual attention to appropriately grade the muscle contraction for a specific result in the myoelectric hand. The client must learn how to pick up the object without crushing it. Too strong a grasp crushes the object being held (Figure 43-29). Good grasp control through training with foam, cotton balls, or wet sponges will help the client develop the control necessary to handle paper cups, vegetables, boxes, lotion bottles, and sandwiches or even to hold someone's hand.⁶⁶

Working on approach, grasp, and release in multiple arm positions then follows. The client will attempt to grasp objects at counter height, at table height, overhead, on the floor, at cupboard height, alongside the body, and behind the body. The client with a trans-humeral amputation who uses a body-powered or electric elbow should ensure that the position of the terminal hand and the angle of elbow flexion are appropriate to complete the grasp in a natural manner. Often, the client automatically adjusts the body using compensatory body motions (e.g., bending forward rather than adjusting the elbow position or pre-positioning the hand). It is important to discourage this adjustment because it looks unnatural, becomes habitual, and may lead to secondary musculoskeletal problems in the neck, shoulder, or trunk. A mirror can help clients see the way their bodies are positioned and visualize how their sound arms would approach a particular object or activity. The therapist often must remind the client to maintain an upright posture and to avoid extraneous body movements.

Release is accomplished by visualizing a wrist extension contraction or a quick “hand up” or “fingers open” in the person with a trans-radial amputation. This response should become automatic if good preprosthetic training of the muscles has been provided.

The ability to perform specific movements will eventually take less conscious effort, and movements will become automatic. The wearer now has muscle endurance and prosthesis tolerance sufficient for 1-hour therapy sessions. Next, functional activities are introduced into the therapy program.

Functional Training

Now the person transfers prosthesis control into purposeful activities. The prosthesis is used as a functional assist in most bilateral activities. Therefore, most functional activities are accomplished with the uninvolved arm and hand as dominant. Other than perhaps for practice, it is not appropriate to train a person with a unilateral amputation to eat holding a spoon, to write, or to brush his or her teeth using the myoelectric hand. In almost all cases, the sound hand becomes the dominant extremity and performs these tasks. Occasionally, if the right arm was dominant and is amputated, and if the client was fitted with a myoelectric hand in a timely manner, he or she may prefer to use the myoelectric hand for some of these activities. The critically important component of sensory feedback is often the determining factor in deciding which hand to use. A client with an amputation almost always chooses to perform activities with a hand that has feeling. A myoelectric hand lacks this distal sensory feedback. Feedback is provided more proximally through the action of muscle contraction, yet responding to this stimulus is difficult for the wearer.

The therapist will review a list of bilateral ADLs with the client to determine which tasks are most important for him or her to accomplish. The therapist will focus on these purposeful and occupation-based activities during training, stressing throughout that the myoelectric TD is used as an assist and a stabilizer (Figure 43-30). If unilateral tasks are presented to the client, his or her need to operate the prosthesis is minimized or absent. These tasks should be avoided for the purpose of training. The bilateral activities listed in Table 43-2 are good examples for practice.

With repetition, these activities and many others will become easier to perform, occurring almost automatically. It is important to reinforce and emphasize the fact that bathing, grooming, and hygiene skills involving water must be done without a myoelectric TD or with a myoelectric TD that is water resistant, because of the damaging effects of water on the electric motor and battery.

Vocational and Leisure Activities

As training proceeds and a sense of the person's self-acceptance and comfort with the amputation is heightened, the therapist will address the subject of return to work. Ideally, the therapist makes an on-site visit. If possible, the

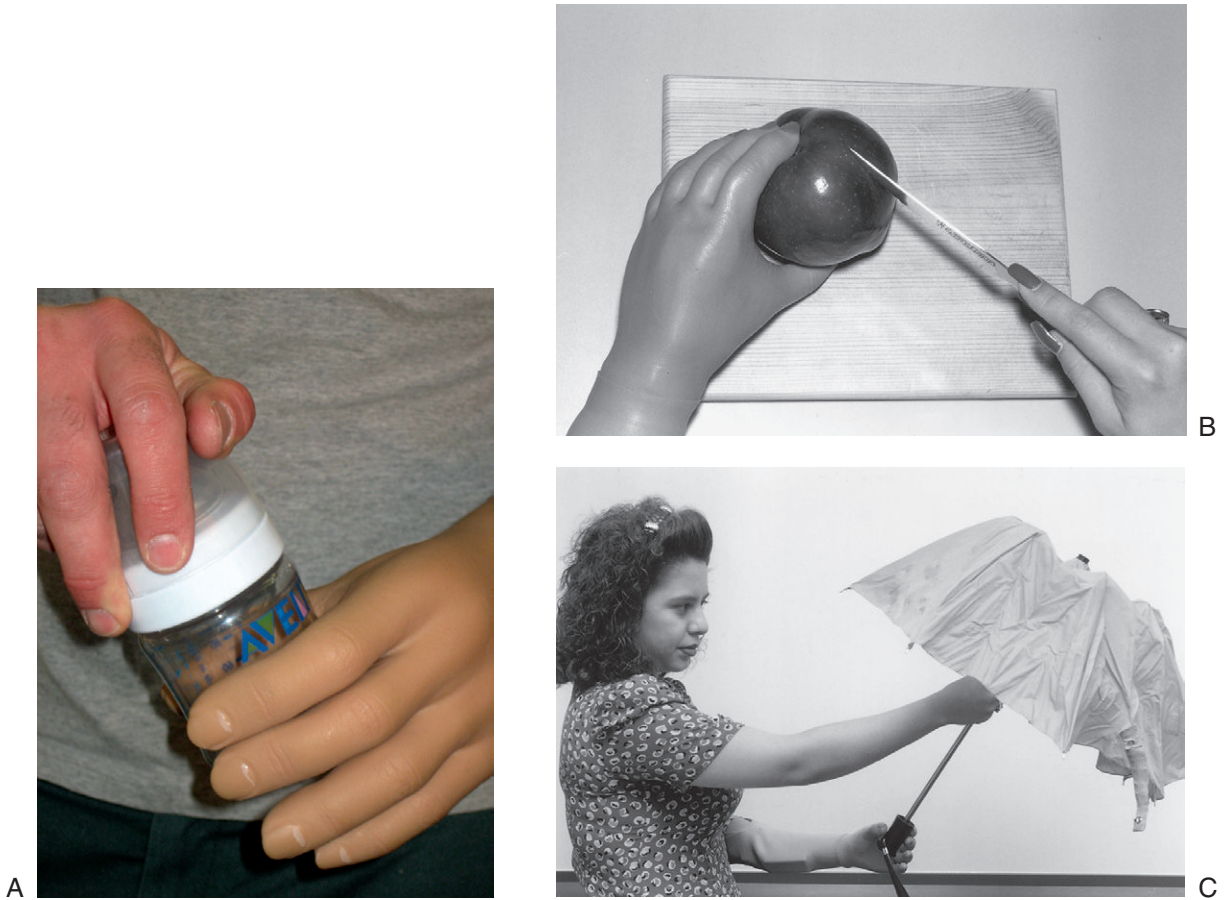

FIGURE 43-30 Activities of daily living. **A**, Opening a jar is accomplished with the myoelectric hand holding the jar and the sound hand turning the lid. **B**, Cutting an apple is accomplished with the myoelectric hand holding the apple while the sound hand holds the knife to cut. **C**, Opening an umbrella is accomplished by holding the base knob of the umbrella with the myoelectric hand and using the sound hand to open as normal.

■ **TABLE 43-2** Roles of Myoelectric Hand and Sound Hand in Bilateral Activities of Daily Living

Activity	Myoelectric Hand	Sound Hand
Cutting meat	Hold the fork with prongs facing downward; hold the knife as grip strength increases.	Hold knife. Hold fork.
Opening a jar (see Figure 43-29, A)	Hold the jar.	Turn the lid.
Opening a tube of toothpaste	Hold the tube.	Turn the cap.
Stirring something in a bowl	Hold the bowl with a strong grip.	Hold the mixing spoon or fork.
Cutting fruit or vegetables (see Figure 43-29, B)	Hold the fruit or vegetable firmly.	Hold the knife to cut.
Using scissors to cut paper	Hold the paper to be cut.	Use scissors in normal fashion.
Buckling a belt	Hold the buckle end of belt to keep stable.	Manipulate long end of belt into buckle.
Zippering a jacket from bottom up	Hold anchor tab.	Manipulate pull tab at base, and pull upward.
Applying socks	Hold one side of socks.	Hold other side of socks, and pull upward.
Opening an umbrella (see Figure 43-29, C)	Hold base knob of umbrella.	Open as normal.

various job requirements can be discussed and then practiced in a simulated, step-by-step process during a therapy session. If changes and adjustments to the work environment are necessary, the therapist will advise regarding these modifications. This intervention can often be enhanced by collaboration with the vocational counselor. In Roberto's case, the occupational therapist was instrumental in describing to the counselor what skills and abilities were safe and reasonable to attempt with body-powered and electric prostheses. This improves the match of the individual to the occupation identified. (See Chapters 14 and 15 for additional information.)

Leisure and recreational occupations are also critically important to discuss at this time because these activities contribute not only to physical well-being but also to psychological well-being. The TDs used for sports and recreational activities are not generally myoelectric. If the activity is something that requires fine motor skills, an electric TD may be beneficial. The author worked with an individual with bilateral limb amputations who was fitted with bilateral electric prostheses and who was able to successfully resume his fly-tying business. As discussed in the first section of this chapter, Sports and Recreation Technologies, LLC, offers a number of excellent TD adaptation components, including an Amputee Golf Grip (Figure 43-31, A)

and a Super Sports TD (Figure 43-31, B). Clients are encouraged to continue engagement in any recreational activities that they performed before the loss of their limb (see Chapter 16 for additional information).

Self-management Instruction

During training and the review that takes place at the conclusion of training, information regarding a wearing schedule, care instructions, and additional tasks to practice should be shared with the wearer and his or her family members. A follow-up appointment should be made at this time, and a list of the rehabilitation team members and their telephone numbers provided, so the client may contact the appropriate person when problems arise.

Summary

The rehabilitation process for clients with upper limb loss can be challenging and rewarding. In the case of a transhumeral amputation, shoulder disarticulation amputation, or bilateral limb loss, training and expertise on the part of the therapist are essential. The therapist can review several resources to enhance his or her knowledge in this area of occupational therapy intervention.

A

B

FIGURE 43-31 TD adaptation components. **A**, Amputee Golf Grip is a high-performance prosthetic golf accessory that allows smooth swings and complete follow-through. **B**, Super Sports terminal device is a highly flexible, strong, prosthetic sports accessory for volleyball, soccer, football, floor exercise gymnastics, or any activity in which shock absorption, safety, and bilateral control are important.

Threaded Case Study Roberto, Part 2

Roberto's inability to work is based on his inability to function with the prosthesis in bilateral activities. Roberto's cultural, physical, social, and personal contexts affect his rehabilitation, and the occupational therapist must address each of these to facilitate his successful adaptation in ADLs and work. His belief in his role as the sole financial provider for his family means that the therapist must address his return to work as a vital component of his rehabilitation.

The therapist must clearly document the benefits of an electric-powered prosthesis over a body-powered prosthesis if the former facilitates Roberto's return to successful gainful employment and ADL independence.

Because Roberto's involvement with his children is important to him, the therapist must promote his ability to function comfortably in social settings. Roberto's performance skills of temporal organization, adaptation, and organization of space and objects are addressed in occupational therapy intervention to enhance function with his prosthesis in usual activities, especially those that involve bilateral function. The therapist presents the following activities to Roberto that allow him to practice the skills of pre-positioning the prosthesis, recognizing the role of the prosthesis as an assist, and developing problem-solving strategies when approaching activities: drying dishes, folding clothes, shuffling cards, washing car or house windows, pushing a lawn mower, sweeping with a broom, using hand-held tools to repair something, taking money in and out of his wallet, emptying trash at home and in the clinic, and assembling electronic or mechanical parts.

Communication of results of the occupational therapy evaluation and Roberto's performance in treatment to the vocational evaluator and the vocational rehabilitation counselor is essential in the coordination of Roberto's care and his return to successful employment.

Roberto's satisfaction with function, level of ADL independence, and return to gainful employment is the outcome measure used to assess the efficacy of the occupational therapy intervention. He was highly motivated to meet the goal of returning to work that he identified at the initial occupational therapy interview and was successful in meeting this goal. Roberto participated in the vocational counseling and testing program offered through his state agency. He secured a position as a full-time janitor in a public elementary school.

Future occupational therapy interventions will focus on recommending a work schedule that gradually increases his endurance and function, educating him about a home exercise program of strengthening and stretching, and practicing job activities (simulation and actual) with the prosthesis and the residual arm, especially those tasks that remain challenging: lifting heavy items, using mops and brooms, climbing ladders, and carrying supplies.

The potential of individuals with upper limb loss is limitless; they often are able to accomplish activities that no one ever would have predicted. The success of rehabilitation does not rest solely on the quality of training in use of the prosthesis. Rather, success depends on such complex factors as the quality of medical management, the type and fit of the prosthesis, client factors, performance skills and patterns, and the client's interest in learning to use the prosthesis, as well as conscientious follow-up once the rehabilitation phase is complete. Follow-up is critically important and is often overlooked.

Perhaps the most important aspect of a successful rehabilitation program is the client's desire to become more independent. All team members should cultivate and reinforce this desire, which is a pivotal ingredient of successful intervention. The effectiveness of the occupational therapist during this important process will remain with the client for life.

■ SECTION 3: | Lower Limb Amputations

JENNIFER S. GLOVER

Levels of Lower Limb Amputation

Lower limb (LL) amputations are typically discussed as above-knee or below-knee; however, variability exists even within these categories (Figure 43-32). Generally, the more proximal an amputation is, the greater is the functional challenge presented to the person with the amputation. Proximal LL amputations include hemipelvectomy and hip disarticulation amputations, resulting in loss of the entire lower limb; such severe amputations are typically performed in cases of trauma or malignancy. Wound healing from such proximal amputations is often slow, and skin grafting may be required for full healing. In cases of hemipelvectomy, a muscle flap will cover the internal organs.

A transfemoral or **above-knee amputation** (AKA) results in loss of the knee and everything distal to it. Residual limb length from an AKA typically varies from 10 to 12 inches (5.4 to 30.5 cm) from the greater trochanter⁷; transfemoral amputations can also be classified as upper, middle, or lower third, indicating the amputation distance from the ischium. A through-the-knee (disarticulation) amputation does result in loss of knee joint function, but it allows a high level of prosthesis control and mobility.

A transtibial or **below-knee amputation** (BKA) preserves the knee and thus eliminates the necessity for a mechanical knee joint in the prosthesis. The residual limb from a BKA typically varies from 4 to 6 inches (10.1 to 15.2 cm) in length from the tibial plateau.⁷ A **Syme's amputation**, or ankle disarticulation, results in loss of both ankle and foot function and is typically performed in cases of trauma or infection. A transmetatarsal amputation results in severing the foot through the metatarsal bones,

Threaded Case Study Lena, Part 1

Lena is a 72-year-old woman who lives by herself in a one-story house near downtown. She was widowed 5 years ago and has two adult children who also live in town. Lena has adult-onset diabetes as well as chronic obstructive pulmonary disease (COPD). She worked part-time as a clerk at a department store until her 50s, when she retired because she could no longer stand comfortably for long periods of time. After retirement, Lena would drive for shopping and appointments and would walk the short distance to church. The circulation in Lena's legs got progressively worse over the years, and she began to spend increasing amounts of time at home. Lena's day usually involved watching television, birdwatching through the window, and occasionally painting ceramic figurines.

At 62, Lena stubbed her toe on her left foot, cutting it. The circulation in her foot was not sufficient for it to heal, and the toe was amputated. She had another toe amputated 2 years later, and 2 weeks ago she had a below-knee amputation (transtibial) of her left leg because of wounds that would not heal.

Lena has just been transferred to a skilled nursing facility in her hometown. The occupational therapist met with Lena for her initial evaluation today, after which the two set goals for Lena's course of treatment.

Critical Thinking Questions

1. What is an area of occupation that will make Lena feel like herself again?
2. What treatment activities can be used to best address challenges presented by Lena's amputation and help her return to participation in her chosen occupations?
3. How can the occupational therapist help Lena prepare not only to return home but also to reduce her risk of rehospitalization?

but the ankle remains intact. Clients may experience amputation of toes; although amputation of the first toe impairs ambulation by preventing toe-off (which is the end of the stance or support phase of gait), loss of the small toes does not usually result in impaired ambulation. In Lena's case, the amputation is considered a BKA because her left leg was amputated approximately 5 inches below the tibial plateau.

Causes of Lower Limb Amputation

In the United States, 95% of LL amputations are performed as a result of complications of PVD²⁶; ultimately, 25% to 50% of these cases are due to diabetes mellitus.⁵⁴ Trauma is the second most common cause of amputation in the United States, but it is the leading cause in developing

FIGURE 43-32 Levels of lower extremity amputation.

(From Paz JC, West MP: *Acute care handbook for physical therapists*, ed 2, Oxford, 2002, Butterworth-Heinemann.)

countries because of land mines and other environmental hazards.⁵⁴ Amputation may also be performed in cases of malignancy in an effort to prevent it from spreading to other sites or systems in the body.

In Lena's case, diabetes mellitus and PVD resulted in poor circulation in her LLs. Because of this complication, blood flow to her left foot and leg was not adequate for her limb to heal, even from what initially appeared to be a small wound. Therefore, she was obliged to undergo

progressive amputations of her left LL, eventually leading to her recent BKA.

Postsurgery Residual Limb Care

Skin care and positioning are extremely important throughout the course of rehabilitation, especially immediately after surgery. Once the surgical wound has begun to heal, some form of specialized postsurgical dressing will be used to help prevent swelling and to shape the residual limb for ease of future prosthesis use. Wrapping with an elastic bandage, such as an Ace wrap, is a common method to control edema after surgery. However, smooth wrapping does require skilled and consistent technique, which is necessary to prevent poor shaping of the residual limb. A series of gradually smaller residual limb shrinkers can be worn as an alternative to elastic bandage wrapping, to encourage constant, even shrinkage of the residual limb for fit with a final prosthesis. Both elastic bandages and shrinkers can be used early after surgery, even if the client's surgical wound still has a dressing on it. In such a case, a nylon stocking would first be applied to prevent the bandage or shrinker from dislodging the dressing. Once the final prosthesis is made and adjusted, the client frequently will continue to wear a shrinker during the day when he or she is not wearing the prosthesis, as well as at night. This shrinking and shaping process can take up to 3 months or longer in some cases, depending on the client's condition.

If the client (or his or her caregiver) is unable to demonstrate proper technique with wrapping or shrinker use, a Jobst compression pump may be used. The pump is an air-filled sleeve that surrounds the residual limb, placing constant, equal pressure on all sides, quickly shrinking and shaping the residual limb. A rigid dressing, or cast, is frequently used for active clients after surgery. The end of the cast is made to work with a simple training prosthesis, so the client can begin training for standing and walking immediately. Scar massage may be necessary later in the healing to prevent adhesions and enhance comfort around the surgical site; this massage technique can be taught to the client. The Ace wrap bandaging of Lena's residual limb was performed by nurses in the hospital. After Lena's arrival at the skilled nursing facility, the nursing staff consulted the occupational therapist to determine whether Lena had the cognitive and visual function, as well as the necessary motor skills, to learn how to apply her own wrap or shrinker and to perform her own scar massage.

Lower Limb Equipment and Prostheses

Movement and time out of bed are typically reduced immediately after LL amputation. The surgery itself can make movement uncomfortable, and many persons who have undergone amputation surgery have preexisting conditions that may further reduce mobility. For these reasons, clients

FIGURE 43-33 Wheelchair with support for residual limb.

may require the use of bed rails or a metal trapeze bar hanging over the bed to help reposition themselves in bed and to transition between supine and sitting. Wheelchairs also present a challenge because the client is no longer able to support the affected limb by resting the now absent foot on the floor or on the footrest of the wheelchair. A **residual limb support** is basically a padded board that is placed on the seat of the wheelchair; it has an extended component on the side of the affected limb that projects forward from the seat of the chair (Figure 43-33). This extension provides a surface for the residual limb to rest upon, thus placing the limb in a nondependent position and reducing stresses placed on the hip joint. A person with a BKA is often at risk for developing a flexion contracture of the knee joint, and residual limb support can facilitate extension of the knee in sitting, thus helping to prevent both edema in the residual limb and contracture of the knee joint.⁷³ A residual limb support is sometimes still referred to, in less acceptable terminology, as a stump support. For a person with bilateral LL amputations, the large wheels on the wheelchair must be placed farther back to accommodate the change in body weight distribution. Antitippers, commercially available wheelchair accessories, can also be used on the back of the chair to reduce the likelihood of tipping backward during weight shifting.

Most clients will use a walker during at least the initial phases of their rehabilitation. Some clients with LL amputations will go on to use a walker at all times for ambulation. Both four-footed (standard) and two-wheeled (rolling) walkers may be used, depending on the client's individual characteristics and needs. It has been suggested that using a two-wheeled walker may allow those with prosthetic limbs to ambulate more quickly and with less interruption,⁶⁹ but

walker choice should always be made on the basis of a total assessment of the client's abilities and needs.

Many types of prostheses are available for the LL, and technology is improving daily. For all prostheses, comfort, ease of application, appearance, and function of a prosthesis, including the client's ability to perform ADLs and IADLs with use of the affected limb, correlate significantly with the client's walking distance and with his or her perceived quality of life after an LL amputation.⁴⁰ It is very important for the rehabilitation team to keep this in mind during a client's fitting for and training with a prosthesis.

The main components of an LL prosthesis are the socket, a sock or gel liner, a suspension system, a pylon, and a terminal device. For some prostheses, an articulating joint is also necessary. The socket is the direct connection between the residual limb and the prosthesis. A person's residual limb may change in volume during the day and over the course of time, presenting challenges for maintaining an adequate fit within the socket. This challenge is frequently addressed by adding to, or removing socks from, the residual limb to adapt to its volume changes. Smart variable geometry socket (SVGS) technology was developed to help reduce this challenge.²¹ SVGS adds and removes liquid from the intrasocket environment on the basis of intrasocket pressure during wear, continuously accommodating for residual limb volume changes and thus maintaining the fit of the socket without having to remove the prosthesis. Static elastomeric liners are also used for the prosthesis socket; the choice of liner is based on variables such as fit, comfort, friction tolerance, and price.⁵⁷ Various suspension mechanisms are used to attach the socket to the residual limb, including belts, straps, wedges, or suction; sometimes mechanisms are combined to ensure appropriate fit.

The **pylon** is the structure that attaches the socket to the TD (Figure 43-34). Vertical shock pylons function as shock absorbers for LL prostheses. Many clients who have had an LL amputation express a preference for walking with these devices.¹⁹ Such shock absorption is especially beneficial during high-impact activities, such as running, and for other activities that are part of daily life for many clients, such as descending curbs and stairs. A pylon can be a basic, static device that provides minimal cosmetic benefits; it can also be a dynamic device, such as that outlined in the preceding paragraph, and can be modified to provide a close cosmetic match with the client's unaffected limb.

The TD is the prosthetic foot, which provides a stable weight-bearing surface and can itself function as a shock absorber. The many types of available TDs provide varying degrees of mechanical ankle movement and dynamic response, according to the needs and abilities of the client. Specialized TDs—indeed, entire LL prostheses—are designed to accommodate the challenges presented by various sports and activities (Figure 43-35). To help select the best prosthesis, Lena's prosthetist consulted with her occupational therapist to explore the activities and lifestyle to which Lena wished to return.

FIGURE 43-34 A typical pylon.

Participation in Areas of Occupation

OT Practice Note

A thorough occupational history along with evaluation and analysis of occupational performance, obtained during the initial evaluation, will help the occupational therapist to identify areas of strength and of challenge for the client who has undergone a limb amputation.

For some clients, particularly those who underwent a traumatic amputation, the activities to which they wish to return are ones that they engaged in right up to the point of injury or illness. However, given the nature of PVD and diabetes, many clients with LL amputations experience a progressive decline in function over the course of several years. For these clients, amputation and subsequent rehabilitation, although difficult, may allow a return to fulfilling occupations that had been absent from the clients' repertoire for quite some time.

Participation in most ADLs will be affected by LL amputation. Although a client with an LL amputation will be learning new mobility techniques in physical therapy, he or she must also participate in occupational therapy to learn new functional mobility techniques with which to accomplish familiar tasks. Bathing, dressing, personal hygiene, grooming, and toilet hygiene will likely need to be addressed as part of an occupational therapy intervention program. Personal device care must be addressed if the client is using an LL prosthesis. Participation in IADLs will also be affected. Particular attention should be paid to care of others, care of pets, child rearing, community mobility, health management and maintenance, home establishment and management, meal preparation and cleanup, safety and emergency maintenance, and shopping. The areas of rest and sleep may also present challenges to a person with a new LL amputation. For example, one's evening routine may be disrupted by having to perform it from a wheelchair instead of at an ambulatory level (sleep preparation). A client may experience difficulties interacting with his or her spouse in the sleeping space as they both adjust to a new amputation (sleep participation). The occupational therapist should assess how these areas of occupation may be impacted by the amputation, and should help the client develop adaptations that facilitate improved rest and sleep. Treatments addressing phantom sensations may also benefit the client's rest and sleep. (See Chapter 13 for further information.)

Participation in educational, work, play, and leisure activities is usually affected by LL amputation and should be addressed during occupational therapy, as should social participation. Although intervention often assumes a greater role with these areas of occupation later in the rehabilitation

process, they still can be addressed even during the acute rehabilitation phase, thus reinforcing to the client that these are areas of occupation in which a return to active participation is indeed possible. It is essential that the occupational therapist help clients to explore all avenues of an occupation in which they may wish to participate, ensuring that even activities that had been abandoned in the past are possible again.³³ As a result of changes in function after amputation, clients may not be able to return to participation in prior work or leisure activities or to participation at the level to which they were accustomed. In such cases, the occupational therapist should help clients explore other opportunities that they might find fulfilling through identification of interests, skills, and opportunities.

Early in her course of occupational therapy at the skilled nursing facility, Lena spoke with her therapist about how much she missed walking to her church and helping to bake pies for its annual autumn festival. Lena said that she stopped doing this about 10 years ago because it became so difficult; she then discussed feelings of isolation and uselessness. Lena said that she had been known throughout her town for her pies, and she proudly recounted how each year people would tell her that she should open her own restaurant. Although Lena and her occupational therapist had initially set her long-term goals for independence with self-care and basic home management, they decided to add a goal for community re-entry that focused on being able to re-engage in this occupation.

Client Factors

Structures related to movement, as well as skin and related structures, are always altered by an LL amputation. The status of other body structures must also be assessed, however, to determine the level of support or challenge that these structures might present during the rehabilitation process.

Neuromuscular and movement-related functions will be altered by LL amputation, and this will affect occupational performance after surgery. This alteration of function may occur not only in the affected limb but also in other parts of the body. Because of changes in the affected limb, greater stresses will be placed on the rest of the body; a person's unaffected leg as well as his or her arms will experience increased weight bearing during many functional activities, and both surgical wound healing and increased time in bed will place greater demand on skin functions.

Of particular importance is attention to sensations of pain. Up to 84% of persons who have had an LL amputation have experienced phantom limb pain.¹¹ In such an instance, the client may experience sensations in the part of the limb that has been removed, such as feelings of cramping, squeezing, shooting, or burning pain. In these cases, the therapist can use desensitization techniques (such as massage of the residual limb), exercise, hot and cold therapy, or electrical stimulation⁵⁴ to help decrease these sensations

and allow the client to more easily and comfortably participate in chosen occupations.

Clients with PVD already have compromised cardiovascular function, and care must be taken to determine how much activity can safely be tolerated during therapy. A client's mental and sensory functions will affect the way in which therapy, including education, is delivered; they will also affect what types of prosthesis and equipment are used.³¹ Some clients may be able to incorporate new techniques quickly, recalling information from one session or even from reading material, and may be able to independently apply this learning to new situations. However, other clients will require adaptation of training and may require prolonged treatment to turn the new techniques that they have learned into habits. Understanding a client's values, beliefs, and spirituality will further help the therapist to develop a treatment program and choose interventions that are tailored to that client and best meet his or her needs.

The occupational therapist found that Lena would need to increase her upper body strength to help support herself during transfers and ambulation with the walker. She also needed to improve her postsurgical postural alignment and gait patterns to participate in her chosen occupations. Lena was experiencing pain and sensitivity in her residual limb. However, Lena's mental functions were found to be strengths, and her vision and the sensation in her hands, although slightly diminished, were functioning at a level sufficient to support her desired functional activities. Additionally, Lena's belief that good efforts yield results, as well as her commitment to her spiritual and social communities, would facilitate her engagement in her occupational therapy program.

Performance Skills

The most overt effects of LL amputation will be evident in the area of motor and praxis skills. Adjusting posture, coordinating movements, maintaining balance, and bending are altered after surgery, and the client must address each of these skills in therapy to return to a full repertoire of occupations. Sensory and perceptual skills may also be affected by the amputation, and a client may have had prior difficulty with these skills caused by impaired sensory function. The client's cognitive skills (such as judging, sequencing, and multitasking) and communication and social skills will affect his or her participation in treatment and the therapist's choice of treatment methods.

Lena's occupational therapist found that, as she expected, Lena exhibited impairment in stabilizing, aligning, positioning, walking, reaching, bending, moving, transporting, lifting while standing, and pacing. The therapist also found that cognitive skills were at functional levels for Lena. However, Lena did exhibit difficulty with adaptation as she began attempting to perform activities with a changed body structure and in different positions. The therapist also noticed that Lena was having difficulty with social skills,

exhibiting trouble focusing and collaborating during many occupations. The therapist would need to address these areas in therapy to help Lena return to her optimal level of participation in occupations.

Performance Patterns

Whatever a client's performance patterns were before the amputation, they are likely to be altered after amputation. The client may already have useful habits, routines, rituals, and roles that can be drawn upon in therapy to facilitate his or her return to prior levels of occupational performance. However, for many clients, the occupational history will reveal prior impoverished habits and lack of, or maladaptive, routines that may present challenges to the rehabilitative process. Although Lena's diabetes and PVD placed her at increased risk for poor wound healing, she never developed the habit of routinely checking her feet and legs for cuts or infections. This impoverished habit led to three amputations on her left leg. Lena's morning routine in her kitchen involved crossing the room many times and carrying multiple items in her hands at once. In conversations with her occupational therapist, Lena did indicate that she had already begun to drop things during this routine, that she had nearly fallen a few times, and that she worried about being able to safely make her own breakfast at home.

Psychosocial Repercussions

Amputation of a limb represents a loss and therefore involves a grief process. This process involves dealing with one's feelings regarding change in body structure, functional abilities, and participation in occupations. It can also involve anger, acknowledgment of unpleasant realities regarding one's health status, and fears about one's functional and financial future. Social acceptance and community function are also significant concerns for a person who has undergone an amputation. These are all areas that can be addressed by an interdisciplinary rehabilitation team in an effort to help the client adapt and should inform all aspects of occupational therapy intervention.

The occupational therapist may use several techniques to help a person adapt to his or her amputation and create a new sense of self. The therapeutic relationship and the therapeutic use of self can provide a safe environment and catalyst for the client to discuss feelings of loss, thoughts regarding body changes, and fears for the future. The therapist can teach the client coping skills for dealing with anxiety and depression, as well as techniques for improving postsurgical body image.⁵² The consultation process can include recommendations for workplace adaptations, as well as suggestions for how to make the home more accessible to a client with a new amputation. The therapeutic use of occupations that have been graded to the client's current abilities provides opportunities to master skills and experience success. The therapist's encouragement during such

sessions not only fosters development and provides support but also provides evidence to the client that recovery of function and return to participation in chosen occupations are indeed possible⁵²; this knowledge fosters hope and a vision of the future.

It is important to recognize that an outside observer's rating of a person's adaptation to an LL amputation may not be the same as that person's self-rating. A surgeon may rate success on the basis of healing of the surgical wound, a prosthetist on the fit between residual limb and prosthesis, a physical therapist on the client's ability to ambulate, and an occupational therapist on the client's ability to participate in areas of occupation. However, clients may place greater emphasis on other criteria in their determination of successful adaptation to an LL amputation. Some related variables that appear of primary concern to clients include feeling comfortable while being active in the presence of strangers, not feeling like a burden to one's family, being able to care for others, and being able to exercise recreationally.⁴⁰

Context and Activity Demands

An understanding of the client's contexts, environments, and demands of daily activities will help the therapist design a treatment program that will best help the client re-engage in chosen occupations within his or her everyday environment. It will also help the therapist adapt the activity demands of the client's chosen occupations to facilitate greater independence and development of proficiency. Lena's occupational therapist took a detailed floor plan of Lena's bedroom and was able to move the furniture in her room into the skilled nursing facility, so it closely approximated her bedroom setup at home. When Lena performed her morning and evening ADLs within the room, she was then doing so in a more natural environment. Lena's therapist initially made significant adaptations to Lena's morning routine demands, wheeling Lena up to the sink in the bathroom for sponge-bathing and bringing her clothes to her in the bathroom, where she would stand with the help of a grab bar, so the therapist could pull Lena's pants up. Over the course of time, as Lena improved her performance skills, improved her performance patterns, and incorporated into her routine new ADL techniques taught during therapy, her occupational therapist was able to decrease the adaptation of activity demands, and Lena progressed to independence with routines that she would be able to sustain at home.

Additional Considerations for Elderly Clients

Although LL amputation may be performed to preserve function or to save the client's life, it does carry an increased mortality risk as the age of the client increases. One study

of older persons who underwent a BKA found the survival probability after BKA to be 77% at 1 year, 57% at 3 years, and 28% at 7½ years.³⁵ Because this increased mortality risk is related not only to the amputation surgery but also to preexisting health and environment factors, attention to the overall health status of the client is of utmost importance.

Many body structures and functions are already compromised in elderly clients, making the rehabilitation process longer and more delicate. An elderly person may take more time to recover from the effects of anesthesia after surgery, including effects on cognition and the respiratory system. For unilateral amputees, leg balance on the unaffected limb is a significant predictor for prosthetic use.⁵⁹ Because balance may already be decreased and cognitive skills may have declined, elderly clients learning to use a prosthetic limb may experience greater challenges. Elderly clients have already experienced many losses, which may include family and friends, home, health, and function; the psychological sequelae of amputation can be all the more traumatic when layered over these previous losses.

Review Questions

1. Define the following abbreviations: AE, TD, BE, AKA, and BKA.
2. List six reasons for amputation.
3. What are the four main reasons for LL amputation?
4. What are the primary goals of amputation surgery?
5. Name the two types of surgical procedures that can be performed, and list the advantages of each.
6. Name at least four postsurgical factors that can interfere with prosthetic training and rehabilitation. How is each solved?
7. Define neuroma. How does it affect wearing of the prosthesis?
8. What is the difference between phantom limb and phantom pain?
9. What are some of the typical and expected psychosocial consequences of limb loss?
10. How can members of the rehabilitation team facilitate adjustment to amputation and prosthesis wear?
11. Which arm function is lost and which functions are maintained in a long trans-radial amputation?
12. What is the purpose of the preprosthetic program?
13. Describe activities and exercises suitable for the preprosthetic period.
14. Before the TD on a trans-humeral prosthesis can be operated, what must the wearer do?
15. How does the prosthesis wearer pre-position the TD?
16. Name three types of electric TDs.
17. How is functional training graded?
18. What is the source of power that activates the electric-powered prosthesis?
19. What are some advantages of the electric-powered prosthesis?
20. What is a hybrid prosthesis?

Threaded Case Study | Lena, Part 2

Amputation of a lower limb has a significant functional impact on a person, but return to an active and fulfilling life is still possible. Lena required extensive assistance to take care of herself when she entered the skilled nursing facility, but her goal was to return home independently able to take care of herself and her home. During the course of occupational therapy, Lena realized that she had been slowly decreasing her participation in the very activities that helped her feel active and vital and helped her define who she was. She then decided to work with her therapist toward being able to reclaim these activities, particularly going back to her church and helping to bake pies for its upcoming autumn festival.

During the course of her occupational therapy, Lena's therapist presented her with activities that addressed the areas that Lena needed to improve to reach her goals. These goals, which Lena had identified as of interest to her, were adapted to provide an appropriate level of challenge. Because Lena liked to watch birds and had enjoyed decorative painting in the past, her occupational therapy sessions included building and painting birdhouses. This increased Lena's upper body strength and provided progressive challenges to her sitting and eventually standing balance, facilitating her return to independence with ambulatory tasks and providing an activity that Lena could perform at home and a product that she could donate to her church's fall festival.

As Lena's stay at the skilled nursing facility neared its end, she participated in community re-entry sessions with her occupational therapist. Because Lena had mentioned her desire to help bake pies with the congregation for the festival, she and her occupational therapist visited the church together during a community re-entry session; this gave Lena a chance to interact

with some of the members of the baking committee so that they could see Lena's capable self, allaying their fears about interacting with a person with a disability and setting the expectation that Lena would be involved. Through supported engagement in this social community occupation, Lena gained confidence that she is still an accepted and desired member of her community. Together, Lena and her occupational therapist identified potential challenges presented by the layout of the kitchen. Lena engaged in trials and problem-solving strategies with her therapist to determine methods to allow safe participation in baking. In preparation for her return to the church as a member of the baking team, Lena then perfected these techniques in the occupational therapy kitchen back at the facility.

Lena's occupational therapist also worked with Lena to discuss the ways in which some of her prehospitalization habits and routines had contributed to high-risk situations and to identify strategies to help reduce her risks of rehospitalization. Lena learned how to perform her own lower body skin checks and was performing them regularly by the end of her stay. She went home with a daily routine that would help her stay active throughout the day but also incorporated techniques that minimized periods of prolonged standing and reduced the amount of energy required to accomplish tasks. Lena's family then reorganized items in her kitchen, according to recommendations determined by Lena in collaboration with her occupational therapist, so that her environment placed less strain on her during daily activities. Lena went home independent with her daily activities, able to engage in individual and social occupations that made her feel happy and vital, and reclaimed a role that had long been abandoned.

21. What does muscle site control training mean?
22. Describe the relative roles of a prosthesis and a sound arm and hand in the following activities: cutting meat, opening a jar, using scissors, buckling a belt, using an eggbeater, and hammering a nail.
23. Name two significant concerns for the residual limb immediately after surgery.
24. What is the purpose of a shrinker?
25. What should be done with the wheelchair to accommodate the residual limb? To accommodate a person with bilateral AKAs?
26. Name the main components of an LL prosthesis.
27. What is the purpose of using a sock on the residual limb?
28. How will LL amputation affect other parts of the body?
29. How might LL amputation affect an individual's participation in areas of occupation?
30. Which performance skills are most likely to be affected after LL amputation?
31. How can preexisting performance patterns affect a client's participation in occupations after the amputation?

32. What are the potential psychosocial repercussions of LL amputation?
33. How can ADL activity demands be adapted to foster greater independence after LL amputation?
34. What additional considerations does LL amputation present for elderly clients?

Metabolic equivalent

■ **Learning Objectives** After studying this chapter, the student or practitioner will be able to do the following:

1. Briefly describe the cardiovascular system and its function.
2. Identify the significance of ischemic heart disease and valvular diseases of the heart.
3. Differentiate between modifiable and nonmodifiable risk factors.
4. Identify signs and symptoms of cardiac distress.
5. Describe the course of action that should be taken if signs and symptoms of cardiac distress are present.
6. List the psychosocial considerations for persons with cardiovascular or pulmonary disease.
7. Describe methods for determining the heart rate and blood pressure.
8. Determine the rate-pressure product given the heart rate and blood pressure.
9. Give a brief overview of the respiratory system, and identify its primary function.
10. Define chronic obstructive pulmonary disease.
11. Identify pulmonary risk factors and psychosocial considerations.
12. Describe dyspnea control postures, pursed-lip breathing, and diaphragmatic breathing.
13. Describe a relaxation technique, and explain its purpose.
14. List interview questions that will help the clinician know what the patient understands about intervention.
15. List the principles of energy conservation.
16. Explain the significance of a metabolic equivalent chart in the progression of activity, and describe how to use it.

Threaded Case Study | Franklin, Part 1

Franklin is a 48-year-old auto mechanic who experienced substernal chest pain rated 10 of 10 on a pain scale, accompanied by nausea and shortness of breath, while working under an automobile 2 days earlier. He had been working 60 hours per week and had not taken any time off despite feeling “under the weather” for a few weeks before these most recent severe symptoms. Acute anterolateral myocardial infarction complicated by subsequent congestive heart failure was diagnosed. He is married and the father of three children aged 9, 5, and 4. His wife works full-time and was unable to manage his care at home, so he was temporarily placed in a skilled nursing facility.

During the initial occupational therapy evaluation, the occupational profile revealed that Franklin is anxious and expresses concern that he will die in the facility, just as his father did. He inherited the auto repair shop from his father and wants to be able to hand it off to his 9-year-old son when he retires. He reports that his wife “is a very desirable woman and a hardworking mother.” He wants to return home and to his work. He is able to safely walk to the bathroom, according to physical therapy findings. Besides playing catch with his son and attending Little League games, Franklin’s typical day is spent working and watching TV, 7 days a week.

The occupational therapy evaluation also indicates that Franklin, though anxious, was cooperative and motivated to participate in therapy. Despite not being formally tested, the client factors of strength, range of motion, and perceptual and

cognitive ability were found to be grossly functional during a routine activity of daily living assessment of a 2.5–basal metabolic equivalent (MET measurement is described elsewhere in the chapter) task involving seated sponge bathing and dressing. His vital signs were appropriate during the evaluation, except that his blood pressure fell 20 mm Hg in recovery (3 minutes after completion of bathing), and Franklin became symptomatic (experiencing nausea and shortness of breath). His symptoms and vital signs stabilized after 5 minutes of rest. Franklin needed frequent cues to pace the activity and demonstrated little knowledge about the signs and symptoms of cardiac distress. His risk factors include male gender, family history, smoking, and a sedentary lifestyle.

Franklin is concerned whether he will be able to do everything for himself if he is discharged home.

Critical Thinking Questions

1. What probative questions might the occupational therapist ask to clarify what Franklin means by “able to do everything for himself”?
2. What skills must Franklin acquire to reduce his risk for another cardiac event?
3. What areas of occupation might the therapist choose for the next intervention session, and based on Franklin’s occupational profile, what goals might be included in his occupational therapy intervention plan?

In this chapter the term *patient* is used instead of *client* to reflect the practice setting and the acute nature of the diagnoses in the individuals described in the case studies.

Individuals with disorders of the cardiovascular or pulmonary system may be severely limited in endurance and

performance in areas of occupation, including activities of daily living (ADLs) and instrumental activities of daily living (IADLs). Occupational therapy (OT) services may benefit such individuals and are available throughout the continuum of health care. An understanding of the normal

function of the cardiopulmonary system, the pathology of cardiopulmonary disease, common risk factors, clinical terminology, medical interventions, precautions, and standard treatment techniques will guide the occupational therapist in providing effective care and promoting recovery of function in clients with compromised cardiovascular or pulmonary systems.

Every living cell of the body has three major requirements for life: (1) a constant supply of nutrients and oxygen, (2) continual removal of carbon dioxide and other waste products, and (3) a relatively constant temperature. The cardiovascular and pulmonary systems play key roles in meeting these requirements.³⁰

Anatomy and Circulation

The heart and blood vessels work together to maintain a constant flow of blood throughout the body. The heart, located between the lungs, is pear shaped and about the size of a fist. It functions as a two-sided pump. The right side pumps blood from the body to the lungs; the left side simultaneously pumps blood from the lungs to the body. Each side of the heart has two chambers: an upper atrium and a lower ventricle.

Blood flows to the heart from the venous system. Blood enters the right atrium, which contracts and squeezes the blood into the right ventricle. Next, the right ventricle contracts and ejects the blood into the lungs, where carbon dioxide is exchanged for oxygen. Oxygen-rich blood flows from the lungs to the left atrium. As the left atrium contracts, it forces blood into the left ventricle, which then contracts and ejects its contents into the aorta for systemic circulation (Figure 44-1). Blood travels from the aorta to the arteries and through progressively smaller blood vessels to networks of very tiny capillaries. In the capillaries, blood cells exchange their oxygen for carbon dioxide.

Each of the ventricles has two valves: an input valve and an output valve. The valves open and close as the heart muscle (myocardium) contracts and relaxes. These valves control the direction and flow of blood. The input valves are the mitral, or bicuspid, valve (between the left atrium and ventricle) and the tricuspid valve (between the right atrium and ventricle). The output valves comprise the aortic and pulmonary valves.

The heart is living tissue and requires a blood supply (through an arterial and venous system of its own), or it will die. Coronary arteries cross over the myocardium to supply it with oxygen-rich blood. The coronary arteries are named for their location on the myocardium (Figure 44-2). Cardiologists generally refer to these arteries by abbreviations, such as “LAD” for “left anterior descending” and “RCA” for “right coronary artery.” The LAD artery is on the left, anterior portion of the heart and runs in a downward direction; it supplies part of the left ventricle. Blockage of this coronary artery will interrupt the blood supply to the left ventricle. Because the left ventricle supplies the body and

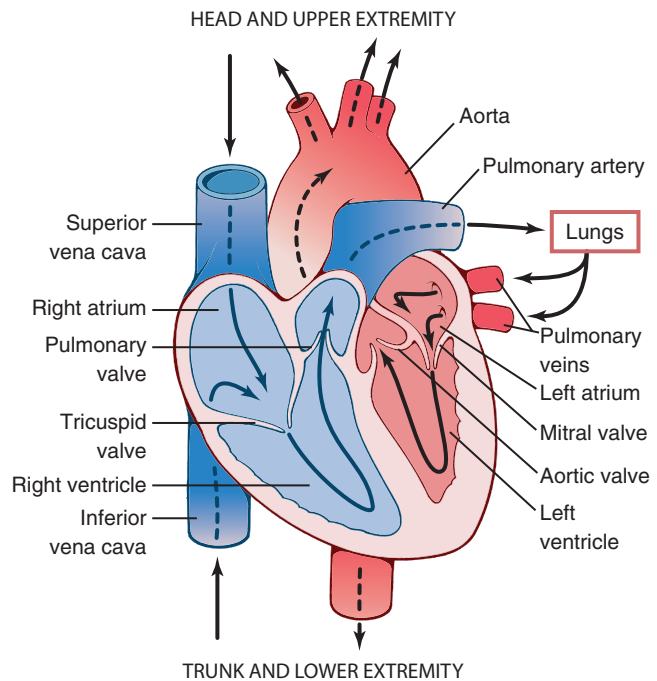

FIGURE 44-1 Anatomy of the heart.

(From Thibodeau GA, Patton KT: *The human body in health and disease*, ed 5, St. Louis, Mo, 2010, Mosby.)

brain with blood, a heart attack caused by blockage of the LAD artery can have serious consequences.

What Causes the Heart to Contract?

In addition to the ordinary muscle tissue of the heart, the myocardium is composed of two other types of tissue: nodal and Purkinje. These tissues are part of a specialized electrical conduction system that causes the heart to contract and relax (Figure 44-3). An electrical impulse usually originates in the right atrium at a site called the sinoatrial node. The impulse travels along internodal pathways to the atrioventricular node, through the bundle of His, to the left and right bundle branches, and then to the Purkinje fibers. Nerve impulses normally travel this pathway 60 to 100 times every minute, first causing both atria to contract, pushing blood into the ventricles, and then provoking the ventricles to contract. The electrical impulse created by the heart's conduction system can easily be studied. Electrodes placed on a person's limbs and chest can pick up the heart's electrical impulse, which can be translated to paper as an electrocardiogram (ECG). The resulting ECG tracing is frequently used to help diagnose cardiac disease.

The sinoatrial node responds to vagal and sympathetic nervous system input.²¹ This is why the heart rate (HR) increases in response to exercise and anxiety and decreases in response to relaxation techniques, such as deep breathing and meditation. Each cell within the electrical conduction system of the heart can respond to, conduct, resist for a brief

FIGURE 44-2 Coronary circulation.
 (From Andreoli TE, Benjamin IJ, Griggs RC, Wing EJ: *Andreoli and Carpenter's Cecil essentials of medicine*, ed 8, Philadelphia, Pa, 2010, Saunders.)

period, and generate an electrical impulse. Because of this capacity, electrical impulses causing the heart muscle to contract can be generated from anywhere along the electrical conduction system. This is desirable when part of the conduction system has been damaged and is unable to do its job, but it is undesirable when life-threatening conduction irregularities develop.

Cardiac Cycle

HR and blood pressure (BP) determine cardiac output, the amount of blood ejected by the heart each minute. The cardiac cycle occurs in two phases: input (diastole) and output (systole).

FIGURE 44-3 Cardiac conduction.

(From Hall JE, Guyton AC: *Guyton and Hall textbook of medical physiology*, ed 12, Philadelphia, Pa, 2011, Saunders.)

During the input phase, blood flows through the atria and into the ventricles. The atria contract and push more blood into the ventricles. Once the pressure inside the ventricles is equal to the pressure in the atria, the input valves (tricuspid in the right ventricle and mitral [or bicuspid] in the left ventricle) close. The ventricles then contract, which results in rapidly increasing ventricular pressure. When the pressure inside the ventricles exceeds the pressure in the blood vessels beyond, the output valves (pulmonary in the right and aortic in the left) open, and diastolic BP is attained.

The ventricles continue to contract and squeeze blood under greater and greater pressure into the pulmonary and body circulation. Systolic BP is attained when pressure in the emptying ventricles falls below pressure in the blood vessels beyond, which causes the output valves to close.

Ischemic Heart Disease

Ischemic heart disease (ischemia) occurs when a part of the heart is temporarily deprived of sufficient oxygen to meet its demand. The most common cause of cardiac ischemia is coronary artery disease (CAD). CAD is the most common type of heart disease and the leading cause of death in the United States in both men and women.³³ CAD usually develops over a period of many years without causing symptoms. The internal wall of an artery can become injured. Once the wall is damaged, it becomes irregular in shape and more prone to collect plaque (fatty deposits such as cholesterol). Platelets also gather along the arterial wall and clog the artery, thereby creating a lesion in the same manner in which rust can clog a pipe. The artery gradually narrows and thus allows a smaller volume of blood to pass through it. This disease process is called atherosclerosis.

If a coronary artery is partially or completely blocked, the part of the heart supplied by that artery may not receive sufficient oxygen to meet its needs. Persons with partial blockage of a coronary artery may be free of symptoms at rest but have angina, a type of chest pain, with eating, exercise, exertion, or exposure to cold. Angina varies from individual to individual and has been described as squeezing, tightness, fullness, pressure, or a sharp pain in the chest. The pain may also radiate to other parts of the body, usually the arm, back, neck, or jaw. Angina has also been confused with indigestion. Rest or medication (or both) will frequently relieve angina. Usually, no permanent heart damage results. Angina is a warning sign that should not be ignored. It is a sign that CAD is present—that the individual may be a candidate for a heart attack.

Chest pain that is not relieved by rest or nitroglycerin indicates a myocardial infarction (MI), or heart attack. A patient who has this type of pain should seek emergency medical help immediately. Individuals who attribute their symptoms to anxiety and stress are more likely to delay emergency care.⁴² In the case of Franklin, his substernal chest pain was a warning sign that one or more of his coronary arteries were blocked. The blood flow to the heart muscle was interrupted, and starved of the necessary oxygen, Franklin's heart began to die. MI is significant because part of the heart muscle dies as a result of lack of oxygen. If a substantial section of the heart is damaged, it will stop pumping (cardiac arrest).

Restrictions in activity are prescribed for the first 6 weeks after a heart attack because newly damaged heart muscle, like any injured body tissue, is easily reinjured.¹⁴ During a heart attack, metabolic waste products accumulate in the damaged myocardium and make it irritable and prone to electrical irregularities such as premature ventricular contractions. A delicate balance of rest and activity must be maintained to allow the damaged area of myocardium to heal while also maintaining the strength of the healthy part of the heart. OT is frequently recommended to guide the patient toward a safe level of activity, or participation in occupation, during this acute period of recovery. Franklin requires guidance from the therapist in recognizing signs of fatigue, determining when rest breaks are needed, and choosing activities that can be performed safely.

At approximately 6 weeks after an MI, scar tissue forms and the risk of extending the MI decreases. The scarred part of the heart muscle is not elastic and does not contract with each heartbeat. Therefore, the heart does not pump as well. A graded exercise program will help strengthen the healthy part of the myocardium and improve cardiac output.⁴³

CAD can also lead to congestive heart failure (CHF). Similarly, infections can lead to CHF. This disease process develops over time with the heart becoming progressively weaker. CHF occurs when the heart is unable to pump effectively enough to meet the demand and fluid backs up

into the lungs or the body. The fluid buildup in the lungs causes shortness of breath. Fluid overload is serious because it puts a greater workload on the heart as the heart strains while attempting to clear the excess fluid, which may result in further congestion. Heart size is often enlarged in persons with CHF because the heart muscle thickens (hypertrophy) from working so hard. Diuretics can be prescribed for persons with CHF to promote fluid loss through the urinary system. Low-sodium diets and fluid restrictions reduce the overall amount of fluid in the body. CHF cannot be cured, but with diet, medications, and rest, people with this condition can live longer and participate more fully in life.

Once an acute exacerbation of CHF is controlled, gradual resumption of activity will promote improved function. If activity is resumed too quickly, another acute episode may follow. Patients who have difficulty resuming their former level of activity may self-limit their recovery. OT can guide clients with acute CHF toward an optimal level of function via graded self-care tasks. “About 5.7 million people in the United States have heart failure, and it results in about 300,000 deaths each year.”³⁵

Table 44-1 delineates the four functional classifications of heart disease. OT can be of great benefit to persons with stage III and IV heart disease and can provide preventive programs for persons with stages I and II.

Valvular Disease

The heart valves, which are responsible for controlling the direction and flow of blood through the heart, may become damaged by disease or infection. Two complications result from valvular disease: volume overload and pressure overload. A fibrous mitral valve will fail to close properly, and blood will be regurgitated back to the atria when the left ventricle contracts. Volume overload results when fluid accumulates in the lungs, thereby causing shortness of breath. Volume overload increases the potential for atrial fibrillation, which results in irregular and ineffective contractions in both atria. Blood flow through the heart slows, and blood clots (emboli) may develop in the ventricles. Many cerebrovascular accidents are caused when emboli ejected from the left ventricle enter the circulatory system of the brain.

If the aortic valve fails to close properly (aortic insufficiency), CHF or ischemia may result. Another disorder of the aortic valve is aortic stenosis (narrowing), which results in pressure overload. The left ventricle, which must work harder to open the sticky valve, becomes enlarged, and cardiac output decreases. Ventricular arrhythmia (irregular rhythm of heartbeats), cerebral insufficiency, confusion, syncope (fainting), and even sudden death may result from aortic stenosis. Surgery to repair or replace the damaged valves is frequently recommended.

Cardiac Risk Factors

Many scientific studies have been conducted to determine the causes of heart disease. The most famous of these, the Framingham study,¹⁰ helped identify many factors that put an individual at risk for atherosclerosis. Risk factors are divided into three major categories: those that cannot be changed (heredity, male gender, and age), those that can be changed (high blood pressure, cigarette smoking, cholesterol levels, and an inactive lifestyle), and contributing factors (diabetes, stress, and obesity). Other factors that contribute to CAD include sleep apnea, high levels of triglycerides, and high levels of C-reactive protein.³⁴ The more risk factors that an individual has, the greater the individual's risk for CAD. All team members—the physician, nurse, physical therapist, case manager, social worker, nutritionist, and occupational therapist—should support the patient's attempts to reduce risk factors.

Medical Management

A heart attack is a medical emergency, and treatment with aspirin and oxygen is usually initiated before diagnosis. Nitroglycerin and other measures to control chest pain are included in these early measures.³⁷ After emergency treatment, heart attack survivors are typically managed in a coronary care unit, where they are closely observed for complications. Approximately 90% of persons who have suffered an MI will have arrhythmia.⁴ Heart failure, the development of blood clots (thrombosis and embolism), aneurysms, rupture of part of the heart muscle, inflammation of the sac around the heart (pericarditis), and even death are potential outcomes of MI. Close medical management is imperative.

Generally, patients are managed for 2 to 3 days after MI in an intensive care unit. Once their condition is stabilized, they graduate to a monitored hospital bed. Patients typically stay 4 to 6 days in the hospital after an acute MI. Vital signs are monitored closely while activity is gradually increased. OT personnel may be called on to monitor the patient's response to activity and educate the patient about the disease process, risk factors, and lifestyle modification.

Various surgical procedures can correct the circulatory problems associated with CAD. Balloon angioplasty, also called percutaneous transluminal coronary angioplasty (PTCA), and coronary artery bypass grafting (CABG) are most common. During PTCA, a wire mesh tube, called a stent, may be implanted into the coronary artery to keep the artery open.⁹

In PTCA, a catheter is inserted into the femoral artery and guided through the circulatory system into the coronary arteries. Radioactive dye is injected into the arteries, and the site of the lesion is pinpointed. A balloon is then inflated at the site of the lesion to push the plaque against the arterial wall. When the balloon is deflated and the catheter removed, improved circulation to the myocardium

■ **TABLE 44-1** | Comparison of Three Methods of Assessing Cardiovascular Disability

Class	New York Association Functional Classification	Canadian Cardiovascular Society Functional Classification	Specific Activity Scale
I	This category includes patients with cardiac disease but without resulting limitations in physical activity. Ordinary physical activity does not cause undue fatigue, palpitations, dyspnea, or anginal pain.	Ordinary physical activity, such as walking and climbing stairs, does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion during work or recreation.	Patients can perform to completion any activity requiring ≤ 7 METs (e.g., can carry objects that weigh 80 lb, do outdoor work [shovel snow, spade soil], and do recreational activities [skiing, basketball, squash, handball, job/walk 5 mph]).
II	This category includes patients with cardiac disease resulting in slight limitations in physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitations, dyspnea, or anginal pain.	Ordinary activity is somewhat limited. This includes walking or climbing stairs rapidly; walking uphill; and walking or climbing stairs after meals, in cold, in wind, when under emotional stress, or only during the few hours after waking. This also includes walking more than two blocks on a level surface and climbing more than one flight of stairs at a normal pace and in normal conditions.	Patients can perform to completion any activity requiring ≤ 5 METs (e.g., have sexual intercourse without stopping, garden, rake, weed, roller skate, dance the fox-trot, walk at 4 mph on level ground) but cannot and do not perform to completion activities requiring ≥ 7 METs.
III	This category includes patients with cardiac disease resulting in marked limitation in physical activity. They are comfortable at rest. Less than ordinary physical activity causes fatigue, palpitation, dyspnea, or anginal pain.	Ordinary physical activity is significantly limited. This includes walking one to two blocks on a level surface and climbing more than one flight in normal conditions.	Patients can perform to completion any activity requiring ≤ 2 METs (e.g., shower without stopping, strip and make the bed, clean windows, walk 2.5 miles, bowl, play golf, dress without stopping) but cannot and do not perform to completion activities requiring ≥ 5 METs.
IV	This category includes patients with cardiac disease resulting in an inability to carry out any physical activity without discomfort. Symptoms of cardiac insufficiency or angina syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.	Patients are unable to carry out any physical activity without discomfort; angina syndrome may be present at rest.	Patients cannot perform to completion any activity requiring ≥ 2 METs and cannot carry out activities listed above (Specific Activity Scale, class III).

METs, metabolic equivalents.

From Goldman L, Hashimoto B, Cook EF, et al: Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale, *Circulation* 64:1227, 1981.

usually results. Ensuring that the patient rests in bed for 8 hours after PTCA helps prevent hemorrhage from the femoral artery.

If a lesion is too diffuse or if an artery reoccludes after PTCA, CABG may be performed. The diseased section of the coronary arteries is bypassed with healthy blood vessels (taken from other parts of the body), thus improving the coronary circulation. In performing CABG, the surgeon usually opens the chest wall by cracking the sternum and spreading the ribs to gain access to the heart. Postsurgical precautions to prevent trauma to the new graft sites, incisions, and sternum generally last about 8 weeks after surgery

and include the following: avoiding Valsalva maneuvers (e.g., straining during a bowel movement), avoiding rapid movement of the upper part of the body, adhering to a 10-lb lifting restriction, wearing compressive hose, refraining from driving (which creates problems because of upper body torque), and traveling in a seat without an airbag when riding in a car. “Following CABG, 85 percent of people have significantly reduced symptoms, less risk of future heart attacks, and a decreased chance of dying within 10 years.”³²

Arrhythmias that cannot be controlled with medication may be managed by the insertion of a pacemaker in the

TABLE 44-2 | Common Cardiac Medications

Category	Common Names	Purpose and Uses	Reason Prescribed
Angiotensin II receptor blockers (or inhibitors)	Losartan (Cozaar) Irbesartan (Avopro)	Keep blood pressure from rising by preventing angiotensin II from having an effect on the heart	Control high blood pressure Control heart failure
β-Blockers	Atenolol (Tenormin) Propranolol (Inderal)	Decrease heart rate and cardiac output, lower blood pressure, and make the heart beat more slowly and with less force	Treatment of abnormal cardiac rhythms and chest pain
Calcium channel blockers	Amlodipine (Norvasc, Lotrel) Diltiazem (Cardizem, Tiazac)	Interrupt movement of calcium into cells of the heart and blood vessels	Used to treat high blood pressure, angina, and some arrhythmias
Diuretics (water pills)	Furosemide (Lasix) Hydrochlorothiazide (Esidrix, HydroDIURIL)	Cause loss of excess water and sodium by urination	Lower blood pressure. Reduce edema in lungs and extremities
Vasodilators	Nitroglycerin Minoxidil	Relax blood vessels. Increase supply of blood and oxygen to the heart while reducing its workload	Ease chest pain
Digitalis preparations	Digoxin (Lanoxin)	Increase the force of cardiac contractions	Treatment of heart failure and arrhythmias, atrial fibrillation
Statins	Statins Resins Nicotinic acid (niacin)	Lower blood cholesterol levels	Lower LDL, raise HDL, and lower triglyceride levels
Anticoagulants	Warfarin (Coumadin)	Decrease blood clotting time	Prevent clots from forming Prevent strokes
Antiplatelet agents	Aspirin Dipyridamole	Prevent clots by preventing platelets from sticking together	Prevent clots after MI; with unstable angina, ischemic stroke, plaque
ACE inhibitors	Fosinopril (Monopril)	Expand blood vessels, lower levels of angiotensin II. Make the heart work more easily	Treat high blood pressure and heart failure

ACE, angiotensin-converting enzyme; HDL, high-density lipoprotein; LDL, low-density lipoprotein; MI, myocardial infarction. From Cardiac Medications at a Glance: American Heart Association, Inc., 2008.

chest. Wires are run from the pacemaker to specific spots on the heart. The pacemaker delivers a small electrical impulse to the heart muscle and sets the pace of the heart's electrical conduction. The impulse may be set to deliver a regular impulse or to send an impulse only if the heart rate drops below a certain number of beats per minute (demand). Modern pacemakers can monitor physiologic responses such as BP and temperature. Implantable cardioverter-defibrillators (ICDs) may also be used to treat cardiac arrhythmias. An ICD can both pace the heart muscle and deliver a high-energy impulse to reset the heart muscle if certain dangerous arrhythmias develop.

When the heart's pumping ability has become too compromised by CHF or cardiomyopathy, a heart transplant or

heart-lung transplant may be considered. After the healthy tissue of a recently deceased person is harvested, the patient's diseased organ (or organs) is removed, and the harvested tissue is transplanted into the patient's body. Transplant patients are typically maintained on special medication to decrease the risk for organ rejection. Nearly 50% of all heart transplant recipients survive for 10 years. Most recipients resume normal lifestyles, but only about 40% return to work.³⁶

Cardiac Medications

Knowledge of the purpose and side effects of cardiac medication promotes understanding of the patient's response to activity. Table 44-2 lists common cardiac medications.

Psychosocial Considerations

Persons who have experienced MI pass through a number of phases of adjustment to their disability. Fear and anxiety develop initially as patients confront their mortality. Sedatives may be prescribed to reduce stress and allow rest so that the cardiovascular system can begin to heal. Once stabilized, patients must confront the reality of their physical limitations.¹⁵

As patients begin to resume more normal activities, such as self-care and walking around the ward, feelings of helplessness may begin to subside. Patients feel more secure when familiar coping mechanisms allow them to respond to the stress, but some former coping mechanisms (e.g., smoking, drinking, consuming fatty foods) are harmful and should be discouraged and replaced by newly learned coping strategies, often those taught by the occupational therapist and other members of the intervention team. Typically, the nutritionist directs the patient toward healthy food choices, the physical therapist provides guidance toward exercise, and the nurse oversees management of medications.

Denial is common in patients with cardiac disease. Patients in denial must be closely monitored during the acute phase of recovery. Persons in denial may ignore all precautions and could stress and further damage their cardiovascular systems.

Depression is common 3 to 6 days after MI and may last many months.³ Increased morbidity and mortality, reduced modification of risk factors, and reduced quality of life have been associated with depression in cardiac patients.²⁴ Clinical evidence supports psychosocial counseling after MI that focuses on improving self health appraisal, improving social support, and establishing an effective means of coping to improve quality of life.⁴⁷ The patient's family must be included in the education so that their misconceptions and anxieties do not compound the patient's fears. In Franklin's case, his fear of dying in the facility, as his father did before him, could influence him to resist any activity.

Cardiac Rehabilitation

During the first 1 to 3 days after MI, stabilization of the patient's medical condition is usually attained. This acute phase is followed by a period of early mobilization. Phase 1 of treatment, inpatient cardiac rehabilitation, includes monitored low-level physical activity, including self-care; reinforcement of cardiac and postsurgical precautions; instruction in energy conservation and graded activity; and establishment of guidelines for appropriate activity levels at discharge. Through monitored activity, the ill effects of prolonged inactivity can be averted while medical problems, poor responses to medications, and atypical chest pain can be addressed.

Phase 2 of treatment, outpatient cardiac rehabilitation, usually begins at discharge. During this phase, exercise can be advanced while the patient is closely monitored on an outpatient basis. Community-based exercise programs

follow in phase 3. Some individuals require treatment in their place of residence because they are not strong enough to tolerate outpatient therapy.

Health care costs can be significantly reduced and positive health effects can result from comprehensive cardiac rehabilitation.²³ Additional research indicates reduced mortality in selected patients who have undergone cardiac rehabilitation after acute MI.⁴¹ Cardiac rehabilitation has also been found to benefit patients with left ventricular dysfunction by improving physical work capacity.¹⁸ Patients who acquire skills in relaxation and control of breathing after MI have been found to require fewer hospitalizations and less expensive medical management even 5 years after the MI.⁴⁸ Early and accurate identification of the signs and symptoms of cardiac distress and modification of treatment to remedy distress are imperative to the well-being of the patient. If the clinician observes any of the signs of cardiac distress (Table 44-3) during treatment, the proper response is to stop the activity, allow the patient to rest, seek emergency medical help if the symptoms do not resolve, report the symptoms to the team, and modify future activity to decrease the workload on the heart.

Box 44-1, the Borg Rate of Perceived Exertion Scale, is a tool used to measure perceived exertion. The patient is shown the scale before an activity and instructed that a rating of "6" means no exertion at all and a rating of "19" indicates extremely strenuous activity, equal to the most strenuous activity that the patient has ever performed. After the activity has been completed, the patient is asked to appraise his or her feelings of exertion as accurately as possible and give the activity a rating.

Patients' perceptions of their illness can have an impact on their ability to make the changes in lifestyle necessary for healthy living after an acute coronary event. Individualized intervention plans that address the unique physical, social, and psychologic concerns of the patient improve the integration of lifestyle changes and functional improvement.^{20,26,28}

Monitoring Response to Activity

When the patient's response to an activity is being assessed, symptoms provide one indication that the patient is or is not tolerating the activity. HR, BP, rate-pressure product (RPP), and ECG readings are other measures that may be used to evaluate the cardiovascular system's response to work.

Heart Rate

HR, or the number of beats per minute, can be monitored by feeling the patient's pulse at the radial, brachial, or carotid sites. The radial pulse is located on the volar surface of the wrist, just lateral to the head of the radius. The brachial pulse is found in the antecubital fossa, slightly medial to the midline of the forearm. The carotid pulse, located on the neck lateral to the Adam's apple, should be palpated gently; if overstimulated, it can cause the HR to drop below

TABLE 44-3 | Signs and Symptoms of Cardiac Distress

Sign/Symptom	What to Look For
Angina	Look for chest pain that may be described as squeezing, tightness, aching, burning, or choking. Pain is generally substernal and may radiate to the arms, jaw, neck, or back. More intense or longer-lasting pain forewarns of greater ischemia.
Dyspnea	Look for shortness of breath with activity or at rest. Note the activity that brought on the dyspnea and the amount of time that it takes to resolve. Dyspnea at rest with a resting respiratory rate of greater than 30 breaths per minute is a sign of acute congestive heart failure. The patient may require emergency medical help.
Orthopnea	Look for dyspnea brought on by lying supine. Count the number of pillows that the patient needs to breathe comfortably during sleep (1, 2, 3, or 4 pillows needed to relieve orthopnea).
Nausea/emesis	Look for vomiting or signs that the patient feels sick to the stomach.
Diaphoresis	Look for cold, clammy sweat.
Fatigue	Look for a generalized feeling of exhaustion. The Borg Rate of Perceived Exertion Scale is a tool used to grade fatigue (see Box 44-1). Cerebral signs—ataxia, dizziness, confusion, and fainting (syncope)—are all signs that the brain is not getting enough oxygen.
Orthostatic	Look for a drop in systolic blood pressure and hypotension of greater than 10 mm Hg with a change in position from supine to sitting or sitting to standing.

60 beats per minute (bradycardia). To determine HR, the clinician applies the second and third fingers (flat, not with the tips) to the pulse site. If the pulse is even (regular), the clinician counts the number of beats in 10 seconds and multiplies the finding by 6. The thumb should never be used to take a pulse because it has its own pulse.

All clinicians who assess HR, as well as patients, should be able to note the evenness (regularity) of the heartbeat. HR can be regular or irregular. An irregular heartbeat may be described as regularly irregular, which means that there is a consistent irregular pattern (e.g., every third beat is premature), or it may be described as irregularly irregular,

Box 44-1

Instructions for Using the Borg Rate of Perceived Exertion Scale

During the work we want you to rate your perception of exertion (i.e., how heavy and strenuous the exercise feels to you and how tired you are). The perception of exertion is felt mainly as strain and fatigue in your muscles and as breathlessness or aches in the chest. All work requires some effort, even if only minimal. This is also true if you move only a little (e.g., walking slowly).

Use this scale from 6 to 20, with 6 meaning “no exertion at all” and 20 meaning “maximal exertion.”

- 6—“No exertion at all” means that you don’t feel any exertion whatsoever (e.g., no muscle fatigue, breathlessness, or difficulty breathing).
- 9—“Very light” exertion, such as taking a shorter walk at your own pace.
- 13—A “somewhat hard” work, but it still feels OK to continue.
- 15—It is “hard” and tiring, but continuing isn’t terribly difficult.
- 17—“Very hard.” This is very strenuous work. You can still go on, but you really have to push yourself and you are very tired.
- 19—An “extremely” strenuous level. For most people this is the most strenuous work that they have ever experienced.

Try to appraise your feeling of exertion and fatigue as spontaneously and as honestly as possible without thinking about what the actual physical load is. Try to not underestimate and to not overestimate your exertion. It’s your own feeling of effort and exertion that is important, not how this compares with other people’s. Look at the scale and the expressions and then give a number. Use any number you like on the scale, not just one of those with an explanation behind it.

which means that there is no pattern to the premature or skipped beats. HR irregularities include skipped beats, delayed beats, premature beats, and beats originating from outside the normal conduction pathway in the heart. Although an irregular HR is not normal, many individuals function quite well with an irregular rate. Clinicians should note the client’s normal rate pattern, as well as any variations. A sudden change in HR from regular to irregular should be reported to the physician. An ECG or other diagnostic test may be ordered on the basis of such findings. When the HR is irregular, the number of beats should be counted for a full minute. Patients can be taught to take their own pulse and monitor the response of HR to activity. As a general rule, HR should rise in response to activity.

Blood Pressure

BP is the pressure that the blood exerts against the walls of any vessel as the heart beats. It is highest in the left ventricle during systole and decreases in the arterial system with

distance from the heart.⁴⁹ A stethoscope and BP cuff (sphygmomanometer) are used to indirectly determine BP. The BP cuff is placed snugly (but not tightly) around the upper part of the patient's arm just above the elbow, with the bladder of the cuff centered above the brachial artery. The examiner inflates the cuff while palpating the brachial artery to 20 mm Hg above the point at which the brachial pulse is last felt. With the earpieces of the stethoscope angled forward in the examiner's ears, the dome of the stethoscope is placed over the patient's brachial artery. Supporting the patient's arm in extension with the pulse point of the brachial artery and the gauge of the stethoscope at the patient's heart level, the examiner deflates the cuff at a rate of approximately 2 mm Hg per second. Listening is imperative when recording BP. The first two sounds heard correspond to systolic BP. The examiner continues to listen until the last pulse is heard and diastolic BP is attained.

Physicians usually indicate treatment parameters for the HR and BP of patients in medical facilities. Parameters are frequently written in abbreviations, such as "Call HO if SBP > 150 < 90; DBP > 90 < 60; HR > 120 < 60." (In other words, "Call the house officer or physician on call if systolic BP is greater than 150 or less than 90, if diastolic BP is greater than 90 or less than 60, and if HR is greater than 120 or less than 60.")

HR and BP will fluctuate in response to activity, and cardiac output is affected by both HR and BP. Measurement of the RPP can give a more accurate indication of how well the heart is pumping. The RPP is the product of HR and systolic BP ($RPP = HR \times SBP$). It is usually a five-digit number but is reported in three digits by dropping the last two (for example, $HR 100 \times SBP 120 = 12,000 = RPP 120$). During any activity, the RPP should rise at peak and return to baseline in recovery (after 5 to 10 minutes of rest).

Correctly reading and interpreting an ECG is a skill that requires hours of learning and practice for proficiency. Electrocardiography is not available in most nonacute settings. The reader is referred to Dubin's *Rapid Interpretation of EKGs*,¹¹ which is an excellent resource for persons unfamiliar with the subject.

There are many similarities in the evaluation and treatment of persons with cardiac disease and those with pulmonary dysfunction. A review of the pulmonary system and its disease processes follows.

Anatomy and Physiology of Respiration^{4,29,31}

While the heart provides oxygen-rich blood to the body and transports carbon dioxide and other waste products to the lungs, the respiratory system exchanges oxygen for carbon dioxide. The cardiac and pulmonary systems are interdependent. If no oxygen were delivered to the bloodstream, the heart would soon stop functioning for lack of oxygen; conversely, if the heart were to stop pumping, the lungs

Threaded Case Study Harriet, Part 1

Harriet is a 64-year-old widow and mother of an adult daughter. She retired 3 years ago from her housekeeping job because of fatigue and shortness of breath. Chronic obstructive pulmonary disease was diagnosed at that time. She has been smoking cigarettes since the age of 20 and currently smokes one pack per day. She shares a small one-bedroom apartment with her terrier Sir Filo. There is a first-floor laundry room in her building. Harriet's daughter lives three blocks away and checks on her mother daily. Harriet's baseline level of function 4 weeks ago consisted of walking the dog around the block slowly, fixing meals, doing laundry, and performing activities of daily living independently. She also enjoys playing bingo on Tuesday nights at her local church and cards with her widowers-and-widows group. Her daughter assists her in grocery shopping and cleaning.

Harriet was released from the acute care hospital 3 days ago, her condition having been stabilized after an acute exacerbation of her chronic obstructive pulmonary disease. Since her recent discharge, her daughter empties Harriet's bedside commode, shops for groceries, and fixes dinner for Harriet and Sir Filo. Results of the occupational therapy evaluation indicated that Harriet became short of breath when combing her hair. She was unable to pace her activity, to coordinate pursed-lip breathing with activity, or to assume dyspnea control postures when needed. She was receiving 2 L of oxygen by nasal cannula at all times. Harriet wants to be able to feed Sir Filo herself, stating that dogs become attached to people who feed them. She does not want her daughter to empty her commode and wants to be able to prepare dinner for herself. She does not want to be a burden to her daughter but rather to enjoy visiting with her.

Critical Thinking Questions

1. What goals may Harriet find relevant in her therapy?
2. What safety concerns might arise?
3. Do Harriet's goals appear realistic given her baseline level of function?

would cease functioning for lack of a blood supply. All body tissues depend on the cardiopulmonary system for their nutrients.

The respiratory system supplies oxygen to the blood and removes waste products, primarily carbon dioxide, from the blood. Air enters the body via the nose and mouth and travels through the nasopharynx to the larynx or voice box. From there, the air continues downward into the lungs by way of the trachea or windpipe. The trachea consists of ribbed cartilage approximately 10 cm long. When the trachea or pharynx becomes blocked, a small incision may be made in the trachea to allow air to pass freely into the lungs. This procedure is called a tracheotomy.

The trachea divides into two main bronchi that carry air into the left and right lungs. The bronchi continue to

FIGURE 44-4 Major structures of the respiratory system.

(From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 7, St. Louis, Mo, 2010, Mosby.)

branch off into smaller tubes, called bronchioles. Bronchioles are segmented into smaller passages called the alveolar ducts. Each alveolar duct is divided and leads into three or more alveolar sacs. The entire respiratory passageway from bronchi to alveolar sacs is often referred to as “the pulmonary tree” because its structure is much like that of an upside-down tree, with the alveolar sacs representing the leaves.

Each alveolar sac contains more than 10 alveoli. A very fine, semipermeable membrane separates the alveolus from the capillary network. Across this membrane, oxygen is transported and exchanged for carbon dioxide. Carbon dioxide is exhaled into the air after traveling upward through the “pulmonary tree” (Figure 44-4).

With the exception of the nose and mouth, all the airways are lined with cilia and coated with mucus. Mucus and cilia provide a filtering shield that protects the fragile airway respiratory structures from dust and germs.

The musculature of the thorax helps in inspiration and expiration. During inspiration, the muscle power for breathing air into the lungs is provided primarily by the diaphragm. Originating from the sternum, ribs, lumbar vertebrae, and lumbocostal arches, the diaphragm forms the

inferior border of the thorax. The muscle fibers of the diaphragm insert into a central tendon. Innervated by the left and right phrenic nerves, the diaphragm contracts and domes downward when stimulated. This downward doming of the diaphragm enlarges the volume of the thorax and causes a drop in pressure in the lungs relative to the air in the environment. Air then enters the lungs to equalize inside and outside pressure. Accessory muscles, the intercostals and scalenes, are also active during inspiration. The intercostals maintain alignment of the ribs, and the scalene helps elevate the rib cage.

At rest, expiration is primarily a passive relaxation of the inspiratory musculature. The lungs help draw the thorax inward as the inspiratory muscles relax. Forced expiration requires active contraction of the abdominal muscles to compress the viscera and squeeze the diaphragm upward in the thorax. Expiration can be further forced by flexing the torso forward and pressing with the arms on the chest or abdomen. As the volume of the thorax decreases, air is forced out of the lungs.

Accessory muscles in the neck and collarbone region can be recruited to assist in respiration when lung disease is active or other respiratory musculature is impaired.

Innervation of the Respiratory System

Breathing is mostly involuntary. A person does not have to think to take a breath. The autonomic nervous system has control over breathing. With anxiety and increased activity, the sympathetic nervous system will automatically increase the depth and rate of inspiration.

Inspiration and expiration have a volitional component. Volitional control allows us to control our breathing as we swim and to play the harmonica. Additionally, receptors within and outside the lungs can, when stimulated, cause changes in the depth and rate of breathing. Although the pons, medulla, and other parts of the brain provide the central control for breathing, they adjust their response to input from receptors in the lungs, the aorta, and the carotid artery.

Chronic Lung Disease^{2,4,38}

Common chronic disorders of the lungs for which pulmonary rehabilitation is typically prescribed include chronic obstructive pulmonary disease (COPD) and asthma.⁴ COPD is characterized by “damage to the alveolar wall and inflammation of the conducting airways”² and includes emphysema, peripheral airway disease, and chronic bronchitis. COPD has been diagnosed in more than 15 million Americans, including Harriet.

Emphysema is a condition in which the alveoli become enlarged or ruptured, usually because of a restriction during expiration or a decrease in elasticity of the lungs.⁴⁹ Chronic emphysema is most prevalent in men between the ages of 45 and 65 who have a history of chronic bronchitis, smoking, working in areas with high levels of air pollution, or exposure to cold, damp environments. Persons with chronic bronchitis experience shortness of breath (dyspnea) on exertion, and as the disease progresses, dyspnea occurs at rest.

Inflammation, fibrosis (thickening of the connective tissue), and narrowing of the terminal airways of the lungs are the physiologic changes that occur with peripheral airway disease. Smoking and other environmental pollutants irritate the airways, which leads to the development of abnormal terminal airways. Coughing and spitting up mucus from the lungs are common clinical manifestations of this disorder. The disease process may never progress beyond this initial phase, or it may evolve into emphysema and full-fledged COPD.

Chronic bronchitis is diagnosed after a 2-year period of repeated episodes, lasting longer than 3 months, of mucus-producing cough of unknown origin. A direct relationship exists between the development of chronic bronchitis and a history of cigarette smoking. Clinical manifestations of the disease increase as the pack-year history increases. Pack-year history is calculated by multiplying the number of packs of cigarettes consumed per day by the number of years of smoking. Harriet began smoking at the age of 20. She is

64 years old now. Therefore, her pack-year history is $64 - 20 = 44 \times 1 \text{ pack/yr} = 44 \text{ pack-years}$. As with other forms of COPD, the onset of physical disability is typically gradual, with dyspnea on exertion representing the initial phases of disability and devolving to shortness of breath at rest.

Asthma is characterized by irritability of the bronchotracheal tree and is typically episodic in onset. Persons suffering from asthma experience wheezing and shortness of breath that may resolve spontaneously or necessitate the use of medication for calming the airway. Persons with asthma may be free of symptoms for periods between the episodes of wheezing and dyspnea. Some individuals appear to have a genetic predisposition to asthma. Allergenic causes of asthma may include pollen and respiratory irritants such as perfume, dust, and cleaning agents. Bronchospasm occurring with exposure to cold air or induced by exercise is sometimes the first clinical manifestations of asthma. Irritation of the airway leads to narrowing of the air passages and interferes with ventilation of the alveolar sacs. If obstruction of the airway is significant enough, a reduction in oxygen levels in the bloodstream will result in hypoxemia.¹³ If left untreated, a severe asthmatic episode may result in death.

Pulmonary Risk Factors

Cigarette smoking is the primary cause of COPD, and smoking cessation will slow the progression of disability in persons with COPD.³⁹ Because cigarette smoke is a pulmonary irritant, it may also be a causative agent in asthmatic episodes. Other environmental irritants, such as air pollution, chemical exposure, and dust, are contributory risk factors in the development of COPD and asthma.

Medical Management

COPD is a progressive, chronic disease. The onset of the disease is insidious. When patients initially seek medical attention, they are frequently seen in a physician's clinic rather than at a medical center. Besides evaluating the patient's medical history and symptoms and performing a physical examination, the physician will assess the patient's history of smoking and occupational exposure to respiratory irritants. Blood work and an x-ray examination will be performed to further assess the patient's clinical status. Medications prescribed for persons with pulmonary disease include anti-inflammatory agents (e.g., steroids and cromolyn sodium), bronchodilators (e.g., albuterol and theophylline) to help open the airway, and expectorants (e.g., iodides and guaifenesin) to help loosen and clear mucus. Flu shots and pneumococcal vaccines are recommended. Oxygen therapy may also be prescribed at a specific flow rate. Occasionally, persons receiving oxygen therapy may be tempted to increase the liter-per-minute flow in the erroneous thinking that more is better. This can result in retention of carbon dioxide and lead to failure of the right side of the heart.

Persons in acute respiratory distress may initially be managed with a ventilator before being weaned to oxygen. Ventilators provide mechanical assistance to the process of inspiration and do not increase the number of healthy alveolar sacs. Ventilators will not slow the end-stage disease process of COPD. Mechanical ventilation is frequently prescribed for persons with an acute exacerbation of the disease process caused by pneumonia, influenza, or CHF.

When a patient's endurance decreases sufficiently to impair performance of ADLs, the physician may refer the patient to OT. Regrettably, the client is not likely to be seen by an occupational therapist or receive an assessment of occupational lifestyle as the first line of defense.

OT Practice Notes

Frequently, the occupational therapist's role in treating clients with COPD involves salvage rather than prevention of the disease process. Earlier intervention by an occupational therapist is critical for prevention of disease.

Signs and Symptoms of Respiratory Distress

Dyspnea is probably the most obvious sign of a breathing difficulty. In the most severe form of dyspnea, the patient is short of breath even at rest. Clients with this level of dyspnea are unable to utter a short phrase without gasping for air. When reporting that a client has dyspnea, the practitioner should note the precipitating factors and associated circumstances; for example, "Harriet becomes short of breath when washing her face while seated in front of the sink."

Other signs that the body is not getting enough oxygen include extreme fatigue, a nonproductive cough, confusion, impaired judgment, and cyanosis (bluish skin color caused by insufficient oxygen in the blood).

Psychosocial Considerations

Because COPD is a progressive, debilitating physical illness, it is not surprising that the psychosocial effects of the disease are considerable. Chan identified five themes related to barriers preventing engagement in occupation for people with COPD: uncertainty about progression of the disease, attributing the cause of the disease to external factors, progressing restriction in activity and isolation, anxiety and depression, and passive acceptance.⁶ Persons with anxiety and depression are more inclined to experience relapses after initial emergency department visits,⁸ and 96% of patients with COPD have reported disabling anxiety.¹ Other patients with COPD complain of faintness or difficulty concentrating.¹² Training in progressive muscle relaxation can be a successful tool for controlling the dyspnea and anxiety and for lowering the HR.⁴⁴

Most cardiac and respiratory disease processes are preventable. Individuals with these diseases may lack basic skills in coping and setting limits with themselves or with others. The therapist's role includes encouraging the patient to engage in activities that will develop his or her skills and promoting resumption of occupations that bring value, meaning, and participation back into the patient's life. With these skills, the patient begins to see himself or herself as a person actively making choices to get better. By working with Harriet on ways to engage with her dog when she does not have the endurance to take a walk, the occupational therapist not only teaches energy conservation but also conveys this information in a meaningful manner to the patient.

Most persons with end-stage COPD realize that they will die as a result of their disease. Fear of death from suffocation is misplaced. Persons with such concerns should be referred to their physician, who can reassure them that individuals with CO₂ retention die peacefully in their sleep.¹⁹

Pulmonary Rehabilitation

The goal of pulmonary rehabilitation is to stabilize or reverse the disease process and return the patient's function and participation in activity/occupation to the highest capacity. A multidisciplinary rehabilitation team working with the patient can design an individualized intervention program to meet this end. Accurate diagnosis, medical management, therapy, education, and emotional support are components of a pulmonary rehabilitation program. OT personnel are frequently part of the patient's team, which is headed by the patient and also includes the physician, nurse, and the patient's family and social supports. Respiratory therapists, dietitians, physical therapists, social workers, and psychologists may also be team members. Roles of team members vary slightly among facilities. Knowledge of specialized pulmonary treatment techniques is imperative for each team member when treating persons with pulmonary disease.

Intervention Techniques

Dyspnea Control Postures

Adopting certain postures can reduce breathlessness. In a seated position, the patient bends forward slightly at the waist while supporting the upper part of the body by leaning the forearms on a table or the thighs. In a standing position, relief may be obtained by leaning forward and propping oneself on a counter or shopping cart.

Pursed-Lip Breathing

Pursed-lip breathing (PLB) is thought to prevent tightness in the airway by providing resistance to expiration. This technique has been shown to increase use of the diaphragm and decrease accessory muscle recruitment.⁵ Persons with COPD sometimes instinctively adopt this technique, whereas others may need to be taught it. Instructions for PLB are as follows:

1. Purse the lips as if to whistle.
2. Slowly exhale through pursed lips. Some resistance should be felt.
3. Inhale deeply through the nose.
4. It should take twice as long to exhale as it does to inhale.

Diaphragmatic Breathing

Another breathing pattern, which calls for increased use of the diaphragm to improve chest volume, is diaphragmatic breathing. Many persons learn this technique by placing a small paperback novel on the abdomen just below the xiphoid process (base of the sternum or breastbone). The novel provides a visual cue for diaphragmatic movement. The patient lies supine and is instructed to inhale slowly and make the book rise. Exhalation through pursed lips should cause the book to fall.

Relaxation

Progressive muscle relaxation in conjunction with breathing exercises can be effective in decreasing anxiety and controlling shortness of breath. One technique involves tensing muscle groups while slowly inhaling and then relaxing the muscle groups while exhaling twice as slowly through pursed lips. It is helpful to teach the patient a sequence of muscle groups to tense and relax. One common sequence involves tensing and relaxing first the face; followed by the face and the neck; then the face, neck, and shoulders; and so on, down the body to the toes. A calm, quiet, and comfortable environment is important for the novice in learning any relaxation technique. Biofeedback in conjunction with relaxation therapy promotes more timely mastery of relaxation skills.¹⁷

Other Treatments and Considerations

Physical therapists are generally called on to instruct patients in chest expansion exercises, a series of exercises intended to increase the flexibility of the chest. Percussion and postural drainage use gravity and gentle drumming on the patient's back to loosen secretions and help drain the secretions from the lungs. By isometrically contracting the arms and hands while they are placed on the patient's thorax, the therapist may transmit vibration to the patient. Vibration is performed during the expiratory phase of breathing and helps loosen secretions. Percussion and postural drainage may, however, be contraindicated in acutely ill patients and those who are medically unstable.

Humidity, pollution, extremes of temperature, and stagnant air have deleterious effects on persons with respiratory ailments. The therapist and patient should take these factors into consideration when planning activity.

Migliore's guidelines for the management of dyspnea provide a clinical progression and direction for the integration of dyspnea control techniques with progression of activity.²⁷

Individuals with chronic respiratory or cardiovascular limitations are frequently restricted in their ability to perform ADLs. OT intervention can promote improvements in the client's life management skills and quality of life.

Evaluation

Review of the Medical Record

A review of the medical record will identify the patient's medical history (diagnosis, severity, associated conditions, and secondary diagnoses), social history, test results, medications, and precautions.

Patient Interview

It is common courtesy and good medical practice to begin every encounter with a patient by introducing oneself and explaining the purpose of the evaluation or intervention. Good interviewing skills, including asking the right questions, listening to the patient's response, and observing the patient while responding, are considered integral aspects of the therapeutic use of self. Thoughtful, probing questions will help the patient and therapist identify areas of concern and lay the groundwork for establishing mutually agreeable goals. The therapist should observe the patient for signs of anxiety, shortness of breath, confusion, difficulty comprehending, fatigue, abnormal posture, reduced endurance, reduced ability to move, and stressful family dynamics. Interview questions should not only seek clarification of information that was unclear in the medical record but also clarify the patient's understanding of his or her condition and treatment.

A patient with a history of angina should be asked to describe what the angina feels like. If the patient has also had an MI, the patient should be asked whether he or she can differentiate between the angina and the MI chest pain. Clarification of symptoms before treatment can prove invaluable should symptoms arise.

Asking patients to describe a typical day, to identify activities that bring on shortness of breath or angina, and to tell how their physical limitations interfere with the activities or occupations that they need to do or most enjoy doing will reveal problems that are meaningful and relevant to the patient.

Clinical Evaluation

The purpose of clinical assessment is to establish the patient's present functional ability and limitations. The content of an occupational therapist's clinical evaluation will vary from patient to patient and from setting to setting. Clients with impairments in the cardiovascular system will require monitoring of HR, BP, signs and symptoms of cardiac distress, and possibly ECG readings during an assessment of tolerance to postural changes and during a functional task. [Table 44-4](#) provides a summary of appropriate versus

TABLE 44-4 | Cardiovascular Response to Activity

	Appropriate	Inappropriate
Heart rate (HR)	Increases with activity to no more than 20 beats/min above the resting heart rate	HR more than 20 beats/min above the resting heart rate (RHR) with activity, RHR ≥ 120 , HR drops or does not rise with activity
Blood pressure (BP)	Systolic blood pressure (SBP) rises with activity	SBP ≥ 220 mm Hg postural hypotension (≥ 10 -20-mm Hg drop in SBP, decrease in SBP with activity)
Signs and symptoms	Absence of adverse symptoms	Excessive shortness of breath, angina, nausea and vomiting, excessive sweating, extreme fatigue (RPE ≥ 15), cerebral symptoms

RPE, rate of perceived exertion.

inappropriate responses to activity. Individuals with disorders involving the respiratory system should be monitored closely for signs and symptoms of respiratory distress. If an oxygen saturation monitor is available, the patient's range of motion, strength, and sensation may be grossly assessed within the context of the ADL assessment. The patient's cognitive and psychosocial status will become apparent to a skilled clinician via interview and observation.

After completing the evaluation, the clinician has sufficient information to formulate an intervention plan. In establishing the intervention goals and objectives, the clinician verifies that the patient agrees with the intervention plans and projected outcome.

Intervention

Client goals, present clinical status, recent occupational performance history, response to current activities and occupations, and prognosis all help guide the progression of intervention for persons with cardiovascular or respiratory impairment. Clients with significant cardiac or pulmonary impairment, limited recent ability to participate in occupation, inappropriate responses to activities and occupations or orthostatic change, and a poor prognosis will progress very slowly. Individuals with little impairment of the heart or lungs, a recent history of normal occupational performance, appropriate responses to orthostatic change and activities and occupations, and a good prognosis will progress rapidly by comparison.

Progression and Energy Costs

The energy costs of an activity or occupation and the factors that influence energy costs can further guide the clinician in the safe progression of activity or participation in occupation. Oxygen consumption suggests how hard the heart and lungs are working and is indicative of the amount of energy needed to complete a task. Resting quietly in bed requires the lowest amount of oxygen per kilogram of body weight, roughly 3.5 mL O₂/kg body weight. This can also be

expressed as 1 basal metabolic equivalent (MET). As activity increases, more oxygen is needed to meet the demands of the task. For instance, dressing requires 2.5 METs, or roughly twice the amount of energy that lying in bed requires (Table 44-5). Franklin had a 2.5 MET for seated bathing and dressing. Guided by a MET table, the patient's response to activity or occupation, the prognosis, and the patient's goals, the occupational therapist will be able to determine a logical intervention progression. As a general rule, once a patient tolerates an activity (e.g., seated sponge bathing) with appropriate responses, the patient may progress to the next higher MET-level activity (e.g., standing sponge bath).

The duration of sustained physical activity must be taken into account when activity guidelines are being determined. Obviously, persons who have difficulty performing a 2-MET activity must still use a commode (3.6 METs) or bedpan (4.7 METs) for their bowel management. This is possible because a person can perform at a higher than usual MET level for brief periods without adverse effects.

At 5 METs, sexual activity is frequently a grave concern to persons with impaired cardiovascular function and to their partners. Sexual intercourse is intermittent in its peak demands for energy. Patients are frequently able to return to sexual intercourse once they can climb up and down two flights of steps in 1 minute with appropriate cardiovascular responses.⁴⁶ Providing the patient with information about when it is safe to resume sexual activity can reduce anxiety surrounding the resumption of sexual intercourse. Anxiety may be further decreased through discussion of sexual activity guidelines with the patient and partner and identification of various forms of romantic intimacy, such as hand holding and kissing, when intercourse is not feasible. Besides instructing the patient to monitor HR and symptoms of cardiac distress before and after intercourse, the therapist should inform the patient and partner that cardiac medications might affect the patient's libido. The patient should be encouraged to inform the physician of problems related to sexual activity. In many cases the

■ **TABLE 44-5** | Basal Metabolic Equivalent Table of Self-Care and Homemaking Tasks

MET Level	Activities of Daily Living	Instrumental Activities of Daily Living, Work, Play, and Leisure
1-2	Eating, seated ²⁵ ; transfers, bed to chair; washing face and hands; brushing hair ²⁵ ; walking 1 mph	Hand sewing ⁷ ; machine sewing; sweeping floors ⁶ ; driving automatic car, drawing, knitting ⁴⁵
2-3	Seated sponge bath, ⁴⁵ standing sponge bath, ⁴⁵ dressing and undressing, ²² seated warm shower, ⁴⁵ walking 2-3 mph, wheelchair propulsion 1.2 mph	Dusting, ²⁵ kneading dough, ⁷ hand-washing small items, ⁷ using electric vacuum, ²⁵ preparing a meal, ²² washing dishes, ⁴⁵ golfing ⁴⁵
3-4	Standing shower, warm ²² ; bowel movement on toilet ⁷ ; climbing stairs at 24 ft/min ⁴⁵	Making a bed ²² ; sweeping, mopping, gardening ⁴⁵
4-5	Hot shower, ²² bowel movement on bedpan, ²² sexual intercourse ⁴⁵	Changing bed linen ²⁵ ; gardening, raking, weeding; rollerskating ¹⁶ ; swimming 20 yards/min ⁴⁵

physician can adjust the patient's medications to control symptoms (see [Chapter 12](#) for additional appropriate clinical interventions).

Energy Conservation

When patients are taught methods to conserve their energy resources, they will be able to perform at a higher functional level without expending more energy. The principles of energy conservation and work simplification are based on knowledge of the ways in which specific factors cause various cardiovascular responses. Ogden identified six variables that increase oxygen demand: increased rate, increased resistance, increased use of large muscles, increased involvement of the trunk musculature, raising one's arms, and isometric work (straining).⁴⁰ Upper extremity activity has also been shown to require greater cardiovascular output than lower extremity activity, and standing activity requires more energy than seated activity. Extremes of temperature, high humidity, and pollution make the heart work harder. By applying this information, a skilled clinician can suggest modifications in activity that will decrease the amount of energy needed for the task.

Energy conservation training should be individualized for each patient. Time management is an invaluable tool for energy conservation. Time management involves learning to plan one's activity or participation in occupation so that tasks requiring high energy expenditure are interspersed with lighter tasks and rest breaks are scheduled throughout the day, especially after meals. The most important part of educating the client is incorporating his or her active involvement in planning the day. Client involvement increases the likelihood of realistic goal attainment. Rather than prescribing how Harriet might sequence her ADLs,

IADLs, and rest breaks throughout her typical day, the therapist might engage her in a conversation about what works or does not work well for her in her current performance patterns. The therapist would then ask probing questions, such as "Have you tried taking your shower at a different time of day?" and "Would laying your clothes out the night before help your morning go more smoothly?" Such a client-centered approach engages the patient in the process of designing realistic performance patterns that incorporate principles of energy conservation according to his or her own circumstances and values. Through such collaboration, the therapist demonstrates respect for the patient's needs and increases the likelihood that changes will be implemented successfully.

Written material may augment energy conservation instruction. However, until the patient has successfully applied energy conservation principles to activity, the therapist should expect little follow-through with energy conservation recommendations. Practice and practical application of skills are critical to changing behavior.

The specific pulmonary rehabilitation intervention techniques of PLB, diaphragmatic breathing, dyspnea control postures, and relaxation techniques were discussed earlier in this chapter. Exhaling with exertion is another breathing principle for persons with compromised cardiac or pulmonary function. Franklin might be taught to exhale when having a bowel movement rather than holding his breath and straining. Harriet might be taught to exhale when lifting or lowering her pet's water bowl. This technique is more energy efficient and helps control systolic BP responses to activity. It is important for the patient to practice these skills during treatment. Therapeutic support is often critical in learning.

Lifestyle Modification

Modification of lifestyle is a key component in improving cardiovascular health. Exercise education should include the benefits of exercise; a graded program of increased activity and participation in occupation; stretching, strengthening, and aerobic activity; guidelines for monitoring HR, BP, and rate of perceived exertion; cool down; safety issues related to clothing, environmental factors, and warning signs; a plan for resuming exercise if it is skipped for a period; and emergency guidelines. Although the physical therapist typically designs and oversees the exercise program, the occupational therapist can provide valuable insight into forms of exercise that might be meaningful to the patient. Modification of diet may be addressed by the dietitian but can readily be reinforced during meal preparation activities. To stop smoking, refrain from excessive alcohol consumption, and stop abusing drugs are challenging goals for clients who have developed these habits. Support groups, counseling, and medical management play key roles in successful cessation or modification of these risk factors. Occupational therapists believe that enabling the client's participation in rounds of personally meaningful and healthy occupations can also play a key role in supporting health and controlling such risk factors.

Patient and Family Education

As members of the health care team, occupational therapists share the responsibility for patient and family education. The team must instruct the patient and family members in cardiac or pulmonary anatomy, the disease process, management of symptoms, risk factors, diet, exercise, and energy conservation and must reinforce the teaching. Inclusion of family members in an education program provides support indirectly to the client through the family unit. Such support is critical when the client depends on the assistance of a family member to accomplish everyday tasks.

Summary

Healthy persons are able to meet the varying demands of their bodies for oxygen because their heart and respiratory rates adjust to meet oxygen demand. When either the cardiovascular or the pulmonary system (or both) is compromised, the ability to perform normal activities or occupations declines. This chapter is intended to guide the occupational therapist in the treatment of clients with impairment of the heart or lungs and in designing programs to maximize clients' independent performance in areas of occupation to support participation in context. The two case studies presented in this chapter and related information portray the range of problems involving client factors, contextual issues, performance skills, and performance patterns that typically interfere with the client's ability to perform customary activities and occupations.

Threaded Case Study Franklin, Part 2

Reflecting on the case of Franklin, who had just experienced his first MI at the age of 48, the reader should consider the importance of really listening to the patient and following up with probative questions to develop more client-centered and thus more relevant goals. The first question the reader was asked to consider while reading the chapter was "What probative questions might the occupational therapist ask to clarify what Franklin means by being 'able to do everything for himself' "? Franklin provided some clues in his occupational profile that readily yield themselves to further exploration. Besides independence in ADLs, identification of potential concerns in his role as father, husband, and provider might be addressed more thoroughly by (1) asking whether he assists his children with homework and sporting activities and participates in other child care responsibilities, (2) asking whether he and his wife would like to discuss safe resumption of sexual activities, and (3) clarifying the job-specific tasks that are most relevant for him to return to work.

With regard to the second question, there are numerous skills and strategies Franklin might benefit from learning and applying to his participation in daily life and meaningful occupations so that he can reduce his risk for another cardiac episode. These include the following: (1) recognizing the signs and symptoms of cardiac distress; (2) monitoring his HR; (3) grading his ADLs and modifying participation in other meaningful occupations according to his comfort level; (4) using relaxation techniques when stressed or anxious; (5) implementing emergency measures; and (6) modifying or redesigning his lifestyle, including stopping smoking and instituting exercise and healthy eating routines.

Finally, the reader was asked to consider what areas of occupation might the therapist choose for the next intervention session and, depending on Franklin's occupational profile, what goals might be included in his OT intervention plan. Repeating the seated sponge bathing task or combining energy conservation techniques with seated showering would be a good choice of activities for the next therapy session. Franklin's initial response to seated sponge bathing was inappropriate. By incorporating practice in safely pacing the activity and self-monitoring his HR, his therapist will begin practical application of the skills essential to safe management of his cardiac condition. OT intervention will most likely end before Franklin returns to work. It is critical for him to understand how he might apply energy conservation principles to his work in the auto shop. The occupational therapist intervenes by using education to engage Franklin in a conversation about ways that he might adapt these principles to his work. Thus, the therapist sets the groundwork for carryover of principles into that setting. Franklin is asked questions such as "Where might you place your tools to decrease the number of trips across the room?" and "How might you apply the principle of exhale on exertion when changing an oil filter?"

Threaded Case Study Harriet, Part 2

When considering the case of Harriet, the reader was asked what goals she might find relevant in her therapy. Harriet identified several meaningful goals during the initial occupational therapy evaluation, including feeding her dog Sir Filo, preparing her own dinner, and being able to empty her bedside commode herself. Another question involved the safety concerns that might arise in treating Harriet. Additional goals relevant to her safety include learning to pace her activity, coordinating her breathing with function, increasing her ability to assume dyspnea control postures when needed, and increasing her safety with oxygen. The oxygen line not only poses a potential trip hazard but also presents a fire hazard given her meal preparation goals and smoking habit. Smoking cessation is a goal that can be explored but will be meaningful only if Harriet wants to quit. Finally, the reader was asked to determine what goals appear realistic given Harriet's baseline level of function. Given her baseline level of function, all the goals she identified appear to be realistic.

Review Questions

- Describe the heart, including its size, anatomy, and functional parts.
- Name the heart valves, and give their locations and functions.
- Discuss the relationship between the coronary arteries and health of the heart.
- List and describe the symptoms of cardiac distress.
- What are the typical psychosocial responses to a diagnosis of heart disease?
- How is cardiac response to activity monitored? How does the therapist know that a change in level of activity is warranted?
- Describe the functional parts of the pulmonary system.
- What is COPD, and what is its significance for occupational performance?
- What can the OT practitioner do to help prevent or reduce the incidence of COPD?
- Demonstrate the recommended dyspnea control postures.
- Compare pursed-lip breathing with diaphragmatic breathing. When should one be used rather than the other?
- Describe the appropriate evaluation content and approach for patients with cardiac and pulmonary problems.
- What is a MET, and what is the clinical value of a MET table for occupational therapists?
- How would you teach energy conservation techniques to the following individuals, all of whom have cardiac or pulmonary disease?
 - A 40-year-old female marathon runner
 - A 50-year-old homemaker and adoptive mother of eight (including three children younger than 6 years)
 - A 60-year-old air conditioner repairman
 - A 72-year-old man who says his main pleasures are riding thoroughbreds, drinking good Kentucky bourbon, smoking cigars, and enjoying the company of lovely women

■ Chapter Outline

Prevention
Early postdiagnosis phase
Postoperative phase
Chemotherapy
Radiation therapy
Rehabilitative phase
Palliative care
Psychologic and emotional aspects of living with cancer
Long-term and special chronic disease issues
Disease progression
Summary
Review questions

■ Key Terms

Cancer	Oncology
Metastases	Edema
Surgery	Hospice
Chemotherapy	Palliative
Radiation	Lymphedema

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe cancer and its diagnosis and medical and surgical treatments.
2. Identify common psychologic conditions associated with life-threatening illness and loss.
3. Identify strategies for helping patients cope with the side effects of the treatments of cancer.
4. Identify common physical dysfunction issues resulting primarily from the cancer and secondarily from the treatment.
5. Identify techniques used in addressing a variety of occupational therapy goals for cancer patients according to practice setting.
6. Identify problems that may arise as a result of the disease process or the sequelae of disease that could affect a person's occupational roles, activities of importance to those roles, and task performance; identify possible solutions to the problems.

 **Threaded Case Study | Mary, Part 1**

Mary is a 35-year-old married woman and mother of three small children in whom Hodgkin's lymphoma has recently been diagnosed. Her doctor noticed a lump on palpation of her neck during a routine physical examination. Mary has undergone chemotherapy and is receiving radiation treatment to the mantle region of the right side of her chest. After the second of 4 planned weeks of radiation therapy, Mary has been experiencing edema and a glovelike distribution of numbness in her right hand (irradiated side). Lymphedema and radiation-induced brachial plexopathy were diagnosed. Mary is a teacher and uses her right hand to write on the board. In her role as a wife and mother, she does all of the shopping, cooking, and cleaning for her family. Mary is also a "soccer mom" and prides herself on the fact that she has not missed one of her children's soccer games in 3 years.

On administration of the Canadian Occupational Performance Measure, Mary voiced concern about being able to drive, interact with families (because she can no longer

shake hands), and write on the blackboard. Mary is also concerned about being able to do her basic and instrumental (higher-level) activities of daily living. She states that she expects that her husband will assist with grocery shopping, but she wants to be able to do the laundry, lay out soccer uniforms and clothing for her children, drive, cook, and perform light housekeeping.

The Assessment of Motor and Process Skills suggested that Mary needs some assistance in problem-solving and implementing strategies to compensate for the functional loss in her arm and hand. She is at risk for injuring her arm and hand because of the sensory loss. She could also benefit from training in energy conservation and work simplification. Because Mary is driving primarily with one hand, she could benefit from adaptations to her car that would increase her safety while driving. The table below provides an analysis of Mary's situation.

Occupation	Impairment	Activity Barrier	Participation Barrier
Housewife Wife Mother	Loss of bimanual function	Inability to use the arm in tasks requiring the use of both hands: hand-washing clothes Shopping and carrying bags home on public transportation	Lack of access to technology that could assist her in doing tasks efficiently by herself; lack of funding to purchase a vehicle (social/environmental factors) for community mobility and instrumental activities of daily living (e.g., shopping, yard work, infant/child care, and cooking adaptations)
Work: teacher	Mobility and sensory impairment	Cannot sustain the closed chain activity needed for holding chalk in her hand and writing concepts, diagrams, etc., on the blackboard	Need for access to technology to allow her to project images instead of writing on a blackboard Workstation modification needed: sit to lecture versus standing Need for assistance to determine how to advocate for her needs within the workplace (social justice issue)
Soccer enthusiast	Fatigue Mobility and sensory impairment	Cannot sit in the bleachers for an entire soccer game Lacks enough access and postural support to comfortably remain at the game	Need for assistance from others to set up a supportive, comfortable chair on the ground adjacent to the bleachers Need for a lightweight megaphone so that her child can hear her cheers

At the end of treatment Mary returned to work. She uses a high stool to teach the class so that she conserves her energy for activities that she will need to do later in the day with her family. Mary has further adapted her workstation (i.e., classroom) by asking her employer to obtain a specialized overhead projector. She now writes on overheads instead of the blackboard. The students like Mary's class—she always uses colors to write and teaches with fun overheads and comics. Mary has explained to her students that she had an injury that prevents her from using her arm and hand but is trying to do all that she did before by using the new

adaptations. Mary has received lots of support from the students and the community.

At home, Mary's husband Tom has been doing the shopping and vacuuming. Mary is able to prepare meals, load the dishwasher, and lift her children into her lap from a seated position. She dresses herself independently and needs only occasional help to put on a necklace or bracelet when she goes out. Mary has learned to take rest breaks and "power naps." She has joined a SHARE support group and reports that she is so grateful for having found new friends and inspiration from the group.

Mary's doctor informed her that her cancer is now in remission. She will need to see the doctor every 3 months for the next year. She will need to be watched closely for recurrence for the next 5 years, but the doctor is very positive about her response to treatment.

Mary's lymphedema has been contained at a minimal level. She performs self-massage and wears a gradient compression bandage daily. Although she has permanent nerve damage that prevents the return of functional use of her hand, Mary states that people are very supportive and comment less and less on her condition. She says that her lymphedema has become "the least of my problems." Mary recognizes the signs of infection and monitors measurements of her arm weekly, thereby increasing her self-awareness of any changes in the condition. She seems pleased that the edema has become a background issue in her daily life.

Mary states that she continues to be a "soccer mom." Her second child is now playing in a junior league. She says that her participation in occupational therapy has given her a new lease on life, and she is grateful to feel in charge of the things that give her life meaning. Although she is sad about the function she has lost, she looks forward to seeing her children

grow and spending years to come with her best friend, her husband.

Critical Thinking Questions

1. What difficulties in occupational performance would you anticipate from the sensory disturbance in her right hand?
2. What occupational roles may have to be modified, and what changes would you recommend?
3. What additional assessments may be helpful when developing an intervention plan for Mary?
4. How would you decide which approach to use with Mary, and when would you reassess or potentially alter this approach depending on the disease process? What types of information or clues from her health and medical disease management would require you to reframe your intervention and approach to care?
5. Can you give some examples of how occupational therapy may be helpful to Mary throughout her disease and recovery process? How will Mary potentially benefit across her life span from periodic reassessment and intervention from an occupational therapist?

Cancer is a broad grouping of diseases, all of which are linked by the presence of malignant tumor cells growing in the body.² This abnormal cellular growth can be due to external factors, such as tobacco smoking, or due to internal factors, such as inherited mutations. Cancers are described by the type of tissue in which they arise: carcinoma (within an organ or epithelial tissue), sarcoma (connective tissue), chondroma (cartilage), lymphoma (lymphatic tissue), or leukemia (blood-forming tissue). Malignancies can be graded according to their rate of growth with terms such as *low grade* for slowly developing malignancies and *high grade* for rapidly developing malignancies and can adapt within and spread throughout the body (*metastasizing*). An additional grading system used to convey the spread of malignancy is the TNM system. The "T" refers to the extent or size of the primary tumor, the "N" identifies whether the cancer cells are detected in regional lymph nodes, and the "M" reports the presence or absence of metastases. Metastases are pieces of tumor that have traveled in the circulatory system and reseeded themselves in new organs or tissues in the body. When biopsy of a metastatic lesion is performed (the lesion is sampled to observe its histology or tissue type), the cells of the lesion appear similar to the cells in the tumor of origin. For example, breast cancer that metastasizes to the lung is breast cancer, not lung cancer, at the cellular level. Tumors occupy space within an organ system and interrupt the function of that organ. For example, liver tumors or lesions can cause the affected person to have abnormal liver function, as observed on a blood test or through a clinical sign such as jaundice.

Tumor cells sometimes secrete hormonelike substances. These pseudohormones disrupt the function of organs. The

clinical picture may appear as something unrelated to cancer; there is often no tumor mass, just freely circulating tumor cells resulting in a paraneoplastic syndrome. For example, lung cancer can cause a paraneoplastic syndrome that looks like quadriplegia. Paraneoplastic syndrome is often considered in the differential diagnosis when polyneuropathy or dermatomyositis is seen. The presence of acute-onset quadriplegia without evident physical trauma suggests that lung cancer may be an underlying cause. Blood tests will detect tumor markers, and the cancer can be diagnosed. Once the cancer diagnosis is known, chemotherapy or procedures that can filter the neoplastic cells from the blood (e.g., photopheresis) can rapidly change and possibly improve the functional clinical picture. Cancers are "staged," or classified, in an effort to predict prognosis and identify appropriate intervention (Table 45-1).

The most common cancers in the United States continue to be lung cancer in both men and women.² After lung cancer, the most common cancer in women is breast cancer and in men is prostate cancer. Although cancer can develop in anyone, the risk for development of cancer is greater as the individual ages, and "78% of all cancers are diagnosed in persons 55 years and older" (p. 1).

Prevention

Occupational therapists can serve an important role in cancer prevention. For example, influencing a person's choice of and ability to change habits and behavior that negatively influence health is one preventive approach. Occupational therapists can give positive health messages to all the people with whom they are in contact and thereby

■ **TABLE 45-1 | Cancer Staging: TNM Definition**

Stage	Primary Tumor (T)	Nodal Involvement (N)	Distant Metastasis (M)
I	Tumor 5 cm or less in size; no invasion of adjacent tissues	No positive regional nodes	No (known) distant metastasis
II	Tumor greater than 5 cm in size; no invasion of adjacent tissues	No positive regional nodes	No (known) distant metastasis
III	Tumor outside the organ in fat and surrounding soft tissues	No positive regional nodes	No (known) distant metastasis
	Tumor size greater or lesser than 5 cm; no invasion of adjacent tissue	Positive regional nodes	No (known) distant metastasis
IV	Tumor outside the organ in fat and surrounding soft tissues or tumor invading adjacent organs	Positive regional nodes	No (known) distant metastasis
	Tumor 5 cm or less in size; no invasion of adjacent tissues; tumor outside the organ in fat and surrounding soft tissues or tumor invading adjacent organs	Regional nodes may be positive or negative	Distant metastasis present

Data from Norton JA, Le HN: Adrenal tumors. In DeVita VT Jr, Hellman S, Rosenberg SA, editors: *Cancer: principles and practice of oncology*, ed 6, Philadelphia, Pa, 2001, Lippincott Williams & Wilkins, p. 1770.

encourage sustained healthy habits. Children and adolescents may not start smoking if they hear a positive smoking prevention message or if they are involved as role models in an education project focused on communication with their peers or siblings.

Occupational therapists can also intervene by helping smokers quit smoking. In 1998, the Representative Assembly of the American Occupational Therapy Association voted to support the “Smoking Cessation Clinical Practice Guideline” of the Agency for Health Care Policy Research.¹ This action supports the role that occupational therapists may play in helping their clients set health improvement goals to prevent chronic disease and disability. Smoking cessation initiatives are one example of a cancer prevention intervention. These preventive interventions, such as smoking cessation, may be individual, group, or population based and geared to reach any age group. Other prevention efforts may focus on self-examination and follow-up in scheduling and going for cancer detection tests (e.g., breast self-examinations, mammograms, Pap smears, and colonoscopies) or may focus on developing healthy habits for activity.

OT Practice Notes

Because the focus in occupational therapy is on helping people achieve a balanced lifestyle that supports a balance between self-care, work, play and leisure, and rest, occupational therapists are a natural group of professionals to be involved in cancer prevention initiatives.

Early Postdiagnosis Phase

The occupational therapist also plays an important role in working with persons with cancer who are recovering from such invasive procedures as surgery, chemotherapy, and radiation therapy. This level of occupational therapy (OT) intervention may occur in a hospital, home health, or community health setting and is most often provided in the context of an intervention team.^{12,16} People who experience a change in their functional status and have difficulty participating in daily activities such as self-care, work, play, and leisure or have difficulty in the ability to rest can benefit from OT.⁶ Prevention of long-term disability, restoration of normal function, and support of function through rehabilitative means or provision of palliative (comfort) care are all appropriate reasons for OT referral. In particular, strategies such as energy conservation and activity management have been effective in meeting the occupational needs of those in whom cancer has been diagnosed. During the postdiagnostic phase as the client begins cancer treatment, adverse health effects such as impaired physical or psychosocial functioning may be experienced.¹⁶ These needs often go unmet, particularly in those who have had changes in employment status secondary to the cancer and are also receiving chemotherapy. In one investigation, more than 63% of individuals in whom cancer was diagnosed reported a need for various rehabilitative services, and yet many of these needs were not being met. The role of the occupational therapist should also be one of advocate to ensure that individuals who are receiving cancer treatment also obtain the necessary rehabilitative services.

Mary voiced concerns regarding her ability to perform meaningful roles within her family. These concerns should be addressed throughout the OT intervention program.

The initial intervention for cancer may involve a series of treatments, including surgery, chemotherapy, radiation therapy, or immunotherapy, each of which has side effects. Surgery may include removal of a mass, more resection of tissue in addition to the mass (for staging of the disease or for complete removal of tumor-invaded tissue), reconstructive surgery to correct cosmetic or functional defects or the surgical resection, or amputation. Before surgery, the therapist can be involved in client education and training to prepare the client for what to expect after the surgery. Some researchers believe that training the client preoperatively may improve functional outcomes and reduce the rehabilitation needed in the postoperative recovery phase.

Postoperative Phase

In the early postoperative stage, the occupational therapist may work with clients to encourage and enable them to participate safely in daily occupations and goal-directed activities.⁶ Patients may be frightened to move and may need guidance concerning how much movement is safe to attempt and which movements need to be avoided until healing occurs. Pulling of the incision commonly occurs when patients' bodies are used dynamically in activities. This pulling sensation may be threatening to people who are uncertain about how much movement is too much or too little. The therapist often receives specific movement precautions from the surgeon in the early postoperative phase of OT referral and intervention. Postoperative precautions and protocols vary from surgeon to surgeon and facility to facility and must be verified at the time of referral.

Several types of surgery are used to treat tumors. En bloc resection is removal of the tumor and surrounding or involved tissues in one block or piece. An en bloc resection can be done when the nerves and vascular structures are patent and unobstructed by tumor growth. Radical surgery, including amputation, involves wide surgical resection. The diseased tissue is removed along with surrounding lymphatic tissue and other soft tissue (skin, nerve, muscle, or bone). If the neurovascular bundle to the limb is involved, the limb has to be amputated.

Amputation is a life-altering event that results in loss of a limb or part of a limb (e.g., arm or leg) or a body part (e.g., breast). The loss always causes a visible change in physical appearance. One difference between amputation as a result of diagnosis of cancer and traumatic amputation in an accident or necessitated by complications of a disease (e.g., diabetes) is that cancer requires further medical management beyond traditional wound care and preprosthetic or prosthetic training. The life span, survival rate, and the person's perception of the relative value of such an investment vary and may affect the person's decision about

whether to purchase an artificial limb. For example, someone who has a postamputation life expectancy of 2 years or less may decline a prosthesis because of the expense and the time that must be invested in a training regimen. This person may have other plans for the money or time that are more meaningful to quality of life.

When adapted equipment or techniques are indicated, the occupational therapist may also provide them and train the client to use them to compensate for motion that is lost or compromised after surgery.¹² If surgery causes a temporary change in function, the use of adaptation may be needed only for the immediate, subacute phase of healing. If surgery has caused muscle or bone loss, the functional changes and adaptations may be strategies that will be used for the remainder of life.

Chemotherapy

Chemotherapy is the use of a variety of toxic chemical substances to kill cancer cells in the body. Each form of chemotherapy has its own pattern of possible side effects. Some of the most common side effects that occupational therapists encounter are alopecia (hair loss), peripheral neuropathy, thrombocytopenia (diminished platelet levels and slow clotting time of blood), fatigue (associated with factors such as impaired liver function), changes in the red blood cell composition of blood (e.g., anemia), and function-limiting anxiety and fear. Chemotherapy can also compromise sensory systems, and the person may experience diminished or loss of vision or hearing. Chemotherapy-induced neuropathy usually causes wristdrop and footdrop, which are transient. Neuropathy can also cause burning, tingling pain. Neuropathic pain can severely limit function because afflicted people are reluctant to hold onto objects or to stand on their feet when the pain is serious.

Many people who are undergoing chemotherapy contract opportunistic infections because chemotherapy causes immunosuppression. One infection, cytomegalovirus (CMV), can cause blindness, as well as hepatitis. People who have low vision or blindness and chemoneuropathy have a severe handicapping situation because they cannot use one sensory system (tactile) to substitute for another (vision) functionally. Another infection, a yeast (*Candida albicans*) infection, can cause dysphagia, or an inability to swallow safely. The affected person may have to stop eating by mouth or eat a restricted-consistency diet until the infection resolves.

In the acute phase of hospitalization, clients treated by chemotherapy may be referred to OT because they have been on prolonged bedrest and may have stopped initiating or participating in their self-care. In addition, fatigue may limit the level of participation because a person who is fatigued may not be able or sufficiently motivated to participate in daily occupations.¹⁸ Peripheral neuropathy causes weakness and changes in sensation in the hands and feet. Frequently, people cannot hold onto objects adequately to

use them as intended. Hyperesthesia (tingling, numbness, or burning) and loss of grasp and fine motor hand function can interfere with the ability to complete daily tasks and activities; the person may drop objects or experience pain when trying to use common objects such as a comb or a brush.

Clients who have decreased platelet levels may bleed easily and might have to forgo some normal daily activities for a few days until their blood levels improve. When someone's platelet level is below 45,000/mm³, for example, excessive bleeding of the gums may occur when brushing the teeth. While the platelet level is low, use of a sponge toothette or a glycerine swab may be all that the individual can tolerate until blood levels normalize. Blood levels generally improve as the person's body metabolizes the chemotherapy, in the first few days after a treatment.

Hormone therapy and immunotherapy are also used as forms of chemotherapy. For example, some tumors thrive on estrogens. Hormones can be used to block estrogen receptors or to prevent the body from producing estrogens. These hormones often have the side effect of inducing menopause. Women may complain about mood swings and hot flashes. Immunotherapy is the use of substances that block the response of the immune system or that heighten the response. For instance, white blood cells phagocytose (ingest) cancer cells and carry them through the lymphatic system to other areas of the body. This response can spread cancer locally or carry the cancer cells to other places in the body. Interferon is an immunotherapeutic agent that can be used to fight this spread. People treated with interferon may have a tendency toward hyperactive skin responses, such as forms of eczema. If these individuals are scratched, welts may easily develop. These are normal responses to the drug and should not generate fear or anxiety in clients who use these substances.

Radiation Therapy

Another method of treatment that people may undergo in the acute phase of cancer intervention is radiation therapy. Radiation therapy is the use of radioactive material directly in tumors or the surrounding tissue to kill cancer cells. Radiation is effective when the cancer cells are sensitive to its effects. Radioactive seeds (small pieces or pellets of material) can be directly implanted for a short time in the body (radioactive seed implantation). Seeds are sometimes placed in flexible tubing that is run through the tumor bed. This internal form of radiation therapy is also referred to as brachytherapy and provides directed radiation to specific tissues and limits exposure to surrounding healthy tissue. Another approach involves directing an external beam of radioactivity to a generalized area of the body via a linear accelerator machine. The beam can cover a broad area of a quadrant of the body (wide beam) or be directed to a more focused area (coned down). An occupational therapist may work collaboratively in some settings with the radiation oncology staff to mold body positioners from thermoplastic

(splinting) material. These devices are used to help the client remain in the position needed for the duration of the radiation treatment. Radiation may also be used in late disease as a form of palliative treatment, particularly to reduce pain.

Burns are a possible side effect of radiation treatment. The topical ointments used to treat a burn caused by radiation are different from those used for burns of other causes. The skin absorbs moisturizing agents. These agents can change the surface composition of the skin and result in enhancement of burning at the next radiation treatment. Many interventional radiologists recommend water-based ointments for their clients. Others allow their clients to use silicone gel pads to cover the burn and manage the burn-related pain and discomfort. When people have burns resulting from radiation, they should avoid movement that stretches or pulls the burned area. People may need assistance with range of motion to prevent complications such as frozen shoulder.

Rehabilitative Phase

Therapists who work with people in the acute care phase after treatment of cancer are generally working toward the goal of getting the client ready to go home or be transferred to an inpatient rehabilitation setting, a subacute center, long-term care, or a hospice setting (at home or in a facility).

Clients who have completed their initial cancer treatment may be well enough to participate in aggressive rehabilitation programs. Patients are sometimes admitted to a rehabilitation unit on a trial therapy basis to test their ability to tolerate 3 hours of therapy per day. After initial healing from surgery and after or during chemotherapy regimens, clients who have cancer may be able to tolerate this intensive type of short-term rehabilitation program. On a rehabilitation unit, goals for clients with cancer generally involve restoration and support of function within a rehabilitative model of care (i.e., learning to live with and adapt to changes in functional abilities).⁶ The goal of therapy in a function-based treatment setting is to restore the ability of clients to participate in goal-directed activities that give their lives meaning.

Not all rehabilitative services are provided in an intensive manner.¹² An outpatient clinic provides clients with a 1-day multidisciplinary program designed to meet their individualized needs. OT services, as a member of the team, focus on instruction and issuing adaptive equipment, education in energy conservation techniques, education on the breadth of OT services, and procuring large medical equipment such as wheelchairs and hospital beds. Clients receiving these services, provided during a 1-day session, have indicated significant improvements in pain relief, tiredness, and overall well-being.

Some of the pertinent areas for OT assessment and intervention are analyzed in [Table 45-2](#).

TABLE 45-2 | Areas of Occupational Therapy Assessment and Intervention

Cancer Involvement (Body Structure/Body Function)	Impairment	Activity Restriction	Participation Issues (Personal and Environmental Factors)
Brain	Motor	Mobility	Access Architectural barriers Adaptation
	Sensory	Safety/pain	Safety: need for supervision or a helper Pain: intolerance of participation in activities that exacerbate pain to the level of intolerance Pain medicine: blurring senses, inability to drive or operate heavy machinery
	Cognitive	Planning Sequencing Memory Insight Safety	Inability to lead Lack of ability to plan or implement change
	Neurobehavioral Visual impairment: hemianopia, neglect, low vision, cortical blindness, loss of perception of spatial relationships Motor planning Communication	Interference with ADLs/self-care and instrumental activities Speaking Reading Writing	Social inappropriateness/stigma Loss of occupational roles: work roles, family roles, ability to participate in leisure or sport activities Inability to be independently involved in daily occupations Major change in socialization and loss of sharing ideas Severity of restriction in participation dependent on individual interests and roles
Bone	Loss of motion Pain Impaired mobility Risk for reinjury of the affected part	ADLs (basic and instrumental)	Ability to dress, bathe, and toilet in context Need for adaptation of the environment or the presence of a caregiver Decreased ability to get around Possible effect on employment Severity of restriction in participation dependent on individual interests and roles
Breast	Loss of motion Pain Impaired mobility Risk for reinjury of the affected part	ADLs (basic and instrumental) Shoulder mobility restrictions: sports, etc.	Temporary or long-term disruption in the ability to do housework, job, and leisure activities Risk for injury because of lymphatic compromise; impact on sexuality
Lung	Impairment in shoulder mobility (Pancoast tumor, post-thoracotomy status) Impaired respiratory status Fatigue	ADLs (basic and instrumental) Shoulder mobility restrictions: sports, etc. Respiratory intolerance	Mobility issues, respiratory tolerance, and distance navigated Temporary or long-term disruption in the ability to do housework, job, and leisure activities Risk for injury because of respiratory compromise Need for oxygen or nebulizing equipment

■ **TABLE 45-2** | Areas of Occupational Therapy Assessment and Intervention—cont'd

Cancer Involvement (Body Structure/Body Function)	Impairment	Activity Restriction	Participation Issues (Personal and Environmental Factors)
Colon	Change in the way that the bowel is managed (toileting—colostomy) Change in way that the body is washed (stomal issues) Chemoneuropathy impairment potential Fatigue	ADLs (basic and instrumental) Fatigue Social stigma of a stoma (odor, bag rupture, etc.) Fine motor impairment related to chemotherapy	Socially stigmatizing in community relationships
Prostate	Urinary incontinence Inability to perform sexually	ADLs (basic and instrumental)	Loss of sense of self as a sexual being Stigma associated with incontinence
Head and neck	Inability to swallow/eat Loss of voice Decreased neck and shoulder range of motion, loss of scapular stability	ADLs (feeding and eating, swallowing) Respiratory: management of oral secretions Bimanual overhead mobility activities Intimacy issues	Socially stigmatizing in community relationships Need to change contributory habits (smoking)

ADLs, activities of daily living.

Cancer and cancer treatment can cause a number of problems that result in functional limitations. One problem associated with cancer is impaired mobility. Community mobility—leaving home, crossing the street, getting around the neighborhood, and getting to and from business or medical appointments—is basic to daily life. A number of factors can contribute to impairments in mobility, including sensory loss and weakness.

Weakness and fatigue are common in people with cancer and contribute to restricted activity and community participation.^{6,12} Weakness leads to lack of the endurance needed for navigating distances and to decreased tolerance of sitting or being upright for prolonged periods. Weakness may also limit customary movement within homes or public buildings if architectural barriers are present, such as flights of stairs. Participation in occupational roles may be compromised when a person who has cancer experiences community mobility problems. Although physical activity has been identified as an important part of early-stage cancer treatment programs,⁸ it needs to be balanced with rest. Developing a program that fosters physical activity within the client's daily life can diminish the issues related to weakness.

Edema may result from a number of causes associated with cancer and is often seen in individuals who have breast

Threaded Case Study Mary, Part 2

Mary underwent coned-down external beam radiation therapy involving her right supraclavicular and clavicular region (mantle). When the initial radiation therapy is administered, a wide beam is used, and in Mary's case this beam also irradiated her shoulder joint capsule. Mary experienced stiffness and pain when trying to use her right shoulder with rotation in the joint. She had to stretch her arm several times throughout the day to be able to prepare her arm for use in activity.

cancer.¹⁵ When a tumor invades the tissues near a limb or when lymph nodes adjacent to a body part are resected or irradiated, lymphedema may develop. An inflammatory response of the body, lymphedema is caused by shifting of protein-rich white blood cells flooding the area where the cancer has spread or where scar tissue is forming. Lymph nodes and vessels usually assist in the transit of white blood cells. When they are impaired, fluid may accumulate and cause local swelling in the limb. The edema is a colloid, and colloids are initially fluidlike in nature. Over time, however, colloids may change to be more gelatinous or firm (brawny).

Specific techniques known as manual decongestive therapy or manual lymph massage can be used to diminish the edema.¹⁵ The massage targets the lymphatic structures and pathway of lymphatic flow. Frequently, the limb is bandaged with supportive material that is later alternated with the use of gradient compression support garments (stockings and sleeves). Education is also provided to the client concerning skin and wound precautions and exercises that may assist in decongesting, or clearing, the edema from the involved limb (or limbs). If the limb becomes engorged, reddened, and acutely painful, the patient may have cellulitis, an acute infection of connective tissue. Before the therapist can treat the edema, cellulitis requires antibiotic therapy.

Edema may also result from organ system failure. This type of edema tends to be protein poor and more liquidlike in nature. When it is present only in the limbs (such as in pedal edema), it may be somewhat less serious than when the edema is present throughout the trunk and limbs, a condition called anasarca. Compression bandaging or support garments may be of some help, as long as treating the limbs does not put undue stress on the organs that are experiencing failure (e.g., the heart, lungs, and kidneys).

Edema is uncomfortable, and patients who suffer from this condition may complain of soreness or a chronic aching pain in their limbs. The presence of edema may also limit the person's ability to engage in various occupations or participate in preferred activities.¹⁵ In addition, persons with edema may find it difficult to wear their normal clothing and accessories if use of these items causes circulatory restriction.

Impaired sensation predisposes people to injury from heat sources or sharp tools. If the sensory impairment is hyperesthetic (intensifying sensation), burning pain can decrease the ability to hold objects, to effectively grade the force of grasp or pinch needed to manipulate objects enough to use them, or to tolerate wearing of socks or shoes. The physically disabling condition creates an inability to effectively perform self-care and other daily activities that involve hand function or foot function.³

Impaired cognition is disabling because an affected person may not be able to initiate or follow-through on tasks. With memory impairment, patients may forget what they are doing or why they are doing it. Impaired judgment, if sufficiently grave, means that a person cannot be left alone. The potential risk for injury or elopement from familiar surroundings may be too great a risk to allow any independence. Impaired cognition may be permanent or transient. If the impairment is associated with a central nervous system structural abnormality, the person may recover only rudimentary cognitive skill and may benefit most from the development of cueing systems to complete daily activities. Initial evidence has indicated that cognitive rehabilitation strategies can be helpful to both the client and caregivers of a client who has cognitive impairment from a brain tumor.⁷ If the person has a cognitive impairment associated with metabolism of an anesthetic or the introduction of a new pain medication (opiates such as morphine have this property), cognitive abilities may return to normal baseline when the drug is metabolized by the body. Because the liver's ability to metabolize drugs and anesthetics slows with age, many older persons who undergo major surgery experience this phenomenon. Although the acquired cognitive impairments from anesthetics resolve within weeks of surgery, many people need constant supervision during this recovery phase.

Impaired vision is sometimes associated with brain tumors or CMV infection. Impaired vision of recent onset in a sighted person can be very disorienting. Most sighted people cannot easily orient themselves to daily activities if visual impairment or blindness develops suddenly. The degree of functional impairment will be associated with the daily activities that a person enjoys or needs to complete. For example, a person may not be able to resume driving a vehicle, which limits community mobility. Participation in other basic and instrumental activities of daily living may be severely limited or lost as a result of visual loss.

Chronic fatigue results from a variety of factors after cancer treatment. It may eventually resolve as factors causing the condition resolve and as the body heals after cancer diagnosis and treatment. However, management of chronic fatigue is necessary for coping during the disease and treatment process. Participation in life can instill hope and the perception that some things can change or be positively managed to give clients a sense of being able to control their own life. Both emotionally and psychologically, hope is crucial to recovery.

Strategies that occupational therapists can use to assist clients who have chronic fatigue include energy conservation and work simplification, as well as scheduling intervals of rest between periods of work or activity. When fatigue is severely disabling, an occupational therapist can help the client and caregivers prioritize the tasks and activities that the client wants to do and balance them with the tasks or activities that must be done. Sometimes, helping clients recognize the need for help allows them the opportunity to

Threaded Case Study Mary, Part 3

Mary's lymphedema was mild. She was initially taught to perform her own lymphatic massage, and she wears a compression sleeve and glove during the day when she is using her arm in resistive tasks. She also wears the sleeve and glove when she flies in an airplane so that the edema is not exacerbated by the change in cabin pressure. Mary also knows how to recognize an infection in her arm (the signs of cellulitis) and is aware of steps that she can take to prevent infection when a situation arises that could lead to an infection or a lymphedema flare-up (e.g., cuts, bug bites, pricks from sharp objects, and burns).

choose the truly important and meaningful occupations that define who they are and how they can be contributing members of society.

Palliative Care

After a diagnosis of advanced cancer that clients are not expected to recover from, their physicians can declare or certify them as terminally ill. This legal certification entitles these clients to have access to hospice services. Hospice is a form of palliative care. There are several models of hospice care. Home care hospice occurs in the home of the dying person or a significant other who is caring for the dying person in the final stages of life.^{4,13} Hospice care may also be provided in skilled nursing facilities or in dedicated inpatient hospice settings. The money to cover inpatient care is part of Medicare part A services and therefore often part of a bundled reimbursement charge. Some hospices provide additional, extended services through philanthropic funding. The services in hospices with private funding may provide expanded options that have a greater emphasis on quality-of-life programming, such as services offered during the off hours (evenings and weekends). Palliative care is directed toward achieving comfort and ease of participation in activity.^{5,11,13} Occupational therapists involved in hospice care may intervene directly with the person who is dying or indirectly with families, volunteers, and caregivers as educators, trainers, and intermediaries to improve the quality of life of the person who is dying and those around them.¹⁷ Some examples of this role are to adapt the environment, train caregivers to assist with daily life tasks, counsel for psychologic or emotional issues related to the disease process, and provide assistance with issues concerning death and dying. Occupational therapists involved in palliative care often conduct home assessments to foster client independence as the client experiences changes because of either the cancer treatment or the course of the disease.⁴ In a time audit the average time spent in actual home assessment was 60 minutes, but the length of time spent in follow-up appointments varied substantially from 1 to more than 3 hours, depending on the changing needs of the client.

OT Practice Notes

Occupational therapists may work with the patient on activities that help the patient plan for death. Reminiscence activities, such as creating memory scrap books, making video “cards,” writing letters, making phone calls, and arranging visits, are examples of creative tasks that can help a dying person revisit relationships and review life.

One OT qualitative study was conducted in the context of the doing-being-becoming framework.⁹ The experiences of 23 (13 male and 10 female) day hospice participants were

investigated through a combination of (1) focus groups, (2) individual interviews, and (3) participant observation. The data were interpreted via constant comparison, coding, and theme-building methodology. Experiences of doing were evident in accounts of losing and maintaining valued occupations and striving to preserve physical and mental functioning. A sense of being through occupational engagement arose in social relationships and self-exploration that enhanced feelings of self-worth. Occupation promoted the experience of becoming by providing fresh learning opportunities and a sense of contributing to others’ welfare.

In palliative care, the occupational therapist may assist in promoting positioning for comfort, providing treatment to prevent or relieve pain, promoting engagement in activity that is physically tolerable, and creating an opportunity to engage in a full occupational life review as part of the process of planning for death. For a client involved in the active process of dying, having an opportunity to resolve life issues is critical.¹¹ Creativity still plays a role. When people create and give something back to others, they live in hope. Hope is essential in all phases of life, even in the process of dying, because it motivates us to live each day to the fullest despite illness and disease.

Psychologic and Emotional Aspects of Living With Cancer

People with cancer may have social, psychologic, and emotional issues that affect their ability to function. Acquaintances may avoid a person with cancer because they do not know how to respond to the news of a life-threatening illness. Some people mistakenly assume that they can catch cancer from the person. Many people, regardless of the stage of their disease, automatically assume that they are dying. In reality, more and more people are surviving for longer periods after a diagnosis of cancer.

Coping mechanisms are essential for dealing with the stress of having cancer, as well as for facing the inevitability of the treatments needed to seek control or cure of the cancer. The emotional side effects of the progression of cancer include fear and anticipation of pain, which produces anxiety and stress. Surgery is usually painful. Chemotherapy can cause painful neuropathies. Burns from radiation are painful. Metastatic lesions on bone, muscle, or nerve are painful. Some positive coping mechanisms for dealing with a rational fear of pain are self-hypnosis, meditation, and other relaxation techniques.¹⁰ An investigation identified the benefits of occupational therapist–administered relaxation techniques. The occupational therapists saw clients, predominantly with breast cancer, for one to four sessions on an outpatient basis. The following relaxation techniques were used during the OT sessions after the use of an induction script addressing breathing patterns: muscular relaxation, autosuggestion using themes of heaviness and warmth, guided visualization in which a client is asked

to imagine a safe and pleasant environment, and unguided visualization in which the client selects his or her own scene to visualize. Participants indicated that they had improved quality of life and improved independence in activities of daily living.

People who also have an anxiety disorder often have heightened anxiety when they are trying to cope with diagnosis and treatment of cancer. They may not be able to sleep. They may be unable to take part in their normal activities and lose perspective on their situation. They may find it difficult to concentrate on normal life tasks. Treatment of anxiety disorder includes supportive counseling and pharmacologic intervention. Once the anxiety is controlled and the fears that underlie the anxiety are addressed, coping behavior can be developed to improve the person's ability to engage in the rehabilitative process.

Many people living with a diagnosis of cancer experience depression. Depression may be reactive or organic in origin. Depression may originate from an organic cause, such as medications, the disease process, or a hereditary predisposition. Depression is characterized by feelings of helplessness and hopelessness. People adjusting to disease or disability go through a normal grieving process. During this time they may experience a number of feelings or stages. The stages of adjustment generally encountered are anger, denial, bargaining, and acceptance. These stages tend to be experienced in combination. Those who are depressed generally have to be able to see something hopeful concerning their personal circumstances for change to occur and for the effects of the depression to lessen.

Participation in support groups may be helpful for some people. Even people with advanced cancer have benefited from participating in support groups. Women with stage IV breast cancer who participated in support groups lived better and longer than those who did not participate in a support group.¹⁴ Although the exact mechanism is not clear, the experience of knowing that others share what you are feeling and that others care about you can have a positive impact on the immune system. Recent studies have shown that even avoidance of pessimism supports health and well-being.

Long-Term and Special Chronic Disease Issues

Lymphedema is edema (enlargement of one or more limbs) that results from impaired lymphatic circulation. The lymphatic circulation can be impaired by lymph node dissection, irradiation of the lymphatics, or a tumor that has spread into the lymphatic vessels or nodes. Lymphedema is protein-rich edema and is inflammatory in nature. Lymphedema can occur throughout the body but is commonly seen by therapists when it impairs function in a limb by changing the mobility of the extremity or by producing pain in the involved limb. Lymphedema in the arm, in

particular, produces a social impairment. A normal approach to social interaction in our society includes extending a hand to shake hands. When a person has lymphedema in an arm and hand, people may react negatively to the appearance of the limb. As discussed previously, publicly sharing knowledge of a diagnosis of cancer can be socially stigmatizing and lead to social rejection.

Self-treatment of lymphedema usually involves following guidelines and education in skin care and wound precautions. The limb is fitted with a compressive garment or wrap. Compliance with the use of garments may be challenging for some people. The pressure against the skin by support garments should feel good to the person. Some people report having difficulty tolerating the squeezing sensation of the support garment at work. Light compression can be provided by a tubular support bandage or by toning gloves or garments. Moderate (20 to 30 mm Hg) to firm (30 to 40 or 40 to 60 mm Hg) compression can be achieved by using a high-gradient garment (e.g., Jobst, Juzo, Medi, or Sigvaris). Manual lymphatic therapy (massage) can be performed by a professional or by the client or caregiver trained to use the technique to correct the lymphedema. Bandaging with cotton-based support bandages often follows massage treatment. A person can be taught self-massage to improve carryover of the treatment program. In addition, pneumatic compression pumps may help reduce edema in the limbs.

Someone who has lymphedema generally self-monitors the condition and may require treatment that continues over an extended period. When the limb is in an inflammatory state, treatment must be ongoing and aggressive to maximally reduce the size of the limb. In time and if the person avoids repeated injury, the frequency of treatment may lessen. People with lymphedema must be consistent in their management of the condition. Cellulitis (infection in the subcutaneous tissues of the lymphatically impaired limb) may occur; the person should be taught to recognize the urgent need for antibiotic treatment and reassessment with the therapist. Untreated cellulitis can lead rapidly to a systemic infection. Once infection becomes systemic, the person will require hospitalization and intravenous antibiotic treatment. As a prophylactic measure, physicians who treat people with cancer routinely give their patients antibiotic prescriptions for rapid self-treatment when a crisis occurs.

Disease Progression

One long-term condition that can develop as a result of spread of disease or as an aftereffect of radiation treatment is brachial plexopathy. The most common complaint associated with the development of brachial plexopathy is progressive loss of function of the arm. Clients complain of clumsiness, inability to hold onto objects, and lack of coordination. The brachial plexopathy associated with cancer treatment or disease progression is irreversible. A person

with this condition will lose function and mobility of the arm. The extremity can become flaccid. When some degree of mobility and strength remains, adapted techniques can preserve function for as long as possible. Some patients benefit from functional splinting to preserve function; for example, tenodesis splinting may be helpful when a patient is motivated to use a splint to support function. When the limb is flail, positioning for protection is crucial. Motor loss may develop in addition to the sensory loss, including loss of protective sensation. Reinforcing safety issues during participation in self-care tasks can support safe participation in daily activities and occupations.

Summary

OT is beneficial for many people who have cancer. Occupational therapists may encounter patients with cancer in inpatient settings, home care, outpatient settings, community-based settings, work settings, and school or early intervention. This area of OT practice is closely aligned with the medical model, given that many people who undergo cancer-related rehabilitation have medical qualifiers that affect their participation in OT. Other OT models are also important in addressing quality-of-life issues.

The most important tools that we have as OT practitioners are (1) our ability to work with our clients beyond the impairment level of disability and (2) our skills as holistic practitioners that allow us to be effective in intervening with people at the activity and participation levels of their occupational abilities. Given the potential side effects of participation in activities, our knowledge of the medical model will enable us in the future to further develop creative and needed interventions for this population—a population for which we must document and produce intervention outcome data.

Review Questions

1. Contrast the role of the OT practitioner in cancer care during the early postdiagnosis phase and the postoperative phase.
2. List and describe side effects of chemotherapy and radiation therapy.
3. Describe how chemotherapy and radiation therapy may affect occupational performance.
4. What are the causes and effects of impaired sensation and cognition during cancer treatment?
5. What are the psychologic and social consequences of a diagnosis of cancer? To what extent do you think that these consequences can be affected by the patient's attitude and by social support? How can the occupational therapist assist the patient in facing and managing psychologic and social challenges?
6. Describe the protocol for managing lymphedema.

■ Chapter Outline

Introduction

Aging as a complex process

Changes in sensory structures and functions

Vision

Hearing

Dual sensory loss

Changes in mental structures and functions

Alcohol abuse

Depression

Anxiety

Changes in musculoskeletal structures and functions

Changes in cardiovascular, immunologic, and respiratory structures and functions

Areas of occupation

Activities of daily living

Instrumental activities of daily living

Rest and sleep

Work

Leisure

Social participation

Intervention

Coping

Caregiving

Aging in place

Wellness and aging

Summary

Review questions

■ Key Terms

Aging in place

Allostatic load

Mild cognitive impairment

Frail elders

Gerontology

Old-old

Oldest-old

Young-old

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe theories of how aging happens.
2. Identify basic age-related changes in sensory functions and body structures.
3. Describe how mental functions may change as a person ages.
4. Identify basic age-related changes in musculoskeletal functions.
5. Identify basic age-related changes in cardiovascular and respiratory functions.
6. Describe how the learning needs and styles of older adults may differ from those of younger persons.
7. Describe what an occupational therapist can do to help an older adult age in place.
8. Describe how a wellness approach can be used with older adults.

Threaded Case Study Marie, Part 1

Marie is a 78-year-old white woman who has just been admitted to a skilled nursing facility. She was home alone washing the dishes when she turned to get the dish towel and fell. Marie stayed at the hospital for a week and underwent treatment of a broken hip (by open reduction and internal fixation) and a urinary tract infection, as well as treatment to help get her exacerbation of chronic obstructive pulmonary disease under control. Marie also has high blood pressure, osteoarthritis of the hands and knees, and cataracts, for which she is scheduled to undergo surgery. This is Marie's second admission to the hospital this year, having previously spent 3 days in the hospital several months earlier because of a transient ischemic attack.

Before admission, Marie lived alone with her daughter living nearby in town. Marie's daughter would visit a few times a week. In years past they would go to the movies and shopping and had season's tickets to the local symphony. However, Marie gradually started to have more trouble doing things outside the home, and her visits with her daughter became restricted to her house. Marie's daughter did the grocery shopping and would pick up medications for Marie, who had stopped driving. At home, Marie enjoyed baking cookies for her neighbors and took great pride in keeping her house neat and tidy. She also enjoyed listening to big band music and used to be an avid dancer.

Marie's occupational therapist in the skilled nursing facility found that Marie had difficulty performing many of her activities of daily living (ADLs) and instrumental activities of daily (IADLs) because of pain in her hip, limited joint mobility in her hip, and limited muscle power. Marie also had difficulty compensating for her impaired hip function as a result of arthritis in her hands and knees. Marie's vision was impaired, and even with glasses she required large print to read. Marie appeared to have good cognitive skills but did require repetition for new learning. Marie and her occupational therapist agreed upon treatment goals of independence in ADLs and IADLs and occupational independence with a functional program to maintain Marie's strength and range of motion.

Critical Thinking Questions

1. What physiologic changes might Marie's occupational therapist expect to find, and how might they affect Marie's participation?
2. What treatment activities might be used to help Marie return to participation in her repertoire of occupations?
3. How can the occupational therapist promote wellness for Marie?

Introduction

The 2000 U.S. census reported that nearly 35 million people 65 years and older are living in the United States,⁸⁵ with that number estimated to have increased to more than

39 million by 2009.⁸⁶ The 65-plus age group accounts for more than 12% of the total U.S. population and is projected to reach 20% of the population by the year 2040.⁸⁷ The percentage of the population 85 years and older is projected to nearly triple between the years 2000 and 2050.⁸⁷ This population explosion of older adults, including the oldest-old (85 and older), requires that society be prepared to meet their special needs. For occupational therapists, this means understanding not only the changes and challenges faced by older adults but also their strengths and resources. Occupational therapists and assistants work with older adults not just in assisted living and skilled nursing facilities but also in acute care, inpatient rehabilitation, outpatient clinics, home care, and community health. This specialty service area is challenging and can also present huge rewards. Another growing area of focus for occupational therapists and assistants is to provide preventive treatment through well-elderly programs and interventions. This population is the most complex and is at a stage in their lives where changes may be occurring physically, socially, cognitively, and in the culture around them, all of which have an impact on their occupational independence.

This chapter provides an introduction to the special needs of older adults in clinical practice. It takes a developmental perspective and starts with aging as a process that occurs throughout life, with complex interactions between person, environment, and occupation. Changes that are generally seen in sensory, mental, musculoskeletal, cardiovascular, immunologic, and respiratory structures and functions as a result of age are introduced. The chapter then discusses older adults engaging in areas of occupation and how participation may change over time, as well as the intervention process and special considerations when working with older adults. Finally, concepts related to coping and the older adult in context and environments such as home and within caregiving relationships are addressed.

Aging As a Complex Process

The field of gerontology, or the study of aging, has advanced many hypotheses for why and how people age. The process of aging is complex and inescapable, with an increased prevalence of degenerative diseases and the potential for physiologic decline in several body systems. Researchers question the extent to which decline is a normal part of aging. Most biologic theories can be roughly grouped according to two major suppositions.^{11,23,57} Some researchers believe that aging is the result of preprogrammed genes that contain a master plan in which various mechanisms are triggered and cause cells to die.^{32,81} Other theorists believe that aging is the result of accumulated cell damage. A number of accidental events occur, including free radical damage to genetic material and damage to cell components.^{13,61,62} The rate of mutation errors also increases as the

number of cell replications increases. Additionally, immune system malfunction may cause cell damage and death.^{9,89} Most experts agree that aging-related pathology involves both programmed genetic changes and accidental events.⁷¹ Some of this aging-related pathology can be attenuated by environmental and lifestyle changes.

Improvements in sanitation, standards of living, medical care, technology, and access to health care have contributed to a longer life span. The price of this longevity has been a higher incidence of chronic medical conditions and associated limitations in daily activities, primarily in old-old individuals, since the basic processes that are necessary to sustain life can have deleterious effects later in life.^{17,24,88} Functional limitations caused by chronic conditions increase with age. More than a third of persons 65 years and older identify a chronic condition that imposes some limitation in everyday living, but only 10% report that the limitation affects a major activity. The four most frequently reported medical conditions in later life are arthritis, heart disease, hearing impairment, and orthopedic impairment. Three fourths of the old-old, 75 years and older, identify one disability, and more than half report two or more disabling conditions. Old-old adults have twice as many problems with ADLs as do young-old (65 to 74 years of age) adults. Of the old-old, 40% also have problems with IADLs.⁸⁸ Despite chronic medical conditions, older adults are generally able to adapt and maintain function until very late in life.¹⁸

The concept of allostatic load has become important in recent years. Allostatic load is a cumulative index of biologic risk that explains more than the sum of individual measures for mortality risk.⁷⁷ It is important to adopt this holistic view of the individual and understand that, for example, the presence of hypertension, high cholesterol, and diabetes increases health risk exponentially. Such a view can also be taken of other areas in a person's life. Older adults with low vision who also have difficulty hearing and diabetic neuropathy with altered sensation in their fingers will have an exponentially greater challenge in adapting daily activities to achieve functional independence. Older adults with great medical complexity are sometimes termed "frail." These elders are particularly vulnerable and require an evaluation and treatment approach that truly takes into account the whole person, within context and in interaction with their occupations.

Changes in Sensory Structures and Functions

Aging creates changes in all our systems, especially our sensory systems. In addition, older adults are often more susceptible to a number of diseases and chronic conditions or to the cumulative effect of having a disease for a long period. This is especially true of the visual and hearing systems.

Vision

Normal aging of the visual system takes place at varying degrees, depending on genetic factors and lifestyle choices. These changes in the visual system are related to the eye structure itself and to the mechanisms of visual processing in older adults. (For a full discussion of how the visual system works, please refer to [Chapter 24](#).)

Because vision is such a critical sensory system in humans and plays a significant role in social interactions and safety, any decrease in vision can have an impact on an older adult's ability to engage in full participation of life. An occupational therapist may be seeing a client with low vision as a primary diagnosis or as an underlying secondary diagnosis. At times no diagnosis has yet been made, and the occupational therapist can encourage the client to see an eye care professional so that the best correction can be obtained if glasses are worn and the client's eye health can be evaluated and addressed. Because the visual system is such a specialized sensory system in the body, it is recommended that any practitioner working in this area use the many opportunities and resources within the field of practitioners serving the blind and visually impaired.

In the older adult population it is estimated that 33% have some form of vision-reducing eye disease by the age of 65.^{21,91} Normal aging in the eye creates a number of changes. As the eye ages, the cornea becomes thicker and more opaque and the lens becomes less elastic, which in turn decreases accommodation, or the ability to make a change from distance to near vision. This condition is called presbyopia. Presbyopia occurs so universally that nearly everyone older than 55 requires some type of corrective lens to be able to read.⁷⁴ The lens of the eye may also become more opaque and eventually result in a cataract. Clouding of the lens can be gradual enough that an older adult is not aware of a change in color vision and a decrease in overall vision until the disease is well advanced and occupations have been affected. The iris muscles tend to atrophy, which causes the pupil to constrict. This makes it more difficult for the eye to bring enough light in for the retina to work effectively. The macula (used for central vision), which is part of the retina, has a decreased number of cones and therefore a decrease in effective color discrimination. The rods (peripheral vision) of the retina decrease and are less sensitive. There is also a decrease in the ability to transition between light and dark. Night vision is more difficult for older adults. The need for additional light increases with each decade, and the cones need increased light to effectively discriminate colors. Contrast sensitivity also decreases because of these changes in the eye structures. All these changes in the anterior portion of the visual system make it more difficult to adjust for the changing visual requirements of life.^{74,76} Because of her cataracts, Marie's occupational therapist will need to pay close attention to components such as task lighting, visual contrast, and layout during her home evaluation. The occupational therapist can then make recommendations for changes that will decrease Marie's

likelihood of future falls and increase her likelihood of remaining at home successfully.

In addition to the natural changes in the visual system, the incidence of macular degeneration and diabetic retinopathy, which destroy central vision, is high. Any neurologic disease that affects the brain will more than likely affect the visual system. This can be seen with such diseases as multiple sclerosis and Parkinson's disease. Peripheral vision is affected by various conditions, including glaucoma, retinitis pigmentosa, and field cuts related to acquired brain injuries such as stroke. Vision accounts for a high percentage of the sensory information that we use to participate in occupations. When visual acuity is reduced, as can occur in older adults, self-sufficiency in ADLs and IADLs may be decreased, the potential for falls is increased, and an increase in depression may be seen. It is an all-encompassing system that has an impact on every other perceptual system in the body.^{53,91}

When looking at vision functionally, it can be divided into central field functioning and peripheral field functioning. Each category tends to have a different impact and also different treatment goals. Central visual loss (such as is seen with macular degeneration) takes away part or all of the fine detailed vision that we use for reading, shopping, community mobility, and leisure activities.⁶³ During treatment the client should be encouraged to make an appointment with an eye doctor to provide the best prescription and to assess eye health. Something key to remember in any evaluation or treatment is that if a client wears glasses, they need to be worn to elicit the best performance.

Four keys of treatment to enhance participation are magnification, lighting, contrast, and organization. Magnification helps make the object larger on the retina so that the brain has more sensory input for processing. This may be accomplished by bringing the object closer to the client, such as with lenses, magnifiers, and electronic magnification. Because of occupational therapy's involvement in assistive technology and with the increase in all areas of technology, electronic visual enhancement may become the most popular with the older adult population in the future. There are ways to read or to be read to that are now economically feasible for almost every client. Computers come with magnification programs already installed for those with a visual impairment. Other electronic magnification devices can be used in multiple settings to increase the ability to see functionally. Each state has an agency whose mission is dedicated to providing low-vision service for the blind and visually impaired. There are also national and local service agencies and vendors for products. The American Occupational Therapy Association has recognized low vision as an appropriate area of specialization.

Lighting is an important component of vision and includes not only the type of light but also where it is placed. It should be close to the task and in a position to avoid any glare. Glare in a room may be controlled by window dressings or changing locations in a room.

Contrast sensitivity is the ability to detect detail when gradation between an object and the background is subtle. An example might be a white banister on a white wall in a hallway that a client is unable to see or pouring coffee into a black cup. With poor contrast sensitivity, it would be impossible to discriminate between the background and the object. This has a functional impact not only on living tasks but also on mobility. Contrast and contrast sensitivity are an important part of how well someone sees to function. It is strongly associated with reading performance, mobility, driving, and face recognition.⁷⁶ Persons with central visual loss may isolate themselves from friends and family because they can no longer recognize those close to them and are embarrassed. A component of contrast sensitivity is often glare.

Organization is the fourth principle of treatment to consider. Decluttering, grouping by function, and organizing objects can eliminate what has been called "visual static." An older adult with low vision is then able to more easily find and use the tools needed during a task.

With peripheral field loss (such as seen with glaucoma or retinitis pigmentosa), mobility becomes an issue because of loss of part of the visual field. Central vision is often spared during this disease process. With field deficits, older adults can have difficulty using their environmental context effectively and consistently. Other areas of participation that may be affected by visual field loss include driving, shopping, financial management, and meal preparation. Grooming may also be affected by field loss.⁹⁰ Many older adults with peripheral field loss are able to function independently within their living environment because they rely on the habit of navigation rather than their vision. However, the field loss becomes more apparent and function decreases when the older adult is in an unfamiliar situation. Treatment would include more effective use of scanning for detection of items. It is within occupational therapy's scope of practice to work on mobility as related to familiar space and ADL training. Teaching of mobility outside the familiar should be referred to an orientation and mobility specialist.

Hearing

Hearing is a multistep process in which sound waves result in vibration of the eardrum and movement of the ossicles. This movement is transferred to the fluid medium of the cochlea within the inner ear. The hair cells in the cochlea turn these vibrations into nerve impulses. Any impedance such as ear wax, ear infection, or hair cells that have died will have an impact on what is perceived as sound.⁷⁴ Generally, with normal aging there is a gradual progressive loss called presbycusis. Environmental factors may contribute to an increase in this loss, as may genetic factors and gender differences. Sound seems muffled to older adults. It becomes more difficult for older adults to be able to separate background and foreground noise.⁷⁴ Hearing loss is a common chronic condition that is seen in older adults. Anywhere

from 33% to 87% of the older population in the community have some form of impairment.⁶³ There is increasing evidence that in addition to the ear and its parts, the central nervous system plays a part in the ability to perceive speech in a naturalistic environment.⁹⁴ With hearing loss, participation may be limited in the area of phone use, socialization, safety, and participation. Because the sound is muffled or the older adult has difficulty separating foreground and background noise, it may take longer to process what is being said. This loss is gradual and a person often compensates through lip reading. Older adults affected by hearing loss may isolate themselves from others and stop participating and socializing with family and friends. Treatment needs to take hearing loss into consideration when recommending adaptive strategies to older adults.

Dual Sensory Loss

When one sense is impaired, the other senses are relied on more heavily to interpret social cues, physical cues, and safety cues. With both visual and hearing loss, or what is often termed dual sensory loss, the impact is that much greater. It is estimated that 23% of people older than 81 years have some degree of dual sensory impairment.⁷ Dual sensory loss is typically considered hearing and vision, although a decrease in the tactile system could also make participation and adjustment difficult for an older adult. The combination of loss in more than two sensory systems is considered multisensory loss.

Changes in Mental Structures and Functions

The brain decreases in weight and size with older age, even in those with normal cognitive function.^{75,82} Some neurons shrink with age and others are lost. It is estimated that we use only a small percentage of the neurons in our brain, so the effect of these changes could be very small. It is also normal to see neurofibrillary plaques and tangles in older brains,^{75,82} although excessive levels can be indicative of Alzheimer's disease (see [Chapter 35](#) for more details). Messages moving through the nervous system may not get through as quickly as they used to,⁸² thereby slowing the speed of some cognitive functions such as memory. This reduction in the efficiency of transmission of signals in the nervous system may contribute to the declines seen in some mental functions.

Sleep patterns change in older adults, with these individuals generally spending more time in bed but sleeping less than they did in younger years.⁷⁵ More awakening occurs throughout the night or early in the morning, which can make nighttime sleep less restful. Older adults also tend to take more naps than do younger adults and thus get their sleep at multiple times during the day. These depletions in rest can reduce the rejuvenation that occurs during sleep (see [Chapter 13](#) for more discussion).

Changes in cognition often affect the ability to function because information processing and problem solving are so vital to safety and independence in ADLs. Actual cognitive decline can be a major threat to quality of life, and this threat is compounded when physical function, especially sensation, is impaired as well.⁴⁷ Many of these cognitive changes are related to treatable, temporary, or manageable medical problems. Some of the more important considerations when working with an older adult include medication side effects, alcohol and nonprescription drug use, vision and hearing deficits, nutritional deficiencies, stress, sleep dysfunction, depression, and medical illnesses such as diabetes, high cholesterol, and high blood pressure. These conditions may also be predictive of functional decline.¹⁵ Cognitive decline becomes more substantial with each new medical condition that develops.

Occupational therapists find that cognitive capacity greatly affects the client's ability to benefit from rehabilitation. A more detailed discussion of cognitive aging can be found in other sources.^{46,47,49} Cognition as a mental function is also discussed in [Chapter 26](#). Age-associated differences are seen in almost all aspects of cognition in healthy older adults, but this difference is typically minor, with more time and more extensive processing being required; it is not usually disabling, although it may be annoying. Age-associated differences in cognition do not generally present serious implications for ADLs and IADLs.^{47,58} Researchers have found that cognitive processing efficiency, especially for working memory, information processing, and reaction time, is 1.5 times slower in older adults than in middle-aged or young adults.³⁸ Generally, older adults can, with effort and training, remember details with the same accuracy as younger persons.

Loss of memory is a concern for many older adults. Memory involves the retention, storage, and retrieval of information. Memory requires adequate attention to sensory-perceptual cues at the initial stages of reception and encoding.^{48,78} Age differences have been found in working memory—one component of short-term memory. Older adults exhibit poorer function in complex deliberate processing (i.e., simultaneously performing a cognitive task while trying to remember the information for a later task) than they do in automatic processing (i.e., remembering how to perform an activity).^{38,78} Older adults also have a decreased ability to inhibit thoughts that are irrelevant to the task.⁴⁸ Age-related deficits have been found in the recall of information when it is retrieved from secondary (storage) memory levels, and this deficit worsens with advancing age.^{12,46,47} However, the overall effects of age-related differences or changes in memory on daily function are minimal. Most healthy older adults are able to compensate for reduced processing resources by using the relevant context of situations, targeting environmental cues, providing environmental supports, rehearsing with elaboration, and developing new skills built on personal associations. Another area of aging-related effects is impairment in recent episodic

memories that are being retrieved. Frequently, rehabilitation services rely on an older adult's use of this type of information, and it is important to develop these episodic memory skills until they become automatic and a part of procedural memory in long-term memory stores.⁴⁷

When impaired cognition (especially memory) interferes with relationships, diminishes daily function, or affects quality of life, the causes should be explored because many of them are potentially treatable. Milder forms of memory loss are present in significant numbers of older adults. The *Diagnostic and Statistical Manual of Mental Disorders IV-TR* (DSM-IV-TR)⁴ includes a classification of aging-associated cognitive change as "age-related cognitive decline" or age-associated memory impairment, a part of normal aging affecting as many as 90% of older adults.⁴⁷ This is not a psychiatric disorder. Among the criteria for these cognitive changes is a decline in memory that is sufficient to worry the older adult but not in excess of normal age function, as seen with dementia. The decline must be within normal limits when the client is compared, through psychometric testing, with others who are the same age. Older adults who are tired, under stress, sick, or distracted are more likely to experience slower thinking and recall, experience more difficulty attending to and organizing information, and have difficulty recalling information, especially names, placement of objects, and tasks requiring multiple actions.⁴⁷

Memory loss that falls outside normal limits by one standard deviation on test scores, with more severe memory lapses evident in recent memory that are persistent and begin to interfere with work and social activity (not ADLs), is identified as mild cognitive impairment (MCI).^{4,64} In 50% of individuals with MCI, dementia develops within 3 years, although symptoms may have been evident for up to 7 years previously.^{47,64} When cognitive impairment becomes so severe that it affects daily function, particularly a significant decline resulting in dependence in ADLs, a diagnosis of dementia is often made.

Differentiated from dementia is delirium, a condition that is estimated to affect between 20% and 56% of hospitalized older adults.³³ The cardinal features of delirium include an acute onset and inattention, which can consist of difficulty focusing, concentrating, maintaining, and shifting attention.³³ People who are delirious can have difficulty following multistep commands and have disorganized thoughts, as well as an altered level of consciousness. Delirium can fluctuate during the course of the day, even with lucid intervals occurring. Although delirium can resolve, most people with the condition still experience some symptoms 6 months after diagnosis. Treatment is often nonpharmacologic and focuses on reorientation strategies such as the use of clocks, calendars, familiar objects from home, and personal contact to reinforce orientation.³³ Also beneficial in communication is frequent eye contact and the use of clear instructions. It is important to maintain a quiet environment as much as possible and to involve the client in both self-care and general decision making.

Therapists working with older adult clients will encounter varying degrees of cognitive decline, and it is essential that they screen for cognitive impairments and consider cognition as a major factor when planning the intervention approach and carrying out interventions. Levy suggests that occupational therapists can make an important contribution in the early detection and monitoring of cognitive decline by regularly assessing mental status on an informal basis during intervention and formally screening during the initial evaluation and periodically thereafter.⁴⁷ Assessments such as the Mini-Mental State Examination,²⁶ with scoring adjusted for age, culture, and educational level, are helpful as screening tools.¹ An assessment tool such as the Functional Activities Questionnaire⁶⁵ has been used to assess functional abilities in IADLs to distinguish older adults who are experiencing more severe cognitive impairment from those who are experiencing MCI.^{1,84}

Approximately 22% of individuals who are 65 years or older meet the diagnostic criteria for a mental disorder.^{36,83} It is important to remember that even if the prevalence rates of mental disorders in the older adult population stay the same, the number of older adults with mental disorders will rise as the crude number of adults surviving into old age across the world also increases.³⁰ Mental disorders in older adults may occur as a result of one of the following scenarios:

- Continuation or recurrence of a condition that first emerged earlier in the person's life
- First appearance of a disorder that was already present in latent form (e.g., a mental health liability from the past that has been exacerbated in old adulthood, as when developmental issues remain unresolved)
- New mental disorder occurring in later life

Pathologic mental conditions often occur in older adulthood because of physiologically based changes in brain function or brain disorders. Less frequently, the cause is an inability to adapt to changes, losses, and transitions, or these factors may exacerbate an existing condition. Older adults who have adjusted poorly to previous stressors, who are overwhelmed by multiple simultaneous stressors, or who have little social support are particularly vulnerable. Anxiety is the most common mental disorder in older adults (11.5%), followed by severe cognitive disorders (6.6%) and depressive disorders (4.4%).⁸³ Alcohol abuse and personality disorders are less common but are still cause for concern because they further complicate the clinical picture.

Alcohol Abuse

Alcohol abuse may be considered a hidden disease in later life because many older adults who drink alcohol, particularly men, do so at home.^{50,83} Symptoms of alcohol abuse include an increased tolerance of the effects of the substance and increased consumption over time. Older adults are more susceptible to the effects of alcohol, even when they consume less of it, because of age-related changes such as

decreased liver and kidney function and reduced water content and body mass. Many older adults are taking medications, and the concurrent use of alcohol and use or abuse of medications can lead to a greater risk for intoxication or toxicity. Substance abuse leads to increased accidents, greater risk for falls, poor nutrition, poor hygiene, increased mental health problems (e.g., depression, delirium, dementia, and psychosis), a higher suicide rate, higher risk for disease (e.g., liver disease, cancer, cardiovascular problems, and diabetes), and increased mortality. Physicians may not regularly question older adult clients about their drinking habits; moreover, if the client does disclose that he or she drinks alcohol, the physician may minimize the severity and consequences. Generally, heavy drinking is defined as 12 to 21 drinks per week.⁸³ The CAGE (acronym for its four questions) questionnaire is useful in screening for alcohol abuse.²² Effective interventions include self-help groups such as Alcoholics Anonymous, counseling, psychotherapy, and medications. Occupational therapists may ask older adults questions from the CAGE questionnaire. It is anticipated that alcohol abuse will increase in older adults as baby boomers age because this cohort has a greater history of alcohol abuse than the current cohort of older adults does.⁸³

Depression

The rate of major depression is relatively low—about 5% or less in older adults³¹ according to the DSM criteria of depressed mood and loss of interest or pleasure in activities, significant weight loss or gain, sleep disturbance, psychomotor agitation or retardation, fatigue, feelings of worthlessness, loss of concentration, and recurrent thoughts of death or suicide.

Older adults are less likely to report dysphoric symptoms or express hopelessness, both benchmarks for a diagnosis of major depression. The presence of depressive symptoms notwithstanding, a type of subclinical depression seems to increase with advancing age, especially in women and when symptom-based assessments are used. Depressive symptoms and syndromes have been identified in 8% to 20% of older community residents.^{2,27} The symptoms (associated with depression) most frequently reported by older adults are fatigue, difficulty waking in the early morning, difficulty going back to sleep, and memory complaints. These complaints are less likely to include sadness (e.g., hopelessness, worthlessness, thoughts of death, wanting to die, and suicide), but this pattern of complaints leaves the older adult at increased risk for subsequent functional impairment, cognitive impairment, psychologic distress, and death.²⁸

Suicide is a major risk in late-life depression. Caucasian men between the ages of 60 and 85 years have an increased risk for suicide, especially if they are 85 and older, have a medical illness, or live alone. Many saw their physician within 1 month of the suicide.⁸³ Mortality from other diseases, such as heart disease and cancer, has been linked to depression.

The incidence of depression in older adults may be higher than reported because of underreporting or lack of recognition.⁴⁴ Many health care providers focus on somatic symptoms and link patient complaints to a succession of physical problems without screening for depression. Risk factors for late-life depression include persistent insomnia, unresolved and untreated grief after the death of a loved one, and structural neuroanatomic changes (e.g., enlarged lateral ventricles, cortical atrophy, increased white matter, decreased caudate size, and vascular lesions in the caudate nucleus).⁸³

Depression may increase the degree of disability associated with several medical conditions and negatively affect rehabilitation outcomes. Depression may also complicate the clinical picture of dementia or cause complaints and symptoms that are confused with dementia.⁷⁰ Depression can have a major influence on the engagement of an older adult in occupational performance areas, including ADLs, IADLs, and social participation. Older adults are not likely to seek intervention for depressive symptoms, perhaps because myths about aging create the mistaken belief that depression is inevitable and justifiable. Other barriers to intervention are lack of access to care or the need to be stoic. Occupational therapists in all geriatric settings should screen for depressive symptoms in older adults if it is not being done by other health care professionals. Screening measures include the Geriatric Depression Scale⁹⁶ and the Beck Depression Inventory.⁵

Theories abound regarding the causes of depression. One theory proposes that depression is biologic in nature and may result from medications (toxicity) and certain somatic illnesses. A second theory suggests that depression is really a reaction to the stress of illness or disability. Depression can be treated successfully with medications in most cases. Clients can return to previous energy levels and again take pleasure in life. Occupational therapists can help clients regain lost occupations, develop pleasurable and health-promoting routines, learn how to reframe events, change habits of nonproductive thinking, develop social contacts, and experience success.

Anxiety

Anxiety disorders are also common in older adults, but these conditions have received much less attention. Anxiety usually begins earlier in life and infrequently in late life, the most common disorder being a phobic anxiety disorder.⁸³ Anxiety disorders may take various forms:

- Recurring, sudden episodes of intense apprehension with shortness of breath and chest pain (panic disorders)
- Fear and the disproportionate avoidance of a perceived danger (phobic disorder)
- Chronic, persistent, and excessive anxiety (generalized anxiety disorder)²⁹

Biologically based explanations for age-related anxiety suggest that it may be associated with changes in neurotransmitters, decreased noradrenergic function, side effects of some medications, and anxiety-like symptoms of medical conditions (e.g., myocardial infarction or pulmonary embolism). Worry or “nervous tension,” rather than specific anxiety syndromes, may be more important in older adults. Anxiety symptoms that do not fulfill the criteria for specific syndromes are reported in up to 17% of older men and 21% of older women.⁸³ From a psychologic perspective, older adults may in fact have a realistic basis for their anxiety.²⁹ It is not uncommon for anxiety to coexist with depression and other mental disorders.⁸³ Anxiety may be related to concerns about pain, safety, memory loss, fear of the unknown, finances, or caregivers. Anxiety may be crippling when it interferes with attention, memory, enjoyment of pleasurable events, social skills, and the ability to begin or follow through with the therapy program.

Changes in Musculoskeletal Structures and Functions

It is frequently assumed that to be old is to be weak, but this is not necessarily so. Although age-related changes do occur in the musculoskeletal system, older adults also have the capacity to maintain or even increase their strength in later years. Exercise is highly effective in older adults,⁵² as is a program of functional activity, as long as it is adapted to the client’s special needs.

Early in life the body builds bone mass, with a peak at around 35 years.^{19,75} After this age, calcium is gradually lost from the bones, which results in loss of bone strength. This condition is termed *osteopenia* when bone volume reaches below-normal levels because of bone resorption exceeding bone synthesis. This is different from *osteoporosis*, in which the reduction in bone mass is significant enough to cause fractures. Primary osteoporosis occurs when the bones become more porous but no other disease is causing this process. Secondary osteoporosis can be due to a number of different processes, including rheumatoid arthritis, diabetes, and drug use (especially corticosteroids).⁷⁵

Joints also exhibit normal age-related changes. Over time a reduction in joint range of motion of 20% to 25% can be seen.⁵² As people age, the water content in tissues, including cartilage, decreases.⁷⁵ Cartilage also becomes stiffer and has less of a cushioning effect for the joint over time.¹⁹ The cartilage surfaces become rougher in areas of each joint with the greatest stress, thereby reducing the smoothness of movement. These changes are more significant in areas of increased wear and tear, but they are even seen in sedentary individuals. At a pathologic level, articular cartilage can degenerate to such a point that pain and stiffness result, as well as impaired movement, which can be diagnosed as *osteoarthritis* (see Chapter 38 for further details). This is the case with Marie, who has osteoarthritis causing pain and

stiffness in her hands and knees. Her occupational therapy practitioner must pay close attention during treatment sessions that this condition is not exacerbated and can train Marie in the use of joint protection techniques for daily activities. Although pain and decreased joint mobility are often factors limiting a person’s function, arthritic changes can be seen radiographically in the joints, even in individuals with no other symptomatology. Changes are seen in tendons and ligaments, which also have reduced water content over time.⁵² Increased cross-linking of collagen fibers likewise occurs and can cause stiffness of the collagen. Tendon and ligament strength declines with age,⁷⁵ as does the strength of attachment to bone, which results in decreased joint stability and greater risk for injury.

In general, older adults exhibit some muscle atrophy.⁷⁵ This is due in part to age and in part to disuse, and it is difficult to distinguish the two. Some motor units and muscle fibers are lost over time, with the loss being most pronounced in fast-twitch fibers.⁷⁵ Denervation of fast fibers in aging can be followed by reinnervation from slow fibers and result in this conversion. It takes more time for older muscles to recover from use, and the recovery may not be complete, thereby resulting in decreased muscle endurance. The decrease in muscle mass and contractile force is termed *sarcopenia*,⁵² which can be a consequence of age or a disease process and result in decreased muscle power.

Changes in Cardiovascular, Immunologic, and Respiratory System Structures and Function

Although high blood pressure is a pathologic function and not part of normal aging, it is normal for systolic blood pressure to increase with age because of increased stiffness of the arteries.⁴⁰ Athletic individuals have lower systolic pressure than do sedentary individuals, but systolic pressure is still, on average, higher than that in younger individuals. Veins also dilate and stretch with age, and their valves function less efficiently,⁷⁵ so blood return to the heart is slowed down. With age the heart requires slightly longer rest periods between beats, or longer recovery,⁷⁵ which may have an impact during activities requiring a higher heart rate. The maximum attainable heart rate declines with age, though not as steeply as in those who exercise. Cardiac output is also somewhat decreased,⁷⁵ which may explain some of the fatigue felt by older adults during strenuous activities. *Arteriosclerosis* is hardening of the arteries and can occur in older persons, and symptoms may include headache or dizziness.⁴⁰ *Atherosclerosis* is a form of arteriosclerosis in which plaques decrease the diameter of the arteries.

Immunologic function is decreased at multiple levels. The thinner skin of elderly persons provides less of a barrier to infectious agents with increased risk for skin tears and subsequent infection. Fewer cilia are found in the lungs, which reduces the body’s ability to keep infectious agents

out of the lungs.⁷⁵ There is also evidence that immunity is decreased at a cellular level, with a reduction in adaptive immune responses, such as those of T cells.⁷⁵ Older adults' susceptibility to urinary tract infections is increased because of the increased fragility of the urethra with age.⁵⁹

Production of mucus in the respiratory system, which helps prevent respiratory infections, is decreased,⁷⁵ and thus older adults' susceptibility to these ailments is increased. The cough reflex is also less effective.⁷⁵ Numerous changes occur and can result in chest wall stiffness, such as kyphosis (appears hunched over), calcification of the costal cartilages, and scoliosis.⁸ This limits chest expansion and requires increased use of the diaphragm for breathing. This heightened energy requirement just to breathe can increase older adults' fatigue even when at rest or during light activities. The efficiency of oxygen–carbon dioxide exchange is also decreased because of increased residual volume in the lungs, enlarged alveoli, and fewer capillaries.⁸

Areas of Occupation

Activities of Daily Living

ADLs have been discussed throughout the chapter as different areas of functional decline have been reviewed. One area of dysfunction is the urinary tract system, which results in incontinence. Incontinence is a problem that is difficult to talk about but frequently experienced. However, treatments are available. The likelihood of incontinence increases with older age, although it can be experienced at any age. It is often viewed as a concern for women, but men experience it as well. Clients may not bring up this problem on their own, but it can be broached in a sensitive manner by the therapist. Treatment sessions can address management of the incontinence, but referral can also be made to specialists who work in this area.

Weight loss is a trigger to assess multiple areas of occupation to see what may be contributing to the problem. An individual who has been losing weight could have difficulty chewing because of poor dentition or ill-fitting dentures, swallowing, or feeding, and an occupational therapist or speech therapist may be able to help remedy the problem. However, older adults may also be losing weight because of difficulty preparing meals, transporting food within the kitchen, grocery shopping, or getting to the store or restaurant or because they do not like eating alone but have become isolated during mealtime. They may also have difficulty sitting comfortably at the table or maintaining an appropriate posture for feeding and eating.

Functional mobility should always be assessed carefully because many older adults experience changes in this area. Falls frequently take place during the course of routine daily activities, such as entering the bathroom or putting dishes away in the kitchen. Marie fell while reaching for a towel, an activity that she performed every day. Over the course of time, however, this familiar activity had indeed become

dangerous as Marie experienced a decline in her balance and more arthritic pain in her knees. Marie had not adapted her techniques for functional mobility as her abilities changed, which placed her at higher risk for falls and injury.

An older adult may use an assistive device for mobility, although it may not be used all the time. Sometimes individuals are self-conscious in public and may use a cane or walker only at home. Others feel comfortable walking in their home environment or using the furniture to help maintain their balance at home but will use a device when walking long distances. It is important to ask each client about a variety of situations to ensure an understanding of how the client maneuvers in different settings.

Older adults are more likely to have a number of assistive devices. Hearing aids, glasses, shoe orthotics, reachers, and many other devices may be part of the daily routine for an older adult. Care of these items may become more difficult as clients experience changes in their body structures and functions. For example, manipulation of a hearing aid for cleaning may become difficult, and the client may fear dropping it. Declines in vision that require glasses may make it more difficult to see when the glasses are dirty or whether the prescription needs to be adjusted. It is important to not only ask about but also observe a client caring for personal devices to accurately determine when intervention is necessary.

Personal hygiene and grooming can become more difficult in later years because of potentially impaired sensory functions and range of motion. For example, it is difficult to pluck a whisker when it cannot be seen or to trim toenails when clients cannot reach their feet. However, just because grooming is difficult does not mean that it is not important to an individual. An occupational therapist can go through the grooming routine and needs with clients and help them identify alternative strategies to accomplish these tasks. Marie's occupational therapist made a recommendation for using a magnifying mirror with a light so that Marie could see better to apply her makeup. Marie's therapist also worked with her to find grooming tools, such as a hairbrush and a toothbrush, that had wider handles to reduce the pain in Marie's hands and improve her grip during self-care. Toilet hygiene may also become challenging, and an apparent lack of hygiene may be due to difficulty performing the task rather than inattention or lack of caring.

Older adults may still be sexually active. This is an important area of human interaction but also a very sensitive one to discuss. Many conditions that older adults may experience can affect their sexual activity. Individuals who have just suffered a heart attack may be concerned about whether their cardiovascular system can handle the stress of sexual activity, or a person who has just undergone a hip replacement may wonder whether there are any safe positions that will not endanger the healing hip. This may be a difficult subject for a client to bring up, so a comprehensive occupational therapy program will include questions to broach the subject, should the client wish to discuss such

concerns (please see [Chapter 12](#) or individual chapters addressing the aforementioned diagnoses for more detailed discussion).

Instrumental Activities of Daily Living

Older adults often provide care for others, be they a spouse, a grandchild, a pet, or a friend. Health events can interrupt clients' performance of these activities and even cause them to question long-held roles. Rehabilitation care is often focused on a client's ability to maintain self-care, but it is imperative that the occupational therapist understand other potential caregiving roles in the client's life. Treatment can then incorporate a focus that helps the client return to independence in care of others or find ways to adapt these tasks or seek assistance.

Community mobility can be a very sensitive subject for many older adults who are used to being independent in getting where they want to go when they want to go there. Driving can become more difficult for many different reasons, from visual impairment to cognitive deficits and limited range of motion. The occupational therapist is often called on to assist in evaluating whether an older adult is still safe to drive. There are driving specialists, many of whom are occupational therapists, who can assess everything from the fit between client and car to whether the client demonstrates safe skills for on-the-road driving. In many situations, referral to one of these specialists is appropriate. Some older adults, such as Marie, have already curtailed driving but may not be aware of other community mobility resources, such as public transportation or low-cost van service. In Marie's town there was a senior services van that provided low-cost, conveniently scheduled transportation to locations within the city limits. Marie's occupational therapist helped teach her how to sign up for and use this van, which helped Marie regain independence within her community. When assessing other areas of occupation, such as religious observance or shopping, it is important to also assess community mobility. Participation in some areas of occupation may have declined simply because it has become too difficult to get to the necessary location.

A comprehensive occupational therapy program will address safety and emergency maintenance. This includes preparedness, such as having a list of emergency contacts near the phone and the client carrying a cordless phone at home. Especially for older adults, this also includes knowing what to do in case of a fall. Training in how to fall, how to assess oneself after a fall, and how to safely maneuver on the ground and call for assistance is invaluable for an older adult and can be taught by the occupational therapist or assistant.

Community-based occupations, such as going to the pharmacy, out to eat, or to the grocery store, can be intimidating to an older adult who has experienced a health event. In some rehabilitation settings it may be possible to work with the client in actual community settings to help restore

both independence and confidence. Marie and her occupational therapist used the senior van service to take a trip to the grocery store, where Marie had a chance to implement the joint protection techniques that she learned in the clinic within a real community setting. Even when such outings are not possible, treatment within a facility can and should replicate components of these occupations.

Rest and Sleep

Sleep can be a difficult area of occupation for older adults, partially in light of the natural changes in body structure and function. However, it may also be due to occupational imbalance and can be addressed by the occupational therapist. Assessment of sleep preparation includes whether clients can make their bed, close the curtains so that early morning light does not awaken them, and lock the doors to feel secure. Assessment of sleep participation includes whether the client can use the bathroom during the course of the night or monitor the safety of a spouse who might wander during the early morning. These areas are very appropriate for an occupational therapy treatment program to address.

Work

Although many individuals retire at the age of 65, many are also still employed. When performing an initial evaluation it is important to ascertain the client's employment status and to be prepared to address the area of work in treatment if it is still part of the client's life. Volunteer work is also often part of an older adult's repertoire of occupations and is just as important as paid employment. Paid and volunteer work may present the need to do on-site community evaluations so that the client can prepare for re-engaging in these occupations. The occupational therapist may also be called on to help the client in retirement preparation or adjustment so that the transition is as smooth as possible.

Leisure

Leisure activities are an important part of daily life for older adults. However, they can be difficult to address directly in treatment because of many third party payer restrictions regarding treatment goals. Nonetheless, it is often possible to incorporate a client's leisure interests into treatment activities to enhance participation and carryover, even if there is no direct goal for these activities. In the skilled nursing environment, it may be possible to design a functional maintenance program for a client that involves recreation activities to address particular functional or treatment goals as well (see [Chapter 16](#) for more information).

Social Participation

Engaging in activities with others is critical for older adults but can also become more difficult. Changes in transportation options can affect whether a person can participate in community activities, as can concerns about whether a

location has adequate lighting, handrails to help with balance, crowds that may jostle the older adult, accessible bathrooms, or easily understood directions and instructions. The occupational therapist can be of particular assistance in assessing a community environment and making recommendations for adaptation to promote the participation and independence of older adults. Incorporation of family and friends into treatment, as directed by the client, can also help ease concerns about what a client can safely do and can often support increased client participation in social activities.

Two well-known studies, the USC Well Elderly Study^{16,35,54} and the Wellness Program for Older Adults,⁵⁵ have demonstrated that occupational therapy intervention that addresses prevention efforts for older adults living in the community enhances ADLs, IADLs, physical and mental health, occupational functioning, and life satisfaction. Because occupational therapists and assistants play a role in the very personal aspects of an older adult's life, they can address modification of components of occupations that are important to an older adult either in a group setting or in individual treatment before it becomes problematic for the older adult. This can be done through a community model and results in an overall increase in participation by older adults and an increase in quality of life.

Intervention

The intervention process involves teaching and learning. Adults have specific learning needs. Integrating the learning needs of an older adult into the intervention will increase the effectiveness of the teaching session. Some of the assumptions in the following list are related to adult learning and are pertinent to occupational therapy intervention:

- Adults need to understand the reasoning behind the learning.
- Adult learners bring a breadth of experience and knowledge to learning situations.
- Adults are willing and ready to learn whatever is necessary.
- Adults are typically pragmatic and willing to learn things that will help them in day-to-day experiences.
- The greatest motivator is internal pressure.

In addition to the preceding principles, it is important to remember the following when working with older adults⁴⁸:

- Processing of information takes longer than it does for younger adults.
- Elaboration of information involves making connections between the new information and building on or making additional associations to existing knowledge.
- Strategies that group information in an organized way promote effective storage.

- Attending to the internal and external contextual factors during the learning process and recreating these contextual factors for later retrieval significantly improve remembering.
- Using stored information repeatedly strengthens the pattern of connections by rehearsing, using, and practicing.
- Providing cues that offer opportunities for recognition or matching information with previously learned information is more effective than not providing external associational cues and expecting free recall of information.

Knowles also recommends an environment of mutual trust, respect, and acceptance of differences.⁴¹ During initial contacts with an older adult, the therapist must take the time to listen to and get to know the client. By the time that intervention begins, the occupational therapist will have an understanding of the client's learning style, deficits that may require specific types of teaching, and any cognitive or perceptual deficits that should be considered. The pace and style of the intervention will be individualized to suit the client's learning needs.

There is great heterogeneity within the older population. Although many older adults experience changes in their body structures that have an impact on their function, whether a particular individual is affected and how much vary. For example, many older adults are not as strong as they were in younger years, and some may even be experiencing difficulty performing daily activities, such as lifting grocery bags, because of weakness. However, there are also some older adults who have maintained excellent strength through either an exercise program or their normal regimen of functional activities. It is important to assess an older client's status rather than make assumptions about it and to use this information to guide treatment.

Each older individual has lived a long life, rich with experience. This experience should be respected during intervention. Even though the therapist assesses strengths and challenges and designs a treatment plan that helps clients progress toward their goals, clients are still the best judge of what fits within their own life. For example, older adults have for many years been putting shoes on a certain way or walking a certain path from the bed to the bathroom. They may also have already developed their own adaptive techniques for accomplishing tasks that have become difficult, such as sitting on a chair to don shoes. Sensitivity must be used when recommending changes in the environment or behavior. The occupational therapist can certainly teach clients the safest and most efficient manner to perform an activity. However, although a client's particular technique for accomplishing a task may not be optimal, care should be taken to assess whether it is still functional and safe.

Treatment activities should always be age appropriate. Many older adults enjoy treatment activities that are fun

and playful, including games and crafts. These activities should be assessed carefully, however, to be sure that they are appropriate for each individual client. While searching for occupations that present just the right challenge for the client, it may be tempting to use tasks that meet most specifications for treatment but may also be demeaning. If an older adult complains that an activity is childish, significant benefit from participating will probably not be achieved. The match between client and intervention task is especially important for members of this age group. Working with the client during the problem-solving phase of treatment also enhances an older adult's self-esteem and problem-solving ability. It also brings into play the years of experience that an older adult has gained and can be accessed in problem solving.

Older adults require more time for recovery during and between activities. This is important for muscle and cardiac function since, for example, the heart requires longer recovery time between beats. Especially during activities causing a high heart rate, the client's response to treatment should be closely monitored. It is not usually necessary to forego desired activities, but it is often a good idea to have more rest time built in to treatment and to train clients to do so in their daily repertoire of occupations.

Threaded Case Study Marie, Part 2

At the facility where Marie was staying there was a weekly "Ladies' Tea" organized by the recreation department. Small desserts were served along with tea, and Marie liked to attend the group. As part of her occupational therapy treatment program, Marie would come down to the rehabilitation kitchen the morning of the tea to bake some homemade cookies for the ladies. She initially had to sit for most of the activity and reported discomfort in her hands when mixing the cookie dough and manipulating the trays. Marie gradually began to incorporate more standing and walking into the activity as her strength increased and she learned to carry items while using her walker. Her occupational therapist taught her joint protection techniques to care for her hands and wrists while still participating in an activity that she enjoyed, and Marie became able to mix the cookie dough without experiencing hand pain. Becoming independent in all these techniques required repetition, but Marie did learn through the weekly guided participation. Marie also began to understand how important her upcoming cataract surgery was because she was having more and more difficulty seeing the ingredients with the glare in the kitchen from the lighting.

Coping

One of the critical components of processing life and changes—especially changes in health or changes in environment—relates to coping style. The emphasis is less

on context and more on how the older adult deals with the reality of a situation. Older adults typically have a well-established style of coping, and regardless of whether their style may be effective or ineffective, it should be considered a client factor that is taken into account for effective treatment.

In assessing the coping abilities of an older adult, the occupational therapist should look at client factors, which are defined by the practice framework as specific abilities, characteristics, or beliefs.³ Areas to consider are emotional stability, information-processing skills, body structure, and physiologic competence, as well as overall health and fitness. All these components that make up the whole person can affect how the person copes. Historical events may have played a significant role in the extent and coping abilities that have been developed and may now need to come into play. Older adults currently still reflect a cohort that has experiences related to World War II, the Korean Conflict, and the Vietnam War. Some older adults lived through the Depression and may have been part of the social upheaval and sociologic changes of the 1960s and 1970s. As a group, older adults have seen wide-sweeping political, social, cultural, economic, and technological changes in their lifetime. Some of the old support systems such as an extended family have changed for many older adults, whereas others have taken new caregiver roles within the extended family that were not prevalent in previous generations—such as parenting grandchildren.

New support systems have become available that this population may not be aware of. One group of support systems uses technology and the Internet extensively. Some older adults are very technologically advanced, whereas others are technologically challenged. Because we are rapidly becoming a technology-based information culture, those who have difficulty accessing the information available on the Internet may not be able to access many of the support systems that have been developed.

Many theories related to coping have been proposed, and the important concept for therapists to remember is that each person has a unique coping style. Tapping into that style will help in all areas of treatment and provide better compliance with planned treatment sessions.

Caregiving

Caregiving is the act of providing care to individuals who for any variety of reasons are unable to care for themselves. The care is often provided to family members or to a significant other. The current cohort of older adults is engaged in a variety of caregiving situations that are part of their occupational identity. Caregiving as an older adult often occurs when a loved one has physical or mental health issues and needs support. Spousal caregivers were found to spend more hours per week caregiving, were caregivers for a longer period, and had a smaller group of people helping them in the caregiver role. In addition, more stress and burden were

reported in this group of caregivers.²⁵ It should also be noted that for other caregivers, the opportunity provides them with an increase in well-being because of their caregiving role.²⁰

A phenomenon that has increased in the past decade is grandparents taking on the responsibility as primary caregivers for their grandchildren. A consideration in all of this is the health of the caregiver. If the caregiver has a disability, it can interfere with the ability to provide care to the dependent person.⁸⁰

Frequently, when health care resources are sought, the health of the caregiver goes unnoticed or considered.⁶⁶ One group of caregivers who are often not addressed and may be involved in occupational therapy treatment are older adults who have children with developmental disabilities. These caregivers have been involved in lifelong caregiving and now may be faced with their own physical and mental challenges. Their occupations associated with caregiving need to be evaluated and options need to be explored that may be more complex than those related to caregivers who are new to the role of caregiving.¹⁰

It is vital for the occupational therapist to be aware of the context, environment, and the requisite occupations that a caregiver may be engaged in. Therapy should involve providing resources that address the emerging needs of the caregiver. Such resources may include referral for counseling, respite resources, or assessment of coping skills and treatment to address prioritizing to better meet the demands.

Aging in Place

Most older adults would prefer to age in place. Home is more than just four walls and a roof. It is a place rich with a variety of meaning attached to the surroundings. These surroundings include the personal objects and the surrounding areas that have meaning and an accumulation of memories that are attached to the familiarity of the personal environment.^{3,42,72,73} Given the option, 91% of adults aged 65 to 74 would prefer to stay where they are. Aging in place helps one maintain control, independence, and privacy—all of which are concerns to older adults.^{68,69} Wanting to age in place is based on the accumulation of memories, habits, roles, and routines, or what may be described as the context or environment. Because many older adults want to age in place, a number of excellent Web-based resources with a primary focus on older adults are available. These resources can be used to gain more depth into the ramifications of aging in place and treatment strategies. A growing number of developers and contractors use universal design in new construction and have an overall goal of creating aging-friendly communities, places where all areas of the community are accessible and user-friendly for older adults and people with disabilities. Many more alternatives are available for older adults to age in place, with the idea being that aging in place relates to the preferred place of residence. The environment, when modified to address a good

person-environment fit, can increase or maintain an older adult's occupational participation. It may be in a single-family dwelling, an apartment, or an assisted living senior complex or with family.^{43,51,56,67}

Until more residences incorporate universal design, evaluations for home modification will continue to be an important part of occupational treatment. Whether it is an actual on-site evaluation or a review of the home and community by report, evaluation of context is important when looking at the whole person.

When evaluating barriers to aging in place it is critical to understand the client factors, the activity demands related to older adults, their performance skills and patterns, and how they all dynamically relate to where an older adult lives.³ The physical features of the place of residence itself, as well as the physical features of the surrounding area, need to be understood. In addition to the physical aspects, the contextual support systems themselves need to be taken into consideration. Some of the key issues that an occupational therapist should consider when assessing this complex relationship are (1) whether older adults can participate as fully as they choose to in this context, (2) whether this environment is safe, and (3) what modifications are needed in how the older adult functions (accommodation), in the environment itself (modification), or in the support systems that are in place or could be put into place (accommodation and modification).⁵⁶

Despite the fact many older adults have a number of chronic conditions, the key to successful aging rests not in longevity or decreasing the chronic conditions but in the capacity to participate and function successfully as circumstances in life change.^{34,72,73} Of the many disabling conditions that may keep a person from aging in place or the combination of several disabling conditions, one that may have the most impact is cognitive decline and an inability to remain safe and independent. Pain can also decrease mental flexibility, which includes immediate and delayed memory, as well as language; it can also decrease physical functioning.^{37,93} Depression can influence cognitive processing and has been associated with cognitive decline.⁹⁵

Another disability that may have an impact on the ability to age in place is a decrease in visual skills. The most common forms of visual impairment are decreases in visual acuity, decreases in contrast sensitivity, increases in sensitivity to glare, decreases in adaptation to the dark, and visual field cuts. Because the visual tracts interface with so many areas of the brain, any process that affects the brain can affect vision (see [Chapter 24](#) for more details). When assessing an older adult's vision, the occupational therapist needs to take into consideration all these areas to get an accurate picture of the person's ability to see.

When performing a home evaluation, it is important to look at the fit between the person and the environment and then consider what modifications or what services can help a person age in place. It is also critical to look beyond the

physical and cognitive to the psychosocial, financial, and support-related change.

An occupational therapist may consider any of a number of home evaluations. Some of the home evaluations are based on performance and some are based on the physical characteristics of a home only. Psychometrically sound evaluations include the Safety Assessment of Function and the Environment for Rehabilitation,⁴⁵ the In-Home Occupational Performance Evaluation,⁷⁹ and the Home and Community Environment assessment.³⁹

Safety when functioning in the home is a primary concern and should be addressed on multiple levels. Common factors to ascertain include whether sufficient lighting and contrast are available for the older adult to be able to see, whether the home is in good repair, whether the person can move around the environment successfully, whether the neighborhood is safe, and whether the older adult is cognitively intact to understand whether risks are present. Once the physical portion of the home evaluation is completed with the particular client in mind—including abilities and inabilities—it is time to address components that are important to aging in place that can be considered part of the extended context of the environment. What services are available in the community? How can the person access these services? Is the person willing and able to access them? Is the person socially isolated? Does the person drive despite not being able to see well enough or not being cognitively intact? Can modifications be made to the routine that will keep the client safe and socially connected? What are the client's social supports? These are just a few of the many questions that a therapist needs to start asking when evaluating a client with regard to aging in place. Because the older adult population is the most diverse, treatment and evaluation must be just as diverse and unique.

Wellness and Aging

Since the beginning of the 20th century, more and more of the population have had increases in life expectancy. Consequently, more emphasis has been placed on healthy or productive aging, not just by scientists but also by policy makers and the public at large. With some creativity, there are many opportunities for occupational therapists to work with older adults and make sure that they are aging in a healthy way. Occupational therapists should work with older adults on all aspects of their lives so that they are ready to face the challenges ahead as they work to age in place and participate fully in life until the very end. As more and more people advance to old age, more emphasis has been placed on research to understand the aging process and debunk the myths of aging.^{14,60}

Because occupational therapy views the person in a holistic manner, it is well within the scope of practice to address wellness and aging. Emerging practice areas are looking at promotion of health on the individual and group level. The

basic tenets of occupational therapy have always helped people identify, realize, and change either the person or the environment in an effort to enhance quality of life.⁹² Provision of services will most likely be in the community. Senior centers, as well as community centers, may provide an excellent venue for new innovative programs. The USC Well Elderly Study^{16,35,54} demonstrated in a dramatic way that occupational therapy intervention based on sound occupational science principles was more effective than other types of group activities and beneficial overall to older adults. These findings, as well as those of Matuska and colleagues,⁵⁵ should encourage every occupational therapy practitioner to address wellness in older adults so that overall quality of life is enhanced. Occupational therapy's emphasis on occupation has a positive effect on the day-to-day functioning of older adults as they age, no matter where they are aging. It addresses all the components that make one a human being.

Summary

The older adult population, which is the most diverse population with whom occupational therapists and assistants work, is the most challenging but equally rewarding group to engage in treatment. Older adults bring a lifetime of experiences, habits, ideas, and problem-solving strategies to the occupational therapy process. They may also bring the experience of functional decline as a result of aging factors, the cumulative effects of a lifetime of habits and experiences, and the possibility of the impact of a variety of chronic and acute diseases.⁶ Evaluation and treatment need to be comprehensive and thorough while taking into consideration the physical, cognitive, and psychosocial components of the older adult. The occupations and roles that are a part of who an older adult is may strengthen the ability to adapt to the current situation that has brought the person into contact with occupational therapy. These same occupations and roles may be the cause of the inability to function and participate at the level that is required or desired by the older adult and his or her support system. The occupational therapist or assistant is in a position to work with the older adult in a respectful and rehabilitational way so that quality of life may be increased and maintained.

Review Questions

1. Describe four keys of treatment to enhance participation by an older adult with low vision.
2. Name three cognitive changes associated with aging, and provide three strategies to enhance the learning of new information.
3. List five age-related physical changes that a therapist would consider in a client who is 80 years of age.
4. Identify areas of occupation to assess whether an older client has recently had significant weight loss.
5. Describe three key considerations when assessing an older adult's home for the potential to age in place.

Threaded Case Study

Marie, Part 3

Marie's occupational therapist was concerned that Marie had retreated from activities outside the home, even those that she had really enjoyed. The therapist drew on Marie's love of young children and the arts and proposed that she try reading to preschoolers at the day care located next door to the skilled nursing facility. Marie thought that this was a good idea and began working toward it. She and her therapist first found that the distance needed to walk to the day care center was still too far and that it would be difficult to maneuver around obstacles on the way and on uneven surfaces. While Marie was working on her ambulation in physical therapy, she could also work on her balance in occupational therapy. Given Marie's love of big band music and tapping into her previous experience, dancing, Marie began to swing-dance in her occupational therapy sessions. At first it was very slow and stepwise, but over time Marie was able to improve her balance and speed and was eventually able to dance the basic steps in time to music with her therapist.

Once Marie was able to get to the day care center, her occupational therapist taught her how to assess her environment for safety and how to pace her activity so that her chronic obstructive pulmonary disease was not exacerbated. By choosing children's books that already had large print and making sure that she had the best light source possible, Marie was able to read to the preschoolers and enjoy a new activity that incorporated previous interests. Marie made arrangements with the preschool to continue coming once a week and to use a senior transport van service to get there after her discharge from the skilled nursing facility.

By the end of Marie's treatment program, she had regained independence in her ADLs and basic IADLs, including baking cookies for her neighbors. She was participating in a weekly activity that would get her out of the home and challenge her with a longer walking distance, thereby providing a functional maintenance program that went beyond exercise. Discovering that she was able to maneuver successfully in the community, Marie also expressed plans to resume going out to eat with her daughter.

HIV Infection and AIDS

MICHAEL PIZZI
GRAHAM TEAFORD

■ Chapter Outline

Origins and current status of HIV infection

Infection process

Transmission

Diagnosis

Pharmacology

Aging and HIV infection

Neurologic sequelae of HIV/AIDS

Neuropathies

Dementia

Early stages of AIDS-dementia complex

Later stages of AIDS-dementia complex

HIV/AIDS pathologies—client factors

Positive prevention

Assessment

Intervention

Prevention of disability

Education and health promotion

Maintaining and restoring performance

Modifications, adaptations, and compensatory approaches to intervention

Advocacy and psychosocial considerations

Summary

Review questions

■ Key Terms

AIDS-defining condition

AIDS-dementia complex

Acute HIV infection

Highly active antiretroviral therapy

Opportunistic infection

Retrovirus

Seroconversion

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Understand the stages of HIV and AIDS.
2. Describe the impact of medical interventions on HIV.
3. Describe how to assess a person with HIV or AIDS holistically.
4. Identify occupational therapy interventions directed toward optimizing health as an occupational participation.
5. Understand the importance of a health promotion and prevention perspective in occupational therapy services for people with HIV and AIDS.

Threaded Case Study
Billy, Part 1

Billy is a lawyer and internal medicine physician living with Tom, his partner of 15 years. The mode of infection for Billy is unknown, and he has lived for more than 20 years with a diagnosis of HIV infection. Billy has been practicing medicine successfully, as well as doing pro bono work as a legal advocate for people infected with HIV and with AIDS. He began highly active antiretroviral therapy approximately 15 years earlier. His CD4⁺ count has remained above 500, and he has not had any opportunistic infections. He continues to be active in his career as a physician and with his pro bono legal work.

He has recently noticed that he has more difficulty with his memory, decreased fine motor coordination, difficulty coordinating his movements, burning sensations in his hands and feet, and lower extremity weakness. These changes have had an impact on his life in a variety of ways, such as difficulty remembering his appointments, taking his medications as scheduled, writing, and awakening at night because of pain.

During the course of developing an occupational profile, he stated that his primary concerns involve how these changes have affected his professional activities. He values his roles as both physician and attorney, as well as his paid employment and his pro bono work. His work has been affected by his diminished writing (requiring more time and effort to write legibly) and his pain (limiting his rest and causing him to have difficulty concentrating on work tasks). However, he is most concerned with his changes in memory because it has caused him forget appointments and miss deadlines, has compromised the quality of his work, and has placed his professional competence and identity at risk. This deficit became his greatest concern because of his pride in having what he calls a “mind like a steel trap.” As a health professional, Billy possesses the knowledge required to care for his own health and well-being; however, he does not apply this knowledge to his own daily life. His partner, though supportive, is becoming increasingly angry, irritable, and concerned, and these emotions appear to have impaired his own occupational performance in work, home, and leisure occupations.

Origins and Current Status of HIV Infection

An estimated 33.4 million people globally are infected with human immunodeficiency virus (HIV) or have acquired immunodeficiency syndrome (AIDS).⁴⁵ Approximately 2 million people die annually of HIV/AIDS, and each year an estimated 2.7 million new HIV infections occur. At least 25 million people have died of HIV/AIDS since the earliest cases of HIV infection were detected.

HIV appears to have originated in Africa; although the exact date of origin is uncertain, the virus has been present

TABLE 47-1 | Distribution of the Estimated Number of Diagnoses of AIDS in Adults and Adolescents by Exposure Category through 2007 with a Breakdown by Sex When Appropriate

Exposure Category	Male	Female	Total
Male-to-male sexual contact	487,695	—	487,695
Injection drug use	175,704	80,155	255,859
Male-to-male sexual contact and intravenous drug use	71,242	—	71,242
Heterosexual contact	63,927	112,230	176,157
Other (includes hemophilia, blood transfusion, perinatal, and risk not reported or not identified)	12,108	6,158	18,266

From Centers for Disease Control and Prevention: Basic statistics, 2007, retrieved May, 1, 2010, from <http://www.cdc.gov/hiv/topics/surveillance/basic.htm#exposure>.

in Africa since at least 1959¹¹ and possibly decades earlier.⁴⁶ The virus is thought to have reached Haiti in approximately 1966. HIV probably migrated to the United States as early as 1969 and has since spread globally.¹⁹

The earliest cases of what is now known as HIV infection were identified in the United States in 1981.⁶ These initial cases of AIDS in the United States were concentrated in men having sex with men, injection drug users, and persons receiving contaminated blood supplies (from transfusions or clotting factor for persons with hemophilia). By 1983, HIV, the virus that causes AIDS, was identified.¹¹ It soon became apparent that HIV is spread by contact with specific body fluids (including blood products, semen, and vaginal fluids). The eventual discovery of HIV as a virus made it apparent that AIDS does not discriminate between genders (Table 47-1), race (Table 47-2), culture, sexual orientation, or age (Tables 47-3 and 47-4). HIV affects all of humanity. It affects not only the people infected with the virus but also their parents, siblings, friends, lovers, children, and coworkers. After a diagnosis of HIV positivity, an individual can be immobilized and drastically alter his or her occupational performance and participation in society, or the individual can treat the diagnosis as an impetus to act in positive, life-transforming ways.

The majority of global HIV cases are caused by exposure to HIV type 1 (HIV-1), with HIV type 2 (HIV-2) being much less common and primarily found in western Africa.

■ **TABLE 47-2** | Estimated Cumulative Cases by Race/Ethnicity

Race or Ethnicity	No. Cumulative Cases Through 2007
White, not Hispanic	404,465
Black, not Hispanic	426,003
Hispanic	169,138
Asian	7,511
Native Hawaiian/ other Pacific Islander	721
American Indian/ Alaska Native	3,492

From Centers for Disease Control and Prevention: Basic statistics, 2007, retrieved May, 1, 2010, from <http://www.cdc.gov/hiv/topics/surveillance/basic.htm#exposure>.

■ **TABLE 47-3** | Estimated Cumulative Cases by Age at Diagnosis

Age (yr)	No. Cumulative AIDS Cases through 2007
<13	9,209
13-14	1,169
15-24	44,264
25-34	322,370
35-44	396,851
45-54	176,304
55-64	43,451
≥65	52,409

From Centers for Disease Control and Prevention: Basic statistics, 2007, retrieved May, 1, 2010, from <http://www.cdc.gov/hiv/topics/surveillance/basic.htm#aidsage>.

The global patterns of the HIV epidemic are complex and vary greatly by region and within different regions. The 2008 United Nations Global AIDS Report⁴⁵ identifies a number of trends:

- The estimated annual number of new infections globally declined from 3 million in 2001 to 2.7 million in 2007.
- An estimated 2 million people died of AIDS in 2007, an increase from an estimated 1.7 million in 2001.
- Half of all persons infected with HIV are women.
- Young persons (15 to 24 years of age) account for an estimated 45% of new HIV infections globally.

■ **TABLE 47-4** | Distribution of Estimated Number of Diagnoses of AIDS in Children* by Exposure Categories

Exposure Category	No. AIDS Cases Through 2007
Mother with or at risk for HIV infection	8,434
Hemophilia/coagulation disorder, receipt of blood transfusion, and risk not reported or not identified	775

*The term *children* refers to persons younger than 13 years at the time of diagnosis.

From Centers for Disease Control and Prevention: Basic statistics, 2007, retrieved May, 1, 2010, from <http://www.cdc.gov/hiv/stats.htm#cumaid>.

- Sub-Saharan Africa is the region most affected by HIV and accounts for 67% of the global total of persons infected with HIV. It is difficult to overstate the social, economic, and human costs that the HIV pandemic has had in sub-Saharan Africa. For example, in Swaziland, the life expectancy fell by half (to 37 years of age) between 1990 and 2007. Swaziland has an estimated adult HIV prevalence of 26%. Overall, 1 in 20 adults in sub-Saharan Africa are estimated to be infected with HIV. The number of children younger than 18 years orphaned by AIDS in sub-Saharan Africa has increased from 2 million in 1995 to nearly 12 million at present.
- In Asia, HIV epidemics in Indonesia, Vietnam, and Pakistan are growing rapidly. The number of persons infected with HIV in Vietnam doubled between 2000 and 2005. New infections are also increasing, though at a lower rate, in Bangladesh and China.
- Infection rates in eastern Europe and central Asia have also increased. The total number of persons with HIV infection in this region is highest in the Russian Federation. HIV infection rates in the Ukraine are increasing at a particularly rapid pace, with new annual infections doubling between 2001 and 2007.
- Infection rates have been stable in the United States but have increased in western Europe.

Severe social consequences have accompanied the current global HIV pandemic (with a disproportionate impact on sub-Saharan African nations). The financial costs to nations include the loss of productive members of society facing life-threatening illness, lowering of overall life expectancy, a growing number of orphans in many countries, and a significant number of persons who are socially marginalized because of bias and discrimination. The increased financial expenses required to address HIV infection consumes the limited social resources needed to meet the urgent health

demands and places an additional burden on many countries. The social costs of HIV infection are more difficult to assess but cause significant hardships globally.

Even though pharmacologic advances have helped extend the life expectancy of persons infected with HIV, improved immune functioning, and delayed the progression of HIV to AIDS, significant barriers to receiving treatment still remain in many countries. considerable progress has been made in recent years in improving the availability of medications in middle- to low-income nations. However, the available supply of medications does not meet the current demand for medications in low-income nations. Additional barriers in accessing these medications include fragmented health care delivery systems, limited HIV testing, and various forms of discrimination.

Currently, an estimated 1.1 million persons in the United States have diagnosed or undiagnosed HIV/AIDS.¹³ An estimated 20% of persons infected with HIV in the United States are unaware of their HIV-positive status. The Centers

for Disease Control and Prevention (CDC) estimates that more than 50,000 new cases of HIV infection occur in the United States each year. The number of new infections per year (incidence rate) has remained relatively stable in recent years. However, the number of persons living with HIV (prevalence rate) has continued to grow as mortality rates from HIV have decreased, in large measure as a result of available and effective antiviral medications (Figure 47-1). The current demographic trends in the United States have changed since the earliest years of the pandemic.

Although overall rates of new infections have been relatively stable in the United States, certain groups are at greater risk for HIV infection and bear a disproportionate burden of HIV. Among different ethnic groups, African Americans are the most disproportionately affected population in the United States. African Americans represent approximately 12% of the U.S. population but account for nearly half of all new infections and nearly half of all persons living with HIV. African American women are six times

■ CDC. HIV prevalence estimates- United States, 2006. MMWR 2008;57: 1073-1076

FIGURE 47-1 Incidence and prevalence rates of HIV infection in the United States.

(From Centers for Disease Control and Prevention: Available at: <http://www.cdc.gov/hiv/topics/surveillance/resources/factsheets/images/graph-lg.gif>. Accessed July 2011.)

more likely to be newly infected with HIV than white women and nearly four times more likely than Hispanic/Latina women. African American men are approximately six times more likely to be newly infected with HIV than white men and nearly three times more likely to be newly infected than Hispanic/Latino men. It is estimated that HIV infection will be diagnosed 1 in 16 African American men at some point in their lives.²⁴

Hispanics/Latinos are also disproportionately affected by HIV in the United States. The rate of new infections in Hispanic/Latino men is more than double that of white men. Hispanic/Latina women are nearly four times more likely to be newly infected with HIV than white women. Hispanic/Latino persons represent approximately 15% of the population of the United States but account for an estimated 17% of new HIV infections and 17% of persons living with HIV. Infection incidence rates in both African American persons and Hispanic/Latino persons have been stable since the early 1990s but remain unacceptably high.

The earliest cases of HIV infection in the United States, though having a broad impact on society, were concentrated in white males.⁶ In contrast, current infection patterns in the United States demonstrate changes in the groups currently at risk, as well as underscore the fact that HIV infection is not a concern of only one ethnic group. Current HIV infection rates by ethnicity are as follows: black, 45%; white, 35%; Hispanic/Latino, 17%; Asian/Pacific Islander, 2%; and American Indian/Alaskan Native, 1%.

Although men having sex with men remain the highest risk group by type of exposure to the virus, rates of heterosexual transmission has increased in recent years. Current HIV infection incidence rates by transmission categories are as follows: men having sex with men, 54%; heterosexual contact, 31%; injection drug use, 12%; and men having sex with men and injection drug use, 4%. Men are nearly three times more likely than women to be newly infected by HIV when examining infection rates by gender in the United States.

The course of the HIV pandemic has changed significantly with the advent of effective medical treatments. For persons with access to effective medications, management of HIV has, to some extent, changed the focus of medical management to the chronic medical needs of persons with HIV infection rather than more acute management of opportunistic infections. In the earliest years of the pandemic, before effective pharmaceutical treatment, death typically occurred within 10 years of HIV infection and 1 to 2 years after the onset of AIDS.²⁸ Mortality rates and the frequency of opportunistic infections have decreased significantly in recent years. However, this also presents public health concerns. The health delivery model in the United States is not always effective in addressing the increasingly chronic needs of persons infected with HIV rather than the more acute cases that were more common in the earlier years of the pandemic.¹⁴ Occupational therapy (OT)

practitioners can potentially play a significant role in the promotion of health and management of chronic medical needs to ensure that persons remain active participants in meaningful occupations.

Infection Process

HIV is the virus that causes AIDS¹¹ and belongs to a class of viruses known as retroviruses. Retroviruses share a unique process of replication characterized by the viral genetic material being encoded by RNA rather than DNA. Retroviruses, including HIV, replicate as viral RNA is transcribed into DNA in the host cell. The cellular process is complex, with many components and processes occurring. The following is a simplified description of the infection process.

The process begins as the virus binds to a cell surface receptor.³¹ During the attachment phase, HIV binds with the surface proteins receptors on the cell membrane. The receptors operate in a lock-and-key fashion, with CD4 being the primary receptor for HIV (although other receptors and processes are also critical in the process of HIV cellular infection). The initial binding with surface receptors is a necessary stage for cellular infection.

Once the initial binding to cell receptors is completed, the virus passes through the cellular membrane and enters the cytoplasm. On entering the cytoplasm, the retrovirus uses an enzyme called reverse transcriptase to synthesize a proviral DNA copy from the viral RNA template (a process referred to as reverse transcription). During this process, the transcriptase reads the RNA material as it is converted to DNA that can be integrated into the host cells' genetic material. However, errors are frequently made in the replication process. As a result, not all copies of HIV DNA are identical. The modifications or mutations during this process contribute to the resistance of the virus to the body's immune system and to certain antiviral treatments.

The completed proviral DNA migrates to the nucleus of the host cell and is inserted into or integrates with the host cell DNA. Once this integration occurs, the integrated viral DNA (or provirus) is replicated along with normal cellular genes as part of the routine cellular division process. Virions containing HIV RNA and HIV proteins are assembled within the host cell body, and an enzyme called protease is required at this phase to divide the polypeptide chain into discreet functional enzymes. The completed HIV virions (containing HIV RNA and HIV proteins or enzymes) are released from the host cell membrane in a process referred to as budding. Once the virions are released and the transcriptase has completed division of the proteins, the mature virus is capable of infecting additional cells. The newly created mature virus resembles the original virus but may also have undergone some variation during the replication process, thus complicating medical treatment.

Transmission

HIV is transmitted through exchange of body fluids via unprotected sex with an infected person, exposure to contaminated blood products (as in transfusions, needle sticks, or injection drug use), or transfer from an infected mother to a child before, during, or after birth.¹⁵ Body fluids with high concentrations of HIV that are known to be capable of transmitting the virus include blood, semen, vaginal fluids, breast milk, and exudates from wounds. HIV is not transmitted through casual (nonsexual) contact with persons.²⁸

In the early years of the AIDS pandemic, many people were infected with HIV because of contamination of the blood supply (primarily through transfusions or clotting factor given to persons with hemophilia). However, the blood supply has been tested for HIV in the United States and many other nations since 1985.¹² Currently, very few infections result from the blood supply or blood transfusions (fewer than 1 in 600,000 transfusions results in infection) in nations with testing programs.

The risk of infection to health care providers is very low.¹⁵ The CDC estimates that the risk for HIV infection following a needle stick is 0.3% and that the risk for infection after exposure of infected blood to the eyes, nose, or mouth is 0.1%.⁹ The risk with exposure of nonintact skin to infected blood is less than 0.1%, and exposure of infected blood to intact skin probably poses no risk at all. HIV is not transmitted through casual contact with other persons. It is important to remember that health care workers, or any other persons, are not at risk for HIV infection through casual, everyday contact with persons infected with HIV. The CDC recommends that health care workers practice universal precautions.

Universal precautions in the workplace include assuming that blood and body fluids from all clients are potentially infectious.⁸ Health care workers should take certain precautions when working with all clients. Such precautions include the routine use of barriers (such as gloves) when anticipating contact with blood or body fluids. Workers should also wash hands and other skin surfaces immediately after contact with blood and body fluids. Finally, although the risk for HIV infection from an accidental needle stick is very low, this route of transmission constitutes the most likely risk for infection in health care workers. Workers should practice careful handling and disposal of any needles or potentially infectious sharp objects.

Diagnosis

HIV is detected by use of a variety of tests.²⁸ The most commonly used tests include a rapid screening test, enzyme-linked immunosorbent assay, and Western blot test. They detect the presence of HIV antibodies following the initial HIV infection. It is important to note that during the process of seroconversion (the immune response producing

detectable antibodies), the person may be infected but not have a positive antibody test result. The process of seroconversion (producing a positive antibody detection test result) may take up to 2 months after the initial infection, and the infected person is capable of transmitting HIV during this time. In addition to antibody tests, other tests are available that detect viral load or P24 antigen and may produce an earlier positive test result.

HIV infection can be categorized along a continuum ranging from asymptomatic persons with high CD4⁺ counts to persons with clinical AIDS (representing the most advanced and serious stage of HIV infection).

In 1993, the CDC revised the categories that determine one's HIV or AIDS status.⁷ They include the following:

- Category 1 (C1): counts of 500 or more CD4⁺ cells per microliter of blood
- Category 2 (C2): counts from 200 to 499 CD4⁺ cells
- Category 3 (C3): counts below 200 CD4⁺ cells

The second set of categories relates to expression of HIV from a clinical perspective:

- Category A: individuals who have been asymptomatic except for persistent, generalized lymphadenopathy seroconversion syndrome. This includes the initial acute onset of HIV exposure.
- Category B: individuals who have never had an AIDS-defining illness but have had some symptoms of HIV infection, such as candidiasis, fever, persistent diarrhea, oral hairy leukoplakia, herpes zoster, idiopathic thrombocytopenic purpura, peripheral neuropathy, cervical dysplasia, or pelvic inflammatory disease.
- Category C: individuals who have or have had one or more of the AIDS-defining illnesses.

An individual is determined to have HIV infection if one category from each set applies. For example, AIDS would be diagnosed if the person is designated category 3 (<200 CD4⁺ cells) and has had at least one AIDS-defining illness. Categories 1 and 2 and A and B are considered HIV positive (a less grave condition), whereas categories 3 and C are defined as AIDS. These categories are used primarily to pinpoint an individual's placement along the continuum of HIV infection.²⁹

Occupational therapists and OT assistants have the opportunity to positively affect the daily lives of people with HIV and AIDS in all of these stages of illness. Promoting health, quality of life, and well-being is one focus of OT intervention.¹

Pharmacology

After well over a quarter century of the HIV epidemic, there is still no cure. Over the years, researchers have made extraordinary progress in the development of medications to alter the course of the disease. The medications used to treat HIV infection have helped promote healthier

Threaded Case Study Billy, Part 2

Billy appears to have more mental health issues surrounding his illness than physical concerns at this time. He does experience fatigue and slight memory problems. The occupational therapist may ask the following questions:

1. Is the fatigue experienced related to the medical condition or the mental health issues that Billy is experiencing?

In this case, the fatigue that Billy reports could certainly be related to both physical and mental health issues. He could be experiencing AIDS-dementia complex (ADC), which is manifested, in the context of occupational performance, as altered cognitive processing and impaired memory. ADC appears to be related to destruction of subcortical structures in the central nervous system (CNS) and is estimated to be present in more than half of individuals in whom AIDS is diagnosed. A peripheral neuropathy may also be developing, among other conditions. Having an awareness of these disease processes could lead to increased anxiety and fear and possibly depression, especially with regard to the impact on his worker role. Billy should be encouraged to discuss these fears in the context of his daily living occupational performance.

Billy's ability to use effective habits and routines in the workplace might serve to reduce his anxiety about his diminished memory. Devices such as electronic organizers and calendars may be helpful to Billy as memory aids. A conversation about these issues would involve Billy's knowledge of his life situation, thus making the OT sessions very client centered.

2. If Billy is preoccupied with his change in health status, how does he function in his work, home, community, and other contexts?

Using specifically guided questions, the therapist might examine the contexts in which Billy engages to elicit information that might have been unknown to him before OT interventions. He would benefit from an assessment such as the Pizzi Holistic Wellness Assessment (see later).

3. Are there mental and physical health issues that can be incorporated into a prevention and health promotion OT program?

Billy could engage in a reality-checking exercise in which he explores the positive aspects and strengths in his life (e.g., good social support, advanced knowledge in the area of health care). These strengths can help him maintain a positive sense of self and engage in more health-promoting behavior on a physical level, such as a regular exercise program.

functioning in people with HIV and AIDS, which assists in facilitating continued occupational participation.³²

Several classes of antiretroviral drugs are used to treat HIV infection.²⁸ They can be grouped into different classes of medication based on the mechanism by which the drug

Box 47-1

Antiretroviral Drugs Used to Treat HIV Infection

Reverse transcriptase inhibitors: These drugs influence the ability of the enzyme reverse transcriptase to convert HIV RNA into DNA.

Protease inhibitors: These drugs influence the ability of protease to activate proteins in the newly developed viruses and result in immature viruses that are incapable of infecting additional cells.

Fusion inhibitors: These drugs limit the ability of HIV to enter cells by methods that include blocking the specific receptor sites.

Integrase inhibitors: These drugs act on the integrase enzyme to prevent HIV DNA from being integrated into cellular DNA.

Entry inhibitors: These drugs (also known as fusion inhibitors) interfere with the binding of HIV to host cell receptors.

Data from McCutchan JA: Human immunodeficiency virus (HIV). In Merck manual online, 2009, retrieved from <http://www.merck.com/mmpe/sec14/ch192/ch192a.html>.

limits viral replication. These medications act on specific enzymes required for viral replication. By restricting viral replication, these medications can increase the CD4⁺ cell count and thus improve immune function and, as a result, limit the susceptibility of the individual to opportunistic infections. The general categories or classes of drugs are listed in Box 47-1.

HIV has considerable variation as a result of the replication process described previously. HIV quickly develops resistance to any of the antiretroviral medications used individually because of these mutations occurring during replication. Antiretroviral treatment is most effective when the medications are used in combination. Current protocols use multiple antiretroviral medications simultaneously to limit the ability of the virus to develop resistance to a single medication. The combination of medications has the benefit of reducing HIV blood levels more than possible with a single medication, the combination helps prevent drug resistance, and some of the medications used in combination have a synergistic effect (increasing levels of other HIV drugs in blood). The most common combinations of medications include three reverse transcriptase inhibitors or two reverse transcriptase inhibitors and one or two protease inhibitors.

These combined antiretroviral medications are referred to as highly active antiretroviral therapy (HAART). The introduction of HAART has significantly changed the course of the AIDS pandemic.⁴⁴ In the United States, more people than ever before are living with HIV. The increased survival rate is most likely due to a combination of an increasing percentage of persons knowing their HIV infection status and persons receiving access to HAART. It is of

particular importance that persons be tested and be aware of their HIV status. This is significant because it increases the likelihood that these persons will receive HAART at an appropriate time, but it is also significant that persons who are aware of being HIV positive are less likely to transmit the virus (resulting in a further reduction in the incidence of infection).

The use of HAART has significantly extended the life expectancy of persons infected with HIV. Many persons treated with HAART live decades after initial infection.⁴⁴ As a result of the effectiveness of this treatment, the overall prevalence rate of HIV infection in the United States has increased despite incidence rates of the infection remaining relatively stable (see the section “Origins and Current Status of HIV Infection” and Figure 47-1). Overall hospital use has declined since the introduction of HAART, as well as morbidity and mortality in persons infected with HIV.⁵ Medical management of persons infected with HIV now includes multiple medical conditions associated with aging or chronic conditions.

The improved survival rates resulting from access to HAART is a significant factor in the management of HIV infection. However, it should be noted that HAART is not a panacea. Despite prevention and treatment successes in recent years (including HAART), people still die of AIDS. The overall survival rate trends are encouraging, but there still remain too many persons in whom HIV is not diagnosed until late in the course of the infection process, and this represents a missed opportunity for prevention and treatment.¹³ HAART also has potential complications resulting from medication side effects and other issues.

Adherence to HAART is correlated with viral suppression, improved immune function, increased survival from HIV, and improved quality of life.¹⁷ However, maintaining medication compliance is challenging for reasons other than side effects. Persons who begin HAART are often young and frequently display minimal symptoms from HIV at the initiation of HAART. Because HIV infection is a lifelong condition, it may be a challenge for persons to continue adhering to the medication regimen as prescribed. Reasons for poor adherence are many and complex, but there are several predictors of poor medication adherence. Low levels of literacy, psychosocial issues (including depression, limited social support, stress, and dementia), active substance use, cognitive impairment, complex regimens, age-related changes, medication fatigue, and medication scheduling issues are all predictors of poor medication adherence independent of side effects of the medications.¹⁷

Effective use of medications for the treatment of HIV requires consistency in maintaining the schedule of administration of the medications.¹⁷ Failure to maintain consistency with the medications may result in HIV developing resistance to medications and allowing viral replication. HAART reduces the viral load and allows the immune system to continue to function and prevent the presence of opportunistic infections. The effectiveness of the HAART regimen

can be measured by detecting the level of viral load present and by monitoring helper T-cell counts. In many instances, persons taking HAART have a nearly undetectable level of virus. However, once a person is infected with HIV, that person is always able to transmit the virus.

Unfortunately, these life-enhancing medical regimens are associated with myriad side effects, many of which clients receiving OT services will experience. Understanding these side effects is important because they affect occupational performance. Side effects include CNS disorders, peripheral polyneuropathy, gastrointestinal disorders, hepatotoxicity, anemia, pancreatitis, osteopenia and osteoarthritis, lipodystrophy, hyperlipidemia, diabetes, and hyperglycemia. Because of the extensive and varied pharmacologic side effects, many people with HIV have great difficulty in deciding the appropriate time to begin a drug regimen.²³ Persons taking HAART may also be at risk as a result of being unable to take HAART consistently. This can occur because of either side effects or poor medication management (for example, persons with HIV-related neurocognitive deficits are 2.5 times more likely to be at risk for medication noncompliance than are persons without dementia).²²

HAART has been an effective medical intervention that has significantly altered the landscape of HIV infection by creating improved health and well-being for many infected individuals. Unfortunately, access to affordable health care is limited or nonexistent for millions of people worldwide, but recent efforts have made these important medications more accessible.⁴⁵ Despite best practice in medicine, a cure for AIDS remains elusive. However, thanks to medical advances, people continue to live full and productive lives while coping with the daily issues of living with HIV.

Aging and HIV Infection

A few issues related to aging in persons infected with HIV are important and require the attention of the OT practitioner. As HAART prolongs the life of persons with HIV, the presence of HIV with other age-related conditions is becoming more common. Recent research has indicated that both hospitalizations and deaths from HIV-related causes have declined in recent years. The reduction in opportunistic infections and clinical AIDS has resulted in alternative causes of mortality in aging persons infected with HIV. Elderly persons with HIV are more likely to have additional medical comorbid conditions.⁴⁷

Several considerations influence the health outcomes of elderly persons with HIV.²¹ The elderly (classified by the CDC as persons older than 50 years) are a growing demographic in the United States for HIV infection. The number of persons older than 50 years infected with HIV has increased because of at least two factors. The first is sometimes referred to as an “aging cohort effect,” which describes a group of persons infected with HIV earlier in life and age as a result of HAART prolonging life expectancy. The other

factor involves new infections diagnosed in persons older than 50 years. The incidence and prevalence of HIV infection have both increased in persons older than 50.

Some research suggests that persons in whom HIV infection is diagnosed after 50 years of age have worse outcomes than their younger cohorts do. One important factor appears to be that HIV infection is diagnosed in persons older than 50 at a more advanced stage than in their younger counterparts.

Possible explanations for the more advanced progression at the time of diagnosis in older persons with HIV includes less common routine screening for HIV in this population, poorer awareness of the risks for HIV infection and safer sex practices in this age group, and physicians perhaps being less likely to consider HIV clinically. The symptoms or signs of HIV infection may also be more likely to be attributed to comorbid medical conditions or to other conditions more commonly associated with aging populations.

Neurologic Sequelae of HIV/AIDS

A wide range of medical complications are associated with HIV/AIDS, and multiple body functions and body structures can be affected by HIV/AIDS. Neurologic disorders related to HIV infection are common and may be potentially debilitating in performance of activities of daily living (ADLs) and instrumental activities of daily living (IADLs).²⁶ Estimates of the frequency of neurologic disorders vary, but it appears that as many as 66% of persons with HIV may have peripheral neuropathy²⁵ and at least 20% of persons with HIV infection have some type of neurocognitive impairment.⁴⁰ The estimated prevalence of neurocognitive impairment varies considerably, in part because of the clinical standard used to determine the presence of cognitive impairment. If mild cognitive impairment is used as the criterion, the prevalence of neurocognitive impairment is significantly higher.³⁹ Despite the effectiveness of HAART in improving overall immune function, neurologic deficits have persisted, although advanced stages of dementia are less common than before the use of HAART.⁴⁴

Neurologic disorders are of particular concern to occupational therapists working with persons with HIV/AIDS. HIV is capable of passing the blood-brain barrier and entering the CNS.²⁷ HIV has been detected in CNS structures, as well as in cerebrospinal fluid, in persons infected with HIV, including those who are asymptomatic and with functioning immune systems. The neurologic sequelae of HIV/AIDS can be an indirect result of the virus via opportunistic infections (resulting from compromised immune function) or a direct or primary effect of HIV. The presence of neurologic opportunistic infections has been greatly reduced in the United States since the advent of antiretroviral therapies.⁴⁰ However, primary effects of HIV on the CNS remain common and should be considered when addressing the needs of this population. A variety of neurologic conditions or clinical manifestations are associated with HIV/AIDS.

Box 47-2

Neurologic Complications of HIV-1 Infection

HIV-1 Associated

- HIV-1 encephalopathy
- HIV-associated cognitive-motor disorder
- HIV-1 meningitis
- Vacuolar myelopathy
- Peripheral neuropathy
- Distal sensory polyneuropathy
- Antiretroviral toxic neuropathy
- Ascending neuromuscular syndrome
- Mononeuritis multiplex
- Inflammatory demyelinating polyneuropathy
- HIV-associated polymyositis

Opportunistic Infections

- Cerebral toxoplasmosis
- Tuberculosis
- Cryptococcal meningitis
- Cytomegalovirus retinitis/encephalitis/polyradiculitis
- Progressive multifocal leukoencephalopathy
- Other viral/fungal/bacterial/protozoal central nervous system infections
- Neoplasms
- Primary central nervous system lymphoma
- Metastatic systemic lymphoma
- Metastatic Kaposi's sarcoma

However, this section focuses on neuropathies (the most common neurologic complication of HIV/AIDS) and AIDS-related dementia (which can have a profound impact on occupational performance) (Box 47-2). Not all persons display clinically significant neurologic deficits. However, neurologic deficits will develop in a significant number of persons as a result of this process.

Some changes in the course of neurologic deficits do appear to be a result of HAART. Before HAART, the more advanced stages of AIDS dementia were commonly found in the advanced stages of clinical AIDS. As HAART has improved immune functioning and decreased the number of persons with advanced clinical AIDS, the number of advanced dementia cases appears to have decreased as well. Although HIV dementia is common in advanced AIDS,^{38,42} it is also found early in HIV infection and without AIDS or in the presence of opportunistic infections. The prevalence rate is significantly higher when including persons displaying signs of neurologic involvement detected by neuroimaging but without clinical changes or when including persons with mild cognitive impairment.

Despite the effectiveness of HAART in improving overall immune function, neurologic deficits have persisted,⁴⁴ and prevalence rates for dementia, when including mild cognitive impairment, have increased since the advent of HAART,

although advanced dementia is less common.^{2,3,16,18} Some evidence also suggests that the cognitive deficits may be related to a combination of the aging process, extended period of HIV infection, medication side effects, and the comorbid neurologic conditions that are more common in aging persons.⁴

Neuropathies

Peripheral neuropathies are the most common neurologic complication of HIV. They can occur both as a primary effect of the virus and as a side effect of antiviral medications used to treat HIV.²⁷ It is often difficult to distinguish clinically between the two causes of neuropathy. Although many peripheral nerve disorders are associated with HIV, distal sensory polyneuropathy is the by far the most common disorder. Persons with distal symmetric polyneuropathy frequently have burning painful sensations on the distal end of the lower extremities, often accompanied by numbness or tingling sensations. Individuals may also have decreased sensation of thermal stimuli. If lower extremity weakness is present, it is more likely to be distal than proximal. Distal sensory polyneuropathy follows a stocking glove distribution of sensory impairment involving the feet and hands (typically with greater lower extremity involvement initially), and impairment spreads proximally as the condition progresses.

The functional deficits associated with peripheral neuropathy may include numbness or impaired sensation, loss of balance because of diminished proprioception in the lower extremities, and abnormal pain sensations (dysesthesias). Distal sensory polyneuropathy results in damage to both large myelinated and unmyelinated nerve fibers and is clinically similar to diabetic neuropathy (in that small sensory fibers are also involved).

Occupational therapists should assess clients for pain. Chronic pain is a common condition associated with HIV infection in general and with distal symmetric polyneuropathy in particular. The pain may limit occupation performance and is frequently underdiagnosed and undertreated. Current evidence suggests that the pain sensations are probably caused by dysfunctional regulation of pain fibers in both the central and peripheral nervous systems and that it results in severe pain out of proportion to the extent of epidermal nerve fiber loss.

In HIV-associated distal sensory polyneuropathy, it is hypothesized that the abnormal pain may be caused by damage to peripheral nerve fibers as a result of multifocal inflammation and infiltration of activated macrophage into peripheral nerves, with subsequent abnormal activity occurring in uninjured neighboring nociceptive fibers. The abnormal inflammatory response and macrophage infiltration are also found in the dorsal root ganglion. It is possible that this results in changes in neuronal calcium and sodium channels and ectopic impulse generation causing abnormal neuronal hyperexcitability. Finally, it is possible that remodeling occurs in the dorsal horns as a result of A-fiber

sprouting and synaptic formation within lamina II of the spinal cord.

Dementia

ADC is also referred to as AIDS-related dementia, HIV-associated dementia, AIDS encephalopathy, or HIV encephalitis and is a common neurologic condition associated with HIV infection.³⁷ Dementia associated with HIV infection has been identified since the earliest years of the HIV/AIDS pandemic and has been characterized by the cardinal features of progressive dementia with motor and behavioral deficits.³³ ADC appears to be a result of the presence of HIV in the CNS and is a primary effect of the virus. HIV can enter the CNS shortly after the initial infection. The most likely mechanism for entry appears to be infected monocytes passing through the blood-brain barrier.⁴³ The precise mechanism by which infected cells within the CNS are activated and cause dementia is not known at this time. It is possible that the brain may act as a sanctuary for HIV replication inasmuch as the blood-brain barrier may prevent HAART from passing through the barrier to the CNS and create a viral reservoir. The cells that are most frequently infected are macrophages, microglial cells, and astrocytes (although many other cells may also be infected within the CNS). It appears that neurons are rarely if ever infected by HIV.

ADC remains a complication in persons infected with HIV despite the introduction of HAART.⁴¹ ADC is characterized by subcortical involvement and is considered a subcortical dementia. There is evidence of damage to the basal ganglia and caudate nuclei,^{20,34} and the clinical manifestations of ADC have some similarities to other subcortical dementias, including Parkinson's disease and Huntington's disease. Persons with ADC frequently display motor disturbances, such as imbalance, unsteady gait, tremors, difficulty performing fine motor tasks (including handwriting), weakness, and motor-processing delays and reduced speed of motor responses (primarily in the more advanced stages of ADC) (Box 47-3).

ADC may cause impairment of visuospatial function, executive function, and recall of information, as well as slowed psychomotor speed. Persons with ADC may have impaired episodic memory (the ability to remember facts, places, and subjective historical information) and deficits in retrieving information. It appears that ADC spares semantic memory (ability to recall facts and information unrelated to personal experience) and the ability to retain information until the relatively advanced late stages of ADC. Unlike Alzheimer-type dementia, persons in the earlier stages of ADC may not have significant deficits in naming objects or other language functions associated with the cerebral cortex but will probably have deficits in retrieving and manipulating retained information, as well as slowing of information processing.³⁰

Persons with ADC may also exhibit behavioral changes, potentially including increased agitation, apathy, isolation, or changes in personality. Cognitive deficits are also present

Box 47-3

Clinical Manifestations of AIDS-Dementia Complex

Affective—Apathy (depression-like feature)

- Irritability
- Mania, new-onset psychosis

Behavioral—Psychomotor retardation (slowed speech or response time)

- Change in personality
- Social withdrawal

Cognitive—Lack of visuospatial memory (misplacing things)

- Lack of visuomotor coordination (eye movement abnormalities)
- Difficulty with complex sequencing
- Impaired concentration and attention
- Impaired verbal memory (word-finding ability)
- Mental slowing

Motor—Unsteady gait, loss of balance

- Dropping things
- Tremors, poor handwriting
- Decline in fine motor skills

in the earliest stages of ADC. The cognitive deficits are most likely to involve executive function (including delays in information processing, limited attention to tasks, and visuospatial deficits). In the early stages of ADC, the manifestation of these deficits in executive functioning is different from dementia of the Alzheimer type, in which the person typically has more pronounced memory deficits, word retrieval deficits, decreased comprehension or other language difficulties, and disorientation. However, as the dementia reaches more advanced stages and the deficits become more global, it may be difficult to differentiate ADC from dementia of the Alzheimer type.

ADC appears to influence dopamine production, and a subtype of persons with ADC may exhibit mood disorders, including mania, probably as a result of the dopaminergic changes caused by ADC.³⁰ The likelihood of dopamine involvement is also supported by the movement disorders described previously.

The incidence and prevalence of HIV dementia or ADC have changed in the HAART era. It appears that the incidence of ADC has decreased with the use of HAART, but prevalence rates are increasing. One hypothesis is that new multiple patterns or progressions of ADC have arisen following the introduction of HAART.²⁷ The first type is a subacute progressive form of dementia that is seen in untreated persons and marked by severe progressive dementia similar to the pattern seen before HAART. The second pattern involves a chronic active dementia seen in persons prescribed HAART who have poor compliance or exhibit viral resistance. These persons are at risk for progression of the dementia. The final category is chronic inactive

dementia, in which persons receiving HAART with good adherence and viral suppression remain neurologically stable but have some degree of cognitive impairment or early-stage ADC.

Advanced ADC was most common in the late stages of AIDS before the use of HAART. The use of HAART appears to have decreased the frequency of advanced stages of dementia in persons infected with HIV. However, the incidence of cognitive impairment and ADC has not abated despite the use of HAART. It appears that mild cognitive impairment and early-stage ADC are more common than later stages of ADC as a result of HAART, but the overall incidence of cognitive deficits has remained at higher than 20% for persons infected with HIV.

It is important to be aware of the clinical manifestations of ADC during different stages of the dementia.³³

Early Stages of AIDS-Dementia Complex

During the early phases of the disorder, it is possible for the deficits to be overlooked or be attributed to other causes. The early stages are consistent with subcortical dementia and are characterized by difficulty concentrating and attending to task and delayed processing of information, which may require extended time for completion of ADLs; minor forgetfulness and difficulty with executive functioning tasks are not unusual. Motor deficits also occur frequently and include tremors, gait imbalances, lower extremity weakness, and slowing of motor function. Persons may also display behavioral changes, including increased withdrawal from ADLs or social situations, agitation or irritability, and other changes in personality.

The early stages of ADC can potentially have an impact on a number of ADLs and IADLs. Persons may have particular challenges with IADLs involving executive functioning and may have difficulty managing finances, medications, or scheduling and keeping appointments. In particular, tasks involving multiple steps and sequencing may be problematic and lead to difficulties with related IADLs. Persons with HIV-related neurocognitive deficits are much more likely to be at risk for medication noncompliance than are persons without dementia.²² Persons may also have difficulty with tasks requiring sustained attention (for example, the person may have difficulty reading or listening to lengthy conversations). The motor deficits related to ADC may be minimal in the early stages but may be observed by noting difficulty with ADLs involving fine motor coordination, including handwriting, managing clothing fasteners, using utensils during meals, and performing grooming activities (such as shaving or applying makeup). The person may also have difficulty maintaining balance while walking, tremors, and weakness.

Later Stages of AIDS-Dementia Complex

As ADC progresses, the deficits become more generalized or global and may be difficult to distinguish from other types of advanced dementia. It is worth noting that given

the use of HAART, many persons with ADC or minor cognitive impairment have maintained relatively stable cognitive functioning without significant progression of symptoms over an extended period. In these cases, although deficits are present, the person may not progress to later stages of ADC. Late-stage ADC remains most common in people with significant progression of HIV or AIDS. By the late stages, ADC is a condition characterized by global deterioration involving cognition, motor skills, behavioral deficits, and limited insight into the client's condition and deficits. As ADC progresses, the person will probably exhibit significant cognitive deficits, disorientation, general confusion, and impaired speech and language ability. Motor symptoms also progress at this point, with continued weakness, changes in muscle tone (spasticity in particular), ataxia, and dyskinesia. Some behavioral changes are also common as ADC progresses, including disinhibition of behavior and incontinence of bowel or bladder. At this point in the disorder, persons with HIV will probably require assistance in performing all IADLs and most ADLs. Refer to Table 47-5 for a summary of the stages of ADC.

HIV/AIDS Pathologies—Client Factors

People with HIV are living longer and healthier lives as a result of improvements in medications, health education, and behavioral changes. However, medications are costly and often provided only to those who can afford them or have other access to them. Thus, people with HIV who are not privy to information on community resources or whose accessibility is otherwise limited experience numerous opportunistic infections (infections resulting from a compromised immune system), such as *Pneumocystis pneumoniae* infection or Kaposi's sarcoma (the latter being less common).

OT practitioners may see a diverse population of people with AIDS with numerous occupational deficits. Many physical and psychosocial factors indicate the need for OT. Factors experienced by people with HIV and AIDS include, but are not limited to the following:

- Fatigue and shortness of breath
- Impairment of the CNS
- Impairment of the peripheral nervous system
- Visual deficits
- Sensory deficits (including painful neuropathies)
- Cardiac problems
- Muscle atrophy
- Altered ability to cope with and adapt to changes that the illness creates
- Depression
- Anxiety
- Guilt
- Anger
- Preoccupation with illness versus wellness

All these factors affect clients' occupational performance in meaningful, health-promoting daily occupations. OT can benefit all people with HIV and AIDS who experience any of the aforementioned problems.

Positive Prevention

Reflecting the changing needs of people with HIV and in consideration of the improved drugs to combat the disease and its secondary conditions, the term *positive prevention* has been developed and used by the CDC.¹⁰ The Serostatus Approach to Fighting the Epidemic (SAFE) helps reduce the risk for transmission to supplement current risk reduction programs. Several action steps are recommended that focus on diagnosing HIV, linking infected persons to appropriate preventive services, helping them adhere to treatment regimens, and providing support to develop healthy habits for sustaining behavior that reduces the risk associated with HIV infection. It is one of the first programs to dovetail traditional infectious disease control with behavioral interventions. Although occupational therapists may primarily intervene with people who have already been infected, prevention can still be integrated into a holistic program of care.

TABLE 47-5 | Staging of AIDS-Dementia Complex

Stage/Grading	Manifestation
0	Normal
0.5	Subclinical or equivocal—Minimal or equivocal symptoms Mild (soft) neurologic signs No impairment in work or activities of daily living
1	Mild—Unequivocal intellectual or motor impairment Able to do all but the most demanding work
2	Moderate—Cannot work or perform demanding activities of daily living Capable of self-care Ambulatory, but may need a single prop Major intellectual disability or Cannot walk unassisted
3	Severe—Major intellectual disability or cannot walk unassisted
4	End-stage—Nearly vegetative Rudimentary cognition Paraplegic or quadriplegic

Prevention and health promotion can be a primary area of intervention in OT. In primary prevention, the practitioner may develop and implement health education and risk reduction strategies to help individuals and communities understand the impact of reducing risk on occupational participation. An OT primary prevention strategy could be the development of a developmentally appropriate lecture or workshop on abstinence and safe sex for schools, religious groups, and community centers. These workshops could incorporate mental health strategies, culturally relevant information, and interpersonal skill-building exercises, areas in which OT practitioners are well educated.

Secondary prevention, wherein OT services are provided for people who are already infected with the virus, would include activities that create and promote healthy lifestyles and thereby prevent future opportunistic infections and promote balance and well-being. OT intervention focused on providing secondary prevention can significantly affect communities that have large numbers of people who are infected with HIV. An emphasis on establishing and maintaining the habits and routines that support engagement in occupations would be appropriate for secondary prevention programs.

Tertiary prevention is provided when clients suffer from a disability that is secondary to the disease. Tertiary prevention includes a strong emphasis on rehabilitation; health promotion programming can also be included to positively affect a person's lifestyle and provide hope for continued and healthful functioning. Strategies that support continued participation in occupations, even if the occupation has been modified, would be addressed in tertiary prevention programs. An example would be the use of adaptive equipment to support continued engagement in a desired occupation (e.g., woodworking, cooking) when muscular weakness or peripheral nerve damage compromises occupational performance.

Assessment

Pizzi has developed two assessments that focus on enhancing health and well-being (see [Chapter 5](#)): One is for general use, and the other is for use in people infected with HIV.³⁶ The one related to HIV specifically is the Pizzi Assessment of Productive Living for Adults with HIV Infection and AIDS (PAPL; [Figure 47-2](#)).

One of the first assessments in OT specifically designed as a client-centered and subjective health promotion tool is the Pizzi Holistic Wellness Assessment (PHWA).³⁶ An occupational history format is used. The emphasis of the PHWA is to explore an individual's self-perception of health and strategies for self-responsibility. It is vital that practitioners incorporate the goals, beliefs, values, attitudes, and occupational meanings identified by the client being served. Reductionistic interventions (e.g., range of motion, strengthening, cognitive retraining) are incorporated into meaningful occupations and not addressed separately.

The PHWA is a self-assessment tool that incorporates both a qualitative and a quantitative component. Clients self-assess eight areas of health on a scale of 1 through 10. They then address each area with the help of the practitioner in terms of their self-perception of occupational participation in the respective area. This dialog helps clients become aware of important health issues affecting their daily occupational performance. In each area of health, the client explores strategies to optimize health and determines which strategies could be used to promote health and well-being.

Even when it appears that a specific intervention positively changes occupational performance, the person experiences wellness through self-discovery of how to best manage his or her well-being. After self-discovery, the therapy process unfolds collaboratively between the client and therapist.³⁶

Immediate and meaningful occupational areas are identified through this assessment. A holistic view of the client is inherent in the assessment and is guided by the principles of health promotion and the values of OT.

PAPL (see [Figure 47-2](#)) is a holistic assessment for therapists to gather data on the physical, psychosocial, emotional, and spiritual aspects of the client's life. The resultant data are synthesized via the practitioner's clinical reasoning skills to produce a collaborative intervention that is client centered. All areas of occupational performance are addressed.

Holistic assessments are useful for practitioners because they address the multitude of issues and problem areas experienced by people with HIV and AIDS. The clinical reasoning of practitioners will then be challenged to integrate knowledge and skill in all areas of OT to best serve the clients' needs.

In as many as 10% of persons infected with HIV and experiencing chronic pain, no specific cause is known.

Intervention

The OT intervention process involves both the therapeutic use of self by the practitioner and the therapeutic use of occupations and activities. OT practitioners engage and facilitate engagement in meaningful and productive daily life occupations through a variety of techniques, strategies, and inventive programming. Promotion of healthy lifestyles while living with the disease is crucial for all clients infected with HIV. Interventions are individually tailored to meet the many physical, psychosocial, and contextual issues of people with HIV and AIDS. Because of the diverse features of HIV and AIDS, there are many considerations for practitioners when developing plans and goals. These considerations, listed in the following sections, also incorporate several occupational interventions that can be implemented.³⁵

Prevention of Disability

Occupational therapists can play a significant role in primary prevention by participating in occupation-based education for various community groups to reduce the risk

Pizzi Assessment of Productive Living for Adults with HIV Infection and AIDS (PAPL)

Demographics

Name _____ Age _____

Sex _____ Lives with (relationship) _____

Identified caregiver _____

Race _____ Culture _____ Religion _____

Practicing? _____ How does spirituality play a role in your life, if any? _____

Primary occupational roles: _____

Primary diagnosis: _____

Secondary diagnosis: _____

Stage of HIV _____

Past Medical History: _____

Medications: _____

Activities of Daily Living (use ADL performance assessment)

Are you doing these now? _____

Do you perform homemaking tasks? _____

(For areas of difficulty) Would you like to be able to do these again like you did before? _____ Which ones? _____

Work

Job _____ When last worked _____

Describe type of activity _____

Work environment _____

If not working, would you like to be able to? _____

FIGURE 47-2 Pizzi Assessment of Productive Living for Adults with HIV and AIDS (PAPL). LTG, long-term goals; STG, short-term goals.
(Courtesy Michael Pizzi © 1991.)

Do you miss being productive? _____

Types of activity engaged in _____

If not, would you like to? _____ Which ones? _____

Would you like to try other things as well? _____

Is it important to be independent in daily living activities? _____

Play/Leisure (interests and current participation) _____

Sleep issues (habits, patterns) _____

Physical Function

Active and passive range of motion:

Strength:

Sensation:

Coordination (gross and fine motor or dexterity):

Visual-perceptual:

Hearing:

Balance (sit and stand):

Ambulation, transfers, and mobility:

Activity tolerance/endurance:

Physical pain:

Location:

Does it interfere with doing important activities? _____

Sexual function:

Cognition

(Attention span, problem solving, memory, orientation, judgment, reasoning, decision making, safety awareness)

Time Organization

Former daily routine (before diagnosis)

FIGURE 47-2, cont'd

Has this changed since diagnosis? _____

If so, how? _____

Are there certain times of day that are better for you to carry out daily tasks?

Do you consider yourself regimented in organizing time and activity or pretty flexible? _____

What would you change, if anything, in how your day is set up?

Body image and self-image

In the last 6 months, has there been a recent change in your physical body and how it looks? _____ How do you feel about this? _____

Social environment (Describe support available and utilized by patient)

Physical environment (Describe environments where patient performs daily tasks and level of support or impediment for function)

Stressors

What are some things, people, or situations that are/were stressful? _____

What are some current ways you manage stress? _____

Situational Coping

How do you feel you are dealing with:

a) your diagnosis

b) changes in the ability to do things important to you?

c) other psychosocial observations

FIGURE 47-2, cont'd

Occupational Questions

What do you feel to be important to you right now?

Do you feel you can do things important to you now? In the future?

Do you deal well with change?

What are your hopes, dreams, aspirations? What are some of your goals?

Have these changed since you were diagnosed? How?

Do you feel in control of your life at this time?

What do you wish to accomplish with the rest of your life?

for infection and by promoting health. Secondary prevention can be addressed by occupational therapists through various health promotion strategies to enhance occupational engagement and performance with an emphasis on maintaining performance patterns, including significant habits, routines, rituals, and roles. OT intervention addressing tertiary prevention can focus on health promotion and rehabilitation to enhance occupational performance.

Education and Health Promotion

Occupational therapists can provide educational opportunities for clients to address multiple concerns, including energy conservation strategies to address fatigue, generalized weakness, and deconditioning, which are primary physical manifestations of HIV. Energy conservation, work simplification, and occupational adaptations are used to enhance productivity and participation. Education can address proper nutrition, which is vital for people with HIV and AIDS. In addition, occupational therapists can provide educational interventions to promote awareness of clients'

medical status and medication management, as well as to improve awareness of side effects of the medications.

Maintaining and Restoring Performance

Occupational therapists work with clients with HIV/AIDS to maintain or restore occupational performance in the presence of changes in client factors related to HIV/AIDS. Considerations for OT interventions include the following:

1. Control and choices of daily living options must be provided as much as possible. Frequently, people infected with HIV feel a sense of loss of control as the virus slowly invades body systems and manifests itself by further limitations in occupational performance. Providing choices can prove beneficial to clients when control in life is compromised by the virus.
2. Most clients with symptomatic HIV and AIDS have an altered worker role. Specific interventions regarding alternatives to work and productive living are

necessary if work is a valued role. Physical as well as psychosocial work assessment for holistic work-hardening programming is vital.

3. Habit training and adaptation of the routine of daily living are essential interventions and include performance of favored occupations with respect to physical and cognitive status; the level at which the person feels comfortable adapting routines; and times of day, contexts, and with whom the person chooses to perform the occupations. Whenever possible, clients must be given choices of scheduling within their own personal routines and not those that fit health professionals' schedules.
4. Short- and long-term goals must be readily adapted and changed as needed.

Complementary therapies must be considered as interventions before and during occupational performance. Such therapies can include progressive relaxation, biofeedback, prayer, therapeutic touch, traditional Chinese medicine techniques, myofascial release, craniosacral therapy, imagery, and visualization.

Modifications, Adaptations, and Compensatory Approaches to Intervention

Occupational therapists can provide intervention that includes a variety of modifications, adaptations, and compensatory techniques to promote occupational performance skills and patterns. Such approaches include the following:

1. Adaptive equipment and positioning can be used to assist clients in returning to independent performance of ADLs, work, and leisure occupations. Often, people with HIV may reject such equipment even though it can benefit them. This rejection signals rejection of the sick role and sometimes denial of diminished abilities. This attitude must be respected until the time when the person chooses, if at all, to use the equipment.
2. Changes can be made in the physical environment or performance patterns to help the client continue important roles despite medical changes, including fatigue. Energy conservation approaches and work simplification can be useful to allow continued participation in ADLs.
3. A variety of strategies can be used to compensate for cognitive changes that may have an impact on occupational performance, including activities that involve executive function (medication management, work responsibilities, financial management) and motor performance. Occupational therapists can adapt tasks to compensate for neurologic deficits, including sensory loss related to peripheral neuropathies. Therapists can also be involved in modifications to optimize function in persons with ADC and related cognitive deficits.

Advocacy and Psychosocial Considerations

Occupational therapists can be involved in both advocating for clients with HIV/AIDS and helping support client efforts for personal advocacy. More unique psychosocial aspects of HIV rehabilitation are present than in most other physical or psychosocial cases.

Many people with HIV have lost numerous friends to the same disease for which they are receiving therapy; have undergone loss of work and family as a result of discrimination, rejection, or physical inabilities; and may have lost life partners to the same disease. For many clients, all these losses can occur before the age of 40. Women with HIV experience the aforementioned losses but must also frequently cope with poverty and homelessness; women are often under-recognized in the epidemic.

There is no known cure or vaccine for HIV to date, although research is promising. This is a major consideration as a stressor of daily living.

The aforementioned considerations are several areas of intervention that can help maintain and restore occupational performance and prevent secondary conditions and impairments from emerging.

Threaded Case Study Billy, Part 3

Billy required assessment to determine how the changes in client factors and body functions have altered various areas of occupation and life roles. After developing the occupational profile, several types of OT interventions are needed to strengthen mind, body, and spirit. Promotion of the therapeutic use of self, with a nonjudgmental and caring, compassionate attitude, will help Billy relax during OT sessions and engage him in discovering the best ways to establish balance and well-being in his life. As a result of his apparent depression and fatigue, he may be experiencing altered occupational role performance. Fatigue and depression can also impair cognition. Understanding exactly how these roles are compromised and the underlying impairments in body function will help the therapy process unfold, with specific interventions being implemented as appropriate. Billy, as determined through the occupational profile, is a habit-oriented man. Helping him explore his daily habits and routines, understanding the areas in which he senses an impairment (along with OT evaluation data), and encouraging him to adapt to change can help him in restoring both his emotional health and physical well-being.

Using an occupation- and client-centered approach and understanding the disease process afford the occupational therapist unique insight into the best ways to assess and treat people with HIV and AIDS. Promoting health and well-being will also establish a higher quality of life. The focus of OT is always to enable participation in meaningful life occupations that support life satisfaction and quality of life.

Summary

Many changes have taken place since the earliest days of the HIV/AIDS epidemic. Such changes include the demographics of persons infected by the virus, the areas globally in which infections are concentrated, populations infected in the United States, treatments available, survival rates, and medical management of the condition. Fortunately, the development of antiretroviral treatments has extended the life expectancy of many persons with HIV in the United States (and increasingly on a global basis). These encouraging developments also present a number of challenges in managing the chronic health and medical needs of persons infected with HIV.

OT has many roles in addressing the needs of persons with HIV/AIDS. It can help address the range of client factors and performance skills that are affected by HIV/AIDS. Prevention is critical in the management of HIV, and OT can help emphasize prevention and reduce the incidence of HIV infections. OT can also address the needs of persons infected with HIV.

OT assessment should focus on developing an occupational profile that includes the individual's previous occupational performance patterns, roles, habits, and routines to better understand how HIV influences function. Specific assessments can identify which client factors are most affected by HIV and provide guidance for OT interventions. Of particular importance in assessing client factors are the common neurologic deficits that can greatly influence functional performance and are often present even in the absence of opportunistic infections or AIDS.

Occupational therapists can help promote function and independence in ADLs and IADLs by a variety of means and interventions. Such approaches include prevention of disability, education/health promotion, maintaining/restoring performance, modifying/adapting environments, compensatory strategies, advocacy, and addressing psychosocial factors. Through the use of these interventions, OT can help persons with HIV maintain active participation in individual meaningful daily activities and be active in the community.

Review Questions

1. What is the difference between HIV infection and AIDS?
2. What are the routes of transmission of HIV?
3. Name three side effects of the drug regimen that affect the quality of life of persons who have HIV or AIDS.
4. Differentiate primary, secondary, and tertiary prevention programs.
5. Identify one potential neurologic, physical, and psychosocial problem seen in clients who have HIV or AIDS.
6. Why might a client be hesitant to accept the use of adaptive equipment to engage in occupation?

7. What are at least three health promotion and prevention goals for a client with HIV? For a client with AIDS?
8. How might you address caregiver concerns regarding sexuality issues when both partners are in their sexual prime?
9. If a client with AIDS came to you about the perception of prejudice from other health care personnel, how might you respond?
10. List and discuss at least four strategies to promote the health and well-being of Billy and his partner Tom.

■ Chapter Outline

Polytrauma

Types of blast injuries

Polytrauma rehabilitation centers

Polytrauma transitional rehabilitation program

Polytrauma network sites

Long-term management/polytrauma support clinic teams

Summary

Review questions

■ Key Terms

Polytrauma

Traumatic brain injury

Amputation

Triage

Shrapnel

Blast injury

Interdisciplinary

Post-traumatic stress disorder

Assistive technology

Emerging consciousness

Skull flap

Sensory loss

Age-appropriate treatment interventions

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Understand the definition of polytrauma.
2. List several standard occupational therapy assessments used for polytrauma patients.
3. Understand the areas in which the occupational therapist needs basic knowledge to care for polytrauma patients.
4. Understand the term *emerging consciousness*.
5. Understand the importance of an interdisciplinary approach to polytrauma care.
6. Describe the continuum of care process available within the Veterans Affairs system of care.
7. Describe the multisystem effects of a blast injury.
8. Understand the impact of post-traumatic stress disorder on the recovery process.
9. Identify the use of assistive technology in this population.
10. Describe how return-to-work/return-to-school programs can be included in rehabilitation services.
11. Understand the importance of treating the client and family as a unit.
12. Understand the implications of sensory loss for the rehabilitation process.

*The opinions expressed in this chapter do not necessarily represent those of the Department of Veterans Affairs.

Threaded Case Study | Alex, Part 1

Alex, a 25-year-old Caucasian man, sustained a polytraumatic injury from the blast of an improvised explosive device while serving in Iraq. As a result of the blast, Alex incurred a traumatic head injury (diffuse axonal injury and temporal lobe contusion with subarachnoid hemorrhage), a right arm degloving injury, maxillary and mandibular fractures, and traumatic amputation of his right leg below the knee along with a femoral fracture. Additionally, his injuries included a penetrating eye injury with subsequent surgical excision of the foreign body. He also demonstrated clinical signs of post-traumatic stress disorder. Alex is married and his wife was 3 months pregnant at the time of his injury. He was living in Hawaii before his deployment to Iraq; the home is a single level with two steps to enter the home. His role in the marines was marine corpsmen (medic).

Alex was referred to occupational therapy 1 month after injury when he arrived, medically stable, at the polytrauma rehabilitation ward. Initially, Alex had a Rancho 2-3 level with an altered level of consciousness and was evaluated with the Coma Recovery Scale-Revised (CRS-R).¹⁵ Additionally, he was assessed for positioning needs, splinting needs, range of motion (ROM), and gross strength. Because of decreased arousability, restlessness, and an inability to consistently follow commands, much of the psychosocial components, including occupational history and profile, was obtained by interviewing his wife.

Within a week Alex demonstrated improve cognitive abilities as measured by the CRS-R, and functional mobility, activities of daily living (ADLs), and cognitive and visual-perceptual screening was initiated. Alex required minimal assistance for bed mobility, maximal assistance for transfers and wheelchair mobility, and moderate to maximal assist for all ADLs. Cognitively, he was able to follow simple one-step commands 80% of the time, easily became overstimulated and distractible in anything but a quiet environment, had poor endurance, easily became frustrated, and had difficulty with orientation, problem solving, and other executive skill functions. Safety awareness was also impaired. In addition, Alex's visual-perceptual skills were impaired and he demonstrated dysmetria and double vision. Strength and ROM in his left upper extremity were within normal limits; however, his right hand had decreased strength and ROM. Coordination was slightly impaired on the right but normal on the left. Alex also demonstrated signs of hypervigilance and reported difficulty sleeping.

The objectives of occupational therapy intervention included (1) increasing independence in performance of ADLs; (2) achieving increased independence in transfers and wheelchair mobility; (3) achieving and maintaining optimal ROM in all joints of the right upper extremity for function and maintaining ROM in all other joints for optimal seating and positioning; (4) achieving improved visual-perceptual skills or implementing compensatory strategies to promote safety and ease in ADLs, mobility, and performance of instrumental activities of daily living (IADLs); (5) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (6) achieving optimal independence in performing IADLs, including parenting skills; (7) optimizing independent ability to access the community, including transportation; (8) optimizing independence in return-to-school and return-to-work skills; (9) receiving appropriate durable medical equipment to meet both short-term and long-term needs (including wheelchair, cushion, ADL equipment, and prosthetic limb care needs); (10) optimizing the ability to relax and promoting good sleep hygiene; and (11) educating the family and patient in all aspects of care needs, compensatory strategies, and safety recommendations.

Because of significant impairment in cognitive skills, an interdisciplinary team approach was implemented to ensure that compensatory strategies were carried over throughout the day. As Alex gained insight into his deficits and how they were currently having an impact on his life (community skills, employment, parenting, independence in self-care, and self-efficacy), he had mood fluctuations that ranged from depressed to feeling hopeful and accepting of his current situation. Additionally, supporting the family members and working with Alex and his wife as a couple, on their roles in the relationship, and how that has been changed was addressed through psychology service and with a family therapist.

Throughout the chapter, consider the short-term and long-term consequences of Alex's injuries. The many body systems that were affected with this type of polytraumatic brain injury will have effects on client factors, performance skills and patterns, and the relationship of activity demands to selection of optimal equipment and strategies to optimize his performance in all aspects of his life.

Polytrauma

The definition of polytrauma stems from the Latin *poly*, meaning many, and *trauma*. The term is generic and has been in use for a long time for any case involving multiple trauma. It has become common in U.S. military doctors to describe seriously injured soldiers returning from Operation Iraqi Freedom (OIF, Iraq) and Operation Enduring Freedom (OEF, Afghanistan).³⁴

The term *polytrauma* is now consistently used by U.S. military medical personnel and the Veterans Administration

(VA) to describe the multiple, extreme, often totally incapacitating complex of traumatic injuries that individual U.S. service members suffer in the aftermath of war. The severity and complexity of these multiple wounds and injuries would have proved fatal in previous wars. Advances in medicine and especially in battlefield medicine, as well as quick evacuation of these patients to complex trauma centers, have decreased the mortality rate. Many polytrauma injuries include multiple, severe shrapnel injuries leading to multiple amputations, wounds, loss of normal body function and systemic complications, brain damage, sensory

impairment, and partial to full paralysis. This type of complex injuries is not typically seen, even in the trauma centers of major urban centers that are accustomed to gang warfare.

Polytrauma centers have been developed throughout the Department of Veterans Affairs to address the complex medical and rehabilitation needs of these patients. The VA defines polytrauma as “injuries to more than one physical region or organ system, one of which may be life threatening, and which results in physical, cognitive, psychological, or psychosocial impairments and functional disability.”¹⁰ Not only has the VA taken on the challenge of finding best-care practices to optimize the long-term outcome of these clients, but the civilian sector has also begun to adopt the term *polytrauma* and has set out to provide treatment for this population as well.

Types of Blast Injuries

One of the most common causes of polytrauma is exposure to a blast, such as from an improvised explosive device or a rocket-propelled grenade. According to the Defense and Veterans Brain Injury Center (DVBIC),⁸ blast injury can have different effects on the body based on proximity to the blast and the body’s reaction to the blast. The DVBIC indicates that “exposure to blast events can affect the body in a number of ways, in addition, these different injury mechanisms can interact and result in more impairments or prolonged periods of recovery.”

- *Primary blast injury* is the result of exposure to the overpressurization wave or the complex pressure wave that is generated by the blast itself. This blast overpressurization wave travels at high velocity and is affected by the surrounding environment; for example, the effects of the blast wave may be increased in a closed environment such as a vehicle. Air-filled organs such as the ear, lung, and gastrointestinal tract and organs surrounded by fluid-filled cavities such as the brain and spinal cord are especially susceptible to primary blast injury.^{13,23} The overpressurization wave dissipates quickly and causes the greatest risk for injury to those closest to the explosion.
- *Secondary blast injury* is the result of energized fragments flying through the air; these fragments may cause penetrating brain injury.
- *Tertiary blast injury* may occur when the individual is thrown from the blast into a solid object such as an adjacent wall or even a steering wheel. These types of injuries are associated with acceleration/deceleration forces and blunt force trauma to the brain, similar to that observed following high-speed motor vehicle accidents.
- Finally, with severe blast-related trauma, *quaternary blast injury* can occur as a result of significant blood loss associated with traumatic amputations or even the inhalation of toxic gases released by the explosion.⁹

FIGURE 48-1 Learning to break down a new wheelchair.

Impairments from a polytraumatic injury are not predictable, and the outcome for each individual is unique. Some of the common sequelae include brain injury; spinal cord injury; amputation; infections; orthopedic problems such as fractures; wounds; psychologic stressors such as post-traumatic stress disorder (PTSD); crush injuries; burns; auditory and vestibular impairments; eye, orbit, and facial injuries; dental complications; renal, respiratory, cardiac, and gastrointestinal compromise; peripheral nerve injuries; and pain (Table 48-1).

Although the polytrauma population is defined as a unique population, the principles of treatment and the factors that must be considered when planning treatment are applicable to all rehabilitation populations.^{16,28} Some of the factors include young age at the time of injury, developmental stage and life role participation, including work and family role, familiarity with assistive technology, and military culture, as well as ethnic background, PTSD/acute stress reaction, previous or current substance abuse, high incidence of mental health complications and suicide risk, and vocational and community reintegration factors. Additionally, this population may need to be supported by a case manager for an extended period because their life roles and secondary conditions start to have an impact on their function (Figure 48-1).

Treatment and implementation of treatment triage begin at the acute onset of injury.¹² The priority in the field and once in the hospital is medical stabilization. Once medically stable, the occupational therapist (OT) may be consulted, even while the patient is in the intensive care unit. As soon as the individual is ready for a rehabilitation program, his or her needs are again triaged to see which type of rehabilitation program will be the best fit. Within the VA system is the Polytrauma System of Care, which is broken down into several levels of rehabilitation programs, the most acute being the Polytrauma Rehabilitation Center (PRC—inpatient rehabilitation), the Polytrauma Transitional Rehabilitation Program (PTRP—residential treatment),

■ **TABLE 48-1** | Overview of Explosive-Related Injuries

System	Injury or Condition
Auditory or vestibular	Tympanic membrane rupture, ossicular disruption, cochlear damage, foreign body, hearing loss, distorted hearing, tinnitus, earache, dizziness, sensitivity to noise
Eye, orbit, face	Perforated globe, foreign body, air embolism, fractures
Respiratory	Blast lung, hemothorax, pneumothorax, pulmonary contusion and hemorrhage, arteriovenous fistulas (source of air embolism), airway epithelial damage, aspiration pneumonitis, sepsis
Digestive	Bowel perforation, hemorrhage, ruptured liver or spleen, sepsis, mesenteric ischemia from air embolism, sepsis, peritoneal irritation, rectal bleeding
Circulatory	Cardiac contusion, myocardial infarction from air embolism, shock, vasovagal hypotension, peripheral vascular injury, air embolism–induced injury
Central nervous system injury	Concussion, closed and open brain injury, petechial hemorrhage, edema, stroke, small blood vessel rupture, spinal cord injury, air embolism–induced injury, hypoxia or anoxia, diffuse axonal injury
Renal injury	Renal contusion, laceration, acute renal failure from rhabdomyolysis, hypotension, hypovolemia
Extremity injury	Traumatic amputation, fractures, crush injuries, compartment syndrome, burns, cuts, lacerations, infections, acute arterial occlusion, air embolism–induced injury
Soft tissue injury	Crush injuries, burns, infections, slow-healing wounds
Emotional or psychologic	Acute stress reactions, post-traumatic stress disorder, survivor guilt, postconcussive syndrome, depression, generalized anxiety disorder
Pain	Acute pain from wounds, crush injuries, or traumatic amputation; chronic pain syndrome

Polytrauma Network Sites (PNSs—outpatient rehabilitation), and Polytrauma Support Clinic Teams (outpatient rehabilitation).¹⁰ Additionally, the VA offers polytrauma telehealth for those who are not able to come to a local polytrauma site (Figure 48-2.)

Polytrauma Rehabilitation Centers

PRCs provide acute, comprehensive, inpatient rehabilitation and comprehensive interdisciplinary evaluation of patients with varying levels of acuity or severity. A patient at any level on the Rancho Los Amigos Level of Cognitive Function Scale¹⁷ may be admitted. These evaluations help determine the range and types of services needed to manage the full scope of medical, rehabilitation, and psychosocial sequelae resulting from combat injury and the most appropriate setting in which to deliver these services.¹⁰ PRCs maintain a full team of rehabilitation professionals, as well as consultants from other specialties related to polytrauma. PRCs also serve as consultants to other facilities in the Polytrauma System of Care.

As an OT serving on a polytrauma team, it is imperative to have knowledge and experience in treating a wide variety of conditions. For example, rehabilitation care is often focused on head/brain injury. Therefore, the therapist

must have specialized skill in rehabilitation of traumatic brain injury (TBI), including cognitive rehabilitation, visual-perceptual skill training, sensory loss training, and behavioral skill training.^{16,28} Additionally, OTs need to have a solid understanding of the rehabilitation of physical disabilities, including upper extremity rehabilitation, amputation care, functional mobility, burns, wound prevention, balance, and hand therapy, including splinting. Moreover, the OT must be skilled in psychosocial rehabilitation, with a focus on family care, as well as how to work with patients with PTSD, anxiety, and pain.¹⁸ Finally, the OT must be proficient in retraining performance of ADLs and IADLs, as well as community reintegration training.

The OT is just one member of an interdisciplinary team assigned to the PRC. Some of the other team members include the rehabilitation physician (physiatrist), nurses, social work case managers, speech-language pathologists, physical therapists, recreation therapists, counseling psychologists, and neuropsychologists. Some teams also include family therapists, military liaisons, blind rehabilitation and outpatient specialists, and massage therapists. Consulting services play a large part in the care of these patients. Consultants frequently involved in care include plastic surgeons, orthopedists, pain management specialists, psychiatrists,

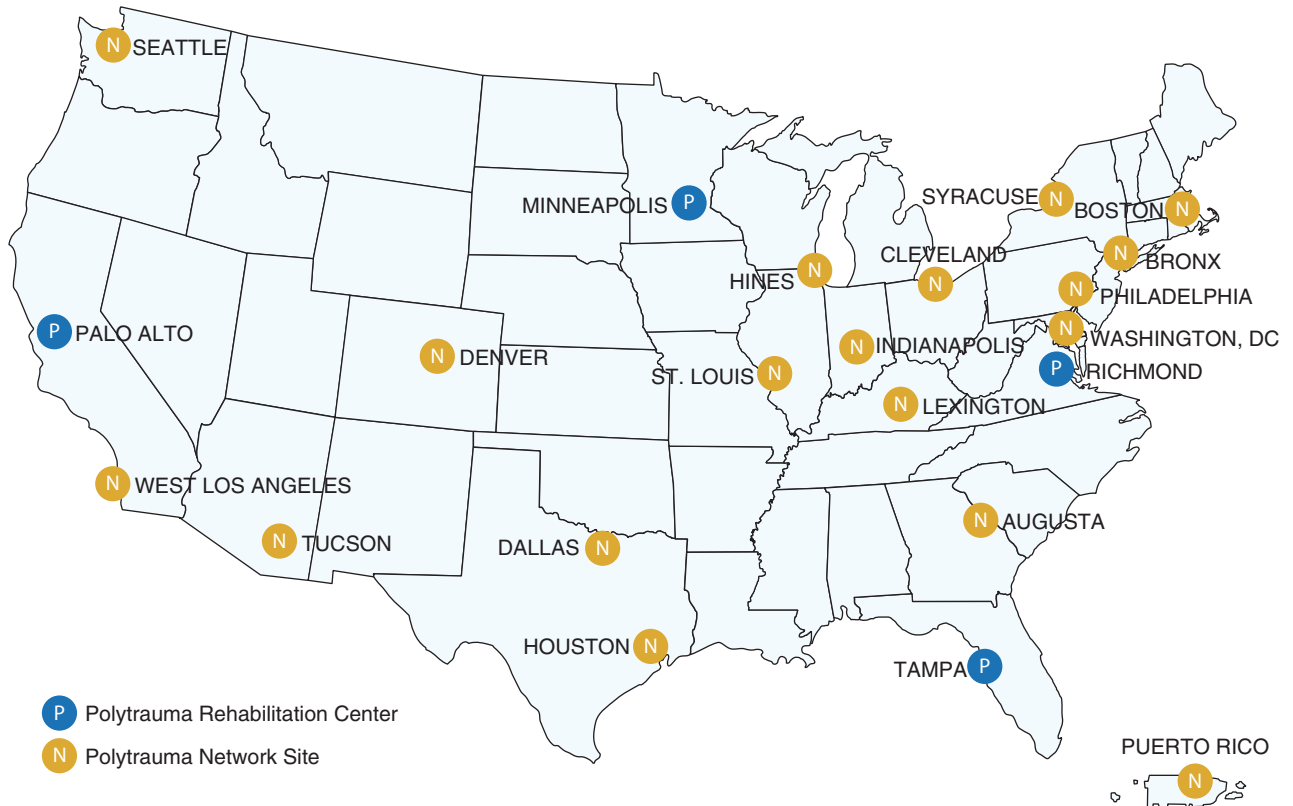

FIGURE 48-2 Map of polytrauma system of care facilities.

dentists, audiologists, neurologists, ophthalmologists, and internists. The key component in the treatment of more acute polytrauma patients is working within and in conjunction with a large team to best serve the patient. The interdisciplinary team meets regularly to ensure that all treating specialists are working as a fluid team to address the primary issues and ensure that the treatment is clinically appropriate and patient centered. Interdisciplinary communication is essential to ensure that all members of the team are re-enforcing techniques and compensations that are initiated by the different disciplines or to collaborate on what techniques and compensations may be most effective to implement for that patient. This often requires cotreatment between disciplines to ensure the best care.^{7,35,36}

Once a patient is admitted to a PRC, the OT is consulted. The OT will always start with a chart review and review the precautions for the client. This population frequently has skull flaps removed and must therefore wear helmets when out of bed. Clients with polytrauma often have infections such as methicillin-resistant *Staphylococcus aureus* and *Acinetobacter*, which require contact precautions (gown and glove); they may also be at risk for seizures, have visual deficits, be at risk for falling, and have behavioral difficulties, as well as PTSD. Once the OT is aware of the patient's background and precautions, the next step is to contact the treatment team to determine whether any additional information is available and then meet with the client. One of the most important pieces of information to

gather is the client's and family's goals and expectations for the rehabilitation program. These goals, as well as the extent of the brain injury, will direct care of the client.

The occupational therapy evaluation is tailored to the needs of the client. For example, clients at Rancho levels 1 to 3 will be evaluated with the CRS-R¹⁴ and the Coma–Near Coma Scale.³¹ Clients will generally be considered to be at the level of “emerging consciousness” if they demonstrate minimal arousal, limited capacity to interact with the environment, significantly impaired ability to follow commands and communicate, and little to no intentional movement.² At this level there is no functional use of objects, which limits the client's engagement in ADLs. A client at the level of “emerging consciousness” will then follow a different pathway from an acute rehabilitation patient. Interventions for these clients often include sensory stimulation, maintenance and restoration of neuromuscular and movement-related functions, prevention of secondary disability, and family education and involvement (see Chapter 34 for additional details). The goal of occupational therapy intervention is to increase arousal, increase functional use of objects, work with speech-language pathologist to determine the most accurate form of yes/no communication, and be able to follow basic commands. In addition, the OT is involved in maintaining or restoring ROM to the upper extremities through passive ROM exercises, splinting, and tone management techniques. The OT will also ensure optimal positioning for seating and maintenance of skin

integrity through cushion and wheelchair evaluation. Once a patient emerges from the minimally conscious state, he or she will transition out of the emerging consciousness program and become an acute rehabilitation candidate (Figure 48-3).

Acute rehabilitation begins with an evaluation of the patient and leads to clinical decision making for triage of needs. Goal setting is based on clinical reasoning with direct input from the client and family members. Goals must reflect occupational performance of functional outcomes. Common evaluation tools focused on assessing body functions include basic goniometry for upper extremity ROM; manual muscle testing; and coordination testing, including standardized assessments such as the Moberg Pickup Test, Purdue Pegboard Test, Jebson-Taylor Hand Function Test, and the Minnesota Rate of Manipulation. Sensory testing is performed, and if needed, Semmes-Weinstein filaments can be used. Basic ADLs and IADLs are assessed. Some examples of assessments that are used for ADLs/IADLs are the Kohlman Evaluation of Living Skills, Executive Function Performance Test, Canadian Occupational Performance Measure, and the VALPAR 5 Workstation Analysis. Transfers and functional mobility are assessed, in addition to skin maintenance and seating needs. Visual-perceptual skills are evaluated; some standardized tools that are used include the Motor Free Visual Perceptual Test, the BiVABA, and Dynavision, and nonstandardized assessments for neglect, saccades, acuity, and color perception are also administered. Finally, basic cognitive skills are evaluated with tools such as the Loewenstein Occupational Therapy Cognitive Assessment, Test of Everyday Attention, Contextual Memory Test, and informal assessments such as components of functional task performance.

Once the evaluation is complete, it is the OT's role to ensure that the client engages in functional activities that promote and maintain optimal upper extremity ROM for later functional tasks. This includes basic self-care tasks along with tone management, splinting, and ROM exercises. Additionally, maintenance of skin integrity is a priority. Many polytrauma clients have shrapnel wounds, burns, and pressure wounds from bed surfaces, seating surfaces, and splints. It is critical that the OT work with the medical provider, nursing, and physical therapy to ensure that client has optimal skin integrity and contact surfaces that provide pressure relief.

If sensory impairments are present, they must be addressed for the client to function within the environment. With decreased sensation in areas such as pain, touch, and temperature, the OT must make sure that the client has training in the use of compensatory strategies for safety. If the patient has hearing loss, it is critical that the therapist face the patient when speaking, speak at a louder volume, or ensure that the client uses appropriate devices to compensate for the hearing loss. Finally, with visual loss, it is important to maintain a clutter-free environment for the client, keep all necessary items and furnishings in the same

place at all times, and orient the client for safe functional mobility within the room. The OT also works closely with the blind rehabilitation outpatient specialist to ensure that client can perform basic ADLs and IADLs by using low-vision or blind rehabilitation techniques and devices.

After these performance components are evaluated, the OT can focus on basic ADLs. This includes issuance of and training on any assistive devices or durable medical equipment needed to optimize independence. For example, a client may need a long-handled mirror to inspect the skin for wounds or observe a healing amputation site. A client may also require specialized feeding tools such as plate guards or rocker knives for one-handed feeding. In addition, clients may require shower benches or grab bars if balance or mobility issues are present. Part of basic ADL performance includes the ability to get to places safely, such as the toilet or shower. Therefore, the OT must address any seating and mobility needs for a client who is nonambulatory. A seating evaluation can be performed as part of the wheelchair assessment for a client who is nonambulatory. Wheelchair issuance includes training on safety, training on mobility, and evaluation of visual-perceptual skills for safe propulsion of the chair. Ambulatory clients who have deficits that affect getting to the toilet or shower safely because of balance issues or motor planning would also need occupational therapy services. Caregiver training is also initiated with ADL and functional mobility training, and as a client progresses, the training needs to be readdressed.

IADLs are also addressed for this population. It may start with simple meal preparation, basic money management, or simple homemaking skills and progress to higher-level money management skills; work-, school-, and family care-related skills; time management; and community living skills. It is important to incorporate cognitive retraining and compensatory strategies to optimize independence in these skills. Clients are often issued and trained on the use of cognitive prosthetic tools such as personal digital assistants (PDAs), alarm watches, and global positioning system (GPS) devices. Use of these tools and the strategies provided for executive skill functions such as pathfinding, problem solving, organization, and planning is then integrated into community reintegration sessions. Community reintegration also includes training on use of public transit, as well as driving rehabilitation.

Many clients who have sustained polytrauma experience PTSD, anxiety, and pain. A polytrauma OT may initiate training in the use of biofeedback for management of stress, relaxation, and management of pain. Additionally, sleep hygiene is addressed by the OT in conjunction with psychology services, medical service, and nursing. The client is able to learn and practice these sleep hygiene techniques while in the PRC to support the use of these skills after discharge.

Throughout the inpatient stay, a client with polytrauma may have many medical procedures and off-unit medical appointments that interrupt the scheduled occupational

therapy sessions. These procedures may result in a change in status and thereby necessitate re-evaluation and reassessment of the client's functional and cognitive status. Updating of goals and priorities must continually be on the forefront as the client's status or the client and family goals change. The families are generally very involved in all aspects of the client's care and are incorporated into the treatment-planning process.

Threaded Case Study Alex, Part 2

On completion of his inpatient PRC stay, Alex was independent in basic ADLs, transfers, and manual wheelchair mobility on indoor and outdoor surfaces. He was fitted for a prosthetic limb and had achieved functional grip strength in his right hand and sufficient coordination to don and doff the prosthesis. Alex was issued a PDA to assist in his memory deficits, performance of IADLs, and organizational skills. He still required minimal assistance to perform basic IADLs such as meal preparation, household management, and financial management. With visual-perceptual skill retraining, Alex no longer complained of double vision and was able to identify and reach for targets accurately. With the use of compensatory strategies, such as deep breathing, biofeedback, and sleep hygiene skills, Alex was sleeping well and less anxious, and his tolerance of frustration had improved. Distractibility continued to have a negative impact on his time management skills and ability to follow through with assignments; however, he was able to create a less distracting environment for himself with cueing. His safety awareness improved, although supervision was still required for higher-level judgment and safety. As Alex transitioned to the PTRP, his occupational therapy program continued and progressed in accordance with his inpatient recommendations. Occupational therapy objectives for the PTRP included (1) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (2) achieving optimal independence in IADLs, including parenting skills; (3) optimizing independent ability to access the community, including transportation; (4) optimizing independence in return-to-school and return-to-work skills; and (5) receiving appropriate durable medical equipment to meet both short- and long-term needs.

Polytrauma Transitional Rehabilitation Program

The PTRP provides comprehensive, postacute cognitive retraining and community re-entry rehabilitation to patients with TBI who have progressed beyond the needs of basic rehabilitation interventions. The goals of this program are to integrate clients back into their community, assist them in achieving independent living, and help them return to their life roles. Not all clients who enter the PTRP have been through a PRC; many are direct referrals from other

VA facilities, from PNSs, and from outside private facilities or military treatment facilities. Because these clients have already achieved the goal of basic inpatient rehabilitation, that is, independence in ADLs and basic functional mobility, the focus while involved in the PTRP is on the higher-level skills needed to return to the community. There is more of a cognitive retraining focus with an emphasis on group work and community. The majority of clients reside within the PTRP facility; however, some clients have already transitioned back to the community and come to the facility for the day program.²⁰

As is similar with all rehabilitation settings, the occupational therapy program begins with an evaluation of the patient and leads to clinical decision making. Goal setting is based on clinical reasoning, input from the patient and family, and the interdisciplinary team goals. OTs in the PTRP use many functional nonstandardized evaluation tools, but they also use standardized TBI evaluation tools such as the Mayo-Portland Adaptability Inventory (MPAI-4).²¹ The MPAI-4 focuses specifically on the most frequent sequelae to be considered during rehabilitation planning or other clinical interventions, such as physical, cognitive, emotional, behavioral, and social problems. MPAI-4 items also provide an assessment of major obstacles to community integration that may result directly from a brain injury, as well as the environment and context of the activity. With input from other team members, including psychology and neuropsychology, speech-language pathology, and physical therapy, realistic goals and community reintegration training can be initiated.

The OT addresses a client's ability to participate in basic IADLs such as money management, including establishing banking accounts, budgeting, financial planning, and paying bills. Additional areas addressed include cooking skills, home management and organization, health management and maintenance, child rearing, pet care, safety awareness and emergency responses, and shopping. The use of compensatory strategies and cognitive prosthetics is integral for IADL retraining, especially for clients with disorders in memory and executive functions. Many of these clients are issued and trained on use of a PDA, which is then reinforced throughout all therapies within the program.

Community reintegration training facilitates the client's ability to access the community. This includes training a client on the use of public transit, addressing driving needs, or addressing the client's ability to procure transportation in the community. It also requires the client to learn path-finding skills, often with the use of a GPS device, and executive skill functions such as trip planning, budgeting, time management, and problem solving. The OT provides opportunities for practice in using strategies and cognitive prosthetics (such as PDAs, smart phones, or GPSs) to aid the client in becoming successful in this occupational performance area.

Another key component of this rehabilitation program is training and interventions to assist the client in meeting

the goals of returning to school and learning. This includes training in basic academic skills such as math, note taking, and general study habits. It also includes exploration of educational needs and interests, some of which may lead to prevocational or vocational participation. The OT must also address any assistive technology needs such as computer access, PDAs, and specialized software designed to increase ability to succeed in school-based programs.

If return to work is the primary goal for the client, the OT must assist him or her in gaining the skills needed to return to productive employment or volunteer activities. The OT may work on goals to identify and select work opportunities based on the client's level of function, as well as likes and dislikes. Occupational therapy services are often provided to retrain the client in how to identify job opportunities, complete and submit appropriate application materials, and prepare for interviewing. Work habits, such as attendance, punctuality, appropriate relationships with coworkers, appropriate dress, completion of assignments, timeliness, and compliance, must also be addressed. The use of cognitive prosthetics is incorporated to assist the client in succeeding in these areas. Finally, the client may not be ready to engage in full-time or even part-time paid employment, and thus volunteer exploration and participation may be the first step in returning to the workforce. The OT may provide job coaching at the work or volunteer site to identify adaptive or compensatory strategies for successful performance.

Leisure exploration, participation, and social skills also need to be addressed by the OT to improve a clients' reintegration into the community. Key elements in addressing these skills include social skills groups, practice on appropriate interactions within the milieu or environment, and role-playing with feedback. Peer interaction, both within the program and within the community, as well as family and community interactions, allows greater practice and skill training. Leisure exploration may include administering interest checklists and assessing abilities and opportunities available. It also includes training in the ability to plan for leisure, obtaining and maintaining equipment and supplies, and balancing leisure participation with work and self-care needs. The OT may work in conjunction with the physical therapist and the recreation therapist to ensure that adaptive sporting equipment and assistive technology are available as needed to best meet the leisure needs of the client.

Stress management also needs to be addressed. Many of these clients experience stress related to adjusting to their limitations, changes in their life roles and patterns, pain or sleep issues, and PTSD. Biofeedback may be used to aid these clients in learning techniques to decrease overall stress reactions, manage pain, and improve sleep. Sleep hygiene education, as well as various mind-body techniques, can also be introduced and incorporated into this program.

Overall, OTs working in the PTRP have to address all the aforementioned areas in the context of clients' current physical and cognitive abilities while also addressing how to

improve their current functional abilities. Any physical limitations such as in ROM, strength, and coordination are addressed to improve functional performance. A client's sensory issues, such as low vision or visual-perceptual skill deficits, must be addressed and compensations incorporated into treatment planning for all the previously mentioned areas of function. Finally, cognitive skills, remediation, and compensation must be addressed to ensure that the patient has an optimal outcome in these areas of function.

As the patient transitions out of the PTRP, the OT plays a role in helping the patient relocate to appropriate housing, makes recommendations for levels of assistance still needed, addresses caregiver training if required, and ensures that prerequisite skills for the housing option are in place. Any durable medical equipment and environmental modifications needed will be addressed by the OT.

Threaded Case Study Alex, Part 3

After 3 months in the PTRP, Alex demonstrated improved integration of his PDA into performance of IADLs. He is now using it for appointment reminders, direction finding, list making, note taking, and medication management, with occasional cueing from the therapist. Although Alex is still unable to drive, he has learned to use the local public transport system and is able to access restaurants, malls, grocery stores, and specialty stores in the local area. Pathfinding with use of the PDA and computer maps is adequate for familiar areas. Safety awareness has improved and Alex is now safe to be left alone for long periods, is able to independently access his local community, and demonstrates improved reasoning and insight in decision making/problem solving. Alex is now independent in light hot meal preparation and basic home management tasks such as laundry and cleaning. He began to volunteer part-time in the local preschool program to address work skills and child care skills. Training in the use of biofeedback has continued, and Alex has become more skilled at self-regulation.

As Alex completed the PTRP, he moved home with his pregnant wife and was referred to a PNS for further occupational therapy intervention. The objectives of OTs in the PNS included (1) promoting the highest level of functional cognition, including implementation of compensatory strategies and cognitive prosthetics to increase independence and safety in all functional skills; (2) achieving optimal independence in IADLs, including parenting skills; (3) maximizing his ability to independently access the community, including transportation; (4) optimizing independence in return-to-school and return-to-work skills; (5) receiving and training on appropriate durable medical equipment to meet both short- and long-term needs; and (6) optimizing independence in the use of stress management and coping skill strategies, including mind-body techniques.

Polytrauma Network Sites

PNSs are outpatient clinics that serve two roles. The first is to provide specialized, postacute rehabilitation in consultation with rehabilitation centers. The OT consults with and provides follow-up based on recommendations made by the inpatient therapists. Depending on the client's current status and outcomes, the client's occupational needs can range from re-education of caregivers in skilled nursing facilities to seating and mobility needs for returning to school or the workplace. Ambulatory clients who have deficits that affect getting to the toilet or shower safely because of balance issues or motor planning would also need occupational therapy services. Another focus may be on reinforcing the integration of assistive technology and other compensatory techniques for optimal independence in performance skills and patterns. The OT creates a treatment plan based on the client's needs (environment, client factors, client and family goals, activity demands, and current performance skills), not one that is based on the particular diagnosis. Treatment is provided in the context and environment most appropriate to meet the needs of the client.

A significant increase in the incidence of mild traumatic brain injury (mTBI) has been seen in service members as a result of serving in the OIF/OEF conflicts.¹¹ There is no standard, agreed-on definition of mTBI. The Department of Veterans Affairs uses the following definition of mTBI in all its TBI screening evaluations: a patient with mTBI is one who has experienced a traumatically induced, physiologic disruption of brain function as manifested by at least one of the following^{8,22,24,30}:

1. Any period of loss of consciousness
2. Any loss of memory of events immediately before or after the accident
3. Any alteration in mental state at the time of the accident (e.g., feeling dazed, disoriented, or confused)
4. Focal neurologic deficit or deficits that may or may not be transient but in which the severity of the injury does not exceed the following:
 - a. Loss of consciousness of approximately 30 minutes or less
 - b. After 30 minutes, an initial Glasgow Coma Scale score of 13 to 15
 - c. Posttraumatic amnesia not longer than 24 hours

Common symptoms of mTBI include headache, dizziness, nausea and vomiting, sleep disturbances, sensitivity to light, sensitivity to noise, slowed processing, memory difficulties, irritability, depression, and visual changes. An individual may experience symptoms at the time of the event or weeks later following the mTBI. The majority of the population who sustain mTBI experience a resolution of symptoms within 3 months.³³ However, 15% to 30% of individuals have ongoing symptoms and are at risk for the development of postconcussive syndrome.^{1,29} In

postconcussive syndrome, the aforementioned symptoms or clusters of symptoms persist for longer than 3 months.⁵

Postconcussive syndrome can have an impact on outcomes at any stage of polytrauma rehabilitation. Sometimes postconcussive syndrome does not become apparent until many of the life-threatening injuries have been stabilized.^{19,30} While in the acute phase of rehabilitation, the symptoms may have an impact on function; however, the focus may be more on the acute injury, not on the persistent postconcussive symptoms. While in the postacute phase, postconcussive symptoms are identified during higher-level functional activities. Patients can also be treated for PTSD when mTBI and postconcussive symptoms are recognized.

Clients who experience multiple blast exposures are at higher risk for more complicated mTBI. This, in conjunction with exposure to stressful environments, increases the risk for mTBI and acute stress reaction/PTSD. This is true for mTBI sustained in automobile accidents in the private sector as well.⁴ The stressful environment, multiple exposures, and acute stress reaction/PTSD can have a significant impact on natural recovery from mTBI.

The symptoms of acute stress reaction, depression, and PTSD are very similar to those of mTBI/postconcussive syndrome and can include difficulties in memory and concentration, sleep problems, impaired attention, irritability, and headache. The best approach for identifying the cause of the various symptoms is to incorporate the treatment team. The PNS uses an interdisciplinary team model to determine the most likely cause of the deficits and the most appropriate treatment to address the symptoms (Figure 48-4).

When the PNS system was developed in 2007, there were no standards for rehabilitative treatment of mTBI. As this diagnosis became so prevalent from the OIF/OEF conflict, the Department of Defense and the Department of

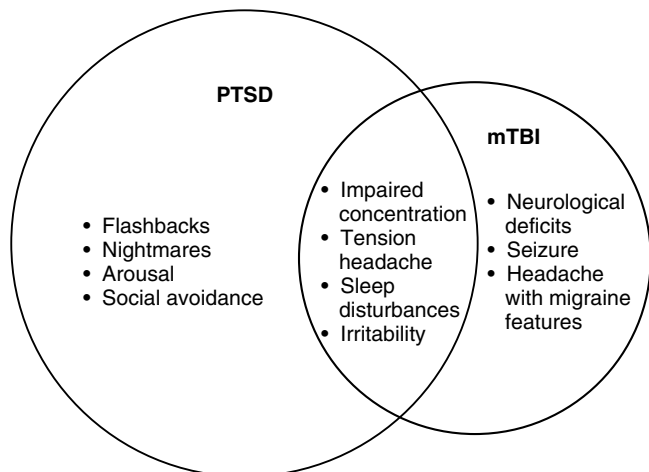

FIGURE 48-4 Common symptoms of mTBI and PTSD.

From Ruff RL, Riechers RG, Ruff SS: Relationships between mild traumatic brain injury sustained in combat and post-traumatic stress disorder. *F1000 Med Rep* 2: 64, 2010 (government publication).

Veteran's Affairs developed best-practice guidelines.¹¹ Additionally, an occupational therapy– and physical therapy–specific guideline was developed by the Propensity Office for Rehabilitation and Reintegration (OT/PT: Clinical Practice Guidance: Occupational Therapy and Physical Therapy for Mild Traumatic Brain Injury). The clinical guidance document recommended treatments focused on client education, visual dysfunction, headache, cognition, resumption of roles, and emotional well-being.

Studies show that mTBI needs to be approached and treated differently from moderate or severe TBI. The goal is to increase awareness of deficits in those with more severe TBI, whereas with mTBI, studies have shown that focusing on abilities, stress management/coping skills, and compensatory strategies improves outcomes.^{3,6,8,27,32,37} Clients with mTBI tend to be overly sensitive to errors and have decreased perceived self-efficacy, which can lead to decreased self-esteem, depression, and isolation. These factors can affect return to life roles and community reintegration. Clients may be able to follow through with routine and familiar tasks yet may demonstrate difficulty in problem solving, insight, and self-control.²⁶

OTs working in the PNS system start the initial interaction with the client during the evaluation. This includes the use of standardized assessments, self-report tools, and observation of performance of functional tasks. The therapist also provides visual-perceptual screening because visual deficits are frequently seen in clients exposed to multiple blasts. From that screening, the therapist can then refer the client for further assessments as needed. The evaluation also includes screening for ADL needs, cognitive deficits, current use of assistive technologies, home modification needs, home management skills, organizational skills, predriving skills, physical rehabilitation needs, emotional regulation, sleep hygiene, pain, headache, and relaxation skills. Additionally, the OT will address current needs in relation to study skills, vocational needs, community re-entry skills, return and transition to life roles (including follow-through with entering school, the workforce, or both), managing a household for the first time, higher-level money management, and parenting skills.

The therapist focuses on client goals in relation to activity demands and any deficits identified. The therapist will address the aforementioned areas by intervention consisting of remediation techniques and training in compensatory strategies, assistive technology, and biofeedback/mind-body techniques. This may include removing distractions, creating routines, and integrating self-awareness training tools. Client education is also an integral part of treatment. Client education may consist of discussing the effects of mTBI, expected outcomes, and how typical stressful situations and sleep problems can have an impact on function. Within the context of this education, the therapist must provide guidance on strategies for increasing insight, using compensatory mechanisms, and achieving effectiveness in participation in desired occupations. Overall, it has been documented

that outcomes are better for mTBI when clients receive adequate education.^{25,28}

Because the PNS works with many returning service members who bring combat driving skills to the civilian environment, their safety in driving skills must be assessed. Such driving skills include attention, multitasking ability, reaction speed, and visual-perceptual skills, as well as addressing stress reactions and hypervigilance. Many soldiers avoid driving or rely on others for assistance. OTs address predriving skills by assessing and remediating performance components. The VA has therapists who are driving rehabilitation specialists. These specialists are trained to evaluate this population by working both with driving simulators and behind the wheel. They also can provide driver's training and adaptive controls or vehicles as indicated.

The PNS as a team is tasked to monitor and follow clients' needs for their lifetime. These network sites provide proactive case management for existing and emerging conditions and identify local resources for both VA and non-VA care.

Threaded Case Study Alex, Part 4

Alex was initially evaluated by the OT at the PNS on a weekly basis and then once a month. Alex's primary concern on initial PNS evaluation was the upcoming arrival of his baby. Although some child care skills were addressed during his volunteer experience, he was unsure of how to care for a newborn, combined with the stressors of lack of sleep, poor tolerance of frustration, and distractibility. Trial and training with a programmable infant simulator were successful in the integration of self-regulating strategies and PDA use and increased his confidence in his abilities. After training on the use of GPS, a feature of his PDA, Alex is able to navigate in unfamiliar areas with confidence. He also completed a driver's rehabilitation program and has been cleared to drive independently. Alex has enjoyed his volunteer experience and has identified teaching as a vocational goal. He is now taking one course per semester at the local community college and is implementing the study skills taught during his PNS sessions.

Monthly, Alex brings in a list of difficulties identified (tracked in his PDA) in work, home care, and child care, and he works with the OT to further address these needs. At the 1-year postinjury mark, Alex reports that he has a well-balanced life with volunteering, school, family, and social/leisure activities.

Long-Term Management/Polytrauma Support Clinic Teams

Long-term polytrauma management is accomplished in clients' home community where they are monitored by either the PNS or Polytrauma Support Clinic Teams. These

teams are groups of rehabilitation providers who deliver follow-up services in consultation with regional and network specialists. They assist in managing the long-term effects of polytrauma through direct care, consultation, and the use of tele-rehabilitation technologies, as needed. Polytrauma telehealth is a burgeoning field in rehabilitation. Telehealth is the use of electronic information and telecommunications technologies to support long-distance clinical health care, client and professional health-related education, public health, and health administration.

Technologies used in telehealth typically consist of videoconferencing, the Internet, store-and-forward imaging, streaming media, and terrestrial and wireless communications. Even though new applications are increasingly being found for the use of these technologies, significant barriers remain in making these technologies an integral part of daily health care practice.³⁸ The OT's role in telehealth is either as a presenter, consultant, or direct care provider.

The Polytrauma System of Care encompasses all the programs described earlier and ensures that there is a smooth, seamless continuum of care for these clients, including case management for life.

Summary

Polytrauma can result in substantial impairments that affect all areas of occupation. The injuries can vary from mild to severe and can include multiple body systems and affect performance skills and patterns. When treating these clients a therapist must take into consideration the specific client factors and the context and environment in which activities will occur. The goal of occupational therapy is to facilitate the client's achievement of optimal independence and functioning. Polytrauma affects the entire family unit, and thus rehabilitation goals must be client and family centered.

Review Questions

1. What is the definition of polytrauma?
2. Differentiate between primary, secondary, tertiary, and quaternary blast injury?
3. What are some common sequelae of polytrauma?
4. What makes a polytrauma patient from the OIF/OEF conflict unique in today's rehabilitation population?
5. In the inpatient/acute unit, what primarily drives the rehabilitation course?
6. Why is an interdisciplinary team more effective than siloed care in treating polytrauma patients?
7. What are the common symptoms of and interventions for mTBI and PTSD?
8. What are the roles and treatment interventions for OTs in treating an emerging consciousness patient?
9. How does the focus of treatment change as the patient progresses through the Polytrauma System of Care?
10. How does PTSD affect the recovery process for a polytrauma patient?
