ecologic approach to the performance of functional tasks (and purposeful movements). This approach emphasizes interactions among the person, the environment, and task performance.¹⁶ The term *task* is not equivalent to *occupation*.⁷ Although several definitions of the term *occupation* have been offered, the elements that distinguish occupations from tasks include the specific meaning to the occupational performance and the occupational performance within a context or environment.⁶ A task is often a small portion of an occupation, such as the task of cutting with a knife and fork within the occupation of self-feeding. Yet an appreciation for the task-oriented approach is associated with an understanding of the potential impact that the task may have upon occupational engagement. The OT practitioner may apply motor learning concepts and may adapt, modify, or otherwise facilitate successful completion of an occupation-based goal.

Application of the TOA directs occupational therapy practitioners to address the performance skill¹¹ deficits of clients while simultaneously incorporating current understanding of neuroscientific concepts. Both the process and the outcome are important in this approach. The net result of this approach is that the client may benefit through improved performance of ADLs. Ultimately, this may support the practice of habits and routines and eventually may facilitate a return to desired, client-centered roles.

Performance Skills and Client Factors

The OTPF-2 identifies client factors and performance skills as separate elements and describes how they impact and are impacted by client interaction with the task and the environment in the performance of ADLs.¹ Fisher provides a background on the process of how to formally and informally assess performance skills and patterns in relation to occupations.⁷ She states that to understand how client factors influence occupational performance, it is important to thoroughly determine how these components affect performance skills during occupational performance.⁷ Thus, it could be inferred that any attempt to assess this relationship without an appreciation for and an understanding of this dynamic process may lead to potentially “misdirected” conclusions. In other words, the OT practitioner may make clinical decisions that are not in the best interests of the client and will not reflect “best practice.”

Table 18-1 identifies performance skills from the OTPF-2.

Table 18-2 identifies client factors from the OTPF-2.

In what way can the occupational therapy practitioner evaluate John to identify what assets and deficits this client may be able to utilize?

It is necessary to understand current client abilities relative to specified task performance. This can be done by measuring particular client factors such as John’s left upper limb active range of motion (ROM) and strength. As discussed in the chapter, it is important to have an understanding of particular areas of deficit before initiating

■ TABLE 18-1 | Performance Skills Defined

Performance Skills	Definition
Sensory perceptual skills	The ability to receive sensory information and interpret that information while engaged in occupational performance.
Motor and praxis skills	The skilled motor behaviors displayed by the individual in interacting with objects, tasks, and environments while engaged in occupational performance. ⁷
Emotional regulation skills	The client’s ability to express, manage, and identify feelings while engaged in occupational performance.
Cognitive skills	The ability of the client to plan, organize, and monitor occupational performance.
Communication and social skills	The client’s actions and behaviors in communicating and interacting with others. ⁷

■ TABLE 18-2 | Client Factors: Comparison at the Person, Organization, and Population Levels¹

CLIENT FACTORS		
Person Level (AOTA)	Organization Level (AOTA)	Population Level (AOTA)
Values: the principles and qualities deemed important Beliefs: the cognitive assignment of truth	Values and beliefs: include an organizational vision statement, values, code of ethics	Values and beliefs: “emotional, purposive, and traditional perspectives” (AOTA, ¹ p. 634)
Spirituality: the personal search for understanding	No comparable factor	No comparable factor
Body functions: include physiologic functions of the body such as sensory, mental, cardiovascular, and respiratory	Functions: include services/ products offered, planning and organizing, mission statement	Functions: economic, social, political, and cultural capital
Body structures: anatomic structures of the body	Structures: departments, leadership/ management	Structures: similar genetics, sexual orientation, health-related conditions

AOTA, American Occupational Therapy Association.

occupational therapy services. This understanding should be combined with observations of John's participation in certain activities, which may include performance of his morning routine such as dressing, brushing teeth, and shaving. The OT practitioner would observe what specific strategies are utilized. If John turned his body to the side to position his left arm across his lap to then place his left arm into the sleeve of a shirt, it is likely that this particular **strategy** maximizes his performance skill. The evaluation process would be a combination of client factor measurement with occupational performance assessment, which would most likely reflect John's abilities to perform these ADLs.

Client factors related to body and structure **function** are important because they inform the OT process and ultimately contribute to an understanding of how these functions (or lack thereof) contribute to the evaluation process and the development of an intervention plan. Additionally, values, beliefs, and spirituality are included as client factors in the OTPF-2.¹ Within the OTPF-2,¹ client factors are differentiated at the person, organization, and population levels; this chapter will primarily address client factors applied at the level of the person. Specific client factors identified at the level of the person may include neuromusculoskeletal functions related to strength, muscle tone, motor reflexes, and voluntary and/or involuntary movement. Global and specific mental functions are important client factors that support incorporation of input gained by one's interaction with a task within the environment. These mental functions, collectively termed *cognition*, are required for a person to make sense of sensorimotor input from the environment. They are important to overall functional ability. Also, the degree to which the central nervous system is intact following damage or the appearance of a lesion will affect a client's occupational performance.

As they relate to UMN cortical lesions, these client factors may result in peripheral soft tissue changes, hypertonia, spasticity, and changes in range of motion. Any combination of these changes will likely influence how a client participates in a particular task. These client factors remain relevant and supportive in their role in the overall OT process. In other words, they are a means to understanding an end that focuses on performance skills, as these skills support the performance of occupations.

Client factors differ from performance skills in that they represent responses to system control. Client factors often can be measured and quantified and include strength, range of motion, visual acuity, muscle tone, and attention. **Client factors** represent bodily functions and what the "body" does, rather than what the "person" does. This distinction is made clear by Fisher,⁷ who stated that client factors are the actual body structures and basic body functions. Additionally, client factors represent what a person can utilize to perform a particular task. Thus, client factors facilitate performance skills, but merely assessing available client factors is not predictive of occupational performance.¹

Performance skills include the motor and praxis, sensory-perceptual, emotional regulation, and cognitive and communication/social skills required to perform specific tasks (i.e., ADLs, instrumental ADLs [IADLs], and work). Fisher⁷ described performance skills as "small units of action [that] are always goal-directed because they are enacted in the context of carrying out and completing a daily life task" (p. 375). Therefore, performance skills are not assessed in the absence of occupational performance but must be assessed while the client is engaged in an occupation. For example, John would like to be able to prepare a dinner that includes cooking on the stove, specifically, cooking pasta and spaghetti sauce. Although assessment of specific body functions may reveal limited isolated active range of motion (AROM) of his left arm, making it difficult for him to hold the handle of the sauce pan while stirring the sauce with his right hand, during the actual task performance, the OT practitioner would also note difficulties in positioning his body appropriately to the stove and poor pacing of actions in the performance skill categories of sensory-perceptual and motor and praxis skills. Motor and praxis skills along with sensory-perceptual skills are required in adequate and appropriate amounts for an individual to interact with an object in the environment during performance of a task in an accurate and efficient manner. This process can be dynamic and complex, and understanding this interaction informs and directs the OT evaluation and intervention. The ability to judge and respond to task demands is an aspect of cognitive performance skills linked to overall occupational performance. If John were to cook pasta and spaghetti sauce for dinner, he would have to sequence the task appropriately by starting spaghetti sauce, then placing water on the stove for the pasta, and, as the sauce simmers, adding pasta to the boiling water. He would need to time all these events appropriately to avoid serving cold pasta with overcooked sauce. Given John's difficulties in attention (a client factor), an OT practitioner may assume that the complex task of cooking spaghetti and sauce would be a challenge. Without observing the actual performance, the therapist may have suggested a checklist as an intervention method without understanding how the sensory-perceptual and motor and praxis performance skills interact with cognitive skills during the occupation of meal preparation. Thus, a person presents with specific deficits (client factors) that affect performance skills, and this may affect occupational performance.

Significant changes/impairments with these client factors may sufficiently influence a client's performance patterns and skills and eventually (adversely) may influence occupational roles. Research indicates that the TOA is more likely to positively influence outcomes when compared with treatment that addresses only client factors.¹⁹ Neuroscientific research is pointing toward the possibility that the central nervous system is organized in such a way that tasks can be addressed through interaction with the environment rather than with specific muscle groups meant to perform specific

tasks. This is consistent with the TOA. Thus, understanding of a client's roles and routines will guide an OT practitioner's ability to address performance skills as they relate to occupational performance. In summary, performance skills are required for interaction with task, object, and environment.²⁰

How would John benefit most from occupational therapy intervention with a focus on performance skills to support improvements in client-chosen activities?

John is motivated to improve his self-care and home management skills. He is able to complete his morning routine and self-care activities with limited physical assistance from another person. He has a supportive family that provides assistance as needed. He stated that he wants to be able to improve his ability to complete his morning routine, self-care activities, and home management tasks. If the OT practitioner were to focus on prioritizing these activities, it would be possible to determine the best way to address reacquisition of these abilities. Although multiple control parameters (a *control parameter* refers to the motor element that influences performance) can influence successful task completion, it is likely that in any particular activity, at least one key parameter may be the most limiting factor to successful task completion. For example, with the shaving activity, John's impaired movement in his left hand compromises bilateral task performance and serves as the control parameter. This impairment, as described in the case illustration, is a result of the inability to have sufficient distal control. It is important to observe the actual performance of the shaving activity when possible to avoid any contrived situations. Merely having John use a safety razor with the cover in place to simulate the act of shaving would not accurately replicate the actual performance of shaving. In this instance, it needs to be determined whether focusing on how the performance skill of bilateral control can be achieved will improve shaving, or if the task needs to be adapted to maximize independence. The OT practitioner can validate these approaches by observing John during the actual task of shaving. This same approach may be taken with each activity to be addressed.

Motor Control Theory

Interaction among the task, the person, and the environment represents important aspects of motor control. **Motor control theory**, that is, the ability to make dynamic changes in/responses of body and limb to complete a purposeful activity,²³ has undergone much development in recent years. This development has expanded our knowledge base, has answered some questions, has introduced other questions, and has permitted a greater appreciation than ever of the complexity of cortical function as it relates to motor performance.

A variety of sources indicate that multisensory input will provide the nervous system with input, which ultimately will lead to improved quality of movement performance and decreased error, and will support more efficient

movement patterns.^{4,18,19} These multiple sensory inputs to learning (or relearning), whether intact or not intact, will work together to contribute to our understanding of interaction with the environment. When one sensory input (or system) is impaired, others may need to compensate. When one part of a system is impaired, the performance pattern is affected. For example, if a person presents with impaired ability to perform dynamic distal (hand and finger) movements as the result of decreased motor control, then he or she may move the proximal upper limb in such a manner as to compensate for this impairment.¹⁷ The net result of this compensatory movement may present as "shoulder hiking" and may include other movements such as lateral trunk flexion or even shortening of the lever arm (i.e., elbow flexion) to control degrees of freedom.²²

John likely "hikes" (abnormally elevates) his left shoulder when movement is initiated as he attempts to reach for objects such as his razor or toothbrush. Doing so allows him to be able to get his left arm to a position from which he can access these items. John may be aware of the fact that he might have reached differently before the CVA. The OT practitioner may ask John to reach for these items with his right hand for comparison (recall that John is right hand dominant). This serves as an informal task analysis. If the position of the items and how John interacts with the objects in the environment are changed, analysis reveals how this may affect the strategy, given available skills.

It is possible that this inefficient movement pattern could be repeated and might eventually develop into a new adapted or maladapted pattern. Unless this process is properly analyzed, the client is more likely to "learn" and repeatedly use this inefficient movement pattern to accomplish a task. Poor and ineffective patterns may emerge, overuse syndromes may occur, and the net result is potentially poor self-efficacy with occupational performance.

Repetition alone as part of a neuromuscular rehabilitation approach is insufficient to create and reinforce cortical reorganization.^{2,11,22} This statement is neither novel nor ground-breaking in its meaning, yet its intent is shared by multiple researchers in a variety of arenas from basic neuroscience to the field of occupational therapy.^{2,11,12,18} It is a well-established hallmark of occupational therapy to develop an occupational profile and to engage the client in meaningful and purposeful activities. Additionally, intense task-oriented training of the sensorimotor cortex is believed to lead to cortical reorganization. Bayona and associates reported that rehabilitation outcomes have greater success when the tasks are meaningful to the patient.² Volpe and colleagues reached this same conclusion.²⁵

Client-centered, therapist-driven, task-oriented approaches may not directly translate to anecdotal or clinically measurable/significant before and after changes. Motor learning concepts²⁵ indicate that the degree to which a task is learned is positively correlated with the "depth" of the "well" in which it is kept. In other words, the more ingrained a task is to a person, the more challenging it may be to

change, or transition, the movement or behavior. The key point at which this transition occurs may also be influenced by control parameters.

Control parameter is a motor control term that pertains to anything that shifts a motor behavior from one manner of performance to another type of performance. Control parameters can be internal to the person (such as strength, vision, for example, John's left visual field deficit) or external (such as location of an object, lighting). Consider the task of washing your back; the length of your arm, the size of your back, and established habits from training all serve as control parameters. Do you attempt to wash your left scapular area with your right or left hand? When the control parameter is a client factor, the occupational therapy practitioner may attempt to address/remediate the client factor.¹⁶ This approach to the OT process, often termed a "bottom-up" approach, assumes that addressing the fundamental client factors will allow the OT practitioner to interact with the client to improve the client's occupational performance. Yet doing so may not translate to improved performance skills or occupational performance. In fact, it is likely that the further the intervention for the client factor is from the actual occupational activity, the less likely it is that there will be a positive correlation between these two items. Ultimately, the degree to which the client factor is impaired will affect the end result and compensatory or adaptive interventions provided by the OT practitioner to the client.

These concepts could provide at least part of the explanation as to why improvements have been measured as clinical outcomes in some well-developed studies in this arena, although limited long-term improvements have been noted. Consequently, it may be challenging to overcome (sometimes poorly) practiced performance skills and patterns. Return to the example of John cooking dinner. He has a left visual field cut, which compromises his ability to obtain visual information, and when the pot with pasta (located on the left side of the stove) begins to boil over, John is not receiving that visual input. He could be trained to visually scan the environment to compensate for the visual field cut; it would be most appropriate to provide this training within a natural environment and with preferred occupations.

Fundamentals of experience-driven **neuroplasticity** include the adaptive capacity of the central nervous system to make fundamental changes and alterations on the cellular and eventually the systems level, which can lead to new learned/adapted behaviors. Key critical "signals" can facilitate such recovery.¹² Additionally, the brain continually reorganizes itself, with or without damage.^{10,12} This process of learning will occur spontaneously, with no explicit learning or formal rehabilitation. Lack of skilled therapeutic intervention may lead to maladaptive behavioral responses. It is skilled learning that occurs through the use of strategies and adaptations to facilitate this adaptive response. This has been shown to occur with the use of the TOA and task-specific techniques. Focus on the performance skill in

therapy allows the opportunity for skilled learning to occur. A person may present with compensatory movements or adaptations to control parameters such as decreased agonist strength. The TOA, with a focus on the person interacting with the task in the environment, can address this limiting performance client factor (compensation), in part by guiding the performance skill via skilled management of the dynamic interaction of these items. Compensatory behavioral changes are a regular part of this process.¹²

John has been attempting to move his left arm as much as possible since the CVA. He tells family and caregivers frequently that he wants to do as much as possible for himself. He is motivated to make improvements. When he attempts to complete self-care activities on his own, he does not make adjustments in the environment. He interacts with objects with poor movement patterns. His performance skills are relative to how he uses objects. The OT practitioner can maximize the quality of the performance skills with a focus on how John brushes his teeth or shaves. This would serve as the foundation for how to modify the task or the environment.

Kleim and Jones¹² identified 10 principles that fit this process: (1) use it or lose it, (2) use it and improve it, (3) specificity, (4) repetition matters, (5) intensity matters, (6) time matters, (7) salience matters, (8) age matters, (9) transference, and (10) interference. These principles come from basic and applied neuroscience research concepts, which have shown that they can influence outcomes. These principles can support evaluation and treatment.

Effective evaluation of the client who presents with upper limb hemiparesis, as has been described in this chapter, should be based on a thorough understanding of the specific impairments (client factors) that affect the performance of occupation-based, client-centered tasks. Although specific client factors may be addressed as part of treatment, this may not necessarily reflect changes in occupational performance. A client may need to improve biceps strength to complete a hand-to-mouth pattern, yet improving biceps strength to a point where the strength is sufficient to facilitate the movement does not guarantee that the task can be completed successfully. Thus, the focus should be on the performance skills and patterns. Observation of the client strategy with use of remaining abilities as it relates to overall function is an important part of the evaluation process. This should occur with respect for current understanding of how skilled interventions by the occupational therapy practitioner may direct learning/relearning and lead to neuroplastic cortical changes. These changes in performance skills can lead to improvements in occupational performance.

Comprehensive evaluation with respect for the TOA requires a thorough assessment of impairment, strategy, and function. As stated earlier in this chapter, the specific impairments are those that occur as a consequence of the UMN lesion. These impairments may include but are not limited to weakness (of the agonist), decreased

coordination, decreased in-hand manipulation, inability to manage agonist and antagonist efficiently, impaired/absent sensation, proprioception, impaired vision, and decreased overall cognitive ability. These impairments may be measured via traditional OT assessment approaches such as manual muscle testing, range-of-motion testing, sensation testing, vision testing, strength (grip) testing (e.g., via a dynamometer), coordination testing (e.g., via the Nine Hole Peg Test), and so on. The appropriate standardized test may be determined in part by the site/setting. The benefit of these assessments is that they provide a pretest foundation from which to measure progress. Yet, these client factors remain relevant in so much as they influence occupational performance via performance skills. Thus, it is important for the OT practitioner to have an appreciation of the strategies and performance patterns utilized by the client.

John has less than five pounds of grip strength in his left hand as measured by the dynamometer. He has impaired sensation of the dorsal aspect of his left hand. He does not visually attend to the environment in his left peripheral visual field. These are client factors. John grasps onto objects such as eating utensils with insufficient strength when he attempts to use his left hand to hold a fork while cutting foods with the knife in his right hand. He is unable to judge the water temperature from a faucet on his left hand before shaving. He does not always attend to the left side of his environment when he is attempting to cook. These are performance skills. He requires assistance and verbal cues to complete his morning routine with good quality. This is occupational performance.

Ultimately, it is the occupational performance that arises from performance skills and patterns supported by clinical observations and leads to clinical decisions for “best practice.” The benefit derived from use of the TOA with respect for current neuroscientific concepts such as cortical neuroplasticity is that the OT practitioner addresses a client’s needs from a “top-down” approach rather than from a “bottom-up” approach. The top-down approach directs the OT practitioner to work with the client from the view of actual occupational performance. Fisher⁷ described these approaches, along with the benefits and potential pitfalls of each. It is possible to complete the impairment-based measurements and progress to function or to start with functional performance and to utilize these observations to guide assessment and treatment, yet caution is suggested when a “motor behavior perspective”⁷ is solely utilized.

John has decreased strength and range of motion throughout his left upper limb. This impairment is observable and measurable. Sole measurement of these items is insufficient to create a client-centered occupation-based treatment plan. It might be possible to measure these client factors. Improvement in strength or range of motion may not reflect improvement in John’s ability to raise his left arm to apply shaving cream to his face. It is important for the OT to understand deficits as they relate to real

performance through some client-identified, clinician-driven approach.

Neuroscience Research Related to Practice

Recent research relating neuroscientific concepts from the animal model (rodent and primate) to the human model provides evidence of the potential benefit of providing skilled learning opportunities to direct cortical reorganization.^{18,19,21} **Cortical reorganization** is the concept that the adult brain has a neuroplastic ability to alter or modify its synaptic connections in the context of performance of a skilled activity—whether or not the brain and the central nervous system are intact. Nudo and coworkers^{18,19} completed ground-breaking research, which demonstrated that by applying skilled learning principles, it is possible to create topographic cortical map changes that directly correspond to specific “pellet retrieval” (distal forelimb) tasks after focally induced cortical lesions appear in these particular representative areas in squirrel monkeys. Task-specific training can lead to increased cortical representation of the trained areas, along with decreased representation of the previously post-infarct compensatory areas. The net result of acquiring performance skills in these primates was improved quality of movement. Most of the “improved performance patterns” occurred via observation and interpretation of behavior by the researcher before and after intervention assessment. This demonstrates the ability of the cortical region to reorganize when demands are placed upon it to function. Of course the process of reorganization is limited, particularly if large sections of the cortex are damaged.

It has been suggested that the OT practitioner should apply these principles from the animal models with caution, because some variables remain to be clarified. Animal (primate) model research in this area has provided invaluable information, yet these conclusions have resulted from specific, focally induced lesions²¹ with clear boundaries as to the lesioned areas. In many instances, adjacent tissue is undamaged.²¹ In humans, research has demonstrated that peri-infarct (cortical) reorganization may occur. Additionally, in humans, the “edges” of the lesioned area are not always clear.²¹ Aside from the clinical implications of these variances, other potential issues may arise from more complex cortical damage. These may include medical complexity, family/caregiver support, comorbidity, cultural expectations, or other client-specific variables. These challenges have not been the focus of study, nor have they been addressed, in the animal model.

What would be the best fit for treatment interventions to facilitate occupational performance for John, given the current available evidence and understanding of neuroscience?

Current research indicates that it may be most beneficial to observe how John participates in particular daily activities. This allows the OT practitioner to understand what repeated behaviors are used and where new strategies may

be effective in assisting John in his desired occupational outcomes. Through this approach, it may be possible for the OT to better fit treatment to John's needs. This also allows the possibility to focus on activities that are of interest to John and to apply concepts related to the task-oriented approach (TOA). This approach is both client centered and occupation based. Specific treatment activities will focus on matching the client performance patterns.

Data from both animal and human models point to the likelihood that client-centered, client-specific intervention plans and approaches may constitute "best practice." This, of course, may introduce challenges regarding how to implement such approaches into the current standard of care. Regardless, the distinction between animal and human models likely will continue to be a topic of discussion. This discussion is relevant when we attempt to consider what defines the aforementioned "best practice." Birkenmeier and associates³ attempted to address this translation from neuroscientific concepts to animal model research to clinical research implementation. Their description of how they made these decisions is one of the most comprehensive presentations on this issue.

The Northstar Neuroscience Phase III Clinical Trial¹⁴ has taken these neuroplastic concepts and knowledge from animal models and applied them to a treatment protocol based on occupational therapy concepts of client-centeredness. This randomized controlled trial included nearly 150 subjects from close to 20 sites. The study was undertaken to investigate the potential benefits of sub-threshold cortical stimulation in combination with "skilled" (already defined in this chapter) learning via a therapy protocol grounded in the TOA. Similar investigations have identified benefits that may be derived from subthreshold (i.e., nonevoked potentials) cortical stimulation to support synaptic connections and dendritic density, and to facilitate overall cortical reorganization.²¹ Although the exact dosage of the stimulation and whether or not specific cortical stimulation to the region responsible for post-lesion upper limb (distal) control or another approach such as transcranial magnetic stimulation (TMS) remain unclear at this time, this area offers potential future benefit.²¹

The treatment protocol for the Northstar Neuroscience Phase III Clinical Trial¹⁴ incorporated the approach of evaluation (and corresponding intervention) of impairment, strategy, and function within the realm of the TOA. The impairment corresponds to the client factor. The strategy corresponds to how the person attempts to perform a task as it relates to occupation, given specific impairments. Function corresponds to how the impairment and corresponding strategy relate to performance skills and patterns. Ultimately, subjects in this clinical trial were evaluated and treated within this framework.

Research therapists evaluated and treated subjects with a focus on performance skills. This focus arose from client-centered occupation-based tasks that were determined for each participant via the Canadian Occupational

Performance Measure (COPM).¹⁵ Clients' self-perceived changes in performance patterns for ADLs were measured by the COPM. Other assessments utilized as outcome measures included the Fugl-Meyer⁸ and the Arm Motor Ability Test.¹³ These latter two are well established, and validated clinical measures were primary outcome measures for this particular study. Clients demonstrated improvement in COPM outcome measures, but significant changes were not noted on the other two measures. Evaluation of clients was carried out according to the principles outlined by the TOA. Treating therapists were trained and followed standardized procedures to focus with the client on client-centered goals. Once an individual improved on a client factor or performance skill, the treating therapist reviewed how that change affected the performance pattern and what this represented in terms of occupational performance. Changes in performance skills noted among participants in this study—addressed through utilization of client-centered functional activities focused on the use of strategies related to task performance—corresponded to changes in client factors. This treatment approach and protocol are consistent with neuroscience concepts of skilled learning supporting cortical changes that may lead to changes (improvements) in occupational performance, performance patterns, habits, routines, and roles. A portion of this protocol included evaluation and understanding of the impact of client factors upon performance skills.

Muscle strength, range of motion, sensation, and a variety of other client factors are necessary to engage in functional activities and therefore are important to measure in a quantifiable manner. An adequate amount of strength, for example, is necessary to grip an eating utensil, and sufficient active range of motion is necessary to complete a hand-to-mouth pattern. Yet the key with this protocol was that neuroplastic concepts were used to link client factors to performance skills to facilitate adaptive plasticity. Isolated work on the client factors of muscle strength and range of motion was not part of the protocol. **Adaptive plasticity** (the innate ability of the central nervous system to adapt or modify behavioral responses after exposure to a challenge to the system) implies that by addressing the performance skill, direct change toward improved quality of occupational performance will occur. As defined, the performance skill occurs in the process of engaging in the occupation and cannot be separated from the occupation.

The examples provided in this chapter reflect neuroscientific knowledge as it relates to how OT practitioners work with the neurologically impaired client; these same fundamental concepts can guide clinical interventions with a variety of other clients across the lifespan.

Although the approach discussed in this chapter may relate to any client, a few other examples have been provided for consideration. This list is not exhaustive. For the sake of this chapter, the focus is on adults. For example, a client who has cancer, chronic obstructive pulmonary disease (COPD), total knee replacement (TKR), or

Parkinson's disease may benefit from the approach discussed in this chapter. The condition will inform the OT practitioner as to origin, clinical and medical presentations, prognosis, and other valuable information. Client factors affected by any condition, such as the ones previously listed, may influence performance skills and possibly performance patterns. Ultimately, this leads to the possibility that habits, routines, and roles may also be affected. Observation and assessment of performance skills may still guide the OT practitioner to a client-centered occupation-based intervention.

John has sustained a right MCA CVA. This condition informs the OT practitioner that he is likely to have left upper limb motor impairment. Additionally, other consequences may result from the CVA. John may have decreased attention and decreased visual attention to the left side. It is important to be aware that John is also a parent and a housekeeper. He wants to return to these roles. Thus, mere measurement of the specific client factors that have resulted from the CVA will not explicitly return him to these roles and routines.

The older client with the TKR may present with decreased bilateral upper extremity strength, not as a result of the TKR but because of deconditioning from diminished activity secondary to knee problems. This decreased bilateral upper extremity strength will limit the ability to efficiently utilize a walker for functional mobility around the home. This client may also have a history of cognitive impairments that affect the ability to learn new concepts. The OT practitioner may have to consider these items in developing a client-centered intervention plan. The framework provided in this chapter indicates that the OT practitioner will likely assess upper limb strength and range of motion. The OT intervention may even include exercises and activities that may improve these client factors. Yet this does not mean that in doing so, the client will improve the performance skill involved in, for example, a morning routine. Nor does it imply that engaging a client in a purposeful activity will translate to improved occupational performance. How a task is practiced in the clinic may not translate to the home environment. Thus, the formal or informal occupational profile and analysis will provide the foundation from which the OT practitioner may link current status to desired outcomes.

Best Practice Occupational Therapy Service

It is important to bring this discussion back to clients who have acquired neurologic deficits to identify how this particular group of clients can best be treated by occupational therapy practitioners. As occupational therapy practice for the adult neurologic practice moves further from an "expert opinion" approach and toward one that is grounded in evidence (whether that evidence supports or refutes traditional practice approaches), much more remains to be learned to determine "best practice." Attempts have been made to pinpoint both current trends and task-specific

training to identify what defines "best practice." In support of this comment, Carter and colleagues⁵ described that much of the effort in rehabilitation research is going in the direction of "motor restoration." Additionally, they stated that the quality of the research is more rigorous than it has ever been in the past.

When it comes to measuring performance and improvements in clients with neuro-insults, it may be true that previous outcome measures used to identify improvements are insufficient at this point in time. For example, some standardized and validated measures that address activities of daily living do so with contrived ADLs. **Contrived** activities are those that are artificially created often in an attempt to re-create real scenarios. Although potential benefits may be derived from using a standardized ADL assessment as a common, consistent approach to measuring performance and conveying performance information that is clearly recognized because of the standardization process, if this standardized process lacks the fundamental elements of the task or is too "contrived," it may affect performance and corresponding measurement of performance. An example of a contrived situation would involve a client "spreading" butter on bread by using a knife on a plate in the spreading motion without the actual bread or butter. In this example, the client may possess the motor control needed for the task, but in the actual task (real-world experience) of spreading butter on the bread, the client may fail to notice that all the butter is located on one corner of the bread, or may use excessive force and tear the bread. These observations would not be possible with a contrived activity but would be immediately noticed if the client is given an actual piece of bread and butter. Wu and coworkers²⁸ described that "real" performance of activities leads to different and "better" results than are attained through imagined or contrived activities. Additionally, a variety of means can be used to measure performance, including time to complete portions of a task, time to complete the entire task, and subjective observations of quality of performance. Further research may advance newer ways to measure performance skills and occupational performance. This does not mean that we, as occupational therapy practitioners, should not attempt to incorporate current trends, concepts, measures/assessments, and techniques.

Other considerations pertain to the impact of how we intervene with clients such as John. Timing, dosage, and method of delivery are important variables needing control in clinical studies, and these variables should also be considered in clinical practice. Although evidence-based practice is expected, using data from an investigation that did not attempt to control these factors needs to be considered with some caution.⁵ Given the competition for space in the cortex after UMN damage,¹⁶ it is necessary for OT practitioners to respond immediately and effectively to client needs. This clinical reasoning process may affect how performance "plateaus" are determined in clinical practice.

Plateau is a term that is all too common in the realm of current rehabilitation practice with persons with upper limb hemiparesis, as well as other conditions across the lifespan. Page and associates²⁰ suggested that the way in which therapists frame the upper limb hemiparetic population may need to be reconsidered. They stated that what defines (1) motor recovery plateau, (2) ability to recover motor function, and (3) when to use different modalities may have to be reconsidered. “Traditional” expectations of most (motor) recovery occurring in 6 to 12 months often guide insurance and are tied into clinical practice. This chapter identifies the reasons why this may not necessarily be the case.

Immediately after a CVA, some clients may be able to participate in a rehabilitative program designed to foster self-care skills, but other clients may be far too ill. The timing, intensity (dosage), and method of delivery for these two clients most likely will vary, but a similar functional outcome may ultimately be met. Hubbard and colleagues¹¹ summarized principles that should be considered for incorporation of task-specific interventions. These suggestions may serve as a guide for “best practice,” while addressing the potential for improvement in performance skills. They suggested that such training/intervention should “be relevant to the patient/client and to the context; be randomly assigned; be repetitive and involve massed practice; aim toward[s] reconstruction of the whole task; and be reinforced with positive and timely feedback.”¹¹ They further concluded that although, as noted in this chapter, much evidence points toward the benefit of task-oriented or task-specific training techniques, “common” practice approaches are grounded in “accepted practice or custom” and may be beneficial at specific points in time. An appreciation for this conclusion and the current state of neuroscience as it relates to this population can serve to transform clinical practice. Given the complexity of human beings, what emerges as “best practice” may incorporate a multifactorial approach to guide client-centered evaluation and treatment, maximize outcomes, and facilitate client habits, routines, and roles.

Summary

It is possible to address client-centered, occupation-based needs with a focus on performance skills. Neuroscientific research indicates that this approach can be applied with the use of certain approaches such as the TOA. The TOA emphasizes a dynamic interaction between the person, the task, and the environment. OT practitioners are trained and able to address control parameters and complete performance analyses to maximize overall occupational performance.

Review Questions

1. What are the advantages of using “real situations” instead of “contrived situations” when assessing clients?
2. What are the advantages of using “contrived situations” instead of “real situations” when assessing clients?
3. What does the term plateau mean in reference to clients who have sustained neurologic insults?
4. What is the difference between a client factor and a performance skill?
5. Using the task of brushing your teeth as part of your morning routine, identify two client factors and two performance skills that influence engaging in this task.
6. What does the term control parameter mean in working with clients who have sustained neurologic insults?
7. Explain the term neuroplasticity.
8. Explain the term cortical reorganization.
9. How do the terms neuroplasticity and cortical reorganization support occupation-based interventions?
10. Explain how the TOA was used in the case of John.

■ Chapter Outline

Performance assessments

Normal muscle tone

Abnormal muscle tone

Flaccidity

Hypotonus

Hypertonus

Spasticity

Rigidity

Muscle tone assessment/reflexes

Guidelines for muscle tone assessment

Manual rating scales for spasticity and hypertonicity

Mechanical and computer rating systems for spasticity and hypertonicity

Range-of-motion assessment in evaluation of tone

Other considerations in tone assessment

Assessing movement and control

Sensation

Medical assessment of muscle tone

Normal postural mechanism

Righting reactions

Equilibrium reactions

Protective reactions

Primitive reflexes

Trunk control assessment

Coordination

Incoordination

Cerebellar disorders

Extrapyramidal disorders

Assessment of coordination

Medical assessment of coordination

Occupational therapy assessment of coordination

Occupational therapy intervention

Intervention for hypertonicity and spasticity

Treatment of rigidity

Treatment of flaccidity

Treatment of incoordination

Surgical intervention for movement disorders

Summary

■ Key Terms

Motor control

Neuroplasticity

Paresis

Flaccidity

Hypotonus

Hypertonus

Spinal hypertonia

Spasticity

Clonus

Rigidity

Decerebrate rigidity

Decorticate rigidity

Hypertonic stretch reflexes

Intrathecal baclofen pump

Postural mechanism

Coordination

Serial casting

Nerve blocks

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Differentiate between upper and lower motor neuron pathologic conditions.
2. List the components of motor control.
3. Describe neuroplasticity.
4. Differentiate between motor control and neuroplasticity.
5. Compare and contrast spasticity and hypertonia.
6. Recognize four types of rigidity.
7. Differentiate between spinal and cerebral hypertonus.
8. Identify all categories of the Ashworth Scale.
9. List standardized assessments designed for evaluating function after cerebrovascular accident.
10. Describe normal muscle tone.
11. List and describe at least four different states of abnormal tone.
12. Describe how to assess muscle tone.
13. List the components of the postural mechanism.
14. List and describe at least four types of cerebellar disorders.
15. List and describe at least four extrapyramidal disorders.
16. Describe how to assess coordination.
17. Identify impairments that are contributing to functional limitations.
18. Describe the principles of neuroplasticity.
19. Link functional training and neuroplasticity.
20. Name several current medical and surgical treatment options for the management of hypertonia.
21. List at least three conservative occupational therapy interventions for hypertonia.

Threaded Case Study | Juan

Juan, a 44-year-old man, was referred to outpatient occupational therapy 2 weeks status post right middle cerebral artery CVA with residual left upper extremity hemiparesis. He is right hand dominant with a history of hypertension. An occupational profile provided the following background information on Juan. He is married and has three adopted children, ages 17, 16, and 11. He is responsible for driving his children to school in the morning. His wife is a homemaker. He is the sole financial provider for his family. His job is very demanding and commission based. Before the CVA, he would work 12- to 16-hour days and averaged 4 to 6 hours of sleep per night. His physician has not yet released him to return to work.

The Canadian Occupational Performance Measure (COPM) was administered to prioritize areas of occupation in which the client was no longer able to perform and to ensure client-centered goal setting. With his left hand, Juan was unable to type on a keyboard, carry a plate or glass without spilling the contents, retrieve coins from a drive-through window cashier, or open his car door. He was most concerned about his ability to keyboard, as this was an essential job function. He would usually carry his drink in his right hand and his plate in his left hand to take to the table. He would open his car door with his left hand, as he often carried his laptop computer in his right hand. His morning routine on workdays included a stop at a fast-food drive-through window for a breakfast sandwich. It was frustrating for him to have to cross his body with his right hand to receive his food and change from the cashier, because it would have been more convenient for him to use his left hand as he had done pre-morbidly.

The occupational therapist assessed his proximal **motor control** first. The client's trunk, scapular, shoulder, and elbow tone, ROM, motor control, and strength were considered within normal limits.

Active range of motion in supination was limited to 20 degrees (normal, 80 to 90 degrees). The supination muscle group was rated 4–/5 on the strength grade scale. Pronation and finger flexor hypertonia were rated moderate on Preston's Hypertonia Scale (see Box 19-3). Extrinsic finger extension strength was rated as 3–, and lumbrical strength (proximal interphalangeal joint extensors) was 2–/5. Static two-point discrimination and kinesthesia tests were normal. The Modified Brunnstrom Stages of Motor Recovery Score was 4 (Table 19-1).

The Graded Wolf Motor Function Test total timed score was 470 seconds with the left upper extremity, and 40 seconds with the right upper extremity. The maximum total time on this test is 1560 seconds, which would mean that the client could not complete any of the test items. The functional ability score mean was 5.5 (normal, 7) with the left upper extremity. The right upper extremity test score was 7 out of 7.

Critical Thinking Questions

As you read the following chapter, answer these questions about Juan.

1. Name the three main reasons why Juan cannot operate a keyboard with his left hand.
2. Describe three primary reasons why Juan cannot open his car door, receive change in his hand from the drive-through window cashier, or carry a glass without spilling the contents with his affected upper extremity.
3. Name three activities that you would prescribe as a part of a home program to improve the motor control of his left finger extensors and forearm supinators. What lifestyle changes would you recommend for this client?

TABLE 19-1 | Modified Brunnstrom Stages of Motor Recovery as a Guideline for Interdisciplinary Spasticity Management in Subjects With CVA or Hemiparesis from Traumatic Brain Injury

Brunnstrom Stage	Brunnstrom Motor Recovery of Arm and Hand	Interdisciplinary Spasticity Management Options
Stage 1	Flaccidity. No active movement.	Prevent contractures with PROM and splinting. Risk for metacarpophalangeal extension contractures.
Stage 2	Beginning development of spasticity, weak synergistic movement of scapular retractors, scapular elevators, elbow flexors, and forearm pronators.	Prevent contractures with PROM and splinting. Risk for shoulder, elbow, forearm, and finger flexion contractures. Promote active movement in gravity-reduced planes.* Blocks and surgery generally are not indicated at this stage.
Stage 3	Spasticity increasing. Synergy pattern can possibly be useful for carrying objects. Synergy patterns or some of their components can be performed voluntarily. Gross grasp is developing, however no finger release. Lateral pinch possible via thumb adduction tone and flexor pollicis longus tone.	Acute: good candidate for nerve or motor point blocks to prevent contractures. Recovery may be facilitated by unmasking movement in antagonists if spastic agonists are weakened through blocks. See text for occupational therapy treatment suggestions. Chronic: after all conservative measures have failed, orthopedic surgery may be done to release contractures to improve hygiene in the hand and ease UE dressing.
Stage 4	Spasticity declining, movement combinations from synergies are now possible. Elbow extension, wrist and finger extension are emerging; however, are not to full range.	Acute: good to excellent nerve block candidate. Better chance of gaining motor control of antagonists with blocks to the spastic agonists. See text for occupational therapy treatment suggestions. Chronic: ongoing blocks three to four times per year if the risk/benefit ratio for orthopedic surgery is not acceptable to the client. Orthopedic surgery options include procedures to gain function and to ameliorate contractures.
Stage 5	Synergies are no longer dominant. Finger extension is full range. Isolated finger extension is possible. Three-jaw chuck pinch is possible but has poor motor control. Emergence of intrinsic function.	Excellent candidate for fine-tuning motor control via blocks (e.g., by blocking the extrinsic flexor pollicis longus with the goal of facilitating intrinsic motor control of the thumb, opponens pollicis, abductor pollicis brevis, and flexor pollicis brevis).
Stage 6	Isolated joint movements are performed with ease. Intrinsic function is normal. All types of prehension.	The client is not a candidate for blocks or surgery. Discharge from occupational therapy, as goals were met.

CVA, Cerebrovascular accident; PROM, passive range of motion; UE, upper extremity.

Note: Upper extremity recovery is variable owing to varying degrees of paralysis. Some clients may never progress through all the stages.

*Blocks refer to chemical denervation with botulinum toxin type A or B or neurolysis or motor point blocks with phenol or alcohol.

Adapted from Brunnstrom S: *Movement therapy in hemiplegia*, Philadelphia, Pa, 1970, Lippincott Williams & Wilkins.

Motor control is the ability to make dynamic postural adjustments and direct body and limb movement in purposeful activity.⁹⁷ Components necessary for motor control include normal muscle tone, normal postural tone and postural mechanisms, selective movement, and coordination. Complex neurologic systems (i.e., the cerebral cortex, basal ganglia, and cerebellum) collaborate to make motor control possible. A neurologic insult such as a cerebrovascular accident (stroke or brain attack), brain injury, or a disease such as multiple sclerosis or Parkinson’s disease affects motor control. Functional recovery depends on the initial amount of neurologic damage, prompt access to medical treatment

that limits the extent of neurologic damage,⁸⁶ the nature of the neurologic damage, whether it is static or progressive, and therapeutic intervention that can facilitate motor recovery.

Plasticity is an important concept in neurologic rehabilitation because it helps to explain why recovery is possible after brain injury or lesion. **Neuroplasticity** is defined as “anatomic[al] and electrophysiologic[al] changes in the central nervous system.”⁹⁷

In some instances, the central nervous system (CNS) is able to reorganize and adapt to functional demands after injury.¹⁸ Motor relearning can occur through the use of

FIGURE 19-1 Sprouting theory of nerve cell replacement. Injury causes loss of nerves B and C. New dendrite connections “sprout” from nerve D to re-establish contact with nerve A.

(From DeBoskey DS, et al: *Educating families of the head injured*, Rockville, Md, 1991, Aspen Publishers.)

existing neural pathways (unmasking) or through the development of new neural connections (sprouting).⁷⁵ In the case of unmasking, it is believed that seldom-used pathways become more active after the primary pathway has been injured. Adjacent nerves take over the functions of damaged nerves. In the case of sprouting, dendrites from one nerve form a new attachment or synapse with another (Figure 19-1).²⁴ It has also been demonstrated that new axonal processes develop in sprouting.⁷⁵

Observing movements during occupational performance is a way to assess motor control. Following evaluation of occupational performance, it may be necessary to evaluate the specific components that underlie motor control. These components include muscle tone, postural tone and the postural mechanism, reflexes, selective movement, and coordination.

OT Practice Notes

A comprehensive assessment can help the client and occupational therapist plan appropriate treatment intervention.

This chapter focuses on the functional effects of lesions in the upper motor neuron system (UMNS). The UMNS includes any nerve cell body or nerve fiber in the spinal cord (other than the anterior horn cells) and all superior structures. These structures include descending nerve tracts and brain cells of both gray and white matter that subserve motor function.

The lower motor neuron system includes the anterior horn cells of the spinal cord, the spinal nerves, the nuclei

and axons of cranial nerves III through X, and the peripheral nerves. Lower motor neuron dysfunction results in diminished or absent deep tendon reflexes and muscle flaccidity. Figure 19-2 illustrates the influence of the upper motor neuron system on the lower motor neuron system.⁶⁶

Performance Assessments

The occupational therapist has the challenge of maximizing the client's ability to return to purposeful and meaningful occupation within his or her physical, cultural, and social environment.⁹³ Therefore, evaluating functional performance is primary in helping clients to set realistic goals. The Canadian Occupational Performance Measure⁶⁰ is an assessment tool that ensures client-centered therapy. This tool helps prioritize the client's functional activity goals in the areas of self-care, leisure, and productivity.⁶⁰

The occupational therapist (OT) can observe the client for motor control dysfunction during assessment of basic activities of daily living (BADLs) and instrumental activities of daily living (IADLs), along with productive and leisure activities. The therapist must observe how problems in motor control affect occupational performance. The therapist must also consider the client's sensation, perception, cognition, and medical status.

Many activity of daily living (ADL) tests are available to assess occupational performance and are useful in observing motor control. The Test d'Évaluation des Membres Supérieurs de Personnes Âgées (TEMPA) is an upper extremity functional activity performance test for clients. This test was developed to help therapists distinguish between “normal and pathologic[al] aging in upper extremity performance.”²⁶ Test items include picking up and moving a jar, writing on an envelope, tying a scarf, and handling coins, among others.²⁶

FIGURE 19-2 Control of movement is comparable with a chariot driver with a team of horses. The upper motor neuron system facilitates or inhibits the lower motor neuron system. The driver is like the brain, the reins are like the upper motor neurons, and the horses are like lower motor neurons and muscles.

(From DeBoskey DS, et al: *Educating families of the head injured*, Rockville, Md, 1991, Aspen Publishers).

OT Practice Notes

The following questions may help to guide observation of motor control dysfunction:

1. Is the client having difficulty with sitting or standing balance?
2. Is the client having difficulty making appropriate postural adjustments of the trunk and limbs to achieve the best position and motions needed to perform the activity?
3. Is trunk control adequate to perform the activity?
4. Do changes in body and head position affect muscle tone?
5. Are primitive reflexes evoked during performance?
6. Is hypertonicity limiting antagonist movement?
7. Are spatial or temporal sequencing problems interfering with coordinated movement?
8. Does weakness prohibit antigravity activity?
9. Are tremors, athetoid, or choreiform movements apparent?
10. Is incoordination apparent (i.e., overshooting or undershooting the target)? Are there extraneous movements?
11. Describe the spontaneous, functional uses of the involved extremities.

Several assessments have been designed to assess function after cerebrovascular accident (CVA). These can be used to observe for motor control problems.

1. The Graded Wolf Motor Function Test (GWMFT) is a new assessment developed to measure functional

gains after a hemiparetic event from cerebrovascular accident or traumatic brain injury.⁷² This test was based on the Wolf Motor Function Test.⁹ It is called “Graded” because there are two levels of difficulty for each task: level A is more advanced, and level B is easier (Figure 19-3). Gorman³⁸ investigated the interreliability and intrareliability of the GWMFT with a sample of eight physical therapist investigators and three subjects. Intrarater and interrater reliability was .935 on the timing scores. Intrarater reliability was .897 and interrater reliability was .879 on the functional ability scores. This is a very useful test that can be used on a wide variety of clients with hemiparesis with varying degrees of motor recovery. More research is needed to confirm the validity and reliability of this test.

In the aforementioned case study, Juan’s mean functional ability score was 5.5 (see Figure 19-3). He performed the test items slowly, with effort and lack of precision.

2. The Wolf Motor Function Test (WMFT) has been used to quantify the motor abilities of chronic clients from a population with high upper extremity function following CVA or traumatic brain injury. It has an interrater reliability range of .95 to .97.⁹
3. The Functional Test for the Hemiplegic/Paretic Upper Extremity¹⁰³ assesses the client’s ability to use the involved arm for purposeful tasks. This test provides objective documentation of functional improvement and includes tasks ranging from those that involve basic stabilization to more difficult tasks requiring fine manipulation and proximal stabilization.

Level B

- 0 Does not attempt with involved arm.
- 1 Involved arm does not participate functionally; however, attempt is made to use the arm. In unilateral tasks the uninvolved extremity may be used to move the involved extremity.
- 2 Does, but requires assistance of uninvolved extremity for minor readjustments or change of position, or requires more than two attempts to complete, or accomplishes very slowly.
- 3 Does, but movement is performed slowly, and/or with effort, and/or with excessive compensatory movements.

Level A

- 4 Does, but requires assistance of uninvolved extremity for minor readjustments or change of position, or requires more than two attempts to complete, or accomplishes very slowly.
- 5 Does, but movement is performed slowly, and/or with effort, and/or with excessive compensatory movements.
- 6 Does; movement is close to normal, but slightly slower; may lack precision, fine coordination, or fluidity.
- 7 Does; movement appears to be normal.

FIGURE 19-3, cont'd

Examples include holding a pouch, stabilizing a jar, wringing a rag, hooking and zipping a zipper, folding a sheet, and putting in a light bulb overhead.¹⁰³

- 4. The Fugl-Meyer⁵⁵ assessment is based on the natural progression of neurologic recovery after CVA. Low scores on the Fugl-Meyer have been closely correlated with the presence of severe spasticity. Fugl-Meyer and associates developed a quantitative assessment of motor function following stroke by measuring such parameters as range of motion (ROM), pain, sensation, and balance. Scores on the Fugl-Meyer assessment correlate with ADL performance.⁵⁵
- 5. The Arm Motor Ability Test (AMAT)⁵⁸ is a functional assessment of upper extremity function. Cutting meat, making a sandwich, opening a jar, and putting on a T-shirt are some of the tasks included in this test. This test has high interrater and test-retest reliability.⁵⁸
- 6. The Motricity Index (MI)²¹ is a valid and reliable test of motor impairment that can be performed quickly.

The test assesses pinching a cube with the index finger and thumb, as well as elbow flexion, shoulder abduction, ankle dorsiflexion, knee extension, and hip flexion.²¹

- 7. The Assessment of Motor and Process Skills (AMPS)⁷ is a standardized test that assesses motor and process skills in IADLs. The test was created by occupational therapists. Although this test is not diagnosis specific, it has been widely used with clients who have had a CVA. Occupational therapy practitioners are eligible to become certified in the use of this test upon completion of a 5-day training course.⁷

After observing functional performance, the occupational therapist usually will find it necessary to assess the performance components that underlie motor control: muscle tone (normal/abnormal), the postural mechanism, muscle tone assessment/reflexes, sensation, and coordination.

Normal Muscle Tone

Normal muscle tone, a component of the normal postural mechanism, is a continuous state of mild contraction, or a state of preparedness in the muscle.⁸⁷ Tone is the resistance felt by the examiner as he or she passively moves a client's limb. It is dependent on the integrity of peripheral and CNS mechanisms and the properties of muscle. When normal muscle tone is present, tension between the origin and the insertion of a muscle is felt as resistance by the therapist when passively manipulating the limb. It is high enough to resist gravity, yet low enough to allow movement. The tension is determined in part by mechanical factors such as connective tissue and viscoelastic properties of muscle, and in part by the degree of motor unit activity. When passively stretched, normal muscle offers a small amount of involuntary resistance.

Normal muscle tone relies on normal function of the cerebellum, motor cortex, basal ganglia, midbrain, vestibular system, spinal cord, and neuromuscular system (including the mechanical-elastic features of the muscle and connective tissues),⁵⁴ and on a normally functioning stretch reflex. The stretch reflex is mediated by the muscle spindle, a sophisticated sensory receptor that continuously reports sensory information from muscles to the CNS.

Normal muscle tone varies from one individual to another. Within the range that is considered normal, the degree of normal tone depends on such factors as age, sex, and occupation. Normal muscle tone is characterized by the following:

1. Effective coactivation (stabilization) at axial and proximal joints
2. Ability to move against gravity and resistance
3. Ability to maintain the position of the limb if it is placed passively by the examiner and then released
4. Balanced tone between agonistic and antagonistic muscles
5. Ease of ability to shift from stability to mobility and to reverse as needed
6. Ability to use muscles in groups or selectively with normal timing and coordination
7. Resilience or slight resistance in response to passive movement

Hypertonicity (increased tone) interferes with the performance of normal selective movement because it affects the timing and smoothness of agonist and antagonist muscles groups. Normalization of muscle tone and amelioration of **paresis** (slight or incomplete paralysis/weakness) are desirable when striving for selective motor control. Some function can be achieved even though tone may not be normal.⁸³

Abnormal Muscle Tone

Abnormal muscle tone usually is described with the following terms: *flaccidity*, *hypotonus*, *hypertonus*, *spasticity*, and *rigidity*. To plan appropriate treatment interventions, the therapist must recognize the differences among these tone states and must identify them during the clinical assessment, to plan the appropriate intervention.

Flaccidity

Flaccidity refers to the absence of tone. The client will have absent deep tendon reflexes. Active movement is absent as well. Flaccidity can result from spinal or cerebral shock immediately after a spinal or cerebral insult. In traumatic upper motor neuron lesions of cerebral or spinal origin, flaccidity usually is present initially and then changes to hypertonicity within a few weeks.⁶³

Flaccidity also can result from lower motor neuron dysfunction, such as peripheral nerve injury or disruption of the reflex arc at the alpha motor neuron level. The muscles feel soft and offer no resistance to passive movement. If the flaccid limb is moved passively, it will feel heavy. If moved to a given position and released, the limb will drop because the muscles are unable to resist the pull of gravity.⁹⁶

Hypotonus

Hypotonus is considered by many to be a decrease in normal muscle tone (i.e., low tone). Deep tendon reflexes are diminished or absent. Van der Meche and Van der Gijn¹⁰⁰ suggested that hypotonus could be an erroneous clinical concept. They performed electromyography (EMG) analysis on the quadriceps muscles in "hypotonic" clients (e.g., peripheral neuropathy, cerebral infarction, other diagnoses) and in relaxed normal subjects in a lower leg free-fall test. They concluded in their study that if a client's limb feels hypotonic or flaccid, this is the result of weakness, not of long-latency stretch reflexes.¹⁰⁰

Hypertonus

Hypertonus is increased muscle tone. Hypertonicity can occur when a lesion is present in the premotor cortex, the basal ganglia, or descending pathways. Damage to upper motor neuron systems increases stimulation of the lower motor neurons, with resultant increased alpha motor activity. Any neurologic condition that changes the upper motor neuron pathways that directly or indirectly facilitate alpha motor neuron activity may result in hypertonicity. Other spinal or brainstem reflexes may become hyperactive, which leads to hypertonus patterns such as the flexor withdrawal or the re-emergence of tonic neck reflexes.⁶³

Hypertonicity often occurs in a synergistic neuromuscular pattern, particularly when seen after CVA or traumatic brain injury. Synergies are defined as patterned movement characterized by co-contraction of flexors and extensors. A typical synergy seen in the upper extremity after CVA or

traumatic brain injury is a flexion synergy.⁶² In contrast, an extension synergy is seen in the lower extremity.

The energy cost in moving against hypertonicity is considerable. It takes a great deal of effort for clients with moderate to severe hypertonicity to move against this drawing force. Antagonist power may be insufficient to overcome the spastic agonist muscle groups. Even clients with mild hypertonicity report frustration during functional activities. Loss of reciprocal inhibition is noted between spastic agonists and antagonists. Clients are unable to rapidly turn off their muscles. The client with an upper motor neuron lesion will have dysfunction in spatial and temporal timing of movement. This makes his/her movements very uncoordinated.¹⁰⁴ This frustration, coupled with the fatigue, decreased dexterity, and paresis associated with UMNS, can influence therapy participation.⁸⁰ Furthermore, the architecture of hypertonic muscles changes over time. The muscles lose their ability to lengthen and shorten because of viscoelastic changes that result from the hypertonia.^{18,54}

The abnormal timing of Juan's distal upper extremity muscles, particularly between the finger flexors and extensors, impaired his coordination so much that he could not play the keyboard with his left hand.

Hypertonicity can increase as a result of painful or noxious stimuli. These stimuli often can be reduced with good medical care. Stimuli that can increase tone include pressure sores, ingrown toenails, tight elastic straps on a urine collection leg bag, tight clothing, an obstructed catheter, urinary tract infection, constipation, and fecal impaction.^{29,51} Other triggering factors include fear, anxiety, environmental temperature extremes, heterotopic ossification, and sensory overload. These factors are true for both cerebral and spinal hypertonicity; however, they are more pronounced in spinal hypertonia. Therapeutic intervention should be designed to reduce, eliminate, or cope with these extrinsic factors.

Clients with hypertonicity often have difficulty initiating movement, especially rapid movement.⁵⁴ Although hypertonic muscles appear to be able to take a lot of resistance, they do not function as normal, strong muscles do. Through the mechanism of reciprocal inhibition, hypertonic muscles inhibit the activity of their antagonists and thus can mask potentially good or normal function of antagonists.^{83,97} Four types of hypertonia are described in the following paragraphs.

Cerebral Hypertonia

Cerebral hypertonia is caused by traumatic brain injury, stroke, anoxia, neoplasms (brain tumors), metabolic disorders, cerebral palsy, and diseases of the brain. In multiple sclerosis, hypertonia is produced from both spinal and cerebral lesions. Tone fluctuates continuously in response to extrinsic and intrinsic factors. Cerebral hypertonia usually occurs in definite patterns of flexion or extension, causing the limb to be pulled in one direction (Figure 19-4).

FIGURE 19-4 A client with right upper extremity dystonic posturing of the wrist and finger extensors. His left wrist shows severe hypertonicity. Tone abnormalities are the result of a traumatic brain injury.

Typically, these patterns occur in the antigravity muscles of the upper and lower extremities (e.g., flexors of the upper extremities, extensors of the lower extremities).

The re-emergence of primitive reflexes and associated reactions alters postural tone. When an individual is lying supine, muscle tone is less than when the individual is sitting or standing. The tone is at its highest during ambulation. Thus, attention to postural tone is important when positioning a client for splinting or casting. A cast or splint fabricated on a client in a supine position may not fit when the client is sitting up because of the influence of gravity and posture on increasing muscle tone.⁸³

Spinal Hypertonia

Spinal hypertonia results from injuries and diseases of the spinal cord. In slow-onset spinal disease (e.g., spinal stenosis, tumor), there is no period of spinal shock. In traumatic spinal cord injury, spinal shock occurs and is characterized by initial flaccidity. Over time (weeks or months), the flaccidity diminishes and hypertonus develops. The affected extremities first develop flexor and adductor tone.¹⁰⁵ Over time, extensor tone develops and becomes predominant in the lower extremities. Spinal hypertonia can lead to muscle spasms severe enough to cause an individual to fall out of a wheelchair, off a gurney, or out of bed. The degree of hypertonicity in incomplete spinal lesions varies, depending on the degree of damage to the spinal cord. The tone tends to be more severe in incomplete spinal cord lesions than in complete lesions.⁸³

Spasticity

Much controversy in recent years has surrounded the difference between **spasticity** and hypertonia. Lance's⁵⁹ definition of spasticity is still accepted by many physicians and therapists. He defined spasticity as "a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes (muscle tone) with exaggerated tendon jerks resulting from hyperexcitability of the stretch reflex as one component of the upper motor neuron syndrome."⁵⁹

Little and Massagli^{62,63} believe that pure spasticity is a subset of hypertonia. It is possible that Lance's definition does not adequately distinguish between the presence of phasic and tonic stretch reflexes, which present different clinical scenarios. This chapter attempts to clarify the differences using current physiatry literature.

Spasticity has three characteristics:

1. Hyperactivity of the muscle spindle's phasic stretch reflex with hyperactive firing of the Ia afferent nerve.
2. Velocity dependence, meaning that the stretch reflex is elicited only by the examiner's rapid passive stretch.^{62,63}
3. The "clasp-knife" phenomenon. This means that when the examiner takes the extremity through a quick passive stretch, a sudden catch or resistance is felt, followed by a release of the resistance. What actually happens is that the initial high resistance of spasticity is suddenly inhibited.⁵⁴

One of the main systems affected when spasticity is present is the pyramidal system, which consists of the corticospinal and corticobulbar tracts. The corticospinal tract controls goal-directed, voluntary movement by influencing the lower motor neuron. The corticobulbar tract influences the voluntary action of the cranial nerves.¹⁸

Therapists often confuse hypertonia with spasticity. These two conditions are similar because both pull the limb into a unilateral direction.

Hypertonia is different from spasticity in two ways:

1. Hypertonia typically is not velocity dependent, that is, rapid movement does not evoke it; rather, slow joint movement elicits hypertonia. Hypertonus persists as long as the muscle stretch is maintained because of the firing of group II muscle spindle afferents (tonic stretch reflex).^{62,63}
2. During passive movement, no catch is felt with hypertonia, as is felt with the clasp-knife phenomenon of spasticity. This is objectively measurable with EMG.⁵⁵

Clonus

Clonus is a specific type of spasticity. This condition often is present in clients with moderate to severe spasticity. Clonus is characterized by repetitive contractions in the antagonistic muscles in response to rapid stretch. Recurrent bursts of Ia afferent activity result in a cyclic oscillation of phasic stretch reflexes.^{54,63} Clonus is seen most commonly

in the finger flexors and ankle plantar flexors.⁶³ The occurrence of clonus can interfere with participation in purposeful activity, transfers, and mobility. Therapists should educate clients and their families about how to bear weight actively because this usually will stop the clonus. Therapists and physicians record clonus by counting the number of beats.⁵⁴ A three-beat clonus can be rated as mild and is less likely to interfere with ADLs than a clonus that is 10 beats or more. Clonus may be elicited during quick stretch tone evaluation or may become apparent during assessment of occupation (e.g., grasping, ambulation). If clonus greatly interferes with ADLs, the client may be a candidate for a referral to a physiatrist or neurologist for oral medication, Botox¹² injection, Myobloc⁷³ injection, or alcohol or phenol motor point block.⁸⁰

Rigidity

Rigidity is a simultaneous increase in muscle tone of agonist and antagonist muscles (i.e., muscles on both sides of the joint). Both groups of muscles contract steadily, leading to increased resistance to passive movement in any direction and throughout the ROM. Rigidity signals involvement of the extrapyramidal pathways in the circuitry of the basal ganglia, diencephalon, and brainstem. It occurs in isolated forms in disorders such as Parkinson's disease, traumatic brain injury, some degenerative diseases, encephalitis, and tumors,²⁵ and after poisoning from certain toxins and carbon monoxide. Rigidity also is seen in conjunction with spasticity in those with stroke and traumatic brain injury. Rigidity is not velocity dependent.⁹⁶

Rigidity is evaluated during muscle tone evaluation (see Figure 19-4). Four types of rigidity are commonly seen:

1. Lead pipe rigidity
2. Cogwheel rigidity
3. Decorticate rigidity
4. Decerebrate rigidity

Both lead pipe and cogwheel rigidity can occur in Parkinson's disease. In lead pipe rigidity, constant resistance is felt throughout the ROM when the part is moved slowly and passively in any direction. This rigidity feels similar to the feeling of bending solder or a lead pipe, thus its name. In cogwheel rigidity, a rhythmic give in resistance occurs throughout the ROM, much like the feeling of turning a cogwheel. It is thought that cogwheel rigidity is lead pipe rigidity with concomitant tremor, which results in the ratchety pattern.⁷⁰ Deep tendon reflexes are normal or are only mildly increased in Parkinson's rigidity.

OT Practice Note

It is crucial for the therapist to document the type of rigidity noted during initial assessment and how it affects the client's performance.

Decerebrate and decorticate rigidity can occur after severe traumatic brain injury with diffuse cerebral damage or anoxia. These abnormal postures occur immediately after injury and can last a few days or weeks if recovery occurs, or can persist indefinitely if there is little or no recovery.

Decerebrate rigidity results from lesions in the bilateral hemispheres of the diencephalon and midbrain. It appears as rigid extension posturing of all limbs and the neck. Bilateral cortical lesions can result in **decorticate rigidity**, which appears as flexion hypertonus in the upper extremities and as extension tone in the lower extremities. Supine positioning increases the abnormal tone, and with either type of rigidity it may be extremely difficult to position clients in a sitting position.⁶³

Muscle Tone Assessment

Objective assessment of muscle tone in the client with cerebral spasticity is difficult because the tone fluctuates continuously in response to extrinsic and intrinsic factors. The postural reflex mechanism, the position of the body and head in space, the position of the head in relation to the body, and stereotypical reflexes and associated reactions all influence the degree and distribution of abnormal muscle tone.⁸⁷

Guidelines for Muscle Tone Assessment

The following steps describe correct procedures for assessing muscle tone.

It is helpful to rate spasticity and hypertonia with the client in the same position, preferably at the same time of day, to enhance reliability, because body and head position influence cerebral hypertonus. The client's upper extremity muscle tone usually is evaluated with the client sitting on a mat table when possible. Remember that the client's trunk posture (e.g., the seated client bearing weight symmetrically vs. slumped or leaning to one side) will affect the results of the tone evaluation. Tone fluctuates from hour to hour and from day to day because of intrinsic and extrinsic factors that influence it. This fluctuation makes accurate measurement difficult, particularly for cerebral hypertonia. Rating tone is still worthwhile, especially in the managed care environment, in which objective measures of progress are needed to justify the continuation of therapy.

Grasp the client's limb proximal and distal to the joint to be tested and move the joint slowly through its range to determine the free and easy ROM available. Note the presence and location of pain. If there is no active movement and if the limb feels heavy, record that the limb is flaccid or "0" in strength. If the limb has some active movement and no evidence of increased tone, the affected muscle or muscle group may be labeled "paretic" instead of "hypotonic." The paretic antagonist muscle can then be graded in strength (usually the strength grade will fall between 1 and 4-). Grading the paretic antagonist muscles provides more objective clinical information than merely labeling the

muscles as hypotonic. Strength grading antagonists can help the occupational therapist to triage phenol block and botulinum toxin type A or B injection candidates who have the potential to improve function; for example, a client with an elbow extension strength grade of 2- (in the presence of elbow flexor tone) would be a better block candidate than a client with a triceps strength grade of 0.

Juan did not have sufficient strength in his supinators (4-/5) or in his finger extensors (extrinsic 3-/5, intrinsic 2-/5) to counteract the pull of moderate finger flexor and pronator hypertonia.

Hold the limb on the lateral aspects to avoid giving tactile stimulation to the muscle belly of the muscle being tested.

Clinical assessment of spasticity involves holding the client's limb as just described and moving it rapidly through its full range while the client is relaxed. Label the tone "mild," "moderate," or "severe." (Refer to tone rating scales defined in the next section.)

Clinical assessment of rigidity and hypertonia involves moving the limb slowly during the range, noting the location of first tone or resistance to movement in degrees and labeling it "mild," "moderate," or "severe." Some physicians find goniometric measuring of the location of the first tone helpful before and after long-acting nerve block. Others find documentation of the limb's resting position helpful before and after injection.⁶⁵

Record findings for various muscle groups or movements.

OT Practice Note

It is important to note the client's overall posture during evaluation of muscle tone. Is the client's posture symmetric, with equal weight bearing on both hips (if sitting) or on both feet (if standing)? Note how the client moves in general. Is the head aligned or tilted to one side? Is one shoulder elevated? Is the trunk rotated or elongated on one side and shortened on the other? Such abnormalities will affect the client's ability to move the limbs normally. Current intervention focuses heavily on quality of movement, achieving as normal motor control as possible during occupation.

Manual Rating Scales for Spasticity and Hypertonicity

Ashworth Scale

The Ashworth Scale⁴ (Box 19-1) and the Modified Ashworth Scale¹⁰ (MAS) are the two scales most widely used to manually rate spasticity.^{75,89} These scales were not designed to differentiate between pure spasticity and **hypertonic stretch reflexes**. They are used to quantify the degree of hypertonus. Controversy can be found in the literature

Box 19-1

Ashworth Scale

- 0 = Normal muscle tone
- 1 = Slight increase in muscle tone; “catch” when limb moved
- 2 = More marked increase in muscle tone, but limb easily flexed
- 3 = Considerable increase in muscle tone
- 4 = Limb rigid in flexion or extension²

From Ashworth B: Preliminary trial of carisoprodol in multiple sclerosis, *Practitioner* 192:540, 1964.

about the validity and reliability of these scales. Brashear and associates concluded that in upper limb spasticity, the Ashworth Scale had good intrarater and interrater reliability when used by trained medical professionals.¹⁴ However, Seghal and McGuire⁸⁸ believed that the Ashworth scale lacks reliability. Pandyan and colleagues^{76,78} noted that the Ashworth Scale and the Modified Ashworth Scale should be used as an ordinal scale of resistance to passive movement; however, they are not valid for assessing spasticity. Preston believes that both scales should be considered nominal because the last stage of each scale is describing rigidity, not spasticity. Rigidity is an extrapyramidal phenomenon and spasticity is pyramidal; therefore the two should not be measured on the same scale.⁸¹

Three studies have demonstrated that the MAS is a reliable scale for assessment of spasticity.^{10,40,41} Four studies have reported that it is not reliable.^{3,8,31,62} Therapists familiar with the Ashworth Scale can help physicians evaluate candidates for neurosurgical procedures. For example, some of the selection criteria for the SynchroMed Intrathecal Baclofen Pump (ITB)⁶⁹ implantation are based on the presence of a two-point reduction on the Ashworth Scale after the test dose of medication is given.⁸³ Resistance encountered during passive muscle stretching is described in Box 19-1.

Tardieu Scale

Both the Modified Tardieu Scale (MTS)¹³ and the Tardieu Scale⁴³ measure spasticity.³⁴ The Tardieu Scale is written in French and was not reviewed. The MTS had an interrater reliability coefficient of .7 and was shown to be more reliable than the aforementioned MAS.³⁹

Mild-Moderate-Severe Spasticity Scale

Some therapists and physicians find a mild-moderate-severe scale easier to use than the aforementioned scales. The scale in Box 19-2 is suggested as a guide for estimating the degree of spasticity.³⁰

Preston’s Hypertonicity Scale

Some therapists and physicians find a mild-moderate-severe hypertonia scale easier to use. The scales in Box 19-3 are suggested as a guide for estimating the degree of hypertonicity.

Box 19-2

Mild-Moderate-Severe Spasticity Scale

- Mild: stretch reflex (palpable catch) occurs at the muscle’s end range (i.e., the muscle is in a lengthened position).
- Moderate: stretch reflex (palpable catch) occurs in midrange.
- Severe: stretch reflex (palpable catch) occurs when the muscle is in a shortened range.

Farber S: *Neurorehabilitation: a multisensory approach*, Philadelphia, Pa, 1982, Saunders.

Box 19-3

Preston’s Hypertonicity Scale

- 0: no abnormal tone is detected during slow, passive movement.
- 1 or mild: first tone or resistance is felt when the muscle is in a lengthened position during slow, passive movement.
- 2 or moderate: first tone or resistance is felt in the midrange of the muscle during slow, passive movement.
- 3 or severe: first tone or resistance occurs when the muscle is in a shortened range during slow, passive movement.

One of the reasons why Juan could not keyboard with his left hand was the presence of moderate hypertonia in his finger flexors. He could not retrieve change in his left hand from the drive-through window cashier because moderate hypertonia in his forearm pronators limited full active supination. One needs to have close to normal supination and functional grasp/release to obtain change from a drive-through cashier.

Mechanical and Computer Rating Systems for Spasticity and Hypertonicity

Mechanically determined parameters of assessing hypertonia may be more reliable than the aforementioned manual methods. McCrea and coworkers⁶⁷ concluded that using a linear spring damper model to assess the hypertonic elbow was reliable and valid. This model is not widely used in clinical practice, nor even in research practice, because of time constraints and difficulty accessing certain muscle groups (e.g., it is easier to set up and measure elbow hypertonia than hip hypertonia in a mechanical tone rating device).

Leonard and associates investigated the construct validity of the Myotonometer (Neurogenic Technologies, Inc., Missoula, Mont), a newly developed computerized, electronic device with a probe (that looks similar to an ultrasound transducer) that is placed on top of the skin over the muscle belly. Measurements were taken over the biceps brachii at rest and during maximum voluntary muscle contraction. They revealed a significant difference between affected and

unaffected extremities in subjects with upper motor neuron spasticity. The authors concluded that the Myotonometer could provide objective data about the tone reduction efficacy of various tone reducing procedures.⁶¹

Clearly, more research is needed in the areas of manual, mechanical, and computer rating systems for assessment of hypertonia. Sehgal and McGuire summed up the controversy over hypertonia/spasticity rating scales quite well: “A uniformly acceptable, reliable and practical measure of spasticity continues to elude the clinician.”⁸⁸

Range-of-Motion Assessment in Evaluation of Tone

Passive ROM (PROM) assessment supplements and often correlates with tone assessment. For example, if a client with acute CVA (1 month after onset) has a wrist ROM measurement of 20 degrees extension (normal, 70 degrees), and if orthopedic causes (e.g., arthritis, fixed contracture) have been ruled out, the therapist should assess the tone in the wrist flexors and the extrinsic finger flexors. Hypertonicity of any of these muscles can prohibit full wrist extension. Assessment of PROM can reveal possible signs of joint changes (e.g., subluxation, dislocation, contracture) that have occurred from chronic hypertonus, such as proximal interphalangeal joints (PIPs) that measure -45 to 125 degrees instead of 0 to 100 degrees. Some physicians find PROM measurements useful in documenting the location of the first tone, or resting position, before and after Botox¹² or Myobloc⁷³ injections.

Juan had only 20 degrees of active supination. His passive range of motion was not limited. He has a soft tissue limitation of active supination as the result of paresis of the supinator and hypertonicity of the pronators; 20 degrees of supination is not enough to orient his hand palm up to hold coins.

Other Considerations in Tone Assessment

Changes in bone or other peripheral structures can lead to ROM limitations. For example, the presence of heterotopic ossification can limit joint ROM. Heterotopic ossification is the formation of new bone in soft tissue or joints, which can lead to joint ankylosis. Heterotopic ossification can occur in individuals with traumatic brain injury and spinal cord injury, along with severe spasticity, or with other types of severe injuries.^{11,53,102} Conversely, the presence of fixed contractures may be incorrectly labeled as hypertonus. Physiatrists and other physician specialists can aid in the diagnosis of contractures with the use of diagnostic short-term nerve blocks, EMG, and/or X-rays.⁸³

Incidentally, Juan had no passive range-of-motion deficits, so he did not have contractures.

Assessing Movement and Control

Along with the assessment of muscle tone previously described, the occupational therapist performs an assessment of upper extremity movement and control. The

therapist identifies where and how much the client’s motor control is dominated by synergies, and where selective, isolated movement is present. The degree to which abnormal tone interferes with selective control is identified. Also, identifying in which direction of movement hypertonicity occurs and how it affects function helps in determining the need for intervention.

Manual muscle testing usually is not appropriate for clients who exhibit moderate to severe hypertonicity or rigidity, because the relative tone and strength of the muscles are not normal, and movement is not voluntary or selective. Tone and strength are influenced by the position of the head and body in space, as well as by abnormal contraction, deficits in tactile and proprioceptive sensation, and impaired reciprocal inhibition.¹⁰⁴ However, if hypertonia is mild and selective movements are possible, it is helpful to grade the strength of the antagonists to measure progress objectively.⁸³

Position change, spinal reflexes, the reticular formation, and supraspinal reflexes influence muscle tone and motor control. Because the level and distribution of muscle tone change as the position of the head in space and of the head in relation to the body changes, tone cannot be assessed in isolation from postural mechanisms, motor function, synergies present, task specificity, and other factors related to motor control.⁴⁸

Sensation

The following sensibility tests are recommended for clients with damage to the central nervous system: static two-point discrimination, kinesthesia, proprioception, pain, and light touch using the Semmes-Weinstein monofilament test.⁵ The therapist can assess light touch more accurately with the Semmes-Weinstein monofilaments because they provide better pressure control than a cotton ball. (Chapter 23 discusses procedures for administration of these sensory tests.)

Medical Assessment of Muscle Tone

Physiatrists, orthopedic surgeons, and neurologists are some of the physicians who may specialize in assessment of muscle tone. They may use static or dynamic surface or percutaneous (needle) EMG. Multiple channels are used in dynamic EMG to evaluate the hypertonicity of many contributing muscles.⁶² EMG helps the physician determine abnormal, excessive electrical activity in muscles. EMG can help physiatrists and neurologists plan and implement short- and long-acting nerve blocks to treat hypertonia. Clients who have local muscle wasting, flaccidity, numbness, or unexplained paresis should undergo EMG assessment to rule out peripheral neuropathy.¹⁰²

Normal Postural Mechanism

The normal **postural mechanism** is composed of automatic movements that provide an appropriate level of stability and mobility. These automatic reactions develop in the

early years of life and allow for trunk control and mobility, head control, midline orientation of self, weight bearing and weight shifting in all directions, dynamic balance, and controlled voluntary limb movement. Components of the normal postural mechanism include normal postural tone and control, integration of primitive reflexes and mass movement patterns, righting reactions, equilibrium and protective reactions, and selective movement.

In clients who have suffered UMNS damage, the normal postural mechanism is disrupted. Abnormal tone and mass patterns of movement dominate clients' movements, and these clients have impaired balance and stability. Movements are slow and uncoordinated. Therapists must assess the extent of damage to the postural mechanism in clients with CNS trauma or disease.

Normal postural tone allows automatic and continuous postural adjustment to movement. Postural control is the ability to control or regulate specific postural outputs. It is important to assess the following automatic reactions, which are part of the postural mechanism, in clients with CNS trauma or disease.

Righting Reactions

Righting reactions direct the head to an upright position. Righting reactions help one assume a position. Automatic reactions maintain and restore the normal position of the head in space and the normal relationship of the head to the trunk, as well as the normal alignment of the trunk and limbs. Without effective righting reactions, the client will have difficulty getting up from the floor, getting out of bed, sitting up, and kneeling.⁹²

Equilibrium Reactions

Equilibrium reactions help one sustain or keep a position. They are the "first line of defense against falling."⁸⁷ Equilibrium reactions, which are elicited by stimulation of the labyrinths within the inner ear, are used to maintain and regain balance in all activities. These reactions ensure sufficient postural alignment when the body's center of gravity is altered by a change in the supporting surface.⁵² Without equilibrium reactions, the client will have difficulty maintaining and recovering balance in all positions and activities.

Protective Reactions

Protective reactions are the second line of defense against falling if the equilibrium reactions cannot correct a balance perturbation. They consist of protective extension of the arms and hands, which is used to protect the head and face when one is falling. Stepping and hopping are examples of lower extremity protective reactions. Without protective reactions, the client may fall or may be reluctant to bear weight on the affected side during normal bilateral activities.⁸⁷

Assessment of Righting, Equilibrium, Protective Reactions, and Balance

Formal testing of these reactions may be difficult because of the cognitive and physical limitations of the client or time constraints of the therapist. The therapist can evaluate righting reactions, however, during transfers and ADLs. Equilibrium and protective reactions can be observed when the client shifts farther out of midline than necessary during functional activities, such as lower extremity dressing.

Balance depends on normal equilibrium and protective reactions. Balance is "the ability to maintain the center of gravity over the base of support, usually while in an upright position."⁵⁶ Balance involves a complex interaction between many systems, including the vestibular, proprioceptive, and visual systems, and motor modulation from the cerebellum, basal ganglia, and cerebral cortex. Occupational and physical therapists must also observe the client's ankle, hip, and step strategies and note areas of breakdown in the kinetic chain.^{28,96}

When assessing a client with CNS dysfunction, the therapist should assess the client's static and dynamic balance before leaving the client unattended on a mat table, in a wheelchair, or during ambulatory ADLs. Dynamic balance involves maintaining balance while moving, and static balance involves maintaining equilibrium while stationary.

The Physical Performance Test assesses physical function during activity. Seven of the nine tested items involve static and dynamic balance.¹⁰¹ The test takes only 10 minutes to complete.⁸⁵ Figure 19-5 shows the test form and test protocol. Two other noteworthy balance assessments are the Tinetti Balance Test of the Performance-Oriented Assessment of Mobility Problems⁹⁴ and the Berg Balance Scale.⁶

Primitive Reflexes

The dominance of primitive reflex movement patterns can interfere with the client's occupational performance. Difficulties that may be encountered are described in the following paragraphs. Observation of these motor behaviors is a way of evaluating for the presence of primitive reflexes.

Brainstem Level Reflexes

Asymmetric Tonic Neck Reflex (ATNR)

The ATNR is tested with the client positioned supine or sitting.

Stimulus: actively or passively turn the client's head 90 degrees to one side.

Response: an increase in extensor tone of the limb on the face side and an increase in flexor tone on the skull side of the limb.³⁷

The client with an asymmetric tonic neck reflex may have difficulty maintaining the head in midline while moving the eyes toward or past midline. The client may

PHYSICAL PERFORMANCE TEST SCORING SHEET

FIGURE 19-5 Physical performance test: scoring sheet.
 (From Reuben DB, Siu AL: An objective measure of physical function of elderly outpatients—the physical performance test, *J Am Geriatr Soc* 38:1111, 1990.)

be unable to (1) extend an arm without turning the head, or (2) flex the arm without turning the head the other way. The client may be unable to move either or both arms to midline, especially when in the supine position, because movement of the arms is dependent on head positioning. This positioning causes asymmetry in the arms. Thus, this reflex makes it difficult or impossible to bring an object to the mouth, hold an object in both hands, or grasp an object in front of the body while looking at it.

Symmetric Tonic Neck Reflex (STNR)

The STNR is tested with the client positioned sitting or quadruped.

Stimulus 1: flex the client's head and bring his/her chin toward the chest.

Response: flexion of the upper extremities and extension of the lower extremities.

Stimulus 2: extend the client's head.

Response: extension of the upper extremities and flexion of the lower extremities.⁵⁷

The client with the STNR will be unable to support the body weight on hands and knees, to maintain balance in a quadruped position, or to crawl normally without fixating the head. The client will have difficulty moving from lying to sitting because when the head is lifted to initiate the task, increased hip extension resists the movement. As he or she struggles to sit up, increased leg extension can interfere. The client will have difficulty with transfers from bed to wheelchair and from wheelchair to bed, because as the arms and neck are extended to initiate the transfer, one or both legs may show increased flexion, which may cause the client to slide under the bed or wheelchair. Additionally, the affected leg may actually lift off the floor, causing an inability to bear weight on that extremity.²³

Tonic Labyrinthine Reflex (TLR)

The TLR can be tested with the client supine with his or her head in midposition. The stimulus is the test position. The response is an increase in extension tone or extension of the extremities. The TLR can also be tested with the client prone with the head in midposition; again, the test position is the stimulus. The response is an increase in flexor tone or flexion of the extremities. The client who exhibits a poorly integrated tonic labyrinthine reflex will be severely limited in the ability to move. Functional limitations include an inability to lift the head in the supine position, to initiate flexion to sit up independently from the supine position, to roll over, or to sit in a wheelchair for long periods. In attempts to move from a supine to a sitting position, extensor tone will dominate until the client is halfway up, when flexor tone begins to take over. Flexor tone continues until full sitting is reached, causing the head to fall forward, the spine to flex, and the client to fall forward. Sitting in a wheelchair for extended periods can

lead to increased extensor tone as the client hyperextends the head to view the environment. The knee is extended, the foot is pushed forward off the wheelchair footrest, and eventually the client may slip or remain in a half-lying asymmetric position.⁵⁷

Positive Supporting Reaction

The positive supporting reaction is caused by pressure on the ball of the foot. This stimulus elicits the following response: rigid extension of the lower extremities due to co-contraction of the flexors and extensors of the knee and hip joints.⁵⁷ One may also see internal rotation of the hip, ankle plantar flexion, and foot inversion. The client with a positive supporting reaction will have difficulty placing the heel on the ground for standing, putting the heel down first in walking, and having normal body weight transference in walking. The client will have difficulty getting up from a chair, sitting in a chair, or walking down steps, because the leg remains in rigid extension and it is not possible to move the joints while weight bearing. The rigid leg can carry the client's body weight but is unable to contribute to any balance reactions. All balance reactions therefore are compensated for by other parts of the body.⁵⁷

Spinal Level Reflexes

Spinal reflexes can occur after an upper motor neuron lesion. They appear because of lack of integration with higher centers. Some examples of exaggerated spinal reflexes are hyperactive deep tendon reflexes, the Babinski sign, flexor withdrawal reflex, crossed extension, and grasp reflex.⁵⁰ Three spinal reflexes are reviewed.⁵⁷

Crossed Extension Reflex

The crossed extension reflex causes increased extensor tone in one leg when the other leg is flexed. Therefore, if the client with hemiplegia who is influenced by this reflex flexes the unaffected leg for walking, a strong extensor hypertonicity occurs in the affected leg and interferes with the normal pattern of ambulation. By the same token, the client can bridge (lift buttocks) in bed with the weight supported by both legs. If the unaffected leg is lifted (with hip flexed), however, a total extension pattern occurs in the affected leg and the bridge cannot be maintained.⁵⁷

Flexor Withdrawal

The client with flexor withdrawal will exhibit flexion of the ankle, knee, and hip when the sole of the foot is touched (swiped heel to ball of foot). This reflex clearly interferes with gait pattern and transfers.⁵⁷

Grasp Reflex

The client with a grasp reflex will not be able to release objects placed in the hand, even if active finger extension is present. The reflexes just discussed are rarely seen in isolation.⁵¹

FIGURE 19-6 Trunk flexor control. Dotted lines indicate trunk starting position, solid lines indicate trunk final position, arrows indicate movement direction, and plus symbols indicate muscle groups primarily responsible for control of the pattern. (Skeletal muscle activity occurs on both sides of the trunk [reciprocal innervation].)

(From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach*, ed 2, St Louis, Mo, 2004, Elsevier Mosby.)

Trunk Control Assessment

Collin and Wade²¹ designed a quick and easily administered test of trunk control that is valid and reliable in clients with a diagnosis of CVA. It involves four timed tests: (1) rolling to the weak side, (2) rolling to the sound side, (3) moving from supine to sitting, and (4) sitting on the side of the bed with feet off the floor for 30 seconds.²¹

To accurately assess trunk control, the therapist must evaluate strength and control in the following muscle groups: trunk flexors, extensors, lateral flexors, and rotators. The client should be sitting upright on a mat table with the feet supported for all tests. Again, the client should not be left unattended on the mat table until the therapist determines that the client has adequate trunk control and sitting balance. The procedures described in the following sections are condensed from *Gillen's Stroke Rehabilitation: A Function-Based Approach*.³⁶

Trunk Flexors

The examiner asks the client to sit upright, to slowly move his or her shoulders behind the hips (eccentric control), and to hold the end-range posture (isometric control) (Figure 19-6, A). The client then is asked to move forward (concentric control) to resume the initial upright posture (Figure 19-6, B).

The examiner should observe for evidence of unilateral weakness, potential for falls, and symmetry of weight shift. A functional test for trunk flexor control is to observe the client move from supine to sitting.

FIGURE 19-7 Trunk extensor control. Dotted lines indicate trunk starting position, solid lines indicate trunk final position, arrows indicate movement direction, and plus symbols indicate muscle groups primarily responsible for control of the pattern. (Skeletal muscle activity occurs on both sides of the trunk [reciprocal innervation].)

(From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach*, ed 2, St Louis, Mo, 2004, Elsevier Mosby.)

Trunk Extensors

Test 1

The client is sitting in a position of spinal flexion with a posterior pelvic tilt and moves into trunk extension while simultaneously moving the pelvis into neutral or into a slight anterior tilt. This test assesses concentric trunk extensor control, which is a prerequisite for lower extremity dressing and forward reach (Figure 19-7, A).

Test 2

The client is seated in an upright posture. The examiner asks the client to maintain an erect spine and lean forward. This test evaluates eccentric trunk extensor control (Figure 19-7, B). For both trunk extensor tests, the examiner should observe signs of unilateral weakness and note end-range control.

Test 3

The client is asked to move his or her shoulders back to assume a seated, aligned, upright position. The trunk extensors are contracting concentrically (Figure 19-7, C).

Lateral Flexors

The client sits in an upright posture. The pelvis is stationary, and the upper trunk laterally flexes toward the mat table. Figure 19-8, A, shows eccentric contraction of the left side and muscle shortening of the right side. The client is asked to return to the original test position (concentric control of the left side) (Figure 19-8, B).

Figure 19-8, C, shows assessment of trunk and pelvis lateral flexion, where movement is initiated from the lower trunk and pelvis. The end position is one of trunk elongation on the weight-bearing side and shortening on the non-weight-bearing side, which involves concentric contraction of the right side.

FIGURE 19-8 Lateral flexor control. *Dotted lines* indicate trunk starting position, *solid lines* indicate trunk final position, *arrows* indicate movement direction, and *plus symbols* indicate muscle groups primarily responsible for control of pattern. (Skeletal muscle activity occurs on both sides of the trunk [reciprocal innervation].)

(From Gillen G, Burkhardt A: *Stroke rehabilitation: a function-based approach*, ed 2, St Louis, Mo, 2004, Elsevier Mosby.)

Lateral flexion is needed for fall prevention when a client is reaching to the side (e.g., shutting a car door).³⁶

Trunk Rotation

The primary muscles responsible for rotation are the obliques. When a person rotates the trunk to the left, the right external and the left internal obliques are recruited. Rotational control is a prerequisite for upper extremity dressing and reaching across the midline. The following three movement patterns are evaluated:

1. The client sits upright and the pelvis is in a neutral, stable position. The client reaches with his or her right arm, across the body, in the direction of the floor. This motion helps in assessment of concurrent flexion and rotation. The motion tests concentric control of the obliques and the back extensors (particularly the thoracic region). Both sides need to be tested.
2. The second movement pattern involves trunk extension with rotation. The upper trunk remains stable, and the lower trunk and pelvis move forward on one side (i.e., shifting forward). Again, both sides are tested.
3. The client is positioned supine for the third movement. The client initiates a “segmental roll by lifting the shoulders from the support surface and toward the opposite side of the body. This pattern is controlled by a concentric contraction of the abdominals (obliques).”³⁶

Coordination

Coordination is the ability to produce accurate, controlled movement. Characteristics of coordinated movement include smoothness, rhythm, appropriate speed, refinement to the minimum number of muscle groups needed, and appropriate muscle tension, postural tone, and equilibrium.

Coordination of muscle action is under the control of the cerebellum and is influenced by the extrapyramidal system.

For coordinated movement, all elements of the neuromuscular mechanism must be intact. Coordinated movement depends on contraction of the correct agonist muscles with simultaneous relaxation of the correct antagonist muscles, together with contraction of the joint fixator and synergist muscles. In addition, proprioception, body scheme, and the ability to judge space accurately and to direct body parts through space with correct timing to the desired target must be intact.

Incoordination

Many types of lesions can produce disturbances in coordination. Disturbances in coordination often stem from cerebellar and extrapyramidal disorders. Noncerebellar causes include diseases and injuries of muscles and peripheral nerves, lesions of the posterior columns of the spinal cord, and lesions of the frontal and post-central cerebral cortex. Paralysis of the limbs caused by a peripheral nervous system lesion prevents testing for coordination, even though CNS mechanisms are intact.

Cerebellar Disorders

Cerebellar dysfunction can cause incoordination that may affect any body region and cause a variety of clinical symptoms. For example, the client may have postural difficulties that include slouching or leaning positions (caused by bilateral lesions) or spinal curvature (caused by unilateral lesions) and wide-based standing. Eye movements, both voluntary and reflexive, may be affected, as well as the resting position of the eye. The following are common signs of cerebellar dysfunction that the therapist may encounter.⁹⁸

Ataxia

Ataxia is manifested as delayed initiation of movement responses, errors in range and force of movement, and errors in the rate and regularity of movement. Poor coordination is noted between the agonist and antagonist muscle groups. This results in jerky, poorly controlled movements. When a client with ataxia reaches for an object, it is apparent that the shortest distance between the client and the object is not a straight line. The client with gait ataxia has a staggering, wide-based gait with reduced or no arm swing. Step length may be uneven, and the client may have a tendency to fall. The client with cerebellar dysfunction isolated to one cerebellar hemisphere will have a tendency to fall on the side of the lesion or dysfunction because of the ipsilateral influence of the cerebellum on the lower motor neurons. Ataxia will result in poor postural stability.^{28,70}

Adiadochokinesis

Adiadochokinesis is an inability to perform rapid alternating movements such as pronation and supination or elbow flexion and extension. Preston tests this by counting how

many cycles a client can perform in a 10-second time frame. A cycle consists of one full repetition of supination and pronation. It is best to test the unaffected (or lesser affected) side first. The affected side is then compared with the unaffected side.⁸⁰

Dysmetria

Dysmetria is an inability to estimate the ROM necessary to reach the target of movement. Two types of dysmetria are known. Hypermetria involves the limb overshooting the target. Conversely, hypometria involves the limb undershooting the target.⁷⁰

Dyssynergia

Literally, dyssynergia is a “decomposition of movement” in which voluntary movements are broken up into their component parts and appear jerky. Dyssynergia can also cause problems in articulation and phonation.^{25,70}

Rebound Phenomenon of Holmes

The rebound phenomenon of Holmes is the lack of a check reflex, that is, the inability to stop a motion quickly to avoid striking something. For example, if the client’s arm is flexed against the resistance of the examiner and the resistance is released suddenly, the client’s hand will hit the client’s face or body.²⁵

Nystagmus

Nystagmus is an involuntary movement of the eyeballs in an up-and-down, back-and-forth, or rotating direction. It interferes with head control and fine adjustments required for balance. Nystagmus can occur as a result of vestibular system, brainstem, or cerebellar lesions.²⁵

Dysarthria

Dysarthria is explosive or slurred speech caused by incoordination of the speech mechanism. The client’s speech may also vary in pitch or may seem nasal and tremulous, or both.²⁵

Extrapyramidal Disorders

Extrapyramidal disorders are characterized by hypokinesia or hyperkinesia. Parkinson’s disease is characterized by hypokinesia (bradykinesia), cogwheel and lead pipe rigidity, a decrease in or loss of postural mechanisms, and a resting, pill-rolling tremor.²⁷

Parkinson’s plus is the name given to a group of movement disorders that have signs of Parkinson’s disease with concomitant neurologic deficits. Progressive supranuclear palsy (PSP) is one such disease.⁵⁰ Clients affected with PSP have “loss of vertical ocular gaze, rigidity of the neck and trunk muscles, dementia, and parkinsonian signs,”⁴⁹ usually in the absence of tremor. Life expectancy is shorter than in Parkinson’s disease. Death often occurs within 6 to 10 years.⁴⁹

Chorea

Chorea is irregular, purposeless, involuntary, coarse, quick, jerky, and dysrhythmic movements of variable distribution. These movements may occur during sleep.²⁵ Two diagnoses often presenting with chorea are tardive dyskinesia and Huntington’s disease. Tardive dyskinesia is a drug-induced disorder, often associated with neuroleptic drug use. Occupational therapists most often see clients who have tardive dyskinesia in psychiatric settings. Huntington’s disease is an inherited, autosomal dominant disease. Clients with Huntington’s disease have an ataxic gait with choreo-athetoid movements. As the disease progresses, rigidity develops. Choreiform movements are faster than athetoid movements.⁵⁰

Athetoid Movements

Athetoid movements are continuous, slow, wormlike, arrhythmic movements that primarily affect the distal portions of the extremities. These movements occur in the same patterns in the same individual and are not present during sleep.²⁵ Adult athetosis can occur after cerebral anoxia and Wilson’s disease. Movement patterns include alternating “extension and flexion of the arm, supination and pronation of the forearm, and flexion and extension of the fingers.”⁴⁹ Athetosis that occurs with chorea is termed *choreoathetosis*.⁵⁰

Dystonia

Dystonia results in persistent posturing of the extremities (e.g., in hyperextension or hyperflexion of the wrist and fingers), often with concurrent torsion of the spine and associated twisting of the trunk.¹ Dystonic movements are often continuous and are often seen in conjunction with spasticity. Figure 19-9 shows a client with a traumatic brain injury, with his right wrist and fingers exhibiting dystonia. Dystonia can be primary or secondary, the latter occurring

FIGURE 19-9 A client with right upper extremity dystonic posturing of the wrist and finger extensors. His left wrist shows severe hypotonicity. Tone abnormalities are the result of a traumatic brain injury.

with other CNS disorders (e.g., hypoxic brain injury, tumor). Segmental dystonia involves two or more adjacent body parts. Generalized and multifocal types of dystonia also exist. Focal dystonia involves only one limb, as seen in writer's cramp, musician's cramp, and spasmodic torticollis.⁴⁹

Ballism

Ballism is a rare symptom that is produced by continuous, abrupt contractions of the axial and proximal musculature of the extremity. Ballism causes the limb to fly out suddenly. It occurs on one side of the body (hemiballism) and is caused by lesions of the opposite subthalamic nucleus.^{25,70}

Tremor

The following are three common types of tremor:

1. Intention tremor, associated with cerebellar disease, occurs during voluntary movement. It is intensified at the termination of the movement and is often seen in multiple sclerosis. The client with intention tremor may have trouble performing tasks that require accuracy and precision of limb placement (e.g., drinking from a cup, inserting a key in a lock).
2. Resting tremor occurs at rest and subsides when voluntary movement is attempted. It occurs as a result of damage or disease of the basal ganglia and is seen in Parkinson's disease.
3. Essential familial tremor is inherited as an autosomal dominant trait. It is most visible when the client is carrying out a fine precision task.⁴⁹

Assessment of Coordination

Medical Assessment of Coordination

Incoordination consists of errors in rate, rhythm, range, direction, and force of movement.³⁵ Therefore, observation is an important element of the clinical examination. The neurologic examination for incoordination may include the nose-finger-nose test, the finger-nose test, the heel-knee test, the knee pat (pronation-supination) test, hand pat and foot pat tests, finger wiggling, and drawing a spiral. Such tests can reveal dysmetria, dyssynergia, adiachokinesis, tremors, and ataxia. Usually the neurologist or the physiatrist performs these examinations. Magnetic resonance imaging and computed tomography scans also may be ordered. Tremors are frequency rated with EMG, which helps the physician accurately diagnose tremor type.⁴⁹

Occupational Therapy Assessment of Coordination

Selected activities and specific performance tests can reveal the effects of incoordination on function. The occupational therapist can observe for coordination difficulties during ADL assessment. The therapist can prepare simulated tasks that require coordinated muscle function, such as writing,

opening containers, tossing and catching a bean bag or ball, or playing a board game.⁹⁰ The therapist should observe for irregularity in the rate of movement and for sudden, corrective movements in an attempt to compensate for incoordination. Movement during the performance of various activities may appear irregular and jerky and may overreach the mark. The following general guidelines and questions can be used when evaluating incoordination:

1. Assess muscle tone and joint mobility first in a sitting position.
2. Observe for ataxia, proximal to distal, during functional upper extremity movement. Are movements away from or toward the body more difficult for the client? Where, within the ROM, is ataxia most prevalent?
3. Stabilize joints proximally to distally during the functional task, and note differences in client performance as compared with performance without stabilization. (Stabilization can be attained by splinting or stabilizing the affected body part against a wall.) Weighted cuffs may be applied to the extremity during task performance to determine whether weighting or resistance decreases the tremor (use caution). Note the amount of resistance provided. Observe whether the weights make the coordination worse. Sometimes the use of weights increases tremor.
4. Observe for tremor. Are the eyes and speech affected?
5. Does the client's emotional status affect coordination?
6. How do the client's ataxia and coordination problems affect participation in occupation?
7. Perform an occupational profile, as well as a performance patterns interview, to ask about the client's roles, routines, goals, and environment to determine which functions are important for the client.

Numerous standardized tests of motor function and manual dexterity are available and can be administered to evaluate coordination. These tests include the Purdue Pegboard,⁸⁴ the Minnesota Rate of Manipulation Test,⁷¹ the Pennsylvania Bimanual Work Sample,⁷⁹ the Crawford Small Parts Dexterity Test,²² the Jebsen-Taylor Hand Function Test,⁵¹ and the 9-Hole Peg Test.⁶⁴ Standardized functional assessments for CVA (e.g., the GWMFT) mentioned earlier in this chapter may be useful for measuring the efficacy of occupational therapy intervention for impaired coordination.⁷²

Occupational Therapy Intervention

Intervention for Hypertonicity and Spasticity

Hypertonicity is only one part of the UMNS. It is very important to treat other performance deficits of the UMNS such as paresis, fatigue, and decreased dexterity. These

deficits can impede function to a greater extent than hypertonia.¹⁴

Before treating hypertonus, the therapist and the physician need to closely evaluate the function of the tone. Hypertonicity can have beneficial effects, such as aiding in standing and transfers, maintaining muscle bulk, and preventing deep vein thrombosis, osteoporosis, and edema. Intervention is necessary when spasticity interferes with ADLs, gait, sleep, or wheelchair positioning, or when it causes severe pain and limits hygiene (e.g., the client is unable to wash hand or axilla) or leads to contractures or decubitus ulcers. Hypertonicity or spasticity may be treated with conservative therapeutic interventions, pharmacologic agents, or surgery.⁸³

Conservative Treatment Approaches

Weight Bearing

For hypertonicity reduction and paresis remediation in the upper extremity, therapists have been using weight-bearing skills/activities for many years when treating clients with upper motor neuron lesions, but evidence of treatment efficacy has not been fully established.

Brouwer and Ambury concluded that corticospinal facilitation of motor units occurred during upper extremity weight bearing. They believed that afferent input from weight bearing increased motor cortical excitability.¹⁵ Chakerain and Larson studied the effects of upper extremity weight bearing on hand opening and prehension in children with spastic cerebral palsy. Computer calculations of clients' hand surface area were performed. An increase in surface area was noted after weight bearing, along with an increase in the maturity of movement components needed for prehension.¹⁹ McIlroy and Maki demonstrated that if the affected arm is used when weight bearing, postural responses occur throughout the weight-bearing extremity, as well as during other perturbations of posture.⁶⁸

Despite the fact that few well-controlled studies document how and why weight bearing works physiologically, it certainly is a requirement for improving functional performance. Clients need upper extremity postural support when reaching to the floor to pick up an object while seated, to prevent falling. When standing, upper extremity weight bearing is needed to reach into a high cabinet to facilitate balance.³⁶

Traditional Sensorimotor Approaches

Proprioceptive neuromuscular facilitation (PNF; see Chapter 31) has been shown to be effective in gaining motor control for a variety of diagnoses.⁹¹ According to the Neuro-Developmental Treatment (NDT) Association,⁷⁴ therapists who follow an NDT approach:

- “Utilize an in-depth analysis of the intricacies of movement and how the details relate to the whole to allow for functional movement in a wide variety of environments.

- Believe that control of movement is based on a complex interaction of many body systems, which are plastic and adaptable, as well as on the tasks presented and the environments in which the tasks are performed. Therefore, function can be altered by changing one or more of these elements.
- Utilize an understanding of the development of atypical movement, as well as the compensations, to help minimize the impact of CNS pathology and prevent the emergence of contractures and deformities which contribute to the functional problems.⁷⁴

Another occupational therapy objective is to have the client manage muscle tone to engage in and complete basic and instrumental activities of daily living. Positioning and movement in patterns opposite to hypertonic or synergistic patterns are important to expand the motor repertoire and develop movement that is as close to normal as possible. At times it is appropriate to facilitate synergistic movements in the client with chronic disease (or if the client does not recover beyond Modified Brunnstrom's stage 3) (see Table 19-1). The synergy patterns can be facilitated to improve lateral pinch or elbow flexion function. The client should be taught how to modulate the abnormal tone or how to instruct others to do so. The client should also be taught how to incorporate the affected upper extremity as much as possible into all ADLs. ADLs, crafts, games, and work activities can be used to teach incorporation of the extremities for a total approach to treatment.⁹⁵ Refer to Chapter 30 for a more detailed review of traditional sensorimotor treatment strategies.

Juan was recovering from an acute CVA. His Modified Brunnstrom Stages of Motor Recovery Score was 4 (see Table 19-1). He had good rehabilitation potential to restore the client factors needed for ADL tasks. The therapist will work with him on acquiring full finger extension and dexterity for keyboarding, as well as on supination activities for opening doors and holding change.

Even when motor control is adequate for participation in occupation, the sensory, cognitive, and perceptual abilities of the client may affect the achievement of functional goals. Perceptual dysfunction may alter the client's abilities, requiring the therapist to focus on perceptual training as well.⁷

Casting

In some cases, unilateral hypertonicity is severe enough to necessitate serial inhibitive casting or splinting (see Chapter 29). Casting in inhibitive postures has been shown to be effective in tone reduction.^{44,105} The beneficial effect of casting on hypertonia and upper extremity contractures has been well documented in the literature.^{8,30,32}

Casting in inhibitive postures is effective because it provides neutral warmth, maintained pressure, and constant joint positioning with static lengthening of muscle.⁴⁷ **Serial casting** is most successful when a contracture has been

present for less than 6 months. The cast may be bivalved (cut in half) and worn as a splint. This helps protect the skin and allows the therapist to work with the extremity out of the cast. However, many clinicians believe that a nonbivalved cast is more effective and actually causes less skin breakdown. A dropout cast, which can be used as part of the serial casting process, includes a cutout area, allowing movement of the joint in the desired direction. For example, for an elbow that has flexor hypertonicity, the dorsal upper arm portion of a long arm cast can be cut out to allow the triceps to be facilitated to extend the arm.

Serial casting should cease when the desired position is achieved and tone is manageable with the last cast or splint. If no evidence is found of increased passive ROM after two to three casts are removed, serial casting must cease; however, the last cast should be kept, bivalved, and used as a “retainer” splint to prevent additional contractures, similar to retainer use in orthodontics. Many innovations have occurred in commercially available spasticity reduction splints that are used to place the wrist and hand in inhibitive postures. The client and the family need to be educated on continuing to incorporate the extremity in occupation, and on bearing weight on the extremity as much as possible to retain the ROM gains achieved during casting.⁸³

Physical Agent Modalities

Physical agent modalities such as cold, superficial heat, ultrasound, and neuromuscular electrical stimulation can be used as preparation for, or in conjunction with, purposeful activity and muscle re-education, provided the therapist has the appropriate training and can prove competency. Ultrasound can help inhibit or reduce hypertonicity temporarily and can increase tendon and muscle extensibility. It is helpful to provide concurrent stretch during the ultrasound procedure.⁸³ Neuromuscular electrical stimulation has been shown to strengthen paretic muscles.^{17,45}

Juan actually did gain strength and range of motion in his finger extensors with the help of neuromuscular electrical stimulation to the extensor digitorum communis muscle group—the extrinsic finger extensors. His extrinsic strength improved from 3-/5 to 4/5 within 1 month.

Distal-to-Proximal Approach

The Functional Tone Management (FTM) Arm Training Program was developed by Saebo Inc. (Charlotte, NC) to address the weaknesses of therapeutic interventions currently applied to the neurologically impaired upper extremity (UE) and hand. The occupational therapists who founded Saebo theorized that because grasp and release capabilities are pivotal to reintegrating the UE into daily activities, a paradigm shift for UE neurologic rehabilitation was needed. Although traditional therapeutic interventions such as Bobath-based programs are based on a proximal-to-distal recovery pattern, Saebo developed the FTM Arm Training Program on the basis of a distal activation model, which focused on the key point of early initiation of UE

FIGURE 19-10 SaeboFlex dynamic orthosis.

(Courtesy Saebo, Inc., Charlotte, NC.)

movements that incorporate grasp and release. To incorporate the hand into the FTM Arm Training Program, Saebo developed a dynamic orthosis for the hand, called the SaeboFlex (Figure 19-10).

The SaeboFlex orthosis assists an individual who exhibits hypertonia in the hand to place the hand in an open, functional position. This positioning is accomplished by means of a fixed wrist support and a finger and thumb spring system of variable strength. Once the hand is open, the client can begin to retrain the finger flexors for improved motor control of the hand. While wearing the SaeboFlex, the client relearns to produce a graded muscle contraction of the finger flexors to grasp an object. The finger and thumb spring system, coupled with the client’s own efforts to relax muscle activation, allows the hand to open enough for the object held in the hand to be released.

Once the client is comfortable using the SaeboFlex, the FTM Arm Training Program can begin. The FTM program combines high-repetition grasp and release with task-specific arm training drills to progress the client toward a functional goal. A significant body of research supports the FTM Arm Training Program^{16,33,99}; however, this program does not require the wrist or finger extension typically needed for participation in a constraint-induced program. Clinically observed improvements with the FTM Arm Training Program include increased AROM at the shoulder elbow and wrist, improved UE Fugl-Meyer scores, and decreased Modified Ashworth scores.³¹ Clients as far as 20 years post insult have shown improvements. Independent research studies using the SaeboFlex and the FTM Arm Training Program are under way.

Pharmacologic Agents

Pharmacologic agents prescribed and administered by physicians include oral medications, short-term nerve blocks, and long-term blocks.

Clients with severe hypertonicity accompanied by severe pain may need evaluation to determine the cause of the pain. Drug therapy and other pain management techniques may be part of the treatment approach. The four commonly used oral medications for spasticity of UMN origin are diazepam, baclofen, dantrolene sodium, and tizanidine. Dantrolene sodium acts at the skeletal muscle. Dantrolene sodium is preferred in cerebral spasticity because it is less apt to cause sedation. However, it can cause weakness and liver damage. Side effects of diazepam include drowsiness, fatigue, and possible addiction. Baclofen is more effective with spinal cord injuries than with cerebral injuries. Its potential side effects include confusion, drowsiness, and hallucinations. Neither diazepam nor baclofen can be discontinued suddenly because to do so may cause seizures. Tizanidine HCl is labeled for spasticity reduction in multiple sclerosis and spinal cord injury. Its side effects may include hypotension, sedation, and visual hallucinations. No matter which drug is used, it is crucial for the occupational therapist to communicate to the medical staff any noted side effects that may interfere with the client's overall function.⁸³

Nerve blocks and motor point blocks consist of injections of a chemical agent to diminish or obliterate tone. Short- and long-term blocks may be used. Short-term blocks are injections of an anesthetic (e.g., bupivacaine) to temporarily reduce pain and muscle tone. Short-term blocks help the physician to differentiate between hypertonus and contracture.⁸² Short-term blocks last from 1 to 7 hours, depending on which anesthetic is used.

Long-term blocks, which usually consist of injections of phenol or botulinum toxin type A (Botox) or botulinum toxin type B (Myobloc), generally last several months. Botox lasts for 2 to 5 months with spastic hypertonia. Botulinum toxin type B has been shown to quell cervical dystonia for 12 to 16 weeks.² Phenol blocks last from 2 to 8 months, depending on whether the motor points (2 to 3 months) or the motor branch (8 months) is injected. Phenol and the botulinum toxins type A and B have different mechanisms of action. Botulinum toxins type A and B exert their effects via chemical denervation, and phenol works via motor point or motor branch neurolysis. Both blocks can be used to diminish or obliterate hypertonicity in the agonist. These blocks help to prevent contractures and render the hypertonic muscle weak or flaccid.^{20,42,77} The effect and time interval of the long-term block provide therapists the opportunity to increase antagonistic strength and function. A combination of long-acting blocks and casting or splinting is often used to treat hypertonicity. Long-term blocks in the upper extremities are commonly used in the subscapularis, brachioradialis, and flexor digitorum superficialis.⁸³

Surgical Methods

Surgery to control hypertonicity is an option. Dynamic EMG can help orthopedic surgeons plan surgery. Orthopedic surgical intervention can improve function or release

contractures. Examples of upper extremity functional surgery include lengthening of the biceps tendon to reduce elbow flexion and to gain elbow extension, thumb-in-palm release, and transfer of the flexor carpi ulnaris tendon to the extensor carpi radialis longus or brevis tendon to decrease the deforming force of wrist flexion while simultaneously augmenting wrist extension.⁸⁰ An example of a contracture release procedure is the flexor digitorum superficialis-to-profundus transfer to gain length in the extrinsic finger flexors.⁴⁶

Therapists will encounter clients with severe spasticity who have undergone a neurosurgical procedure called **intrathecal baclofen pump (ITB) implantation**. This procedure enables baclofen to enter the body at the spinal level and avoids the centrally mediated side effects of oral baclofen. The ITB provides baclofen, a spasticity-reducing medication, directly into the intrathecal (subarachnoid) space via a catheter attached to a subcutaneous implantable pump in the abdomen. The client must undergo a lumbar puncture test dose of intrathecal baclofen to determine candidacy before pump implantation.⁶⁹

ITB has been shown to be very effective in the reduction of severe spinal spasticity and spasticity associated with multiple sclerosis and is also effective for cerebral spasticity. For additional details on medical and surgical treatments and their relation to occupational therapy, the reader is referred to Preston and Hecht's *Spasticity Management: Rehabilitation Strategies*.⁸³

Treatment of Rigidity

Decerebrate and decorticate rigidity can wax and wane. When rigidity is waning, it is recommended that the client be transferred to a wheelchair or a reclining chair because rigidity decreases in sitting. Rigidity is worse during episodes of agitation.⁵⁷ Parkinson's rigidity responds temporarily to heat, massage, stretching, and ROM exercises. Rocking back and forth before standing can aid in the transition.⁶² See Chapter 35 for a discussion of Parkinson's disease and additional treatment strategies for rigidity.

Treatment of Flaccidity

Flaccidity stemming from upper motor neuron dysfunction (e.g., recovering from spinal or cerebral shock resulting from acute CNS insult) is treated with facilitation techniques such as weight bearing, high-frequency vibration, tapping, quick stretch, bed positioning with weight on the flaccid side most of the time, and functional neuromuscular electrical stimulation. Splinting of the hand and wrist may be indicated for support. Therapists should closely supervise splinting because contractures can result from excessive splint wear. Passive ROM exercises also are indicated. The arm can be passively positioned as normally as possible during ADL tasks to provide sensory and proprioceptive feedback. When the client is eating, have him or her place his or her arm on the dining room table, resting on top of a piece of Dycem.²⁹ Client and family education on proper

positioning and joint protection is important to prevent overlengthening of soft tissues and trauma (e.g., having his or her arm fall off of the lap and bump the wheel of the wheelchair).⁸³

Treatment of Incoordination

Treatment of incoordination is difficult. Activities graded on the basis of motor learning and control may be helpful for attaining proximal stability and then mobility. Therapy directed toward the modulation of reflexes and abnormal synergy patterns and the enhancement of postural control mechanisms, such as the righting and equilibrium reactions, can help to improve coordination. Weight bearing, joint approximation, placing and holding techniques, and fixed points of stability (having the client stabilize his elbow or wrist on the tabletop) can be helpful.

It is critical that the therapist encourage the client to use his or her vision to help direct upper extremity movements. The therapist should begin with small ranges of movement and gradually increase them as the client progresses. Initially, work is done in the plane and direction of movement

that are easiest for the client, then work progresses toward more difficult areas. Some of the involuntary movements of cerebellar or extrapyramidal origin, particularly primary movement disorders, are difficult to manage or change. Therapists have greater influence over movement disorders that are associated with traumatic brain injury and stroke.

Methods and devices to compensate for incoordination may be necessary to make BADLs and IADLs safer, more possible, and more satisfying. Obtaining a thorough occupational profile is necessary to make appropriate activity and equipment choices and to determine adaptive strategies that the client can carry over to the home environment. The physician may employ pharmacologic agents or surgical intervention in an effort to dampen tremors or other involuntary movement patterns.⁷⁰

Surgical Intervention for Movement Disorders

Neurosurgical intervention for movement disorders may include stereotactic thalatomy for ballismus, chorea (Huntington's), Parkinson's disease, essential tremor, and athetosis. Surgical treatment for dystonia may include rhizotomy,

Threaded Case Study | Juan, Part 2

Juan has experienced motor control dysfunction secondary to his CVA. The resultant effects have impaired his performance areas of occupation, performance patterns, and performance motor skills, and have affected many client factors. Fortunately, his proximal motor control was not affected by the CVA. His distal motor control was affected enough to impair resuming the premorbid role of primary breadwinner for his family.

Juan cannot operate a keyboard with his left hand for three reasons: (1) the moderate finger flexion hypertonia pulled his fingers into flexion when he tried to keyboard, (2) the antagonist muscles (the finger extensors with the intrinsic being weaker than the extrinsics) are too weak to counteract the finger flexion hypertonia, and (3) he experienced abnormal timing of the agonist/antagonist muscles that impaired his coordination needed for keyboarding. His high timed score (left upper extremity) on the Graded Wolf Motor Function Test provided an objective measure of his coordination deficit.

Juan cannot open his car door, receive change in his hand from the drive-through window cashier, or carry a glass without spilling the contents because of moderate pronator hypertonia. The pronation hypertonia limited his available active range of motion for supination. Furthermore, his supination strength was weak, 4- out of 5—not quite enough to counteract the pronation hypertonicity. This, coupled with impaired dexterity from the stroke, interferes with performance of these activities.

To improve the motor control of his finger extensors, a home program could include releasing a 5-inch foam ball while playing catch. Using his left hand to help wash his face with a washcloth would help him obtain full finger extension. A good intrinsic motor control activity is flipping paper footballs with combined PIP and distal interphalangeal (DIP) finger extension.

For his supinators, one could start by having him control a lightweight hammer in his lap and turning it back and forth into supination and pronation. He could start opening lightweight interior doors with his left hand, then progress to heavier doors like his car door. He could start carrying an empty glass with his left hand and gradually progress to filling it $\frac{1}{4}$ full, $\frac{1}{2}$ full, then $\frac{3}{4}$ full. Occupational therapists trained in neuromuscular electrical stimulation can expedite recovery of range of motion and strength by placing electrodes on the wrist extensors and extensor digitorum communis while the client actively performs composite wrist and finger extension. Another suggested electrode placement would be on the biceps and supinator muscle. For the latter placement, the negative electrode would be placed on the supinator and the positive on the biceps. (An asymmetric waveform would be utilized.) Again, active recruitment of the supination motion would be encouraged.

Clearly, Juan was working too many hours premorbidly. He was not getting enough sleep, and his hypertension was not controlled. Occupational therapy needs to include educating him on balancing work, rest, and leisure activities. While he is recovering, his wife can take over the duty of driving his children to school.

Incidentally, Juan is working full time now, 8- to 9-hour days, and keyboards at 75% of his premorbid speed. All of his goals listed during the COPM interview were met. He has full range of motion in all of his fingers, and his strength grade is 4/5 in the extrinsic finger extensors. His two remaining motor deficits are decreased index finger (PIP) extension strength (3+ to 4-) and decreased speed of PIP extension; it is much slower than that of his other three fingers. His blood pressure is now well controlled. He sleeps 8 to 10 hours per day.

neurectomy, cryothalotomy, or ITB implantation.⁴⁹ Deep brain stimulation has been effective in tremor reduction in essential tremor and Parkinson's disease.^{70,93}

Because of the current managed care system, occupational therapists are receiving more referrals than ever before from primary care physicians. Occupational therapists who have a basic knowledge of medical and surgical options in ameliorating motor control problems can play a triage role in suggesting referral to physician specialists.

Summary

As one can determine from reading the aforementioned case study, the presence of abnormal elements of motor control affects the quality of movement and the ability to perform in areas of occupation. The occupational therapist assesses muscle tone, upper extremity recovery, and coordination, using standardized tests and observation of movement during occupational performance. Results of the motor control assessment can help the client and the therapist collaborate on appropriate intervention. Ameliorating motor control can be a rewarding experience for the client and the therapist.

Review Questions

1. Define plasticity.
2. When would a physician recommend a long-term nerve block or a motor point block?
3. Describe the characteristics of rigidity.
4. Compare and contrast spasticity and hypertonia.
5. Why should the assessment of muscle tone be performed in conjunction with evaluation of the client's overall motor function?
6. Demonstrate how to perform an upper extremity muscle tone evaluation.
7. Describe equilibrium reactions and the functional implications of their presence in motor control.
8. Describe functional difficulties encountered when the asymmetric tonic neck reflex is present.
9. Compare and contrast chorea and athetosis.
10. Describe ataxia.
11. Compare and contrast the following tremors: essential, resting, and intention.

Chapter Outline

Clinical observation

Occupation-based functional motion assessment

Lower extremity

Hip complex

Flexion and extension

Abduction and adduction

Internal and external rotation

Knee

Ankle and foot

Plantar flexion

Dorsiflexion

Inversion and eversion

Upper extremity

Shoulder complex

Shoulder flexion and abduction with scapula upward rotation (overhead movements)

Shoulder extension and adduction with scapula downward rotation

Horizontal adduction and abduction

Internal and external rotation

Extension and adduction

Flexion and adduction

Elbow and Forearm

Wrist and Hand

Summary

Review Questions

Key Terms

Occupation-based functional motion assessment

Functional motion assessment

Individual activity analysis

Objective activity analysis

Clinical observation

Learning Objectives After studying this chapter, the student or practitioner will be able to do the following:

1. Define occupation-based functional motion assessment.
2. Describe why it is desirable to assess motor function through observation of engagement in occupation and performance of activities.
3. State two circumstances in which assessment of performance skills is indicated.
4. Define individual activity analysis, or “dynamic performance analysis.”
5. Describe why it is not possible to perform an accurate objective activity analysis.
6. List at least three questions that can guide the clinical observation and clinical reasoning of the occupational therapy practitioner when conducting an occupation-based functional motion assessment.
7. List factors other than range of motion, strength, and motor control that can affect motor performance.
8. Discuss how information gained from the occupation-based functional motion assessment differs from that gained during assessment of specific client factors.

■ Learning Objectives—cont'd

9. State the minimum level of strength required throughout the lower extremity for normal stance and positioning.
10. Compare levels of muscle strength and associated endurance in the upper extremities.
11. List areas of occupation that can be used to assess functional motion in the upper extremities and in the lower extremities.

Threaded Case Study | Raymond, Part 1

Raymond is a 60-year-old foreman of several lineman crews of the telephone company. He has been with the company for more than 40 years; although he could have moved into a more administrative position over the years, he has always enjoyed working in the field, being a mentor to the younger workers, and dealing with emergencies. He is known throughout his neighborhood as the person to call when help is needed with home repair tasks, whether it be carpentry, plumbing, or electrical work. He is a member of a championship senior softball team and plays most weekends during the season, sometimes traveling out of town to participate in tournaments. He does quite a bit of volunteering through the outreach program at his church and participates in such activities as collecting, preparing, and delivering food to home-bound elderly and driving new immigrants to various appointments. He shares household duties with his wife and enjoys cooking for her.

Rheumatoid arthritis was first diagnosed in Raymond 10 years earlier when he began experiencing pain and stiffness in his shoulders, hips, and knees. His symptoms were managed with medications, and except for occasional exacerbations, he was able to fully engage in occupations that were meaningful to him. In the last 6 months he has experienced an exacerbation of his symptoms. The pain in his shoulders, hips, and knees has increased, and he also began experiencing pain in his wrists and hands. His wife began to notice Raymond's change in mood as he became increasingly reluctant to engage in occupations in which he always took the lead, such as helping his neighbors with home projects, preparing food in his church outreach program, and participating in softball games.

Since he could not do things the way he used to, he did not want to do them at all. He stated that he did not want people seeing him fumbling as he attempted to hold tools or cooking utensils because his grip was so weak, nor did he want to let his teammates down because of the decreased power in his batting swing and decreased speed in running the bases. At work he found himself giving more verbal instructions to his

crew rather than demonstrating techniques as he had always done before; at times he spoke in a gruff, impatient tone, which was surprising to his fellow workers. His frustration with the increased amount of time that it was taking him to complete activities of daily living such as shaving, buttoning his shirt, and putting on the boots that he was required to wear at work was making him irritable. The fatigue he was experiencing at the end of the day “just from trying to move my body around” was also adding to the depression of this client. This previously outgoing person was withdrawing and becoming more and more socially isolated.

The occupational therapy practitioner to whom he was referred began anticipating the needs of this client based on the profile she developed. Evaluating this client as he engaged in occupations in specific contexts would provide the best information for determining intervention strategies that would be most helpful, such as adaptive equipment and joint protection techniques. Obtaining information underlying the client factors (muscle strength, range of motion) contributing to his decrease in function was critical. Arrangements were made to assess the client in his home and to make a job site visit. By observing the client perform occupation-based tasks and motions at work and home, important information concerning his range of motion, strength and endurance, and motor control could be assessed.

Critical Thinking Questions

1. What is the advantage of administering an occupation-based functional motion assessment versus more specific assessments, such as joint measurement and manual muscle testing?
2. What information about the client's muscle strength and joint range of motion can be determined through an occupation-based functional motion assessment? What cannot be determined?
3. What is the value of administering an occupation-based functional motion assessment in different environmental contexts?

Many physical disabilities cause limitations in performance skills and client factors, including joint range of motion (ROM), muscle strength, and motor control. These physical impairments in body functions and motor skills result in limitations in movement that can cause slight to substantial deficits in performance of areas of occupation and prevent pursuit of self-care, work, leisure, and educational

and social activities. An occupation-based functional motion assessment is a way of assessing the ROM, strength, and motor control available for completion of tasks by observing the client during performance of functional occupations (activities of daily living [ADLs], instrumental activities of daily living [IADLs], work, or leisure activities) in varied contexts and environments.¹

Since the primary responsibility of the occupational therapist is to assess occupational performance, identify problems in performance, and plan intervention strategies that will improve the client's ability to fully engage in occupations, the sensorimotor limitations should first be assessed through observation of functional activities. When improvement of performance skills is a goal of the intervention program, assessment of performance skills, occupation demands, and client factors in a variety of environmental contexts such as home, workplace, or school may be indicated to make an objective assessment of the physical limitations and gains (see Chapters 19, 21, and 22 for additional information).

Mental functions, including cognitive and perceptual abilities, such as motivation or the ability to sequence complex movement patterns, interpret incoming stimuli, or make use of coping skills and regulation of behavior, can also affect motor function. These client factors must be considered in any performance evaluation (see Chapters 25 and 26). However, this chapter is limited to consideration of motor function (i.e., ROM, strength, and motor control) during occupation-based functional motion assessment.

OT Practice Note

Except for a few diagnoses, specific assessments of ROM, muscle strength,⁴ and motor control are seldom necessary. For example, performing a full ROM assessment or manual muscle test is time-consuming, can be tiring to the client, and may duplicate other services, whereas assessing these factors while the client is engaging in occupation yields the most comprehensive picture of the client's actual abilities and limitations.

Clinical Observation

It is possible to make a gross assessment of joint mobility and muscle strength by having the client perform the motions associated with functional tasks (i.e., a functional motion assessment). The occupational therapy practitioner could observe as the client reaches overhead, as would occur when putting dishes away in an overhead cupboard, or taking a step to the side, as when stepping into a bathtub.⁷ This will give the practitioner some basic, though nonspecific information about factors that affect function.

In occupation-based practice, muscle strength, ROM, and motor control can be observed during the performance of ordinary ADLs,³ IADLs, work, and leisure tasks. For example, while assessing ADLs, the therapist can observe for difficulties in performance and movement patterns that may signal limited ROM, muscle weakness, muscle imbalance, poor endurance, limited motor control, and

compensatory motions used for function. An occupation-based functional motion assessment has an advantage over functional motion assessment in that although the client will perform motions as just described, there is the added resistance on body structures that will occur as a result of using equipment such as a sliding door, manipulating objects such as cards, or resisting fatigue and having endurance during repetitive activities such as bouncing a ball. In addition, because the client is performing these tasks in environments and contexts that are meaningful, the client's full participation and engagement in the task may be heightened.

Essentially, when observing a client perform selected tasks, the occupational therapist is performing an individual activity analysis, or "dynamic performance analysis,"⁷ to diagnose the occupational performance problems of that client. Since people perform the same task in a variety of ways and because there are so many variables in performance of a task, it is not possible to do an objective activity analysis, one that can be applied universally, and describe the sensorimotor requirements for the myriad of ADLs. The purpose of observation is to understand the client's occupational performance problems in the context of the interaction between the person, the task, and the environment.³ This type of screening will serve the occupational therapy practitioner well in deciding a course of intervention for Raymond, who because of the currently exacerbated status of his disease is not a candidate for more specific assessment of muscle strength (see Chapter 22).

While observing Raymond in his home as he performs the functional tasks described later in this chapter, the therapist will not only be able to assess his available ROM but also make some determination of his muscle strength.

The therapist's scientific knowledge of the particular dysfunction and an analysis of the ways in which activities are generally performed (activity demands) influence the assessment of performance problems and aid in the development of plans to remediate these problems.³

The following are questions to guide the clinical observation and clinical reasoning processes:

1. Does the client have adequate ROM to perform the task?
 - a. Where are the joint limitations?
 - b. What are some possible causes of the limitations?
 - c. Are there true ROM limitations or are the apparent limitations actually caused by decreased muscle strength?
2. Does the client have enough strength to perform the task?
 - a. In which muscle groups is there apparent weakness?
 - b. If strength appears inadequate to perform a task because the client cannot complete the ROM, is there truly muscle weakness or is there actually limited ROM?

3. Does the client have enough motor control to perform the task?
 - a. Is the movement smooth and rhythmic?
 - b. Is the movement slow and difficult (e.g., as seen with spasticity and rigidity)?
 - c. Are there extraneous movements when the client performs the task (e.g., tremors, athetoid or choreiform movements)?

The observing occupational therapy practitioner must also consider the client's understanding of the instructions and perception of importance of the task, as well as the possibility of sensory, perceptual, and cognitive deficits. Analysis of the results of the occupation-based functional motion assessment may indicate that formal assessment of performance skills or body functions is needed. For example, such an assessment may be needed to differentiate muscle weakness from limited ROM or to quantify (with a muscle grade) muscle weakness in specific muscle groups.

Assessing ROM, strength, and motor control by observing the client perform functional activities can aid in selecting meaningful intervention goals relative to improving occupational performance. The therapist can ask the client about his or her ability to perform the tasks of daily living but should also observe the client performing such activities as dressing, walking, standing, and sitting to make an accurate assessment.² Having the client perform ADLs in addition to other tasks associated with his or her habits and routines while interacting in varied environmental contexts can also add to the depth of information concerning the client's ROM and muscle strength. The practitioner delivering occupational therapy services to Raymond has determined that making both a home visit and a job site visit will enhance her understanding of the demands on this client. Observation of Raymond interacting with materials, equipment, tools, and products in these environments will provide information about the critical motions and complex motor patterns required for him to fully engage in the occupations most meaningful to him. Completion of the tasks by Raymond in the timely manner required in these contexts will also give information about the client's endurance and thus provide more information about his muscle strength.

Joint ROM quantification, manual muscle testing, and assessment of motor control (see [Chapters 19, 21, and 22](#)) will give the therapist specific information about the function of the musculoskeletal, neurophysiologic, and sensorimotor systems. Although the tests require minimum to maximum active output by the client, the therapist will not be able to determine the client's ability to integrate these systems to perform specific goal-directed tasks based on the results of these assessments. Rather, the therapist will acquire information about movements of a specific limb or a combination of limbs. Under carefully controlled conditions, the therapist will determine the flexibility of the components of the joint and the strength of muscles to create

movements such as flexion, abduction, and external rotation. However, the client's motor performance capabilities are not measured by these assessments. For example, the manual muscle test cannot measure muscle endurance (number of times that the muscle can contract at its maximum level and resist fatigue), motor control (smooth rhythmic interaction of muscle function), or the client's ability to use the muscles for functional activities.²

OT Practice Note

While observing a client performing functional activities, it would be most helpful if a therapist could also estimate the client's existing ROM, muscle strength, and motor control.

At his job site Raymond had difficulty stepping up into his truck (the cab of which was somewhat elevated as a result of oversize tires) since he did not have enough hip and knee flexion ROM. The occupational therapist also observed that if the truck was parked near a curb or he could first step onto a box and then onto the step of the truck, thus requiring less flexion ROM, he had less difficulty. However, in both instances he lacked sufficient strength in hip and knee extension to launch himself into the truck without compensating with his upper extremities.

Occupation-Based Functional Motion Assessment

The activities listed in the following sections for an occupation-based functional motion assessment are suggested as a general starting place for the student or beginning practitioner. Only upper and lower extremity activities are included. Movements of the face, mouth, neck, and spine are beyond the scope of this chapter. Many more motions and tasks could be suggested in each category. The reader is referred to *Joint Motion and Function Assessment: A Research Based Practical Guide*, 2nd revised edition by Clarkson,² for a comprehensive and detailed discussion of musculoskeletal assessment and its functional application.

Lower Extremity

Because of the somewhat stereotypic movements of the lower extremity, the arrangement of the large muscle groups, and the nature of the overall functions of weight bearing and ambulation, assumptions can be made about muscle strength during functional activities. For example, to assume a normal stance pattern, ambulate without any compensatory gait patterns, or position the lower extremities (without the assistance of the upper extremities) during dressing, a minimum of fair plus (F+) muscle strength is required in the musculature of the hips, knees, ankles, and feet. If muscle strength in the lower extremities is only

F throughout the lower extremity, ambulation without aids will not be possible.⁵ Good to normal muscle strength is required for the endurance to perform the small postural adjustments needed for maintenance of standing, the repetitive movement patterns inherent in walking, and the lifting, maneuvering, and balancing on the lower limbs that usually occur during dressing.

Hip Complex

The hip joints support the weight of the body. Each joint acts as a fulcrum when a person is standing on one leg. Hip movement makes it possible to move the body closer to or farther from the ground, bring the foot closer to the trunk, and position the lower limb in space.²

During functional activities, lumbar-pelvic movements accompany hip movement, which extends the functional capabilities of the hip joint. The hip is capable of flexion, extension, adduction, abduction, and internal and external rotation.²

Flexion and Extension

Full flexion and extension are required for many ADLs and IADLs. Standing requires full hip extension. Squatting, bending to tie a shoelace with the foot on the ground, and toenail care done with the foot on the edge of a chair all require full or nearly full hip flexion. Other activities that require moderate to full flexion and extension are donning panty hose or socks, bathing the feet in a bathtub, ascending and descending stairs or a step stool, sitting and rising in a standard chair, and riding a stationary bicycle.²

Abduction and Adduction

Most ordinary ADLs and IADLs do not require full ranges of abduction and adduction. The main function of the hip abductors is to keep the pelvis level when one foot is off the ground. For ADLs, hip abduction may be used when stepping sideways into a shower or bathtub, donning trousers when sitting, squatting to pick up an object, sitting with the foot across the opposite thigh, getting on a bicycle, or as in the case of Raymond, shifting weight from one foot to the other as he strides when swinging the bat.^{2,6}

Hip adduction brings the foot across the front of the body. An individual uses this motion when kicking a ball, moving an object on the floor with the foot, or crossing one thigh over the other for donning or removing shoes and socks.²

Internal and External Rotation

Internal rotation occurs when a person is pivoting medially on one foot. When a person is sitting, there is internal rotation when the person reaches to the lateral side of the foot for washing or donning socks. Internal rotators are active in walking.²

External rotation with hip flexion and abduction brings the foot across the opposite thigh for donning shoes or socks or for examining the sole of the foot.^{2,6}

Knee

The knee joint supports the weight of the body. With the foot fixed on the ground, knee flexion lowers the body toward the ground and knee extension raises the body. If the foot is off the ground, as in sitting, the knee and hip are used to orient the foot in space.²

ADLs that require moderate to full range of knee flexion and extension are standing and walking, squatting to lift an object from the floor, crossing the ankle of one foot over the thigh of the opposite leg, sitting down and rising from a chair, and dressing the feet.

Ankle and Foot

The foot is a flexible base of support when a person is on rough terrain. It functions as a rigid lever during terminal stance in the walking pattern. It absorbs shock when transmitting forces between the ground and the leg. The foot and ankle function to elevate the body from the ground when the foot is fixed. Dorsiflexion and plantar flexion occur at the ankle joint. Foot inversion and eversion occur at the subtalar joint.²

Plantar Flexion

Full plantar flexion is used when a person is rising on the toes to reach upward to a high shelf. Some plantar flexion is used to depress the accelerator on an automobile or the control pedal on a sewing machine and when donning socks or shoes.

Dorsiflexion

Full range of dorsiflexion is needed to descend stairs. Dorsiflexion is used in such activities as positioning the foot to cut the toenails or tying shoelaces.²

Inversion and Eversion

Inversion and eversion function to provide flexibility when an individual is walking on uneven ground. Inversion is used when the foot is crossed over the opposite thigh to inspect the sole.²

Threaded Case Study Raymond, Part 2

When administering an occupation-based functional motion assessment at Raymond's home, the occupational therapy practitioner was able to observe that in his attempt to don his shoes and socks, Raymond was unable to abduct and externally rotate his hip sufficiently in combination with full flexion of the knee to place the ankle of one foot over the opposite thigh.

Upper Extremity

By simply observing a client engaging in functional activities, the therapist cannot make general assumptions as easily about muscle strength in the upper extremities as in the

lower extremities. There are three reasons why this is the case: (1) the variety of ways in which the upper extremity can be positioned to complete any given task (i.e., there is no one right way to do the task), (2) the complexity of motor patterns possible requiring gross motor and fine motor skill, and (3) the dependency of the distal joints and musculature on the more proximal joints for positioning.

If several people are observed donning shirts, it will be apparent that different techniques are used by each. One person may lift the arm out to the side and increase shoulder abduction as the shirt is drawn onto the arm. Another person might prefer to dress with the arm more in front of the body, thus positioning the humerus in flexion. A third person might hyperextend the humerus as the shirt is pulled on. The difficulty, of course, is determining exactly how much ROM and muscle strength are minimally required at all of the joints involved when so many options are available to perform one task.

In the first two examples of donning a shirt, the musculature of the shoulder complex would certainly have to create more tension than if the humerus were in the adducted position. It would be inappropriate for the therapist to instruct the client on how to don the shirt if the therapist's goal was to attain some information regarding the client's level of independence in dressing and secondarily to make assumptions about ROM and muscle strength.

While observing a client perform occupation-based tasks and motions with the upper extremities, it is important to remember that even when it is not obvious or readily apparent, the muscles of the shoulder complex are contracting with varying degrees of tension. They may have to contract with enough force to position the hand in space and maintain it there, such as when a person is combing hair. At other times the humerus must be held close to the body to provide a stable base from which the forearm, wrist, and hand can maneuver, such as when striking the keys on a keyboard, cutting food with a knife, or writing. It would be an inaccurate assumption that the extremity is just hanging passively at the side when in fact the static contractions around the proximal joints make it possible for the musculature of the distal end of the extremity to work effectively. Conversely, the shoulder complex may have to be a moving unit as opposed to a positioning one, such as when moving groceries from a countertop to shelves in a kitchen cabinet.

General guidelines exist when assessing strength for function in the upper extremities. With good to normal endurance, a client with good (G) to normal (N) muscle strength throughout the upper extremity will be able to perform all ordinary ADLs and IADLs, work, play, and enjoy leisure and social participation occupations without undue fatigue.⁵ A client with fair plus (F+) muscle strength will usually have low endurance and will fatigue more easily than a client with G to N strength. The client will be able to perform many basic ADLs and IADLs independently but

may need frequent rest periods. Work, play, and some social participation occupations may prove to be too strenuous, as in the case of Raymond attempting to hit a ball with force.

A client with muscle grades of fair (F) will be able to move parts against gravity and perform light tasks that require little or no resistance.^{3,5} Low endurance is a significant problem and will limit the amount of activity that can be done. A client with low endurance will probably be able to eat finger foods and perform light hygiene if given the time and rest periods needed to reach the goals.⁵ Poor (P) strength is considered below functional range, but a client with poor strength will be able to perform some ADLs with mechanical assistance and can maintain ROM independently⁵ (see Chapter 30, Section 2, Mobile Arm Supports). Clients with muscle grades of trace (T) and zero (0) will be completely dependent and unable to perform ADLs without externally powered devices. Some activities will be possible with special controls on equipment. Examples include power wheelchairs and electronic communication devices such as voice recognition computers or environmental control systems.⁵

Individuals use a variety of motor patterns when performing a functional task, and no one way is the right way to perform the task. These facts make it impossible for the therapist to predetermine the level of muscle strength, amount of ROM, and degree of motor control needed in the upper extremity to perform any given task. Individual styles of moving, numerous possibilities for compensatory movements when faced with loss of joint flexibility, poor endurance, lack of motor control, impaired sensation, and pain are all factors that may affect the client's ability to generate tension in a muscle or muscle group and sustain muscle activity. The pain that Raymond experiences in his hands may be the primary cause of his inability to manipulate objects such as the buttons on his shirt.

Shoulder Complex

The shoulder complex is the most mobile joint complex in the body. Its function is to move the arm in space and position the hand for function. The shoulder complex is composed of the acromioclavicular, sternoclavicular, scapulothoracic, and glenohumeral joints and the muscles, ligaments, and other structures that move and support these joints. In the performance of functional activities, scapular, clavicular, and trunk motions normally accompany glenohumeral motion. These associated movements increase the range of glenohumeral motion for function. The shoulder complex functions in a coordinated manner that is accomplished through scapulothoracic and glenohumeral movement. This coordinated function is called scapulohumeral rhythm. Thus, movements at the shoulder are actually combinations of several joint motions and are dependent on scapulohumeral rhythm for the performance of any given activity.² Activities such as placing an object (e.g., book, box, or cup) on an overhead shelf or reaching overhead to pull on a light cord require these movements.²

Shoulder Flexion and Abduction with Scapula Upward Rotation (Overhead Movements)

Activities such as placing an object (e.g., book, box, or cup) on an overhead shelf or reaching overhead to pull on a light cord require these movements.

Shoulder Extension and Adduction with Scapula Downward Rotation

Activities such as reaching back for toilet hygiene, Raymond swinging his arm backward when preparing to pitch the softball, reaching backward to put an arm through the sleeve of a coat, and pulling a refrigerator door open require these movements.²

Horizontal Adduction and Abduction

These movements allow the arm to be moved around the body. Reaching the opposite axilla or opposite ear for hygiene activities, opening and closing a sliding door, combing the opposite side of the hair, and reaching the upper part of the back while bathing are some activities that use horizontal adduction and abduction.²

Internal and External Rotation

Some degree of either internal or external rotation accompanies every glenohumeral motion. ROM varies with different positions of the arm. Full range of external rotation is required for reaching the back of the head for combing or washing hair. External rotation is often associated with supination when the elbow is extended, as when rotating a doorknob in a clockwise direction.²

Internal rotation is used when buttoning a shirt, eating, and drinking from a cup. Full range of internal rotation with scapulothoracic motion is used to reach into a back pocket, fasten a bra, put a belt through the belt loops on trousers, or do toilet hygiene. Internal rotation is often associated with forearm pronation, as when placing a pillow behind the lower part of the back, turning a screwdriver to unfasten a screw, rotating a doorknob in a counterclockwise direction, and pouring water from a vessel.²

Extension and Adduction

Extension and adduction are used to return the arm to the side of the body from shoulder flexion and abduction, as after reaching overhead. These motions are also used when quick movement or force is required, as when an individual is closing a vertically oriented window, walking with crutches, or pushing off to rise from an armchair, or when stabilizing the humerus to the lateral aspect of the trunk, as when carrying a basket of laundry.²

Flexion and Adduction

Flexion and adduction are used in activities that require reaching the same side of the body, such as washing the cheek or ear and combing hair on the same side. Slight shoulder flexion with adduction is used for hand-to-mouth activities and putting on an earring back.

Elbow and Forearm

Elbow and forearm movements serve to place the hand for function. Elbow flexion moves the hand toward the body, and elbow extension moves the hand away from the body. Forearm pronation or supination usually accompanies elbow flexion and extension. Pronation and supination position the hand precisely for the requirements of the given activity. The elbow and forearm support the skilled and forceful movements of the hand that are used during performance of ADLs and work activities.²

Full or nearly full range of elbow flexion, usually with some humeral flexion and forearm supination, is used to bring food to the mouth, shave the face or underarms, hold a telephone receiver, place an earring on the ear, and reach the neck level of a back zipper.

Full range of elbow extension, usually with pronation, is used when an individual is reaching to the feet to tie shoes, throwing a ball overhand, and using the arms to push off from a chair. Many other ADLs and IADLs require less than full range of these movements.²

Wrist and Hand

The wrist controls the length-tension relationships of the extrinsic muscles of the hand. It positions the hand relative to the forearm for touch, grasp, or manipulation of objects. Wrist extension and ulnar deviation are most important in performance of ADLs.² It is possible to perform some ADLs when there is loss of wrist ROM by using compensatory movements of the proximal joints.

The primary functions of the hand are to grasp and manipulate objects and to discriminate sensory information about objects in the environment. The arches of the hand make it possible to adapt the hand to the shape of the object being manipulated.

Power grip and precision grip are the bases of all hand activities. Power grip is used when force is required for grasping, such as holding a hammer handle, a full glass, or the handle of a purse or suitcase. Precision grip is used when an object is pinched and when it is being manipulated between the thumb and one or more fingers. Precision grip is used for holding a pencil, moving checkers or chess pieces, turning a key, threading a needle, and opening the cap of a medicine bottle.

The occupational therapy practitioner observed Raymond in his home as he was preparing to make homemade soup. She noted that Raymond easily accessed ingredients that were on the first two shelves of above-counter cabinets but displayed quite a bit of facial grimacing and two attempts at reaching overhead to the top shelf. He was observed to be able to fully open his fingers but not able to make a tight fist. When chopping vegetables, he was able to manage the less resistive ones such as tomatoes and celery but could not exert enough force to cut through carrots. Although he could carry an empty pot to the sink without difficulty, he was not able to stabilize his wrists to carry a full pot of water to the stove. At his job site, the occupational therapy

Threaded Case Study Raymond, Part 3

Because of the difficulty that Raymond experienced when donning his socks and shoes, getting in and out of his truck, reaching overhead, and manipulating and applying the force needed to use kitchen and work tools, the occupational therapist has determined that ROM and muscle testing assessments should be performed for some of this client's specific joints and muscles.

After the occupation-based functional motion assessment, the next step in the occupational therapy process would be for the therapist to plan the intervention. The reader should refer to [Chapter 38](#) on arthritis for some ideas for interventions that could be implemented to return Raymond to participation in his customary rounds of occupation. The reader should also refer back to the beginning of this chapter and reflect on the three probative questions posed at the end of Raymond's case study and be able to describe the advantages of using an occupation-based functional motion assessment, the amount and type of information on Raymond that was gleaned from this assessment, and the value to the occupational therapist of conducting this assessment in both the home and work contexts and environments.

practitioner again noted that Raymond had difficulty holding some of the heavier tools in position and exerting appropriate force, such as with the large wire cutters.

Summary

Many physical disabilities cause deficits in ROM, strength, and motor control that limit occupational performance. The occupational therapy practitioner is primarily responsible for assessing occupational performance, identifying problems in performance, and planning interventions that will improve the client's occupational performance.

Because people perform the same activity in a variety of ways, the level of ROM, strength, or motor control needed to do a task is variable. Physical limitations can be assessed through observation of a client's performance while engaged in a variety of occupations. Therefore, as in the case of Raymond, the therapist must observe the client performing selected tasks in the person-task-environment interaction.³

While assessing the client's ability to perform ADLs, IADLs, work, or leisure occupations, the therapist should observe for sensorimotor problems. Analysis of the results of observation may indicate that an assessment of specific body factors or performance skills is needed.

Questions to guide clinical observation and clinical reasoning and suggested activities to assess function of the upper and lower extremities are outlined in this chapter.

Review Questions

1. Compare and contrast functional motion assessment versus occupation-based task and motion assessment.
2. In occupation-based practice, how are sensorimotor functions first assessed?
3. What is meant by individual activity analysis?
4. Why is it not possible to perform an objective activity analysis?
5. List three major questions that can guide the clinical observation and clinical reasoning of the occupational therapy practitioner when making an occupation-based functional motion assessment.
6. Which factors, other than strength, ROM, and motor control, can affect functional task-motion assessment?
7. How is the information gained from assessment of specific body factors different from that gained in an occupation-based functional motion assessment?
8. What is the minimum level of strength required throughout the lower extremity for normal stance and positioning?
9. List some activities or occupations that can be used to assess general function in the lower extremities: hip, knee, ankle, and foot.
10. Compare levels of muscle strength with endurance in the upper extremities.
11. List some activities that can be used to assess general function in the upper extremities: shoulder complex, elbow and forearm, and wrist and hand.

Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Define active, passive, and functional range of motion (ROM).
2. List the purposes of measuring ROM.
3. Name two methods used to screen for ROM limitations.
4. Name disabilities for which joint measurement is often an assessment tool.
5. Describe how ROM measurements are used to select intervention goals and methods.
6. Describe how to establish ROM norms for clients with unilateral involvement.
7. Describe what the therapist should do before actually measuring the joints with the goniometer.
8. Describe proper positioning of the therapist and methods to support limbs.
9. List precautions for and contraindications to joint measurement.
10. List and describe the steps in the joint measurement procedure in correct order.
11. Describe how to record results of the joint measurement.
12. Measure all the joints of a typical practice subject by using the 180-degree method and correct procedure.
13. Describe at least three intervention strategies that can be used to increase ROM.

Threaded Case Study | Evelyn, Part 1

Evelyn is an 83-year-old woman who sustained a Colles fracture when she fell on her outstretched, nondominant left hand in an attempt to break her fall after tripping on a doorstep as she exited a building. The fracture was reduced, and Evelyn was placed in a hand-to-below-elbow cast for 6 weeks. On removal of the cast, Evelyn's wrist and hand appeared swollen. She complained of pain and stiffness in the carpometacarpal and metacarpal joints of her thumb and the metacarpophalangeal and proximal interphalangeal joints of her fingers. She was unable to make a fist or oppose her thumb to her fingers.

Evelyn is a widow; her two grown children live nearby. Before her injury she was independent in all activities of daily living and

the majority of instrumental activities of daily living. She used public transportation to move around her community, although her children and friends usually drove her to appointments. Evelyn volunteered at the local hospital weekly in its telecare program and called elderly, home-bound persons. She is an accomplished seamstress, makes all of her own clothing, and attends a weekly sewing class, primarily for the camaraderie of the other students, although she states, "There is always something new to learn." She also enjoys baking for her family, gardening, and generally engaging in tasks that contribute to the upkeep of her home. She attends church regularly and enjoys dining out with friends and family members.

Since her injury, her ability to participate in occupations that are meaningful to her has been curtailed. She requires moderate to maximal assistance to hold a eating utensil in her left hand while cutting food with her right, wash and groom her hair, put on jewelry, bathe the right side of her body, transfer out of the bathtub, and engage in home maintenance tasks (e.g., changing bed linen). At her volunteer work site, she is unable to hold the telephone with her left hand while writing with her right hand. When cooking, she has difficulty stabilizing bowls, pots, and pans with her left hand while manipulating a cooking utensil with her right. Evelyn is experiencing a great deal of frustration with her loss of independence and inability to fully engage in occupations that got her out in the community and facilitated interaction with others.

In reviewing Evelyn's occupational profile, the occupational therapist must focus on client factors that are interfering with function. Loss of range of motion (ROM) in her left upper extremity, especially the inability to flex the fingers to make a

fist and oppose the thumb to the fingers, which is required for fine motor activities, is prohibiting the client from fully engaging in the physical, social, personal, cultural, and spiritual contexts that bring meaning to her life. Before determining intervention goals and strategies, the therapist must assess her ROM limitations to establish a baseline for treatment. While reading and studying this chapter, keep in mind Evelyn's ROM limitations and the restrictions that they impose on her engagement in occupation.

Critical Thinking Questions

1. Why should the occupational therapist proceed with caution when assessing the ROM limitations of this client?
2. What is the appropriate sequencing of joint measurement assessment for this client? What methods should be applied first?
3. What is the advantage of joint measurement in evidence-based practice?

Joint ROM is the amount of movement that is possible at a joint.³ It is the arc of motion through which a joint passes when moving within a specific plane. When the joint is moved by the muscles that act on the joint, it is called active range of motion (AROM). When the joint is moved by an outside force such as the therapist, it is called passive range of motion (PROM).³ In normal individuals, PROM is slightly greater than AROM because of the slight elasticity of soft tissue.^{3,10} The additional PROM that is available at the end of normal AROM helps protect joint structures because it allows the joint to give and absorb extrinsic forces. If PROM is significantly greater than AROM for the same joint motion, it is likely that muscle weakness is present.¹³

Decreased ROM can cause limited function and interfere with performance in areas of occupation. Limitations in ROM may occur as a result of injury to or disease in the joint itself or the surrounding joint tissue structures, joint trauma, or joint immobilization. These limitations may restrict the client's ability to perform successfully in chosen day-to-day occupations. Inflexibility at a joint may adversely affect both speed and strength of movement. A client who constantly has to work to overcome the resistance of an inflexible joint will probably demonstrate decreased endurance and fatigue during activity. The functional motion test (see Chapter 20), screening tests, and measurement of joint ROM with a goniometer can all be used to assess ROM.

OT Practice Notes

The primary concern of the occupational therapist is whether ROM is adequate for the client to engage in meaningful occupations.

Methods used to screen limitations in ROM involve the observation of AROM and PROM. To screen for AROM, the therapist asks the client to perform all the active movements that occur at the joint.³ To screen for PROM, the therapist moves the joint passively through all of its motions. The purpose of this is to estimate ROM, detect limitations, and observe the quality of movement, end-feel, and the presence of pain.³ The therapist can then decide at which joints precise ROM measurement is indicated.

Joint Measurement

Body function is a client factor that the occupational therapist must consider when classifying the client's underlying abilities. The therapist will be concerned with the client's ability to retrieve dishes from a cupboard, reach above shoulder level to shampoo hair, or depress the gas and brake pedals in an automobile. Joint measurement is an assessment tool often used for physical disabilities that cause limited joint motion. Such disabilities include skin contracture caused by adhesions or scar tissue; arthritis, fractures, burns, and hand trauma; displacement of fibrocartilage or the presence of other foreign bodies in the joint; bony obstruction or destruction; and soft tissue contractures, such as tendon, muscle, or ligament shortening. Limited ROM can also be secondary to spasticity, muscle weakness, pain, and edema.^{8,13}

ROM measurements help the therapist select intervention goals, appropriate intervention modalities, positioning techniques, and other strategies to reduce limitations. Specific purposes for measuring ROM are to determine limitations that interfere with function or may produce deformity, determine additional range needed to increase functional capacity or reduce deformity, determine the need for splints and assistive devices, measure progress objectively, and record progression or regression. The use of formal joint

measurement will assist in determining the efficacy of intervention modalities and may also serve as evidence in assisting the client to see the outcome of the intervention through quantifiable data.

Normal ROM varies from one person to another. The occupational therapist can establish norms for each individual by measuring the analogous uninvolved part if possible.^{3,4} Otherwise, the therapist uses average ranges listed in the literature as a guide.³ The therapist should check records and interview the client to detect the presence of fused joints and other limitations caused by old injuries. Joints should not be forced when resistance is met on PROM. Pain may limit ROM, and crepitation may be heard with movement in some conditions. Therefore, before beginning joint measurement procedures, the therapist must explain what will be done and ask the client if he or she is experiencing any joint pain and, if so, where it is located and how severe it is. To not cause undue pain, the occupational therapist further explains to the client the importance of indicating any changes in pain throughout the procedure.

Principles and Procedures in Joint Measurement

Before measuring ROM, the therapist should be familiar with average normal ROM ranges, joint structure and function, normal end-feel, recommended positioning for self and the client, and bony landmarks related to each joint and joint axis.^{3,4,10} The therapist should be skilled in correct positioning and stabilization for measurements, palpation, alignment and reading of the goniometer, and accurate recording of measurements.¹⁰ For the most reliable measurements, the same therapist should assess and reassess the client at the same time of day with the same instrument and the same measurement protocol.³

Visual Observation

The joint to be measured should be exposed, and the therapist should observe the joint and adjacent areas.³ The therapist asks the client to move the part through the available ROM, if muscle strength is adequate, and observes the movement.⁴ The therapist should look for compensatory motions, posture, muscle contours, skin color and condition, and skin creases and compare the joint with the non-injured part, if possible.³ The therapist should then move the part through its range to see and feel how the joint moves and to estimate ROM.

Palpation

Feeling the bony landmarks and soft tissue around the joint is an essential skill gained with practice and experience. The pads of the index and middle fingers are used for palpation. The thumb is sometimes used. The therapist's fingernails should not make contact with the client's skin. Pressure is applied gently but firmly enough to detect underlying muscle, tendons, or bony structures. For joint

measurement, the therapist must palpate to locate bony landmarks for placement of the goniometer.³

Positioning of Therapist and Support of Limbs

The therapist's position varies, depending on the joints being measured. When measuring finger or wrist joints, the therapist may sit next to or opposite the client. If sitting next to the client, the therapist should measure the wrist and finger joints on that side and then move to the other side to measure the joints on the client's opposite side. This procedure makes the client more comfortable (eliminating the need to stretch across the midline) and ensures more accurate placement of the goniometer. When measuring the larger joints of the upper or lower extremity, the therapist may stand next to the client on the side being measured. The client may be seated or lying down. The therapist needs to use good body mechanics in posture and in lifting and moving heavy limbs. The therapist should use a broad base of support and stand with the head upright while keeping the back straight. The feet should be shoulder width apart, with the knees slightly flexed. The therapist's stance should be in line with the direction of movement. The limb should be supported at the level of its center of gravity, approximately where the upper and middle thirds of the segment meet. The therapist's hands should be in a relaxed grasp that conforms to the contours of the part. The therapist can provide additional support by resting the part on his or her forearm.³

Precautions and Contraindications

In some instances, measuring joint ROM is contraindicated or should be undertaken with extreme caution. It is contraindicated if there is a joint dislocation or unhealed fracture, immediately after surgery on any soft tissue structures surrounding joints, in the presence of myositis ossificans, or when ectopic ossification is a possibility.³

Joint measurement must always be done carefully. The following situations call for extreme caution:

1. The client has joint inflammation or an infection.
2. The client is taking either medication for pain or muscle relaxants.
3. The client has osteoporosis, hypermobility, or subluxation of a joint.
4. The client has hemophilia.
5. The client has a hematoma.
6. The client has just sustained an injury to soft tissue.
7. The client has a newly united fracture.
8. The client has undergone prolonged immobilization.
9. Bony ankylosis is suspected.
10. The client has carcinoma of the bone or any fragile bone condition.^{3,9}

End-Feel

PROM is normally limited by the structure of the joint and surrounding soft tissues. Thus, ligaments, the joint capsule, muscle and tendon tension, contact of joint surfaces, and soft tissue approximation may limit the end of a particular

ROM. Each of these structures has a different end-feel as the therapist moves the joint passively through its ROM. End-feel is the normal resistance to further joint motion because of stretching of soft tissue, stretching of ligaments and joint capsule, approximation of soft tissue, and contact of bone on bone. End-feel is normal when full ROM is achieved and the motion is limited by normal anatomic structures. Abnormal end-feel occurs when ROM is increased or decreased or when ROM is normal but structures other than normal anatomy stop the ROM.³ Practice and sensitivity are required for the therapist to detect different end-feels and to distinguish normal from abnormal.^{3,10}

End-feel is normally hard, soft, or firm. An example of hard end-feel is bone contacting bone when the elbow is passively extended and the olecranon process comes into contact with the olecranon fossa. Soft end-feel can be detected on knee flexion when there is soft tissue apposition of the posterior aspects of the thigh and calf. A firm end-feel has a firm or springy sensation that has some give, as when the ankle is dorsiflexed with the knee in extension and ROM is limited by tension in the gastrocnemius muscle.³

In pathologic states, end-feel is abnormal when PROM is increased or decreased or when PROM is normal but movement is stopped by structures other than normal anatomy.³ Practice and experience are required to detect end-feel accurately. Normal end-feel for each joint is noted along with the directions for joint measurement that are listed in the following sections.

Two-Joint Muscles

When the ROM of a joint that is crossed by a two-joint muscle is measured, the ROM of the joint being measured may be affected by the position of the other joint because of passive insufficiency.³ In other words, joint motion is limited by the length of the muscle. A two-joint muscle feels taut when it is at its full length over both joints that it crosses and before it reaches the limits of the normal ROM of both joints.⁷ For example, when the wrist is in full extension, passive finger extension is normally limited because of passive insufficiency of the finger flexors that cross the wrist and finger joints. When joints crossed by two-joint muscles are being measured, it is necessary to place the joint not being measured in a neutral or relaxed position to place the two-joint muscle on slack. For example, when finger extension is being measured, the wrist should be placed in neutral position to avoid full stretch of the finger flexors over all of the joints that they cross. Similarly, when hip flexion is being measured, the knee should also be flexed to place the hamstrings in the slackened position.³

Methods of Joint Measurement

The 180-Degree System

In the 180-degree system of joint measurement, 0 degree is the starting position for all joint motions. For most motions, the anatomic position is the starting position. The body

of the measuring instrument, the goniometer, is a half-circle protractor with an axis and two arms. It is superimposed on the body in the plane in which the motion is to occur. The axis of the instrument is aligned with the axis of the joint. All joint motions begin at 0 degree and increase toward 180 degrees.^{3,5,10} The 180-degree system is used most often and is the one used later in this chapter to describe procedures for joint measurement.

The 360-Degree System

The 360-degree system of joint measurement is used less frequently than the 180-degree system. The goniometer is a full-circle, 360-degree protractor with two arms. Movements occurring in the coronal and sagittal planes are related to the full circle. When the body is in the anatomic position, the circle is superimposed on it in the same plane in which the motion is to occur, with the joint axis being the pivotal point. “The 0-degree (360-degree) position will be overhead and the 180-degree position will be toward the feet.”⁵ Thus, for example, shoulder flexion and abduction are movements that proceed toward 0 degree, and shoulder adduction and extension proceed toward 360 degrees. The average normal ROM for shoulder flexion is 170 degrees. Therefore, in the 360-degree system, the movement would start at 180 degrees and progress toward 0 to 10 degrees. The ROM recorded would be 10 degrees. On the other hand, shoulder extension that has a normal ROM of 60 degrees would begin at 180 degrees and progress toward 360 to 240 degrees, and 240 degrees would be the ROM recorded.⁵ The total ROM of extension to flexion would be 240 to 10 degrees—that is, 230 degrees.^{5,6}

Some motions cannot be related to the full circle. In these instances, a 0-degree starting position is designated, and the movements are measured as increases from 0 degree. These motions occur in a horizontal plane around a vertical axis. They are forearm pronation and supination, hip internal and external rotation, wrist radial and ulnar deviation, and thumb palmar and radial abduction (carpometacarpal flexion and extension).⁵

Goniometers

Usually made of metal or plastic, goniometers come in several sizes and types and are available from medical and rehabilitation equipment companies.^{5,10,12} The word *goniometer* is derived from the Greek *gonia*, which means angle, and *metron*, which means measure.^{9,14} Thus, goniometer literally means “to measure angles.”

The universal goniometer (Figure 21-1) consists of a body, a stationary (proximal) bar, and a movable (distal) bar.^{3,10} The stationary bar is attached to the body of the goniometer. The body is a half-circle or a full-circle protractor printed with a scale of degrees from 0 to 180 for the half-circle and 0 to 360 for the full-circle goniometer.^{3,4} The movable bar is attached at the center, or axis, of the protractor and acts as a dial. As the movable bar rotates around

FIGURE 21-1 Types of goniometers.

the protractor, the dial points to the number of degrees on the scale.

Two scales of figures are printed on the half circle. Each starts at 0 degree and progresses toward 180 degrees, but in opposite directions. Because the starting position in the 180-degree system is always 0 degree and increases toward 180 degrees, the outer row of figures is read if the bony segments being measured are end to end, as in elbow flexion. The inner row of figures is read if the bony segments being measured are alongside one another, as in shoulder flexion.

Figure 21-1 shows five styles of goniometers. The first (Figure 21-1, A) is a full-circle goniometer that has calibrations for both the 360-degree and the 180-degree systems printed on its face. This goniometer has longer arms and is convenient for use on the large joints of the body. Figure 21-1, B, shows a half-circle instrument used for the 180-degree system. This goniometer is radiopaque and could be used during radiographic examinations if necessary. Its dial is notched at two places for accurate motion reading, regardless of whether the convexity of the half circle is directed toward or away from the direction of motion. Thus, the evaluator does not have to reverse the goniometer and thereby obscure the scale. A special finger goniometer is shown in Figure 21-1, D. Its arms are short and flattened. It is designed to be used over the finger joint surfaces rather than on their lateral aspects, as is done for most of the larger joint motions. Small plastic goniometers are shown in Figure 21-1, C and E. These are inexpensive and easy to carry. The longer one can be used with both large and small joints. The smaller is simply a larger one that has been cut for use as a finger goniometer. The dials of transparent goniometers are marked or notched in two places.

One important feature of the goniometer is the fulcrum. The nut or rivet that acts as the fulcrum must move freely

yet be tight enough to remain where it was set when the goniometer is removed after measurement of the joint.⁴ For easy, accurate readings, some goniometers have a locking nut that is tightened just before the goniometer is removed.⁵

Other types of goniometers are available. Some have a fluid indicator that provides the reading after the motion is completed.⁵ Others can be attached to a body segment and have dials that register ROM. There are special goniometers for cervical and spine ROM measurements and for forearm rotation.¹² A tape measure or metric scale may also be used on some joints by measuring the distance between two segments—for example, the distance between the chin and chest when measuring cervical flexion and extension, the distance between the center of the tips of two fingers for finger abduction, and the distance between the tip of the thumb and the tip of the little finger for opposition.³

Recording Measurements

When using the 180-degree system, the evaluator should record the number of degrees at the starting position and the number of degrees at the final position after the joint has passed through the maximally possible arc of motion.¹⁰ Normal ROM always starts at 0 degree and increases toward 180 degrees. When it is not possible to start the motion at 0 degree because of limitation of motion, ROM is recorded by writing the number of degrees at the starting position followed by the number of degrees at the final position.³ For example, elbow ROM limitations can be noted as follows:

- Normal: 0 to 140 degrees
- Extension limitation: 15 to 140 degrees
- Flexion limitation: 0 to 110 degrees
- Flexion and extension limitation: 15 to 110 degrees

Abnormal hyperextension of the elbow may be recorded by indicating the number of degrees of hyperextension below the 0-degree starting position with a minus sign, followed by the 0-degree position and then the number of degrees at the final position.¹⁰ This may be noted as follows:

Normal: 0 to 140 degrees

Abnormal hyperextension: -20 to 0 to 140 degrees

There are alternative methods of recording ROM. The evaluator is advised to learn and adopt the particular method required by the health care facility.

A sample form for recording ROM measurements is shown in Figure 21-2. Average normal ROM for each joint motion is listed on the form and in Table 21-1. When measurements are being recorded, every space on the form should be filled in. If the joint was not tested, "NT" should be entered in the space.³

It should be noted that scapula movement accompanies movements of the shoulder (glenohumeral) joint, as outlined. The range of glenohumeral joint motion is highly dependent on scapula mobility, which gives the shoulder its flexibility and wide ranges of motion. Although it is not possible to measure scapula movement with the goniometer, the evaluator should assess scapula mobility by observation of active motion or passive movement before proceeding with shoulder joint measurements. Scapular ROM is noted as full or restricted.³ If scapular motion is restricted, as when the musculature is in a state of spasticity or contracture, and the shoulder joint is moved into extreme ranges of motion (for example, above 90 degrees of flexion or abduction), glenohumeral joint damage can result.

When joint measurements may be performed in more than one position (e.g., as in shoulder internal and external rotation), the evaluating occupational therapist should note on the record the position in which the measurement was taken. The therapist should also note any pain or discomfort experienced by the client, the appearance of protective muscle spasm, whether AROM or PROM was measured, and any deviations from recommended testing procedures or positions.¹⁰

Results of Assessment As the Basis for Planning Intervention

After joint measurement, the therapist should analyze the results in relation to the client's life role requirements. The therapist's first concern should be to correct ROM that is below functional limits. Many ordinary activities of daily living (ADLs) do not require full ROM. Functional ROM refers to the amount of joint range necessary to perform essential ADLs and instrumental activities of daily living (IADLs) without the use of special equipment. The first concern of intervention is to attempt to increase to functional levels any ROM that is limiting performance of self-care and home maintenance tasks.⁸ For example, severe limitation of elbow flexion affects eating and oral hygiene.

Therefore, it is important to increase elbow flexion to nearly full ROM for function. Likewise, severe limitation of forearm pronation affects eating, washing the body, telephoning, caring for children, and dressing. Because sitting comfortably requires hip ROM of at least 0 to 100 degrees, a first goal might be to increase flexion to 100 degrees if it is limited. Of course, if additional ROM can be gained, the therapist should plan the progression of intervention to increase ROM to the normal range.

Some limitations in ROM may be permanent. The role of the therapist in such cases is to work out methods to compensate for the loss of ROM. Possibilities include assistive devices, such as a long-handled comb, brush, shoehorn, and device to apply stockings, or adapted methods of performing a particular skill. (See Chapter 10 for further suggestions for ADL techniques in those with limited ROM.)

In many conditions, such as burns and arthritis, loss of ROM can be anticipated. The goal of intervention is to prevent joint limitation with splints, positioning, exercise, activity, and application of the principles of joint protection.

Limited ROM, its causes, and the prognosis for increasing ROM will suggest intervention approaches. Some of the specific methods used to increase ROM are discussed elsewhere in this text (see Chapters 29 and 39). Such methods include stretching exercise, resistive activity and exercise, strengthening of antagonistic muscle groups, activities that require active motion of the affected joints through the full available ROM, splints, and positioning. To increase ROM, the physician may perform surgery or manipulate the part while the client is under anesthesia. The physical therapist or certified hand therapist may use joint mobilization techniques such as manual stretching with heat and massage.⁸

Procedure for Measuring Passive Range of Motion

Average normal ROM for each joint motion is listed in Table 21-1, in Figure 21-2, and before each of the following procedures used for measurement. The reader should keep in mind that these are averages; ROM may vary considerably among individuals. Normal ROM is affected by age, gender, and other factors, such as lifestyle and occupation.¹⁰ Therefore, the client (C) in the illustrations may not always demonstrate the average ROM listed for the particular motion.

In the illustrations, the goniometer is shown in such a way that the reader can most easily see its positioning. However, the occupational therapist may not always be in the best position for the particular measurement. For the purposes of clear illustration, the therapist is necessarily shown off to one side and may have one hand, rather than two, on the instrument. Many of the motions require that the therapist actually be in front of the client or that the therapist's hands obscure the goniometer. How the therapist holds the goniometer and supports the part being measured

 DIP, Distal interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

is determined by factors such as the position of the client, amount of muscle weakness, presence or absence of joint pain, and whether AROM or PROM is being measured. Both the therapist and the client should be positioned for the greatest comfort, correct placement of the instrument, and adequate stabilization of the part being tested to ensure the desired motion in the correct plane.

General Procedure—180-Degree Method of Measurement^{3,10}

1. The client should be comfortable and relaxed in the appropriate position (described later) for the joint measurement.
2. Uncover the joint to be measured.
3. Explain and demonstrate to the client what you are going to do, why, and how you expect him or her to cooperate.
4. If there is unilateral involvement, assess PROM on the analogous limb to establish normal ROM for the client.
5. Establish and palpate bony landmarks for the measurement.
6. Stabilize joints proximal to the joint being measured.
7. Move the part passively through ROM to assess joint mobility and end-feel.
8. Return the part to the starting position.
9. To measure the starting position, place the goniometer just over the surface of and lateral to the joint. Place the axis of the goniometer over the axis of the joint by using the designated bony prominence or anatomic landmark. Place the stationary bar on or parallel to the longitudinal axis of the proximal or stationary bone and the movable bar on or parallel to the longitudinal axis of the distal or moving bone. To prevent the indicator on the movable bar from going off the protractor dial, always face the curved side away from the direction of motion, unless the goniometer can be read after movement in either direction.
10. Record the number of degrees at the starting position and remove (or back off) the goniometer. Do not attempt to hold the goniometer in place while moving the joint through ROM.
11. To measure PROM, hold the part securely above and below the joint being measured and gently move the joint through ROM. Do not force the joint. Watch for signs of pain and discomfort. (*Note:* PROM may also be measured by asking the client to move actively through ROM and hold the position. The therapist then moves the joint through the final few degrees of PROM.)
12. Reposition the goniometer and record the number of degrees at the final position.
13. Remove the goniometer and gently place the part in the resting position.

14. Record the reading at the final position and any notations on the evaluation form.

Directions for Joint Measurement—180-Degree System

Spine

Cervical Spine

Measurements of neck movements are the least accurate because the neck has few bony landmarks and much soft tissue overlying the bony segments.⁴ Radiographic examination is the best means to make an accurate measurement of the specific joints.¹¹ Measurements may be taken with a tape measure to record the distance between the chin and chest for flexion and extension, between the chin and shoulder for neck rotation, and between the mastoid process and shoulder for lateral flexion.³

Approximate estimates of cervical flexion, extension, rotation, and lateral flexion may be made with the goniometer or by estimating the number of degrees of motion by using a fixed axis and estimating the arc of motion from that point (see Figures 21-3 to 21-10).^{1,4}

Cervical Flexion

0 to 45 degrees (Figure 21-3).

Position of the Client

Sitting or standing erect.

Measurement

The client is asked to flex the neck so that the chin moves toward the chest. The number of degrees of motion may be estimated, or the therapist may measure the number of

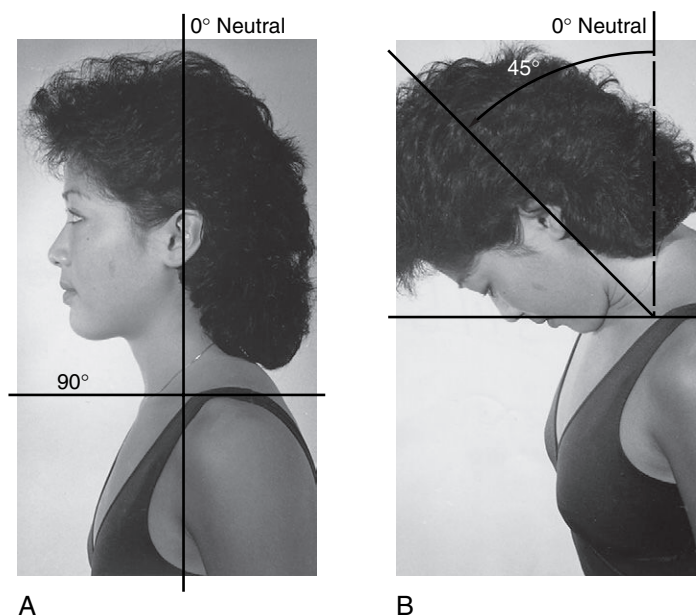

FIGURE 21-3 Cervical flexion. **A**, Starting position. **B**, Final position.

inches or centimeters from the chin to the sternal notch.^{1,3,10} If a goniometer is used, the axis is placed over the angle of the jaw. The therapist grasps the corner of the protractor, which is positioned with the arc upward, and steadies his or her arm by resting it against the client's shoulder. The arms of the goniometer are aligned with a tongue depressor, which the client is holding between the teeth. As the client performs neck flexion, the movable bar of the goniometer is adjusted downward to align with the new position of the tongue depressor.^{4,10}

Cervical Extension

0 to 45 degrees (Figure 21-4).

Position of the Client

Sitting or standing erect.

Measurement

The client is asked to extend the neck as though looking at the ceiling so that the back of the head approaches the thoracic spine. The number of degrees of motion may be estimated, or the number of inches or centimeters from the chin to the sternal notch may be measured.³ If a goniometer is used, the axis is placed over the angle of the jaw. The therapist grasps the corner of the protractor, which is now positioned with the arc downward, and steadies his or her arm against the client's shoulder. The movable bar of the goniometer is moved upward to align with the tongue depressor as the client extends the neck.^{4,10}

Cervical Lateral Flexion

0 to 45 degrees (Figure 21-5).

FIGURE 21-4 Cervical extension. A, Starting position. B, Final position.

FIGURE 21-5 Cervical lateral flexion. A, Starting position. B, Final position.

Position of the Client

Sitting or standing erect.

Measurement

The client is asked to flex the neck laterally without rotation by moving the ear toward the shoulder. The number of degrees of motion may be estimated, or the therapist may measure the number of inches or centimeters between the mastoid process and the acromion process of the shoulder.^{1,3} If a goniometer is used, the axis is placed over the spinous process of the seventh cervical vertebra. The stationary bar may be over the shoulder and parallel to the floor so that the motion begins at 90 degrees, or it may be aligned with the thoracic vertebra for a starting position of 0 degree. The movable bar is aligned with the external occipital protuberance.^{1,10}

Cervical Rotation

0 to 60 degrees (Figure 21-6).

FIGURE 21-6 Cervical rotation. **A**, Starting position. **B**, Final position.

Position of the Client

Lying supine or seated.

Measurement

The client is asked to rotate the head right or left without rotating the trunk. The amount of rotation may be estimated in degrees from the neutral position,¹ or a tape measure may be used to measure the distance from the tip of the chin to the acromion process of the shoulder. The measure is taken first in the anatomic position and then again after the neck has been rotated.³ In the supine position, if a goniometer is used, it is set at 90 degrees and the axis is placed over the vertex of the head. The stationary bar is held steady, parallel to the floor or to the acromion process on the side being tested. The movable bar is aligned with the tip of the nose.^{4,10}

Thoracic and Lumbar Spine

Cervical Flexion

0 to 80 degrees and 4 inches (Figure 21-7).

FIGURE 21-7 Spine flexion. **A**, Starting position. **B**, Final position.

Position of the Client

Standing erect.

Measurement

Four methods of estimating the range of spinal flexion are as follows: measuring trunk forward flexion in relation to the longitudinal axis of the body (the therapist must hold the pelvis stable with the hands and observe any change in the client's normal lordosis), recording the level of the fingertips along the front of the client's leg, measuring the number of inches or centimeters between the client's fingertips and the floor, and measuring the length of the spine from the seventh cervical vertebra to the first sacral vertebra when the client is erect and again after the client has flexed the spine (see Figure 21-7).^{3,10} The fourth is probably the most accurate of these clinical methods.¹ In a normal adult, the average increase in length in forward flexion of the spine is 4 inches (10 cm).³ If the client bends forward at the hips with the back straight, no difference in length will occur.

Cervical Lateral Flexion

0 to 40 degrees (Figure 21-8).

Position of the Client

Standing erect.

Measurement

Several methods may be used to estimate the range of lateral flexion of the trunk. A steel tape measure may be held in place during the motion and be used to estimate the number

of degrees of lateral inclination of the trunk with respect to the vertical position. Other methods include estimating the position of the spinous process of C7 in relation to the pelvis (Figure 21-8); measuring the distance of the fingertips from the knee joint in lateral flexion; measuring the distance between the tip of the third finger and the floor³; and with a long-arm goniometer, placing the axis on S1, the stationary bar perpendicular to the floor, and the movable bar aligned with C7.^{1,10}

Cervical Extension

0 to 30 degrees (Figure 21-9).

Position of the Client

Standing erect or lying prone.

Measurement

The client is asked to bend backward while maintaining stability of the pelvis. If necessary, the therapist stabilizes the pelvis from the anterior when the measurement is taken in the standing position. The range of extension is estimated in degrees from the vertical by using the superior iliac crest as the pivotal point in relation to the spinous process of C7. With the client in the supine position, a pillow is placed under the abdomen and the client's hands are placed at shoulder level on the treatment table. The pelvis is stabilized with a strap or by an assistant, and the client extends the elbows to raise the trunk from the table. A perpendicular measurement is taken of the distance between the suprasternal notch and the supporting surface at the end of the ROM.³

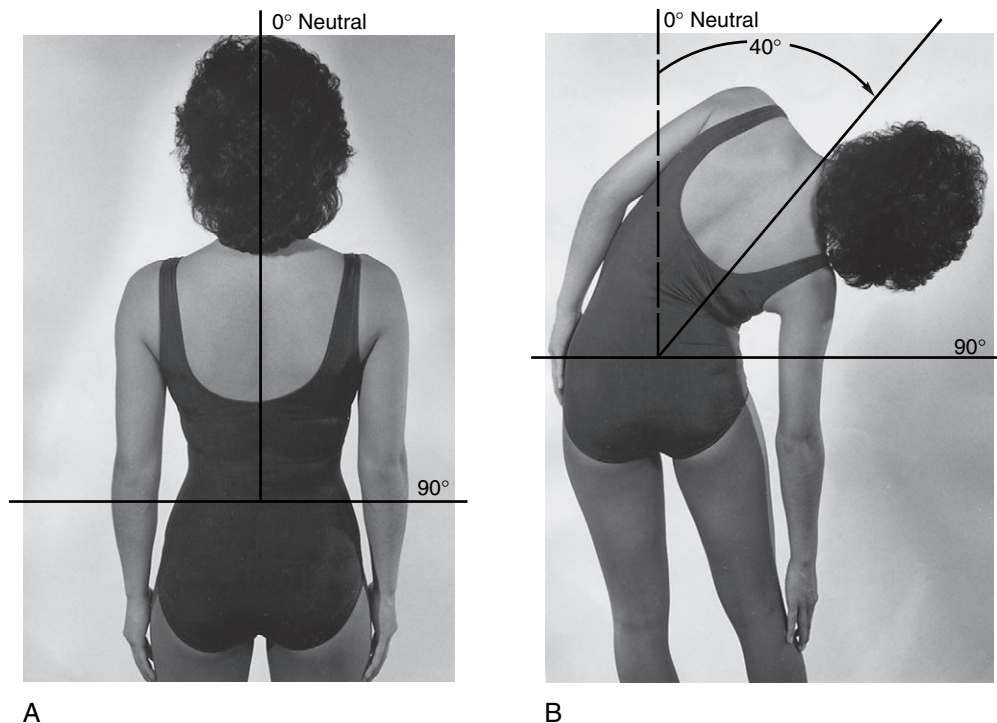

FIGURE 21-8 Spine lateral flexion. **A**, Starting position. **B**, Final position.

Cervical Rotation

0 to 45 degrees (Figure 21-10).

Position of the Client

Supine or standing.

Measurement

The client is asked to rotate the upper part of the trunk while maintaining a neutral position of the pelvis. The therapist may fix the pelvis firmly to maintain the neutral position. This step is especially important if the client is in the standing position. This motion is recorded in degrees by using the center of the crown of the head as a pivotal point and measuring the arc of motion made by the shoulder as it moves upward or forward.

Upper Extremity^{1,3,5,10,11}**Shoulder****Shoulder Flexion**

0 to 170 degrees (Figure 21-11).

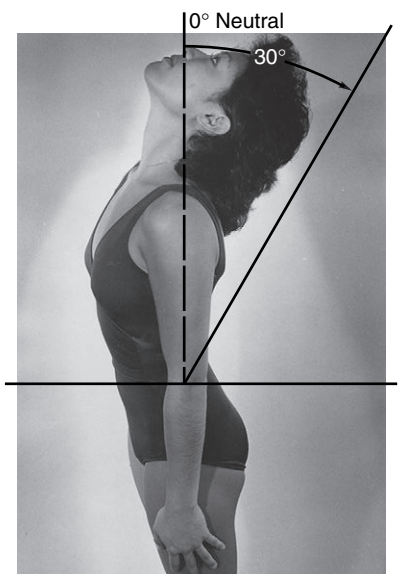

FIGURE 21-9 Spine extension.

Position of the Client

Seated or supine with the humerus in neutral rotation.

Position of the Goniometer

The axis is in the center of the humeral head, just distal to the acromion process on the lateral aspect of the humerus. The stationary bar is parallel to the trunk, and the movable bar is parallel to the humerus. Note that when the shoulder is flexed, the axis point moves upward and backward to the posterior surface of the shoulder. Thus, to take a measurement of the final position, the therapist should place the goniometer on the lateral surface of the shoulder, aligned with the imaginary axis through the center of the humeral head, which is just slightly superior to the crease formed by the deltoid mass.

End-feelFirm.³**Shoulder Extension**

0 to 60 degrees (Figure 21-12).

Position of the Client

Seated or prone, with no obstruction behind the humerus and the humerus in neutral rotation.

Position of the Goniometer

Same as for flexion, but the axis point remains the same for the starting and final positions. Movement should be accompanied by a slight upward tilt of the scapula. Excessive scapular motion should be avoided.

End-feelFirm.³**Shoulder Abduction**

0 to 170 degrees (Figure 21-13).

Position of the Client

Seated or lying prone, with the humerus in adduction and external rotation. Measure on the posterior surface.

A

B

FIGURE 21-10 Spine rotation. A, Starting position. B, Final position.

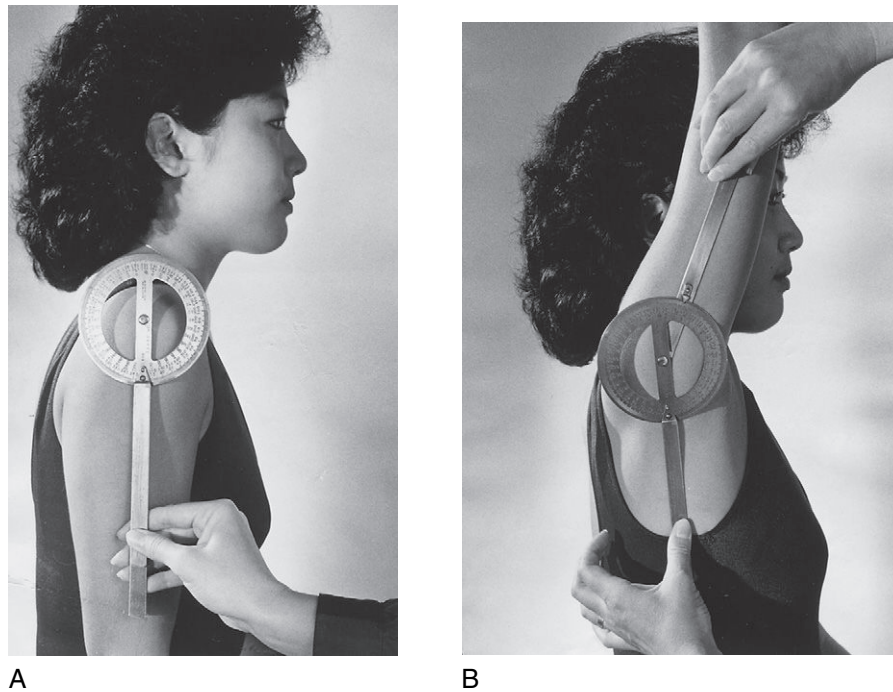

FIGURE 21-11 Shoulder flexion. **A**, Starting position. **B**, Final position.

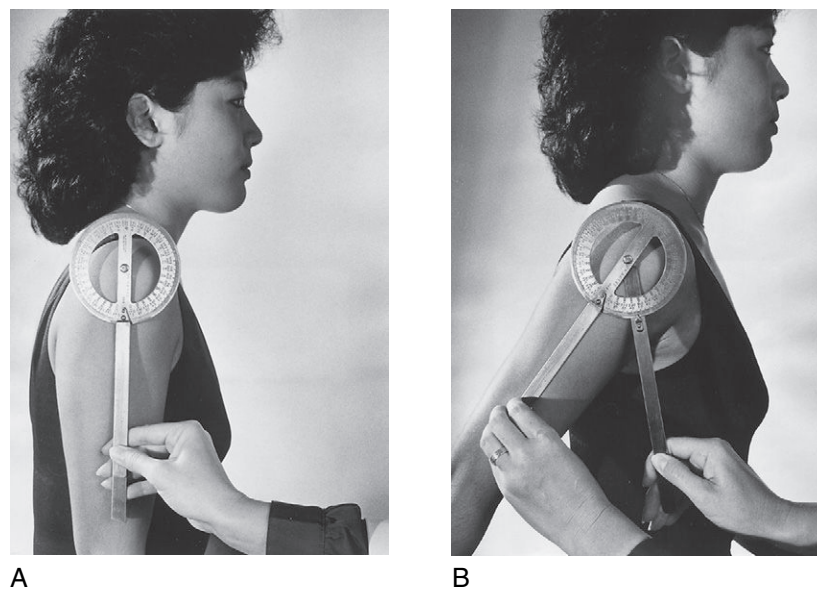

FIGURE 21-12 Shoulder extension. **A**, Starting position. **B**, Final position.

Position of the Goniometer

The axis is on the acromion process on the posterior surface of the shoulder. The stationary bar is parallel to the trunk, and the movable bar is parallel to the humerus.

End-feel
Firm.³

Shoulder Internal Rotation

0 to 60 degrees (Figure 21-14).

Position of the Client

The following position is used if abduction cannot be achieved: seated with the humerus adducted against the trunk, the elbow at 90 degrees, and the forearm at the midposition and perpendicular to the body.³

Position of the Goniometer

The axis is on the olecranon process of the elbow, and the stationary bar and movable bar are parallel to the forearm.

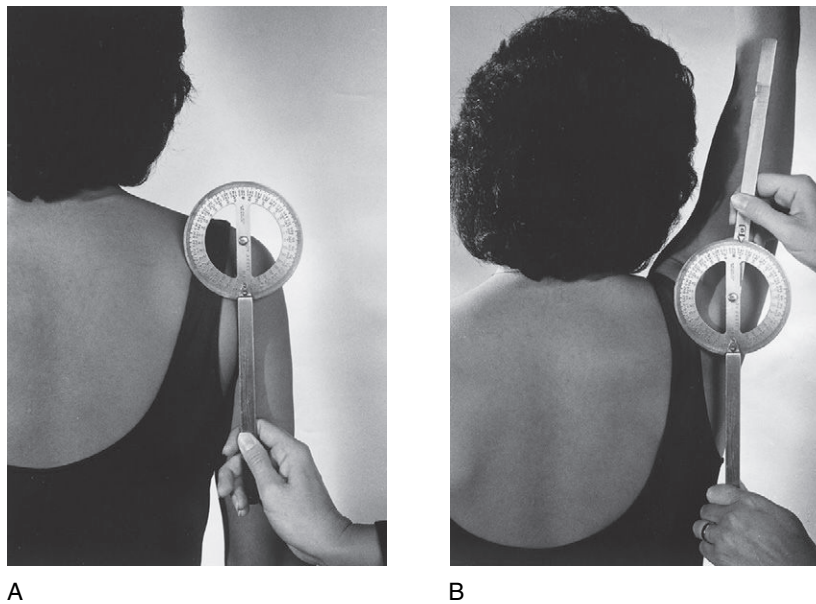

FIGURE 21-13 Shoulder abduction. **A**, Starting position. **B**, Final position.

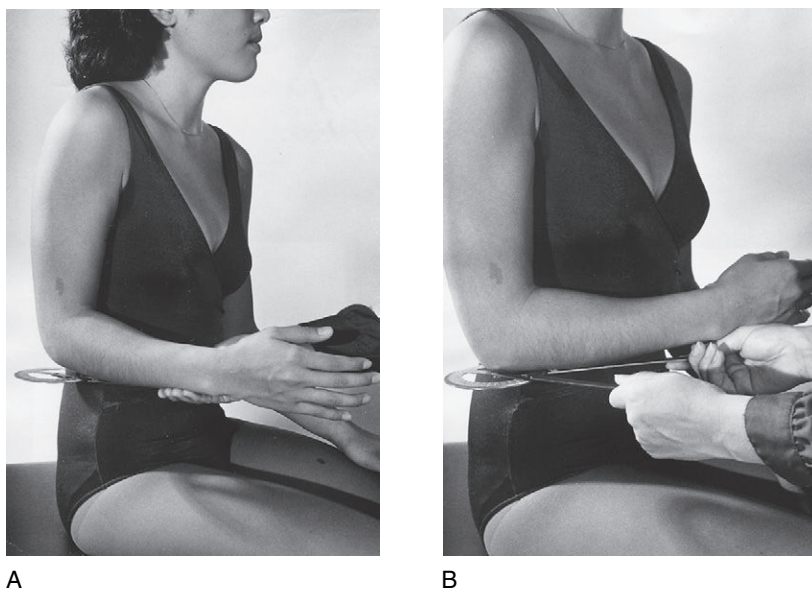

FIGURE 21-14 Shoulder internal rotation, shoulder adducted. **A**, Starting position. **B**, Final position.

Shoulder Internal Rotation (Alternative Position)

0 to 70 degrees (Figure 21-15).

Position of the Client

The following position is used if there is no danger of posterior dislocation and if abduction is possible: prone or supine with the humerus abducted to 90 degrees, the elbow flexed to 90 degrees, and the forearm in pronation, perpendicular to the floor.

Position of the Goniometer

The axis is on the olecranon process of the elbow, and the stationary bar and movable bar are parallel to the forearm.

End-feel

Firm.³

Shoulder External Rotation

0 to 80 degrees (Figure 21-16).

Position of the Client

The following position is used if abduction is not possible: seated, the humerus adducted, the elbow at 90 degrees, and the forearm in midposition, perpendicular to the body.

Position of the Goniometer

The axis is on the olecranon process of the elbow. The stationary bar and movable bar are parallel to the forearm.³

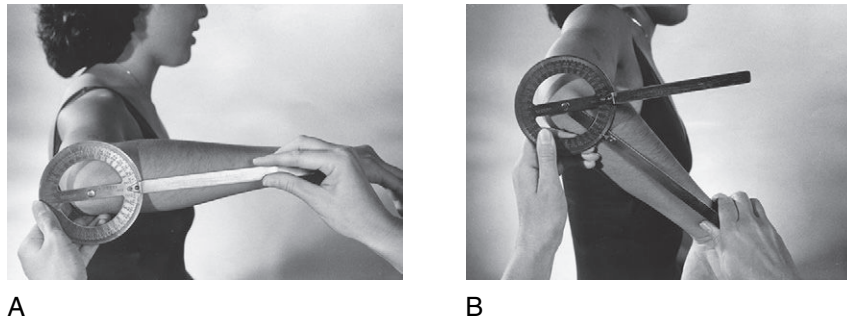

FIGURE 21-15 Shoulder internal rotation, shoulder abducted (alternative position). **A**, Starting position. **B**, Final position.

FIGURE 21-16 Shoulder external rotation, shoulder adducted. **A**, Starting position. **B**, Final position.

FIGURE 21-17 Shoulder external rotation, shoulder abducted (alternative position). **A**, Starting position. **B**, Final position.

Shoulder External Rotation (Alternative Position)
0 to 90 degrees (Figure 21-17).

Position of the Client

The following position is used if there is no danger of anterior dislocation of the humerus³: seated or supine with the humerus abducted to 90 degrees, the elbow flexed to 90 degrees, and the forearm pronated.

Position of the Goniometer

The axis is on the olecranon process of the elbow, and the stationary bar and movable bar are parallel to the forearm.

End-feel

Firm.³

Shoulder Horizontal Abduction

0 to 40 degrees (Figure 21-18).

FIGURE 21-18 Shoulder horizontal abduction. **A**, Starting position. **B**, Final position.

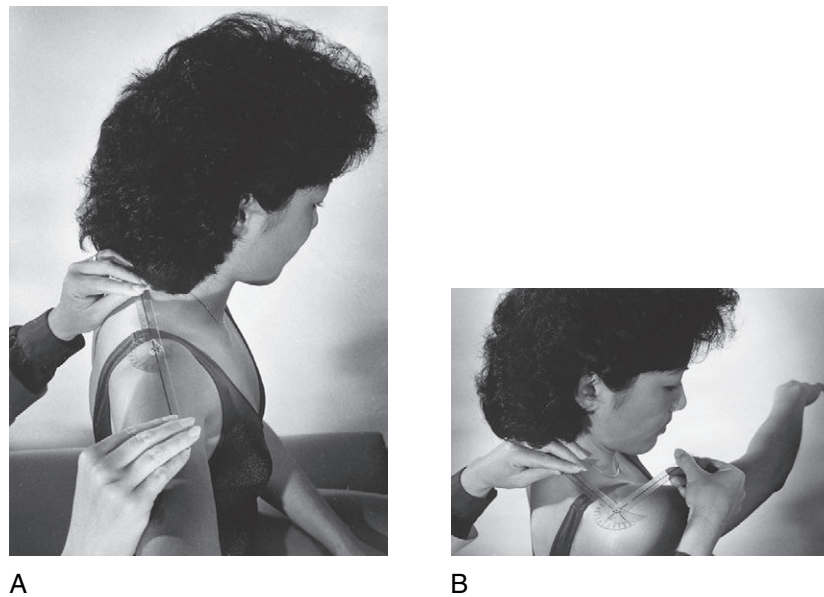

FIGURE 21-19 Shoulder horizontal adduction. **A**, Starting position. **B**, Final position.

Position of the Client

Seated erect with the shoulder to be tested abducted to 90 degrees, the elbow extended, and the palm facing down. The therapist may support the arm in abduction.³

Position of the Goniometer

The axis is over the acromion process. The stationary bar is parallel over the shoulder toward the neck, and the movable bar is parallel to the humerus on the superior aspect.

End-feel

Firm.³

Shoulder Horizontal Adduction

0 to 130 degrees (Figure 21-19).

Position of the Client and Goniometer

Same as for horizontal abduction.

End-feel

Firm or soft.³

Elbow

Extension to Flexion

0 to 135 degrees to 150 degrees (Figure 21-20).

Position of the Client

Standing, sitting, or supine with the humerus adducted and externally rotated and the forearm supinated.

Position of the Goniometer

The axis is placed over the lateral epicondyle of the humerus at the end of the elbow crease. The stationary bar is parallel to the midline of the humerus, and the movable bar is parallel to the radius. After the movement has been completed, the position of the elbow crease changes in relation to the lateral epicondyle because of the rise of the muscle bulk during the motion. The axis of the goniometer should be repositioned so that it is over, although it will not be directly on, the lateral epicondyle.

End-feel

Soft, hard, and firm: flexion. Hard or firm: extension and hyperextension.³

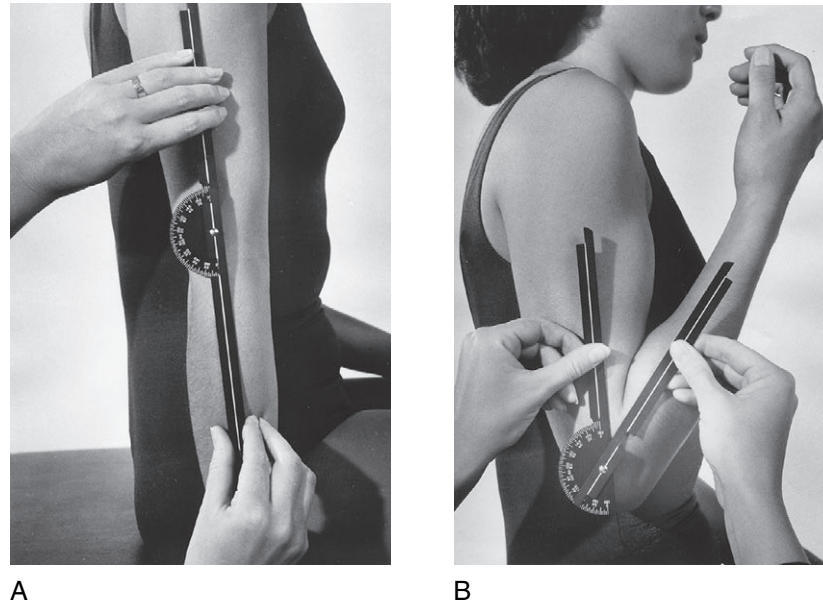

FIGURE 21-20 Elbow flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-21 Forearm supination. **A**, Starting position. **B**, Final position.

Forearm

Forearm Supination

0 to 80 degrees or 90 degrees (Figure 21-21).

Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition.

Position of the Goniometer

The axis is at the ulnar border of the volar aspect of the wrist, just proximal to the ulnar styloid. The movable bar is resting against the volar aspect of the wrist, and the stationary bar is perpendicular to the floor. After the forearm

is supinated, the goniometer should be repositioned so that the movable bar rests squarely across the center of the distal end of the forearm.

Forearm Supination (Alternative Method)

0 to 80 degrees or 90 degrees (Figure 21-22).

Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition. Place a pencil in the client's hand so that it is held perpendicular to the floor.

A

B

FIGURE 21-22 Forearm supination (alternative method). **A**, Starting position. **B**, Final position.

A

B

FIGURE 21-23 Forearm pronation. **A**, Starting position. **B**, Final position.

Position of the Goniometer

The axis is over the head of the third metacarpal, and the stationary bar is perpendicular to the floor. The movable bar is parallel to the pencil.

End-feel

Firm.³

Forearm Pronation

0 to 80 degrees or 90 degrees (Figure 21-23).

Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition.

Position of the Goniometer

The axis is at the ulnar border of the dorsal aspect of the wrist, just proximal to the ulnar styloid. The movable bar is resting against the dorsal aspect of the wrist, and the stationary bar is perpendicular to the floor. After the forearm is pronated, reposition the goniometer so that the movable

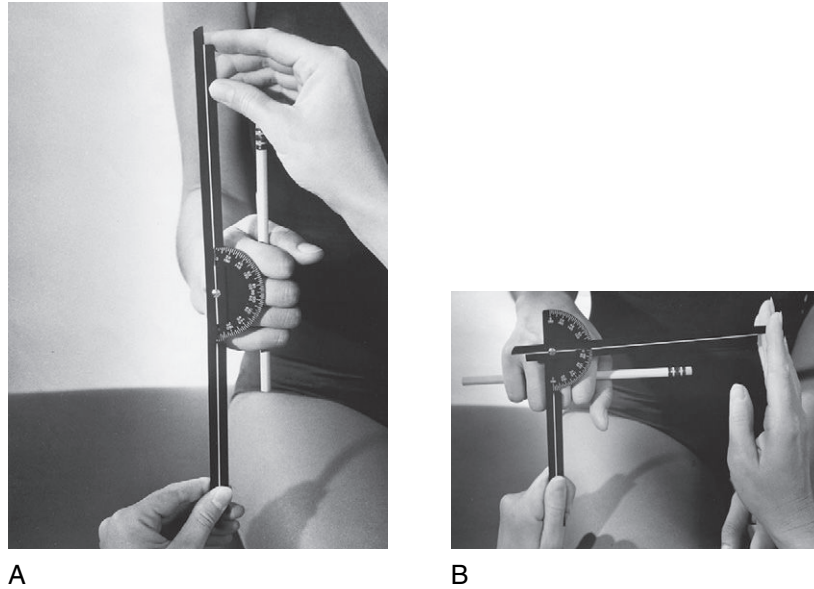

FIGURE 21-24 Forearm pronation (alternative method). **A**, Starting position. **B**, Final position.

FIGURE 21-25 Wrist flexion. **A**, Starting position. **B**, Final position.

bar rests squarely across the center of the dorsum of the distal end of the forearm.

Forearm Pronation (Alternative Method)

0 to 80 degrees or 90 degrees (Figure 21-24).

Position of the Client

Seated or standing with the humerus adducted, the elbow at 90 degrees, and the forearm in midposition. A pencil is placed in the hand so that it is held perpendicular to the floor.

Position of the Goniometer

The axis is over the head of the third metacarpal, the stationary bar is perpendicular to the floor, and the movable bar is parallel to the pencil.

End-feel

Hard to firm.³

Wrist

Wrist Flexion

0 to 80 degrees (Figure 21-25).

Position of the Client

Seated with the forearm in midposition and the hand and forearm resting on a table on the ulnar border. The fingers are relaxed or extended. This measurement may also be taken with the forearm pronated and resting on a table.³

Position of the Goniometer

The wrist is measured with the forearm in midposition, and the axis is on the lateral aspect of the wrist just distal to the radial styloid in the anatomic snuffbox. The stationary bar is parallel to the radius, and the movable bar is parallel to the metacarpal of the index finger.

End-feel

Firm.³

FIGURE 21-26 Wrist extension. **A**, Starting position. **B**, Final position.

FIGURE 21-27 Wrist ulnar deviation. **A**, Starting position. **B**, Final position.

FIGURE 21-28 Wrist radial deviation. **A**, Starting position. **B**, Final position.

Wrist Extension

0 to 70 degrees (Figure 21-26).

Position of the Client and Goniometer

The same as for wrist flexion, except that the fingers should be flexed.

End-feel

Firm or hard.³

Wrist Ulnar Deviation

0 to 30 degrees (Figure 21-27).

Position of the Client

Seated with the forearm pronated, the wrist at neutral, the fingers relaxed in extension, and the palm of the hand resting flat on the table surface.

Position of the Goniometer

The axis is on the dorsum of the wrist at the base of the third metacarpal, over the capitate bone. The movable bar is parallel to the third metacarpal, and the stationary bar is over the midline of the dorsal aspect of the forearm.

End-feel

Firm.³

Wrist Radial Deviation

0 to 20 degrees (Figure 21-28).

Position of the Client and Goniometer

Same as for ulnar deviation.

End-feel

Firm or hard.³

FIGURE 21-29 Metacarpophalangeal flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-30 Metacarpophalangeal hyperextension. **A**, Starting position. **B**, Final position.

Fingers

Metacarpophalangeal Flexion
0 to 90 degrees (Figure 21-29).

Position of the Client

Seated with the elbow flexed, the forearm in midposition, the wrist at 0-degree neutral position, and the forearm and hand supported on a firm surface on the ulnar border.

Position of the Goniometer

The axis is centered on the dorsal aspect of the metacarpophalangeal (MP) joint. The stationary bar is on top of the metacarpal, and the movable bar is on top of the proximal phalanx.

End-feel

Hard or firm.³

Metacarpophalangeal Joint Hyperextension
0 to 45 degrees (Figure 21-30).

Position of the Client

Seated with the forearm in midposition, the wrist at 0-degree neutral position, the interphalangeal joints relaxed or in flexion, and the forearm and hand supported on a firm surface on the ulnar border.

Position of the Goniometer

The axis is over the lateral aspect of the MP joint of the index finger. The stationary bar is parallel to the metacarpal, and the movable bar is parallel to the proximal phalanx. The

little finger's MP joint may be measured similarly. ROM of the long and ring fingers can be estimated by comparison.

An alternative is to place the goniometer on the volar aspect of the hand. With use of the edge of the goniometer, the axis is aligned over the MP joint being measured, the stationary bar is parallel to the metacarpal, and the movable bar is parallel to the proximal phalanx.

End-feel

Firm.³

Metacarpophalangeal Abduction
0 to 25 degrees (Figure 21-31).

Position of the Client

Seated with the forearm pronated, the wrist at 0-degree neutral deviation, the fingers straight, and the hand resting on a firm surface.

Position of the Goniometer

The axis is centered over the MP joint being measured. The stationary bar is over the corresponding metacarpal, and the movable bar is over the proximal phalanx.

End-feel

Firm.³

Proximal Interphalangeal Flexion
0 to 110 degrees (Figure 21-32).

FIGURE 21-31 Metacarpophalangeal abduction. **A**, Starting position. **B**, Final position.

FIGURE 21-32 Proximal interphalangeal flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-33 Distal interphalangeal flexion. **A**, Starting position. **B**, Final position.

Position of the Client

Seated with the forearm in midposition, the wrist at 0-degree neutral position, and the forearm and hand supported on a firm surface on the ulnar border.

Position of the Goniometer

The axis is centered on the dorsal surface of the proximal interphalangeal (PIP) joint being measured. The stationary bar is placed over the proximal phalanx, and the movable bar is over the middle phalanx.

Alternative Method

The joint can also be measured with a ruler. The interphalangeal and MP joints of the fingers are flexed toward the palm. A ruler is used to measure from the pulp of the middle finger to the proximal palmar crease.³

End-feel

Usually hard; may be soft or firm.³

Distal Interphalangeal Flexion

0 to 80 degrees (Figure 21-33).

Position of the Client

Seated with the forearm in midposition, the wrist at 0-degree neutral deviation, and the forearm and hand supported on the ulnar border on a firm surface.

Position of the Goniometer

The axis is on the dorsal surface of the distal interphalangeal (DIP) joint. The stationary bar is over the middle phalanx, and the movable bar is over the distal phalanx.

Distal Interphalangeal Flexion

(Alternative Method)

With the MP joints in 0-degree extension, the client flexes the interphalangeal and PIP joints toward the palm. With a ruler, a measurement is taken from the pulp of the middle finger to the distal palmar crease.³

FIGURE 21-34 Thumb metacarpophalangeal flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-35 Thumb interphalangeal flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-36 Thumb radial abduction. **A**, Starting position. **B**, Final position.

End-feel

Firm.³

Thumb

Metacarpophalangeal Flexion

0 to 50 degrees (Figure 21-34).

Position of the Client

Seated with the elbow flexed, the forearm in 45 degrees of supination, the wrist at 0-degree neutral deviation, the MP and interphalangeal joints in extension, and the hand and forearm supported on a firm surface.

Position of the Goniometer

The axis is on the dorsal surface of the MP joint. The stationary bar is over the thumb metacarpal, and the movable bar is over the proximal phalanx.

End-feel

Hard or firm.³

Interphalangeal Flexion

0 to 90 degrees (Figure 21-35).

Position of the Client

Same as described for PIP and DIP finger flexion.

Position of the Goniometer

The axis is on the dorsal surface of the interphalangeal joint. The stationary bar is over the proximal phalanx, and the movable bar is over the distal phalanx.

Radial Abduction

(Carpometacarpal Extension)

0 to 50 degrees (Figure 21-36).

FIGURE 21-37 Thumb radial abduction (alternative method). **A**, Starting position. **B**, Final position.

FIGURE 21-38 Palmar abduction. **A**, Starting position. **B**, Final position.

Position of the Client

Seated with the forearm pronated and the hand palm down, resting flat on a firm surface.

Position of the Goniometer

The axis is over the carpometacarpal (CMC) joint at the base of the thumb metacarpal. The stationary bar is parallel to the radius, and the movable bar is parallel to the thumb metacarpal.

Radial Abduction (Alternative Method)

0 to 50 degrees (Figure 21-37).

Position of the Client and Goniometer

The client is positioned the same as described in the first method. The axis is over the CMC joint at the base of the thumb metacarpal. The stationary and movable bars are together and parallel to the thumb and the first metacarpals. Neither will be directly over these bones.

End-feel

Firm.³

Palmar Abduction (Carpometacarpal Flexion)

0 to 50 degrees (Figure 21-38).

Position of the Client

Seated with the forearm at 0-degree midposition, the wrist at 0 degree, and the forearm and hand resting on the ulnar border. The thumb is rotated so that it is at right angles to the palm of the hand.

Position of the Goniometer

The axis is at the junction of the thumb and index finger metacarpals. The stationary bar is over the radius, and the movable bar is parallel to the thumb and index finger metacarpals.

Palmar Abduction (Alternative Method)

0 to 50 degrees (Figure 21-39).

Position of the Client and Goniometer

The client is positioned in the same way described in the first method. The axis is at the junction of the thumb and index finger metacarpals. The stationary and movable bars are lined up together, parallel to the thumb and the index finger metacarpals.

End-feel

Firm.³

Opposition

Deficits in opposition may be recorded by measuring the distance between the centers of the pads of the thumb and the fifth finger with a centimeter ruler (Figure 21-40).

End-feel

Soft or firm.³

Lower Extremity^{3,5,6,10}

Hip

Hip Flexion

0 to 120 degrees (Figure 21-41).

FIGURE 21-39 Palmar abduction (alternative method). **A**, Starting position. **B**, Final position.

FIGURE 21-40 Thumb opposition to the fifth finger.

Position of the Client

Supine, lying with the hip and knee in 0-degree neutral extension and rotation.

Position of the Goniometer

The axis is on the lateral aspect of the hip, over the greater trochanter of the femur. The stationary bar is centered over the middle of the lateral aspect of the pelvis, and the movable bar is parallel to the long axis of the femur on the lateral aspect of the thigh. The knee is bent during the motion.

End-feel

Soft.³

Hip Extension (Hyperextension)

0 to 30 degrees (Figure 21-42).

Position of the Client

The client is prone, lying with the hip and knee at 0-degree neutral extension and rotation and the feet over the end of the table.

Position of the Goniometer

Same as for hip flexion.

End-feel

Firm.³

Hip Abduction

0 to 40 degrees (Figure 21-43).

Position of the Client

The client is supine, lying with the legs extended and the hip in 0-degree neutral rotation. The pelvis is level.

Position of the Goniometer

The axis is placed on the anterior superior iliac spine. The stationary bar is placed on a line between two anterior superior iliac spines, and the movable bar is parallel to the longitudinal axis of the femur over the anterior aspect of the thigh. Note that the starting position is at 90 degrees for this measurement and that the recording of the measurement should be adjusted by subtracting 90 degrees from the total number of degrees obtained in the arc of joint motion.

End-feel

Firm.³

Hip Adduction

0 to 35 degrees (Figure 21-44).

Position of the Client and Goniometer

The client is supine, lying with the hip and knee of the leg to be tested in extension and neutral rotation. The leg not being tested should be abducted. The goniometer is positioned the same as for hip abduction.

End-feel

Firm or soft.³

Hip Internal Rotation

0 degree to 45 degrees (Figure 21-45).

Position of the Client

The client is seated with the hip in 0-degree neutral rotation and the hip and knee flexed to 90 degrees. The knee is flexed over the end of the treatment table. A small roll or towel may be placed under the distal end of the femur to maintain it in a horizontal plane. The contralateral hip is abducted, and the foot may be supported on a stool.

Position of the Goniometer

The axis is on the center of the patella. The stationary and movable bars are parallel to the longitudinal axis of the tibia

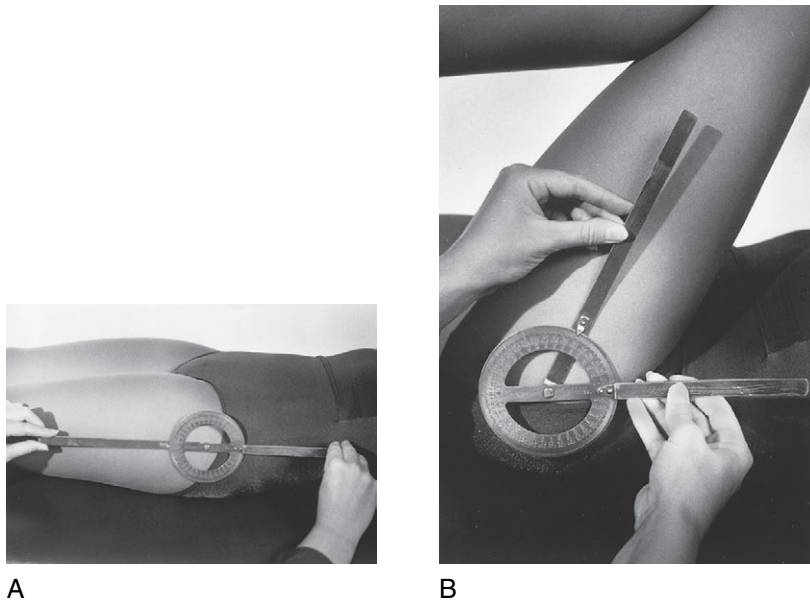

FIGURE 21-41 Hip flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-42 Hip extension. **A**, Starting position. **B**, Final position.

FIGURE 21-43 Hip abduction. **A**, Starting position. **B**, Final position.

FIGURE 21-44 Hip adduction. **A**, Starting position. **B**, Final position.

FIGURE 21-45 Hip internal rotation. **A**, Starting position. **B**, Final position.

FIGURE 21-46 Hip external rotation. **A**, Starting position. **B**, Final position.

FIGURE 21-47 Knee flexion. **A**, Starting position. **B**, Final position.

on the anterior aspect of the lower part of the leg. The stationary bar remains in this position, perpendicular to the floor, whereas the movable bar follows the tibia as the hip is rotated.

End-feel
Firm.³

Hip External Rotation
0 to 45 degrees (Figure 21-46).

Position of the Client and Goniometer

The client is seated with the hip in 0-degree neutral rotation and the hip and knee of the leg to be tested flexed to 90 degrees. The other leg should be (1) flexed at the knee so that the lower part of the leg is back under the table or (2) flexed at the hip and knee so that the foot is resting on the table. These positions allow the motion to take place without obstruction. The trunk should remain erect during performance of the motion. The goniometer is positioned as for internal rotation.

End-feel
Firm.³

Knee

Knee Extension-Flexion
0 to 135 degrees (Figure 21-47).

Position of the Client

The client should be prone or supine, lying with the knees and hips extended and the hip in 0-degree neutral rotation.

Position of the Goniometer

With the client in the prone position, the axis is centered on the lateral aspect of the knee joint at the lateral epicondyle of the femur. The stationary bar is on the lateral aspect of the thigh, parallel to the longitudinal axis of the femur. The movable bar is parallel to the longitudinal axis of the fibula, aligned with the lateral malleolus, on the lateral aspect of the leg.

End-feel
Soft.³

Ankle

Ankle Dorsiflexion
0 to 15 degrees (Figure 21-48).

FIGURE 21-48 Ankle dorsiflexion. **A**, Starting position. **B**, Final position.

FIGURE 21-49 Ankle plantar flexion. **A**, Starting position. **B**, Final position.

FIGURE 21-50 Ankle inversion. **A**, Starting position. **B**, Final position.

Position of the Client

The client should be supine or seated with the knee flexed at least 30 degrees. The ankle is at 90-degree neutral position and the foot is in 0 degree of inversion and eversion.

Position of the Goniometer

The axis is placed below the medial malleolus.³ The stationary bar is parallel to the longitudinal axis of the tibia, and the movable bar is parallel to the first metatarsal. (This measurement may also be taken on the lateral side of the foot.) Note that measurement begins at 90 degrees, so 90 degrees must be subtracted when recording the joint measurement.

End-feel

Firm or hard.³

Ankle Plantar Flexion

0 to 50 degrees (Figure 21-49).

Position of the Client and Goniometer

Same as for dorsiflexion.

End-feel

Firm or hard.³

Ankle Inversion

0 to 35 degrees (Figure 21-50).

Position of the Client

The client is supine with the knee and hip extended and in 0-degree neutral rotation, the ankle in the 90-degree neutral position, and the foot extended over the edge of the table. A small roll is placed under the knee to maintain slight flexion. The alternative position is sitting with the knee flexed to 90 degrees, the leg over the edge of the supporting surface, and the ankle in 90-degree neutral position.

FIGURE 21-51 Ankle eversion. **A**, Starting position. **B**, Final position.

Position of the Goniometer

The axis is placed at the lateral border of the foot near the heel. The stationary bar is parallel to the longitudinal axis of the fibula on the lateral aspect of the leg. The movable bar is parallel to the plantar surface of the heel.

End-feel

Firm.³

Ankle Eversion

0 to 20 degrees (Figure 21-51).

Position of the Client

Same as for inversion.

Position of the Goniometer

The axis is on the medial border of the foot, just proximal to the metatarsophalangeal joint. The stationary bar is parallel to the longitudinal aspect of the fibula on the medial aspect of the lower part of the leg. The movable bar is parallel to the plantar surface of the sole. Note that measurements for inversion and eversion both begin at 90 degrees. Therefore, this amount must be subtracted from the total when measurements are recorded.

End-feel

Hard or firm.³

Summary

Joint measurement is used to evaluate ROM in persons whose physical dysfunction affects joint mobility. Measurements of ROM are used in setting intervention goals, selecting intervention methods, and making objective assessments of progress that allow the therapist to select the intervention methods most likely to target the affected joints.

Before measuring ROM, the therapist should know any precautions or contraindications concerning the client's condition that may determine how extensive the joint measurement procedure can be. The therapist should also know the principles of joint measurement. The procedure for

Threaded Case Study
Evelyn, Part 2

At the beginning of the chapter, Evelyn's case study was introduced. She is an active 83-year-old woman with a rich occupational life who sustained a Colles fracture in her left nondominant upper extremity, had recently had her cast removed, and was experiencing residual problems (including joint ROM deficits). Readers were asked to consider three questions while studying the chapter:

Why should the therapist proceed with caution when assessing the ROM limitations of this client?

The therapist should proceed with caution with all clients; in the case of Evelyn, heightened caution is necessary during joint measurement because of the edema, pain, and stiffness that she is experiencing in the thumb and fingers of her recently injured left wrist. Failure to proceed with caution during measurement of ROM could exacerbate each of these symptoms.

What is the appropriate sequencing of joint measurement assessment for this client? What methods should be applied first?

It is important for the therapist to first have Evelyn actively move her joints through all available pain-free (or with tolerable pain) ROM throughout both her left affected upper extremity and her unaffected right upper extremity (for comparison purposes). Next, the therapist should passively move Evelyn's affected joints through the available pain-free (tolerable) ROM, note the end-feel, and estimate the ROM in those joints. Finally, the therapist measures the affected joints with a goniometer by following the specific sequential directions for measuring each of the joints.

What is the advantage of joint measurement in evidence-based practice?

An advantage of joint measurement in evidence-based practice is that the client's ROM baselines are recorded and the effectiveness of interventions can be determined or substantiated on the basis of the results of follow-up joint measurements. Once these outcome data are collected by the therapist (along with similar data from other clients), a body of evidence regarding effectiveness of intervention is compiled, which in turn can be used to select effective treatment of future clients with similar problems.

measuring joint ROM involves correct positioning of the client and therapist, exposure of the joints to be measured, palpation, appropriate stabilization and handling of parts, and correct placement of the goniometer at the beginning and end of the ROM. To support the efficacy of intervention strategies and modalities, the therapist must also consider which method of reporting will best serve as evidence of effective intervention.

Directions and illustrations for measuring all of the major joint motions in the neck, trunk, and upper and lower extremities are included in this chapter. The content is designed for development of the fundamental techniques of joint measurement. The reader is referred to the references for more comprehensive treatment of the topic.^{3,9,10}

Review Questions

- Describe general rules for positioning the goniometer when measuring joint ROM.
 - With which conditions is joint measurement likely to be used?
 - List and discuss four purposes of joint measurement.
 - Is formal joint measurement necessary for every client? If not, how may ROM be assessed?
 - What is the benefit of conducting precise joint measurement with a goniometer?
 - What is meant by palpation? How is palpation done?
 - What should the therapist look for when observing joints and joint motions?
 - List at least five precautions during or contraindications to joint measurement.
 - What is meant by end-feel?
 - When measuring a joint crossed by a two-joint muscle, how should the occupational therapy practitioner position the joint not being measured?
 - List the steps in the procedure for joint measurement.
 - How is joint ROM measurement recorded on the evaluation form?
 - List the average normal ROM for elbow flexion, shoulder flexion, finger MP flexion, hip flexion, knee flexion, and ankle dorsiflexion.
 - Describe how to read the goniometer when using the 180-degree system of joint measurement.
 - What is meant by functional ROM?
 - List three intervention methods that could be used to increase ROM.
- Repeat the first exercise, but the client should play the role of someone with several joint limitations.
 - Observe the joint motions used in ordinary ADLs/IADLs (e.g., self-care and home management). Estimate the functional ranges of motion for the following joint motions: shoulder flexion, external rotation, internal rotation, and abduction; elbow flexion; wrist extension; hip flexion and extension; knee flexion; and ankle plantar flexion.

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe screening tests for muscle strength assessment.
2. Identify what is measured by the manual muscle test (MMT).
3. List diagnoses for which the MMT is appropriate and those for which it is not appropriate, with the rationale for each.
4. List the steps of the MMT procedure in correct order.
5. Describe the limitations of the MMT.
6. Define muscle grades by name, letter, and number.
7. Administer an MMT, using the directions in this chapter, on a normal practice subject.
8. Describe how results of the muscle strength assessment are used in intervention planning.

Many physical disabilities cause muscle weakness. Slight to substantial limitations of performance in areas of occupation, such as bringing food to one's mouth, lifting a child, removing items from a grocery store shelf, and getting into and out of bed, can result from loss of strength, depending on the degree of weakness and whether the weakness is permanent or temporary. If improvement is expected, the occupational therapist must assess the muscle weakness and plan an intervention that will enable occupational performance and increase strength.

Causes of Muscle Weakness

Loss of muscle strength is a primary symptom or a direct result of the following diseases or injuries:

1. Lower motor neuron disorders, such as peripheral neuropathies and peripheral nerve injuries, spinal cord injury (because those muscles innervated at the level[s] of the lesion generally have a lower motor neuron paralysis), Guillain-Barré syndrome, and cranial nerve dysfunction
2. Primary muscle diseases, such as muscular dystrophy and myasthenia gravis
3. Neurologic diseases in which the lower motor neuron is affected, such as amyotrophic lateral sclerosis or multiple sclerosis

Disabilities in which loss of muscle strength is caused by disuse or immobilization rather than being a direct effect of the disease process include burns, amputation, hand trauma

(unless an accompanying nerve injury is present), arthritis, fracture, and a variety of other orthopedic conditions.

Muscle weakness can restrict or prevent performance in areas of occupation, including activities of daily living (ADLs), instrumental activities of daily living (IADLs), rest and sleep, education, work, play, leisure, and social participation. These limitations are assessed by observation of performance (see [Chapter 20](#)), screening tests, and manual muscle testing (MMT), when indicated.

Screening Tests

Screening tests are useful for observing areas of strength and weakness and for determining which areas require specific MMT.^{6,10,12,18} Screening tests can help the therapist avoid unnecessary testing or duplication of services.¹² These tests are used by occupational therapists in some health care facilities in which MMT is the responsibility of the physical therapy service. Similar to the occupation-based functional motion assessment described in [Chapter 20](#), screening tests are used to assess muscle strength. These tests are not as precise as MMT, and their purpose is to make a general evaluation of muscle strength and to determine areas of weakness, performance limitations, and the need for more precise testing. Screening may be accomplished by the following means:

1. Examination of the medical record for results of previous muscle test and range-of-motion (ROM) assessments

Case Study | Sharon

After a week of experiencing increasing numbness and weakness in her extremities and shortness of breath, Sharon, a 32-year-old woman, was admitted to an intensive care unit at a local hospital with acute respiratory distress, generalized musculoskeletal weakness, decreased sensory processing, and difficulty swallowing. Sharon complained of pain and tenderness in her muscles and was very agitated and fearful. She was diagnosed as being in the acute phase of Guillain-Barré syndrome and was placed on a ventilator.¹¹ The OT practitioner fitted her with resting splints to support her weakened hands and minimize her muscle belly tenderness. When Sharon was moved from intensive care as the progression of the syndrome began to plateau, the therapist was able to greatly reduce her fear by adapting an environmental system that gave Sharon more control of her environmental context, allowing her to operate her call button, room lights, bed, and television.¹⁹

Sharon is a senior editor for a monthly food magazine. She has two children, ages 2 and 6. She has been married for 8 years; her husband is a sales representative for a computer company. They live in a two-story townhouse in an urban community. Sharon primarily works at home, going into the magazine's office once or twice a week. However, once a month, during the week the magazine is being published, her life "becomes a bit crazy," and she may go into the office 5 days. She feels fortunate that she is able to employ a housekeeper/childcare person. In addition to caring for her home and family, Sharon is an avid photographer, exercises at a gym three times per week, and enjoys hiking and camping. She is a regular volunteer at her eldest child's school. She and her husband enjoy an active social life.

Six months after onset, Sharon is now being seen as an outpatient by an occupational therapist. Her disorder is in the recovery phase, with remyelination and axonal degeneration resulting in a generalized increase in muscle strength.¹¹ Sharon continues to be unable to fully engage in occupations that are meaningful to her, primarily because of residual weakness in her distal extremities and moderate limitation in endurance. She is usually in a wheelchair, but she uses a walker in her home. She has an aide that comes in the morning to assist her with bathing and personal grooming and to drive her to her

outpatient appointments. She states that "Although I can do things for myself, it takes so long that I end up being tired before my day even begins. I need help to safely shave my underarms and legs. Curling and blow-drying my hair can be exhausting." Sharon has also indicated that she cannot complete home maintenance tasks such as meal preparation (chopping foodstuff, managing pots and pans) and grocery shopping without assistance. She is unable to fully provide for the care and supervision of her children, especially the 2-year-old, nor can she access the second story of her home on a regular basis. She is limited in her ability to participate in outdoor and community occupations, which formerly brought her a great deal of satisfaction. She has recently been able to resume some of her job responsibilities at home on a limited basis with a voice-activated computer and is "grateful my employer still wants me and has been willing to make accommodations." She indicated that with all the progress she has made, she and her husband are trying to be realistic but are feeling more and more hopeful about her making a full recovery.

In reviewing the above occupational profile, the therapist must focus on those client factors that are interfering with body function, namely, decreased muscle strength and endurance. Maintaining her arms at and above shoulder level without taking several rest breaks when vigorously brushing her back teeth, for example, remains a problem. Another problem is applying enough force to open jars or perform fine motor activities, such as manipulating coins. These deficits are prohibiting the client from fully engaging in occupations for participation in the physical, social, personal, cultural, and spiritual contexts that bring meaning to her life.

Critical Thinking Questions

1. At what stage in this client's recovery should the occupational therapist first administer a muscle strength assessment?
2. Several methods are available for assessing muscle strength; what are they? What information regarding the client's status could be gained from each of these methods?
3. What is the relationship between MMT and graded activity with this client?

2. Observing the client entering the clinic and moving about
3. Observing the client perform functional activities, such as removing an article of clothing and shaking hands with the therapist^{6,12,13}
4. Performing a gross check of bilateral muscle groups¹³

The last method can be performed while the client is comfortably seated in a sturdy chair or wheelchair. The client is asked to perform the motions **against gravity** (movements away from the floor) or in the **gravity-minimized** plane (parallel to the floor) if moving against

gravity is not possible. Active range of motion (AROM) is observed, and **resistance** (application of force) can be given to the test motions to obtain a gross estimate of strength.

In the case of Sharon, who during the acute stage of her illness had very limited muscle strength, the occupational therapy (OT) practitioner would be able to observe changes by observing this client as she moved around her bed in an attempt to position herself. Initially she might require maximal assistance for bed repositioning or for food intake. The therapist will notice a gradual increase in automatic movements of the limbs as Sharon raises her arms to her forehead to brush back her hair with her forearm, cups her

hands around the water glass being held by her husband as she sips through a straw, bends and straightens her legs in an attempt to get comfortable, or momentarily lifts her trunk away from the surface of the bed. Observation of these spontaneous movements as Sharon begins to engage within the context of her environment can serve as preliminary and informal screening of this client's muscle strength.

Manual Muscle Test

Manual muscle testing (MMT) is a means of evaluating muscle strength. MMT measures the maximal contraction of a muscle or muscle group.^{6,7} Criteria used to measure strength include evidence of muscle contraction, amount of ROM through which the joint passes when the muscle contracts, and amount of resistance against which the muscle can contract. Gravity is considered a form of resistance.^{6,7,13} MMT is used to determine the amount of muscle power and to record gains and losses in strength.

Purposes of Manual Muscle Testing

The specific strength measurement of individual muscles through MMT can be essential for diagnosis of some neuromuscular conditions, such as peripheral nerve lesions and spinal cord injury. In peripheral nerve or nerve root lesions, the pattern of muscle weakness may help determine which nerve or nerve roots are involved, and whether the involvement is partial or complete. Careful evaluation can help determine the level(s) of spinal cord involvement and can provide an indication of whether the cord damage is complete or incomplete.¹⁴ Along with sensory evaluation, MMT can therefore be an important diagnostic aid in neuromuscular conditions.

The purposes of assessing muscle strength are to determine the amount of muscle power available and thus establish a baseline for intervention, to discern how muscle weakness is limiting performance in meaningful occupations such as ADLs and IADLs, to prevent deformities that can result from imbalances of strength, to determine the need for assistive devices as compensatory measures, to aid in the selection of occupations within the client's capabilities, and to evaluate the effectiveness of intervention strategies and modalities.¹⁵

Methods of Assessment

Muscle strength can be assessed in several ways. The most precise method is a test of individual muscles. In this procedure, the muscle is carefully isolated through proper positioning, stabilization, and control of the movement pattern, and its strength is graded. This type of muscle testing is described by Kendall and McCreary¹⁴ and Cole, Furness, and Twomey.⁸ Another, and perhaps more common, method of MMT is to assess the strength of groups of muscles that perform specific motions at each joint. This type of testing was described by Daniels and Worthingham,¹⁰ Hislop and Montgomery,^{12,13} and the Rancho Muscle Testing Guide,²⁰

and, for the most part, is the form that is presented later in this chapter.

Results of Assessment as a Basis for Intervention Planning

When planning intervention for maintenance or improvement of strength, the OT practitioner considers several factors in the clinical reasoning process before determining intervention priorities, goals, and modalities. Results of the muscle strength assessment will suggest the progression of the intervention program. What is the degree of weakness? Is it generalized or specific to one or more muscle groups? Are the muscle grades generally the same throughout, or is there significant disparity in muscle grades? If there is disparity, is there an imbalance of strength between the agonist and antagonist muscles that necessitates protection of the weaker muscles during OT intervention or when ADLs and IADLs are performed? When substantial imbalance between an agonist muscle and an antagonist muscle is noted, intervention goals may be directed toward strengthening the weaker group while maintaining the strength of the stronger group. Muscle imbalance may also suggest the need for an orthosis to protect the weaker muscles from overstretching while recovery is in progress. Examples of such orthoses are devices such as the bed footboard, used to prevent overstretching of the weakened ankle dorsiflexors, and the wrist cock-up splint, which can prevent overstretching of weakened wrist extensors.

Muscle grades will suggest the level of therapeutic activity or exercise that can help to maintain or improve strength. Is the weakness mild (G range), moderate (F to F+), or severe (P to 0)?¹⁵ Muscles graded F+, for example, could be strengthened by active assisted exercise or light activity against gravity. Likewise, muscles graded P will require activity or exercise in the gravity-minimized plane, with little or no resistance, to increase strength. (See [Chapter 29](#) for further discussion of appropriate exercise and activity for specific muscle grades.)

Endurance of the muscles (i.e., how many repetitions of the muscle contraction are possible before fatigue sets in) is an important consideration in intervention planning. A frequent goal of the therapeutic activity program is to increase endurance as well as strength. Because MMT does not measure endurance, the therapist should assess endurance by engaging the client in periods of exercise or activity graded in length to determine the length of time that the muscle group can be used in sustained activity. A correlation between strength and endurance is usually noted. Weaker muscles will tend to have less endurance than stronger ones. When selecting intervention modalities for increasing endurance, the therapist may elect not to tax the muscle to its maximal ability, but rather to emphasize repetitive action at less than the maximal contraction to increase endurance and prevent fatigue.¹⁵

Sensory loss, which often accompanies muscle weakness, complicates the ability of the client to perform in an activity

program. If little or no tactile or proprioceptive feedback is obtained from motion, the impulse to move is decreased or lost, depending on the severity of sensory loss. Thus, the movement may appear weak and ineffective even when strength is adequate for performance of a specific activity. With some diagnoses, a sensory re-education program (see Chapter 23) may be indicated to increase the client's sensory awareness and feedback received from the part. In other instances, the therapist may elect to teach compensation techniques to address the sensory loss. These techniques include the use of mirrors, video playback, and biofeedback, which can be used as adjuncts to the strengthening program.

Other important considerations in the therapist's clinical reasoning include the diagnosis and expected course of the disease. Is strength expected to increase, decrease, or remain about the same? If strength is expected to increase, what is the expected recovery period? What is the effect of exercise or activity on muscle function? Will too much activity delay the progress of recovery? If muscle power is expected to decrease, how rapid will the progression be? Are there factors to be avoided, such as vigorous activity or an exercise program that can accelerate the decrease in strength? If strength is declining, is special equipment practical and necessary? How much muscle power is needed to operate the equipment? How long will the client be able to operate a device before a decrease in muscle power makes it impracticable?¹⁵ In the case of Sharon, the therapist must be aware of the change in muscle strength of this client. It is expected that muscle strength will return in a proximal-to-distal pathway, and it is critical to protect the intrinsic muscles of the hand against overexertion to ensure the possibility of full recovery. Frequent muscle testing of select muscle groups will serve as a means to monitor progression of the disease and to assist in the introduction of appropriate intervention strategies.^{11,19}

The therapist should assess the effect of muscle weakness on the ability to perform ADLs; this can be observed during assessment. Which tasks are most difficult to perform because of muscle weakness? How does the client compensate for the weakness? Which tasks are most important for the client to be able to perform? Is special equipment necessary or desirable for the performance of some ADLs, such as mobile arm support for independence in eating (see Chapter 30, Section II)?

If the client is involved in a total rehabilitation program and is receiving several other health care services, the activity and exercise programs must be synchronized and balanced to meet the client's needs rather than the needs of the professionals, their schedules, and possibly their competition. The occupational therapist must be aware of the nature and extent of programs in which the client is engaged in physical therapy, recreation therapy, and any other services. Ideally, all members of the health care team should plan the exercise and activity programs together, to ensure that they complement one another.

OT Practice Note

The therapist must consider the following questions: What is the client doing in each of the therapies? How long is each treatment session? Are the goals of all of the therapies similar and complementary, or are they divergent and conflicting? Is the client being overfatigued in the total program? Are the various treatment sessions provided in rapid succession, or are they well spaced to meet the client's need for rest periods?

On the basis of these considerations and others pertinent to the specific client, the occupational therapist can select enabling and purposeful activities designed to maintain or increase strength, improve performance of ADLs, and enable the use of special equipment, while protecting weak muscles from overstretching and overfatigue.

Relationship Between Joint Range of Motion and Muscle Weakness

One of the criteria used to grade muscle strength is the ROM of the joint on which the muscle acts—that is, did the muscle move the joint through complete, partial, or no ROM? Another criterion is the amount of resistance that can be applied to the part once the muscle has moved the joint through partial or complete AROM. In this context, ROM is not necessarily the full average normal ROM for the given joint; rather, it is the ROM available to the individual client. When the therapist measures joint motion (discussed in Chapter 21), it is passive ROM (PROM) that is the measure of the range available to the client. PROM, however, is not an indication of muscle strength.

When performing muscle testing, the occupational therapist must know the client's PROM to assign muscle grades correctly. It is possible that PROM would be limited or less than average for joint motion, but that the muscle strength would be normal. Therefore, it is necessary for the therapist to have measured joint ROM or to have moved joints passively to assess available ROM before administering the muscle test. For example, the client's PROM for elbow flexion may be limited to 0 to 120 degrees because of an old fracture. If the client can flex the elbow joint to 120 degrees and can withstand moderate resistance during the muscle test, the muscle would be graded G (4). In such cases, the occupational therapist should record the limitation with the muscle grade, for example, 0 to 120 degrees/G.¹⁰ Conversely, if the client's available ROM for elbow flexion is 0 to 160 degrees, and he or she can flex the elbow against gravity through only 120 degrees, the muscle would be graded F– because the part moves through only partial ROM against gravity. When the therapist determines the client's available ROM before performing the muscle test, he or she can grade muscle strength on that basis rather

than by using the average normal ROM as the standard. When assessing Sharon's muscle strength during the recovery phase of her illness, the OT practitioner most likely will find a disparity between the client's PROM and muscle strength, with limitation in strength preventing Sharon from moving her body parts through full available ROM, especially against gravity. The discrepancy will decrease as remyelination and axonal regeneration occur.

Limitations of the Manual Muscle Test

Limitations of MMT are that it cannot measure **muscle endurance** (the number of times the muscle can contract at its maximal level and resist fatigue),⁶ **muscle coordination** (the smooth, rhythmic interaction of muscle function), or motor performance capabilities of the client (the use of muscles for functional activities).⁸

MMT is not appropriate for and cannot be used accurately with clients who have spasticity caused by upper motor neuron disorders such as cerebrovascular accident (stroke) or cerebral palsy. In these conditions, muscles are often hypertonic. Muscle tone and ability to perform movements are influenced by primitive reflexes and the position of the head and body in space. Also, movements tend to occur in gross synergistic patterns that make it impossible for the client to isolate joint motions, which is demanded in MMT procedures.^{2,3,6,7,16}

However, when administered during the final recovery stage, when spasticity and synergy patterns have disappeared and the client has achieved isolated control of voluntary muscle function, MMT may reveal some residual weakness. In these instances, some assessment of strength can be of value in designing a treatment program. (See Chapters 19, 31, Section II, and 32 for methods of evaluating motor function of clients with upper motor neuron disorders.)

Contraindications and Precautions

Assessment of strength using MMT is contraindicated when the client has inflammation or pain in the region to be tested; a dislocation or unhealed fracture; recent surgery, particularly of musculoskeletal structures; myositis ossificans; or bone carcinoma or any fragile bone condition.^{7,15}

Special precautions must be taken when resisted movement could aggravate the client's condition, as might occur with osteoporosis, subluxation or hypermobility of a joint, hemophilia or any type of cardiovascular risk or disease, abdominal surgery or an abdominal hernia, and fatigue that exacerbates the client's condition.^{6,7}

Unlike the PROM assessment discussed in Chapter 21, MMT requires the client's complete involvement in the testing procedure. Therefore, the therapist must be mindful of the client's willingness to expend true effort (especially when resistance is applied), to endure some discomfort, and to understand the requirements of the test. Results of MMT should not be compromised as a result of cognitive and language barriers, or the client's inability to perform the motor skills required for the test.¹³

Knowledge and Skill of the Occupational Therapist

The validity of MMT depends on the knowledge and skill of the OT practitioner in using the correct testing procedure. Careful observation of movement, careful and accurate palpation, correct positioning, consistency of procedure, and experience of the therapist are critical factors in accurate testing.^{10,12-14}

To be proficient in manual muscle testing, the OT practitioner must have detailed knowledge about all aspects of muscle function. Joints and joint motions, muscle innervation, origin and insertion of muscles, action of muscles, direction of muscle fibers, angle of pull on the joints, and the role of muscles in fixation and substitution are important considerations. The therapist must be able to locate and feel contraction of the muscles; recognize whether the contour of the muscle is normal, atrophied, or hypertrophied; and detect abnormal movements and positions. The OT practitioner must use consistent methods in the application of test procedures. Knowledge and experience are necessary to detect substitutions and interpret strength grades with accuracy.¹²⁻¹⁴

It is necessary for the OT practitioner to acquire skill and experience in testing and grading the muscles of normal persons of both genders and of all ages. Many factors affect muscle strength. The age, gender, and lifestyle of the client; the muscle size and type and speed of contraction; the effect of previous training for the testing situation; joint position during the muscle contraction; previous training effects; and time of day, temperature, and fatigue all can affect muscle strength.^{6,7} Experience can help the therapist differentiate among strength grades if these factors are taken into account.¹⁸

General Principles of Manual Muscle Testing

Preparation for Testing

If several tests are to be administered, they should be organized to avoid frequent repositioning of the client.^{12,13,20}

The OT practitioner should observe contour of the part, comparative symmetry of the muscle on both sides, and any apparent hypertrophy (increase in size) or atrophy (shrinking or wasting). During PROM, the therapist can estimate muscle tone. Is there less than or greater than normal resistance to passive movement? During AROM, the therapist can observe the quality of movement, such as movement speed, smoothness, and rhythm, and any abnormal movements such as tremors.¹⁸

Correct positioning of the client and the body part is essential for effective and correct evaluation. The client should be positioned comfortably on a firm surface. Clothing should be arranged or removed so the therapist can see the muscle or muscles being tested. For maximal comfort to the client, the assessment is administered to all muscles

possible in a given position (upright, prone, supine, side-lying) before changing the position of the client. If the client cannot be placed in the correct position for the test, the OT practitioner must adapt the test and use clinical judgment in approximating strength grades.¹⁸ In addition to correct positioning, test validity depends on careful stabilization, palpation of the muscles, and observation of movement.¹⁰

Gravity Influencing Muscle Function

Gravity is a form of resistance to muscle power. It is used as a grading criterion in tests of the neck, trunk, and extremities. In other words, muscle grade is based on whether a muscle can move the part against gravity.¹⁴ Movements against gravity occur in a vertical plane (i.e., away from the floor or toward the ceiling) and are used with grades F (3), G (4), and N (5). Movements against gravity and resistance are performed in a vertical plane with added manual or mechanical resistance and are used with F+ (3+) to N (5) grades. Tests for weaker muscles (O, T [1], P [2], and P+ [2+] grades) are often performed in a horizontal plane (i.e., parallel to the floor) to reduce the resistance of gravity on muscle power. This position has been referred to as the gravity-eliminated, gravity-minimized, or gravity-lessened test position.^{10,14,18} Gravity-eliminated is the common term to designate this position.¹⁶ Because the effect of gravity on muscle function cannot be eliminated completely, gravity-minimized or gravity-lessened may be more accurate terms. The term *gravity-minimized* is used in this chapter.^{10,14}

In many muscle tests, the effect of gravity on the ability to perform the movement must be considered in grading muscle power. It is of lesser importance, however, in tests of the forearm, fingers, and toes because the weight of the part lifted against gravity is insignificant compared with the muscle strength.^{10,14} Therefore, the OT practitioner may choose to do the tests for F (3) to N (5) in the gravity-minimized plane. In other tests, positioning for movements in the gravity-decreased position or the against-gravity position may not be feasible. For example, in the test for scapula depression, positioning to perform the movement against gravity would require the client to assume an inverted position. In individual cases, positioning for movement in the correct plane may not be possible because of confinement to bed, generalized weakness, trunk instability, immobilization devices, and medical precautions. In these instances, the OT practitioner must adapt the positioning to the client's needs and must use clinical judgment in modifying the grading. If tests of the forearm, fingers, and toes are performed against gravity rather than in the gravity-minimized plane, the standard definitions of muscle grades can be modified when muscle grades are recorded. Partial ROM against gravity is graded P (2), and full ROM against gravity is graded F (3).¹⁰ Such modifications in positioning and grading should be noted by the therapist when results of the muscle test are recorded.

For consistency in procedure and grading, gravity-minimized positions and against-gravity positions are used in the manual muscle tests described later, except in cases in which the positioning is not feasible or would be awkward or uncomfortable for the client. Modifications in positioning and grading have been cited with the individual tests.

Muscle Grades

Although the definitions of muscle grades are standard, assignment of muscle grade during MMT depends on the clinical judgment, knowledge, and experience of the OT practitioner,¹⁰ especially when slight, moderate, or maximal resistance is determined. Age, gender, body type, occupation, and leisure activities all influence the amount of resistance that a particular client can take.^{9,10,12-14} Normal strength for an 8-year-old girl will be considerably less than that for a 25-year-old man, for example. Additionally, strength tends to decline with age, and full resistance to the same muscle group will vary considerably from an 80-year-old man to a 25-year-old man.^{7,14} Therefore, the amount of resistance that can be applied to grade a particular muscle group as N (5) or G (4) varies among individual clients.^{9,10,12-14}

The amount of resistance that can be given also varies among muscle groups. Muscle strength is relative to the cross-sectional size of the muscle. Larger muscles have greater strength.^{7,10} For example, the flexors of the wrist are larger and therefore have more power and can take much more resistance than the abductors of the fingers. The OT practitioner must consider the size and relative power of the muscles and the leverage used when giving resistance.¹⁵ The amount of resistance applied should be modified accordingly. When only one side of the body is involved in the dysfunction causing muscle weakness, the OT practitioner can establish the standards for strength by testing the unaffected side first.

Because weak muscles fatigue easily, the results of MMT may not be accurate if the client is tired. There should be no more than three repetitions of the test movement because fatigue can result in grading errors if the muscle becomes tired as a result of low endurance.^{7,8} Pain, swelling, or muscle spasm in the area being tested may also interfere with the testing procedure and accurate grading. Such problems should be recorded on the evaluation form.¹⁸ Psychological factors must be considered in interpreting muscle strength grades. When interpreting strength, the therapist must assess motivation, cooperation, and the effort put forth by the client.¹⁰

In MMT, muscles are graded according to the criteria listed in Table 22-1.^{6,10,12,13,20}

The purpose of using “plus” or “minus” designations with muscle grades is to “fine grade” muscle strength. These designations are likely to be used by the experienced OT practitioner. Two OT practitioners testing the same individual may vary up to a half grade in their results, but there should not be a whole grade difference.¹⁸

■ **TABLE 22-1** | **Muscle Grades and Their Definitions**

Number	Grade	Word/Letter Grade Definition
0	Zero (0)	No muscle contraction can be seen or felt.
1	Trace (T)	Contraction can be observed or felt, but there is no motion.
2–	Poor minus (P–)	Part moves through incomplete ROM with gravity minimized.
2	Poor (P)	Part moves through complete ROM with gravity minimized.
2+	Poor plus (P+)	Part moves through less than 50% of available ROM against gravity or through complete ROM with gravity minimized against slight resistance. ¹⁰
3–	Fair minus (F–)	Part moves through more than 50% of available ROM against gravity. ¹⁰
3	Fair (F)	Part moves through complete ROM against gravity.
3+	Fair plus (F+)	Part moves through complete ROM against gravity and slight resistance.
4	Good (G)	Part moves through complete ROM against gravity and moderate resistance.
5	Normal (N)	Part moves through complete ROM against gravity and maximal resistance.

ROM, Range of motion.

Substitutions

The brain thinks in terms of movement and not in terms of contraction of individual muscles.¹⁰ Thus, a muscle or muscle group may attempt to compensate for the function of a weaker muscle to accomplish a movement. These movements are called trick movements, or **substitutions**.^{6,7,14} Substitutions can occur during MMT. To test muscle strength accurately, the therapist must give careful instructions; eliminate substitutions in the testing procedure by correct positioning, stabilization, and palpation of the muscle being tested; and ensure careful performance of the test motion without extraneous movements. To prevent substitutions, the correct position of the body should be maintained and movement of the part performed without shifting the body or turning the part.^{6,7,14} The therapist must palpate contractile tissue (muscle fibers or tendon) to

detect tension in the muscle group under examination. It is only through correct palpation that the therapist can be certain that the motion observed is not being performed by substitution.^{6,10} Undetected trick movements can mask the client's problems, resulting in inaccurate treatment planning.⁶

In the tests that follow, possible substitutions are described at the end of the directions. The OT practitioner should be familiar with these substitutions to detect them and correct the procedure. Detecting substitutions is a skill gained with time and experience.

Procedure for Testing

Testing should be performed according to a standard procedure to ensure accuracy and consistency. Each of the tests that follow is divided into these steps: (1) position, (2) stabilize, (3) palpate, (4) observe, (5) resist, and (6) grade.

First, the client should be positioned for the specific muscle test. The occupational therapist should position himself or herself in relation to the client. Then, the therapist stabilizes the part proximal to the part being tested to eliminate extraneous movements, isolate the muscle group, ensure the correct test motion, and eliminate substitutions. The therapist should then demonstrate or describe the test motion to the client and should ask him or her to perform the test motion and return to the starting position. The therapist makes a general observation of the form and quality of movement, looking for substitutions or difficulties that may require adjustments in positioning and stabilization. The therapist then places his or her fingers (typically the tips of the index and long fingers—avoid using the thumb because it has its own pulse) for palpation of one or more of the prime movers, or its tendinous insertion, on the muscle group being tested and asks the client to repeat the test motion. While simultaneously palpating the muscle group, the therapist again observes the movement for possible substitution and for the amount of range completed. When the client has moved the part through the available ROM, the therapist asks the client to hold the end position. The therapist removes the palpating fingers and uses the free hand to resist in the direction opposite that of the test movement. For example, when elbow flexion is tested, the therapist applies resistance in the direction of extension. The therapist usually must maintain stabilization when resistance is given. Manual muscle tests use the “break test,” that is, resistance is applied after the client has reached the end of the available ROM.^{12,13}

The client should be allowed to establish a maximal contraction (set the muscles) before resistance is applied.^{10,15} In most tests, the OT practitioner applies resistance near the distal segment to which the muscle is attached after preparing the client by giving the command to hold. Resistance should be applied gradually in a direction opposite to the line of pull of the muscle or muscle group being tested.¹² The break test should not evoke pain, and resistance should

be released immediately if pain or discomfort occurs.¹⁰ Finally, the therapist grades the muscle strength according to the preceding standard definitions of muscle grades. This procedure is used for tests of strength of grades F+ (3+) and above. Resistance is not applied for tests of muscles from F (3) to 0. Slight resistance is sometimes applied to a muscle that has completed the full ROM in the gravity-minimized plane to determine whether the grade is P+. Figure 22-1 shows a sample form for recording muscle grades.

The following directions do not include tests for the face, neck, and trunk. Refer to the references for these tests, as well as for comprehensive treatment of the topic of manual muscle testing.^{6,8,10,12-14}

Manual Muscle Testing of the Upper Extremity

Scapula Elevation, Neck Rotation, and Lateral Flexion

Muscles ¹⁰	Innervation: nerve, nerve roots ^{10,14}
Upper trapezius	Accessory nerve (CN 12), C2-4
Levator scapula	Dorsal scapular nerve, C3-5

Procedure for Testing Grades Normal (N or 5) to Fair (F or 3)^{10,12,13}

1. Position: The client is seated erect with arms resting at sides of body. The OT practitioner stands behind the client toward the side to be tested.
2. Stabilize: A chair back can offer stabilization to the trunk, if necessary.
3. Palpate: Palpate the upper trapezius parallel to the cervical vertebrae, near the shoulder-neck curve.¹⁰
4. Observe: Observe the elevation of the scapula as the client shrugs the shoulder toward the ear and rotates and laterally flexes the neck toward the side being tested at the same time (Figure 22-2, A).¹⁴
5. Resist: Provide resistance by placing one hand on top of the shoulder toward the scapula depression and the other hand on the side of the head toward derotation and lateral flexion to the opposite side (Figure 22-2, B).¹⁴

Procedure for Testing Grades Poor (P or 2), Trace (T or 1), and Zero (0)¹⁰

1. Position: The client should be prone with head in midposition. The OT practitioner stands opposite the side being tested.
2. Stabilize: The weight of the trunk on the supporting surface provides adequate stabilization.
3. Palpate: Palpate the upper trapezius, as described in the previous procedure, while observing the client elevating the shoulder being tested. Because of positioning, the neck rotation and lateral flexion components are omitted for these grades (Figure 22-2, C).

4. Grade: The standard definitions of muscle grades should be used.

Substitutions: Rhomboids and the levator scapula can elevate the scapula if the upper trapezius is weak or absent. In the event of substitution, some downward rotation of the acromion will be observed during movement.^{4,15,20}

Scapula Depression, Adduction, and Upward Rotation

Muscles ^{1,4}	Innervation ^{6,7}
Lower trapezius	Spinal accessory nerve, C3,4
Middle trapezius	
Serratus anterior	Long thoracic nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone with the arm positioned overhead in 130 to 165 degrees of abduction and resting on the supporting surface. The forearm is in midposition with the thumb toward the ceiling.^{12,13} The therapist stands next to the client on the opposite side^{7,10} or on the same side.^{12,13}
2. Stabilize: The weight of the body provides adequate stabilization. This test is given in the gravity-minimized position, because it is not feasible to position the client for the against-gravity movement (head down). If the deltoid is weak, the arm may be supported and passively raised by the therapist while the client attempts the motion.¹⁰
3. Palpate: Palpate the lower trapezius distal to the medial end of the spine of the scapula and parallel to the thoracic vertebrae, approximately at the level of the inferior angle of the scapula.¹⁰
4. Observe: Observe the client while he or she lifts the arm off the supporting surface to ear level.¹² During this movement, there is strong downward fixation of the scapula by the lower trapezius (Figure 22-3, A).¹⁰
5. Resist: Provide resistance at the lateral angle of the scapula, toward elevation and abduction (Figure 22-3, B).¹⁰ Resistance may be applied on the humerus just above the elbow in a downward direction if shoulder and elbow strength are adequate.¹²⁻¹⁴

Procedure for Testing Grades P (2), T (1), and 0

1. Position and stabilize: Position and stabilize the client as described in the previous test. No stabilization is required. The therapist may support the client's arm if the posterior deltoid muscles and triceps are weak.¹²
2. Palpate and observe: Palpate and observe the client in the same manner as described for the previous test (Figure 22-3, C).
3. Grade: The client receives a grade of P if he or she can complete full scapular ROM without the weight of the arm.¹²

KEY

5	N	Normal	Complete range of motion against gravity with full resistance.
4	G	Good*	Complete range of motion against gravity with some resistance.
3	F	Fair*	Complete range of motion against gravity.
2	P	Poor*	Complete range of motion with gravity eliminated.
1	T	Trace	Evidence of slight contractility. No joint motion.
0	0	Zero	No evidence of contractility.
S or SS			Spasm or severe spasm.
C or CC			Contracture or severe contracture.

*Muscle spasm or contracture may limit range of motion. A question mark should be placed after the grading of a movement that is incomplete from this cause.

FIGURE 22-3 Scapula depression. **A**, Palpate and observe. **B**, Resist. **C**, Test for grades P to 0.

Substitutions: Middle trapezius or rhomboids may substitute.⁶ Rotation of the inferior angle of the scapula toward the spine is evidence of substitution.²⁰

Scapula Abduction and Upward Rotation

Muscles^{10,14}

Serratus anterior

Innervation^{10,14}

Long thoracic nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is supine with the shoulder flexed to 90 degrees and slightly abducted, elbow extended or fully flexed. The therapist stands next to the client on the side being tested.^{6,7,10,13,14}
2. Stabilize: Provide stabilization over the weight of the trunk or over the shoulder.⁶
3. Palpate: Palpate the digitations of the origin of the serratus anterior on the ribs, along the midaxillary line and just distal and anterior to the axillary border of the scapula.^{6,10} Note that muscle contraction may be difficult to detect in women and overweight clients.
4. Observe: Observe the client reaching upward as if pushing the arm toward the ceiling, abducting the scapula (Figure 22-4, A).^{6,10}
5. Resist: Provide resistance at the distal end of the humerus, and push the client's arm directly

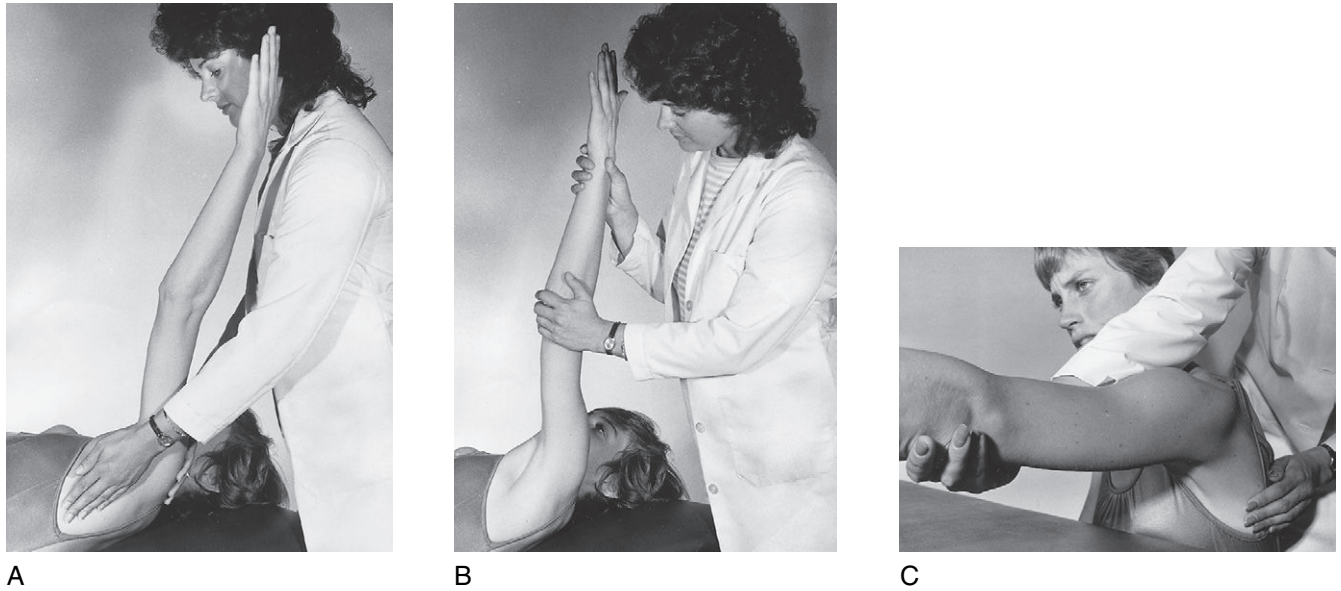

FIGURE 22-4 Scapula abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

downward toward scapula adduction (Figure 22-4, B).^{6,7,10,13} If there is shoulder instability, the therapist should support the arm and not apply resistance. In this instance, only a grade of F (3) can be tested.⁷

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated with the arm supported by the therapist in 90 degrees of shoulder flexion and the elbow extended.^{6,10,13}
2. Stabilize: Provide stabilization over the shoulder to be tested.
3. Palpate: The client is palpated in the same manner as described in the previous section.
4. Observe: The therapist should note any abduction of the scapula as the arm moves forward (Figure 22-4, C).¹⁰ Weakness of this muscle produces “winging” of the scapula.⁸
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The pectoralis major and minor may pull the scapula forward into abduction at its insertion on the humerus; the upper and lower trapezius and contralateral trunk rotation may also substitute.⁶ The therapist observes for humeral horizontal adduction followed by scapula abduction.^{7,14}

Scapula Adduction

Muscles ^{10,14}	Innervation ^{6,10}
Middle trapezius	Spinal accessory nerve, C3,4
Rhomboids	Dorsal scapular nerve, C4,5

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone with the shoulder abducted to 90 degrees and externally rotated and the elbow flexed to 90 degrees, shoulder resting on the supporting surface. The therapist stands on the side being tested.^{10,12-14}
2. Stabilize: The weight of the trunk on the supporting surface usually provides adequate stabilization, or stabilization can be provided over the midthorax to prevent trunk rotation if necessary.
3. Palpate: Palpate the middle trapezius between the spine of the scapula and adjacent vertebrae in alignment with the abducted humerus.
4. Observe: Observe the client lifting the arm off the table, and note any movement of the vertebral border of the scapula toward the thoracic vertebrae (Figure 22-5, A).
5. Resist: Provide resistance at the vertebral border of the scapula toward abduction (Figure 22-5, B).^{6,7,10,13}

Procedure for Testing Grades P (2), T (1), and 0

1. Position and stabilize: The therapist positions and stabilizes the client in the same way as described in the previous test but now supports the weight of the arm by cradling it under the humerus and forearm.¹⁴ The client may also be positioned sitting erect, with the arm resting on a high table and the shoulder midway between 90-degree flexion and abduction.¹⁰ The therapist stands behind the client in this instance.

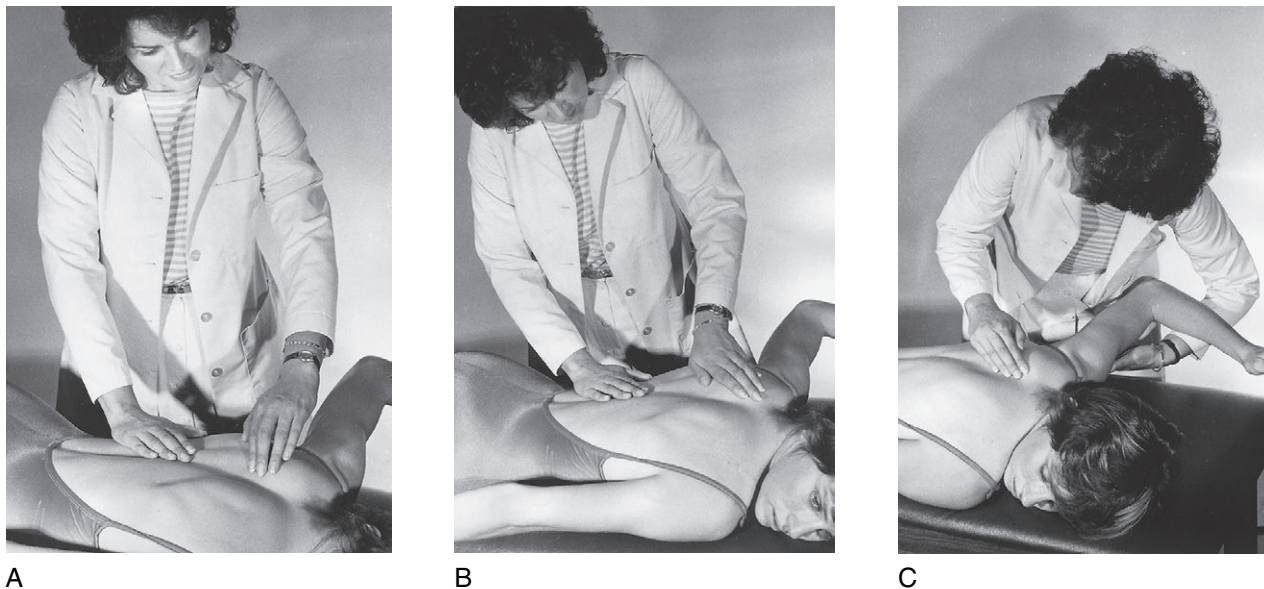

FIGURE 22-5 Scapula adduction. **A**, Palpate and observe. **B**, Resist. **C**, Test for grades P to 0.

2. Palpate and observe: Palpate and observe the middle trapezius. Ask the client to bring the shoulders together as if assuming an erect posture. Observe scapula adduction toward the vertebral column (Figure 22-5, C).
3. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The posterior deltoid can act on the humerus and produce scapula adduction.⁶ Observe for use of humeral extension to initiate scapula adduction. Rhomboids may substitute, but the scapula will rotate downward.^{7,15,20}

Scapula Adduction and Downward Rotation

Muscles ^{7,8}	Innervation ⁶⁻⁸
Rhomboids major and minor	Dorsal scapular nerve, C4,5
Levator scapula	
Middle trapezius	Spinal accessory nerve, C3,4

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone with the head rotated to the opposite side; the arm on the side being tested is placed in shoulder adduction and internal rotation, with the elbow slightly flexed and the dorsum of the hand resting over the lumbosacral area of the back.^{6,12} The therapist stands opposite the side being tested.^{7,8,10}
2. Stabilize: The weight of the trunk on the supporting surface offers adequate stabilization.^{7,14}
3. Palpate: Palpate the rhomboid muscles between the vertebral border of the scapula and the second to fifth thoracic vertebrae.^{10,14} (They may be more easily discerned toward the lower half of the vertebral

border of the scapula, because they lie under the trapezius muscle.)

4. Observe: Observe the client raising the hand up off the back while maintaining the position of the arm.^{7,12} During this motion, the anterior aspect of the shoulder must lift from the table surface. Observe scapula adduction and downward rotation while the shoulder joint is in some extension (Figure 22-6, A).¹⁰
5. Resist: Provide resistance over the scapula toward abduction and upward rotation⁶ (Figure 22-6, B).

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client sits erect with the arm positioned behind the back in the same manner described for the previous test. The therapist stands behind the client, slightly opposite the side being tested.¹⁰
2. Stabilize: The trunk is stabilized by placing one hand over the shoulder, opposite the one being tested, to prevent trunk flexion and rotation.
3. Palpate: The rhomboids are palpated as described previously.
4. Observe: Scapula adduction and downward rotation are observed as the client lifts the hand away from the back (Figure 22-6, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The middle trapezius may substitute, but the movement will not be accompanied by downward rotation.¹² The posterior deltoid acting to perform horizontal abduction or glenohumeral extension can produce scapula adduction through momentum. Scapula adduction would be preceded by extension or abduction of the humerus.^{15,20} The pectoralis minor could tip the scapula forward.⁷

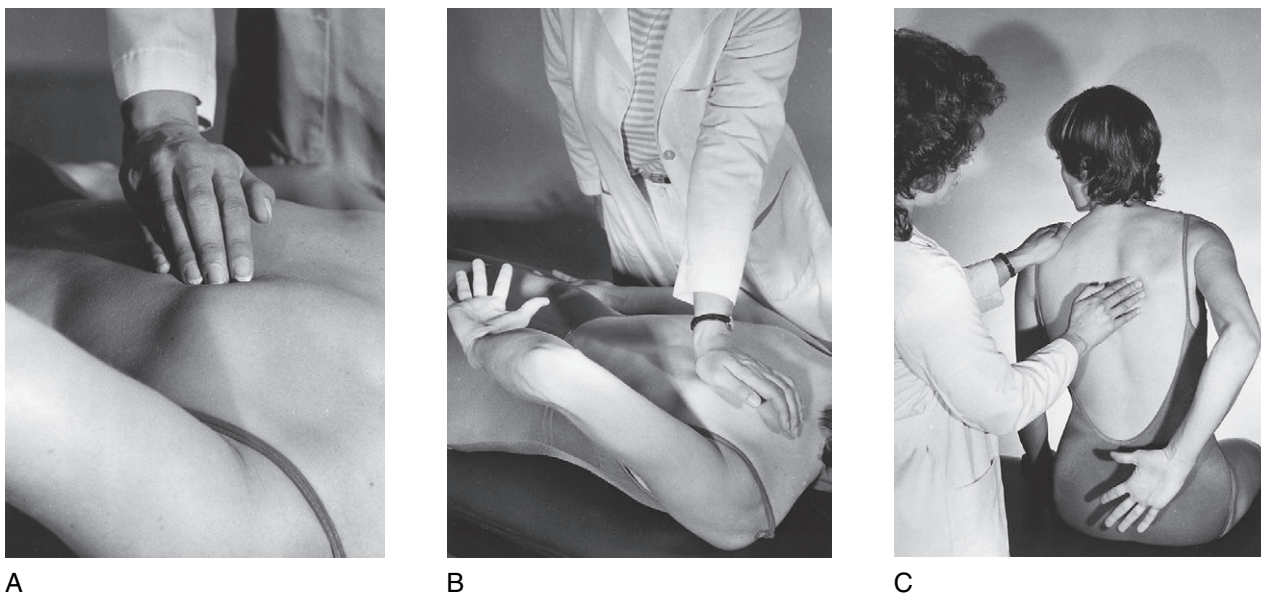

FIGURE 22-6 Scapula adduction and downward rotation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-7 Shoulder flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Shoulder Flexion

Muscles¹⁰

Anterior deltoid

Coracobrachialis

Innervation^{6,10}

Axillary nerve, C5,6

Musculocutaneous nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated with the arm relaxed at the side of the body and the hand facing backward.¹² A straight-backed chair may be used to offer trunk support. The therapist stands on the side being tested and slightly behind the client.^{7,10,20}
2. Stabilize: Provide stabilization over the shoulder being tested, but allow the normal abduction and upward rotation of the scapula that occurs with this movement.^{10,13}
3. Palpate: Palpate the anterior deltoid just below the clavicle on the anterior aspect of the humeral head.⁷
4. Observe: Observe the client flexing the shoulder joint to 90-degree flexion (parallel to the floor; Figure 22-7, A).^{6,10,12}

5. Resist: Provide resistance at the distal end of the humerus downward toward shoulder extension (Figure 22-7, B).^{6,7,8,12}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is placed in a side-lying position. The side being tested is superior. If the client cannot maintain the weight of the arm against gravity, the therapist can support it.^{6,12} If the side-lying position is not feasible, the client may remain seated, and the test procedure described above can be performed with the grading modified.¹⁰
2. Palpate and observe: The therapist should palpate and observe the client in the same manner as described in the previous test. The arm is moved toward the face to 90-degree shoulder flexion (Figure 22-7, C).
3. Grade: The client is graded according to standard definitions of muscle grades. If the seated position was used for tests of grades poor to zero, partial ROM against gravity should be graded poor.^{10,13}

Substitutions: Clavicular fibers of the pectoralis major can perform flexion through partial ROM while performing horizontal adduction. The biceps brachii may flex the shoulder, but the humerus will first be rotated externally for the best mechanical advantage. The upper trapezius will assist flexion by elevating the scapula. Observe for flexion accompanied by horizontal adduction, external rotation, or scapula elevation.^{10,15,20}

NOTE: Arm elevation in the plane of the scapula, about halfway between shoulder flexion and abduction, is called scaption. This movement is more commonly used for function than for shoulder flexion or abduction. Scaption is performed by the deltoid and supraspinatus muscles. It is tested in a way similar to that used for shoulder flexion, described previously, except that the arm is elevated in a position 30 to 45 degrees anterior to the frontal plane.^{6,12}

Shoulder Extension

Muscles ^{4,10,14}	Innervation ^{6,10}
Latissimus dorsi	Thoracodorsal nerve, C6-8
Teres major	Lower subscapular nerve, C5-7
Posterior deltoid	Axillary nerve, C5,6

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the shoulder joint adducted and internally rotated so that the palm of the hand is facing up.^{6,7,12} The therapist stands on the opposite side or on the test side.
2. Stabilize: Provide stabilization over the scapula on the side being tested.
3. Palpate: Palpate the teres major along the axillary border of the scapula. The latissimus dorsi may be palpated slightly below this point or closer to its origins parallel to the thoracic and lumbar vertebrae.^{7,10} The posterior deltoid may be found over the posterior aspect of the humeral head (Figure 22-8, A).
4. Observe: Observe the client extending the shoulder joint.
5. Resist: Provide resistance at the distal end of the humerus in a downward and outward direction, toward flexion and slight abduction (Figure 22-8, B).^{6,7,10,12-14}

A

B

C

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is placed in the side-lying position; the therapist stands behind the client.⁶
2. Stabilize: Provide stabilization over the scapula. If the client cannot maintain the weight of the part against gravity, the therapist should support the client's arm.⁶ If the side-lying position is not feasible, the client may remain in the prone position, and the test may be performed as described for the previous test with modified grading.¹⁰
3. Palpate: Palpate the teres major or latissimus dorsi as described for the previous test.
4. Observe: Observe the client extending the arm backward in a plane parallel to the floor (Figure 22-8, C).
5. Grade: Grade the client according to standard definitions of muscle grades. If the tests for grades poor to zero were done in the prone-lying position, completion of partial ROM should be graded poor.¹⁰

Substitutions: Scapula adduction can substitute. Observe for flexion of the shoulder or adduction of the scapula preceding extension of the humerus.¹⁵

Shoulder Abduction to 90 Degrees

Muscles ^{10,14}	Innervation ¹⁰
Middle deltoid	Axillary nerve, C5,6
Supraspinatus	Suprascapular nerve, C5

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with arms relaxed at the sides of the body. The elbow on the side to be tested should be slightly flexed and the palms facing toward the body. The therapist stands behind the client.^{6,7,12}
2. Stabilize: Provide stabilization over the scapula on the side to be tested.^{6,10,14}
3. Palpate: Palpate the middle deltoid over the middle of the shoulder joint from the acromion to the deltoid tuberosity.^{6,10,14,15} The supraspinatus is too deep to palpate.⁶
4. Observe: Observe the client abducting the shoulder to 90 degrees. During movement, the client's palm

FIGURE 22-8 Shoulder extension. A, Palpate and observe. B, Resist. C, Gravity-minimized position.

FIGURE 22-9 Shoulder abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

should remain down, and the therapist should observe that there is no external rotation of the shoulder nor elevation of the scapula^{6,10,12-15} (Figure 22-9, *A*).

5. Resist: Provide resistance at the distal end of the humerus toward adduction (Figure 22-9, *B*).¹²

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is in the supine position, lying with the arm to be tested resting at the side of the body, palm facing in and the elbow slightly flexed. The therapist stands in front of the supporting surface toward the side to be tested.^{10,12}
2. Stabilize: Provide stabilization over the shoulder to be tested.
3. Palpate and observe: Follow the technique described for the previous test. The therapist asks the client to bring the arm out and away from the body, while abducting the shoulder to 90 degrees (Figure 22-9, *C*).
4. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The long head of the biceps may attempt to substitute. Observe for elbow flexion and external rotation accompanying the movement.¹² The anterior and posterior deltoids can act together to effect abduction. The upper trapezius may attempt to assist. Observe for scapula elevation preceding movement.^{7,15,20}

Shoulder External Rotation

Muscles ^{4,10,14}	Innervation ^{4,10,14}
Infraspinatus	Suprascapular nerve, C5,6
Teres minor	Axillary nerve, C5,6

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the shoulder abducted to 90 degrees and the humerus in neutral (0-degree) rotation, elbow flexed to 90 degrees. The forearm is in neutral rotation, hanging over the edge of the table, perpendicular to the floor.^{6-8,12} The therapist stands in front of the supporting surface, toward the side to be tested.^{10,14}

2. Stabilize: Provide stabilization at the distal end of the humerus by placing a hand under the arm on the supporting surface to prevent shoulder abduction.^{7,14}
3. Palpate: Palpate the infraspinatus muscle just below the spine of the scapula on the body of the scapula⁶ or the teres minor along the axillary border of the scapula.¹⁰
4. Observe: Observe the client rotating the humerus so that the back of the hand is moving toward the ceiling (Figure 22-10, *A*).^{6,7,10,12-14}
5. Resist: Provide resistance on the distal end of the forearm toward the floor in the direction of internal rotation (Figure 22-10, *B*).^{6,10,12-14} Apply resistance gently and slowly to prevent injury to the glenohumeral joint, which is inherently unstable.¹²

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with arm adducted and in neutral rotation at the shoulder. The elbow is flexed to 90 degrees, with the forearm in neutral rotation. The therapist stands in front of the client toward the side to be tested.^{6,7}
2. Stabilize: Provide stabilization on the arm against the trunk at the distal end of the humerus to prevent abduction and extension of the shoulder, and over the shoulder to be tested.^{5,7,20} The hand stabilizing over the shoulder can be used to palpate the infraspinatus simultaneously.
3. Palpate: Palpate the infraspinatus and teres minor as described for the previous test.
4. Observe: Observe the client moving the forearm away from the body by rotating the humerus while maintaining neutral rotation of the forearm (Figure 22-10, *C*).^{6,20}
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: If the elbow is extended and the client supinates the forearm, the momentum could aid external rotation of the humerus. Scapular adduction can pull the humerus backward and into some external rotation. The

FIGURE 22-10 Shoulder external rotation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-11 Shoulder internal rotation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

therapist should observe for scapula adduction and initiation of movement with forearm supination.^{15,20}

Shoulder Internal Rotation

Muscles ^{10,14,15}	Innervation ^{4,5,10}
Subscapularis	Subscapular nerve, C5,6
Pectoralis major	Medial and lateral pectoral nerves, C5-T1
Latissimus dorsi	Thoracodorsal nerve, C6-8
Teres major	Subscapular nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the shoulder abducted to 90 degrees, the humerus in neutral rotation, and the elbow flexed to 90 degrees. A rolled towel may be placed under the humerus. The forearm is perpendicular to the floor. The therapist stands on the side to be tested, just in front of the client's arm.^{6-8,12}
2. Stabilize: Provide stabilization at the distal end of the humerus by placing a hand under the arm and on the supporting surface, as for external rotation.^{6,7,10,14}
3. Palpate: Palpate the teres major and latissimus dorsi along the axillary border of the scapula toward the inferior angle.
4. Observe: Observe the client internally rotating the humerus, moving the palm of the hand upward toward the ceiling (Figure 22-11, A).^{6,10}

5. Resist: Provide resistance at the distal end of the volar surface of the forearm anteriorly toward external rotation (Figure 22-11, B).^{7,10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with the shoulder adducted and in neutral rotation, elbow flexed to 90 degrees with the forearm in neutral rotation. The therapist stands on the side to be tested.^{6,20}
2. Stabilize: Provide stabilization on the arm at the distal end of the humerus against the trunk to prevent abduction and extension of the shoulder.
3. Palpate: Palpate the teres major and latissimus dorsi, as described for the previous test.
4. Observe: Observe the client moving the palm of the hand toward the chest, while internally rotating the humerus (Figure 22-11, C).

Substitutions: If the trunk is rotated, gravity will act on the humerus, rotating it internally.⁶ The therapist should observe for trunk rotation. When the elbow is in extension, pronation of the forearm can substitute.^{10,15,20}

Shoulder Horizontal Abduction

Muscles ^{4,10,15}	Innervation ^{10,13}
Posterior deltoid	Axillary nerve, C5,6
Infraspinatus	Suprascapular nerve, C5,6

FIGURE 22-12 Shoulder horizontal abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the shoulder abducted to 90 degrees and in slight external rotation, elbow flexed to 90 degrees, and forearm perpendicular to the floor. The therapist stands on the side being tested.^{14,15}
2. Stabilize: Provide stabilization over the scapula.^{6,10}
3. Palpate: Palpate the posterior deltoid below the spine of the scapula and distally toward the deltoid tuberosity on the posterior aspect of the shoulder.¹⁰
4. Observe: Observe the client horizontally abducting the humerus, lifting the arm toward the ceiling (Figure 22-12, *A*).¹²
5. Resist: Provide resistance just proximal to the elbow obliquely downward toward horizontal adduction (Figure 22-12, *B*).^{6,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with the arm in 90-degree abduction, the elbow flexed to 90 degrees, and the palm down, supported on a high table or by the therapist.^{6,12} If a table is used, powder may be sprinkled on the surface to reduce friction.
2. Stabilize: Provide stabilization over the scapula.
3. Palpate: Palpate the posterior deltoid, as described for the previous test.
4. Observe: Observe the client pulling the arm backward into horizontal abduction (Figure 22-12, *C*).
5. Grade: Client is graded according to standard definitions of muscle grades.

Substitutions: Latissimus dorsi and teres major may assist movement if the posterior deltoid is very weak. Movement will occur with more shoulder extension rather than at the horizontal level. Scapula adduction may produce slight horizontal abduction of the humerus, but trunk rotation and shoulder retraction would occur.^{6,15,20} The long head of the triceps may substitute. Maintain some flexion at the elbow to prevent this.¹²

Shoulder Horizontal Adduction

Muscles ^{4,12-14}	Innervation ^{4,10,12,13}
Pectoralis major	Medial and lateral pectoral nerves, C5-T1
Anterior deltoid	Axillary nerve, C5,6
Coracobrachialis	Musculocutaneous nerve, C6,7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is supine, with the shoulder abducted to 90 degrees, elbow flexed or extended. The therapist stands next to the client on the side being tested or behind the head of C.^{4,6,7,10,12}
2. Stabilize: Stabilize the trunk by placing one hand over the shoulder on the side being tested to prevent trunk rotation and scapula elevation.
3. Palpate: Palpate over the insertion of the pectoralis major at the anterior aspect of the axilla.⁶
4. Observe: Observe the client horizontally adducting the humerus, moving the arm toward the opposite shoulder to a position of 90 degrees of shoulder flexion.¹⁴ If the client cannot maintain elbow extension, the therapist may guide the forearm to prevent the hand from hitting the client's face (Figure 22-13, *A*).
5. Resist: Provide resistance at the distal end of the humerus, in an outward direction toward horizontal abduction (Figure 22-13, *B*).^{6,7,10}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated next to a high table, with the arm supported in 90 degrees of shoulder abduction and slight flexion at the elbow.^{4,12,20} Powder may be sprinkled on the supporting surface to reduce the effect of resistance from friction during movement, or the therapist may support the arm.⁶
2. Stabilize: Provide stabilization over the shoulder on the side being tested, simultaneously using the stabilizing hand to palpate the pectoralis major muscle.⁶
3. Palpate: Palpate the pectoralis major, as described for the previous test.

FIGURE 22-13 Shoulder horizontal adduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

4. Observe: Observe the client horizontally adducting the arm toward the opposite shoulder, in a plane parallel to the floor (Figure 22-13, C).

Substitutions: Muscles may substitute for one another. If the pectoralis major is not functioning, the other muscles will perform the motion, which will be considerably weakened.¹⁵ Contralateral trunk rotation, the coracobrachialis, or the short head of the biceps may substitute.⁶

Elbow Flexion

Muscles ^{10,12-14}	Innervation ¹²⁻¹⁴
Biceps brachii	Musculocutaneous nerve C5,6
Brachialis	
Brachioradialis	Radial nerve C5,6

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the arm adducted at the shoulder and extended at the elbow and held against the side of the trunk. The forearm is supinated to test for the biceps primarily (forearm should be positioned in pronation to test for the brachialis primarily, and in midposition to test for the brachioradialis).^{10,12,13} The therapist stands next to the client on the side being tested or directly in front of the client.
2. Stabilize: Provide stabilization at the humerus (in adduction).
3. Palpate: Palpate the biceps brachii over the muscle belly, on the middle of the anterior aspect of the humerus. Its tendon may be palpated in the middle of the antecubital space.^{6,7,10} (Brachioradialis is palpated over the upper third of the radius on the lateral aspect of the forearm, just below the elbow. The brachialis may be palpated lateral to the lower portion of the biceps brachii if the elbow is flexed and in the pronated position.¹⁵)
4. Observe: Observe the client flexing the elbow, with hand toward the face. The therapist should observe for maintenance of forearm in supination (when

testing for biceps) and for relaxed or extended wrist and fingers (Figure 22-14, A).^{6,15}

5. Resist: Provide resistance at the distal end of the volar aspect of the forearm, pulling downward toward elbow extension (Figure 22-14, B).^{7,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with the shoulder abducted to 90 degrees and externally rotated, elbow extended, and forearm supinated. The therapist stands at the head of the table on the side being tested. (The client may also be seated, with the side being tested resting on the treatment table, which is at axillary height, the humerus in 90-degree abduction, the elbow extended, and the forearm in neutral position.⁷)
2. Stabilize: Provide stabilization at the humerus. The stabilizing hand can be used simultaneously for palpation here.
3. Palpate: Palpate the biceps as described for the previous test.
4. Observe: Observe the client flexing the elbow, with the hand toward the shoulder.¹⁰ Watch for maintenance of forearm supination and relaxation of the fingers and wrist (Figure 22-14, C).¹⁵
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The brachioradialis will substitute for the biceps, but the forearm will move to midposition during flexion of the elbow. Wrist and finger flexors may assist elbow flexion, which will be preceded by finger and wrist flexion.^{10,12,13,15} The pronator teres may assist. Forearm pronation during movement may be evidence of this substitution.¹⁵

Elbow Extension

Muscles ^{6,10,12}	Innervation ^{10,12-14}
Triceps	Radial nerve, C6-8
Anconeus	Radial nerve, C7,8

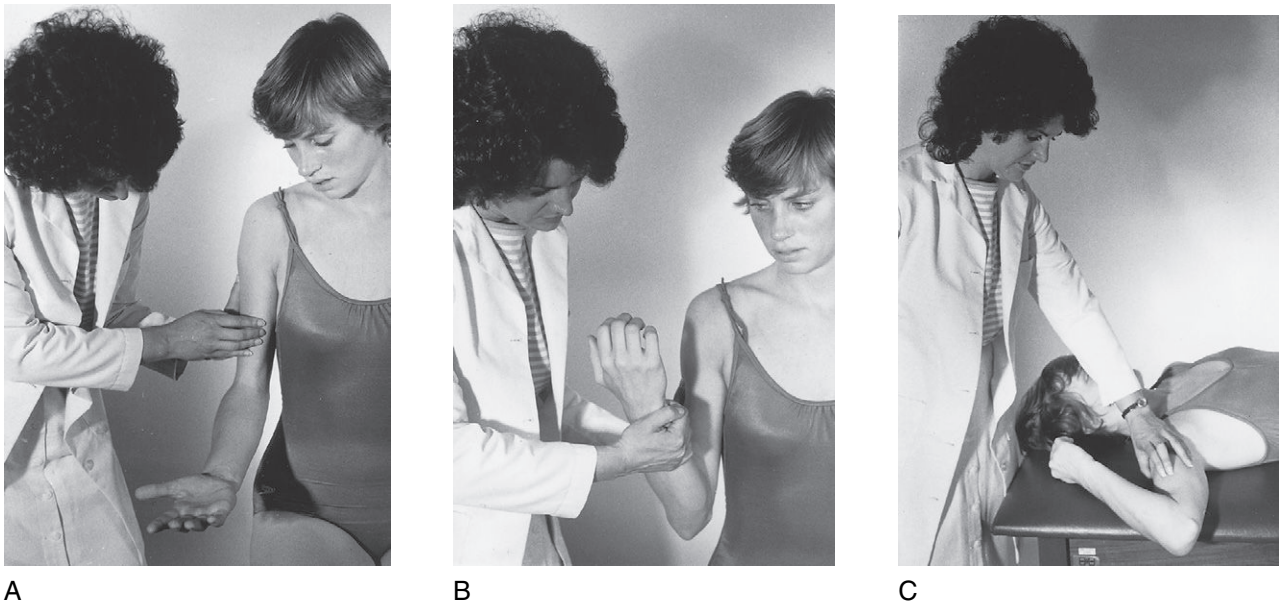

FIGURE 22-14 Elbow flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-15 Elbow extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the humerus abducted to 90 degrees, the elbow flexed to 90 degrees, and the forearm in neutral rotation and perpendicular to the floor. The therapist stands next to the client, just behind the arm to be tested.^{7,14,20}
2. Stabilize: Provide stabilization at the humerus by placing one hand for support under it, between the client's arm and the table.^{12,14}
3. Palpate: Palpate the triceps over the middle of the posterior aspect of the humerus or the triceps tendon just proximal to the olecranon process on the dorsal surface of the arm.^{6,7,10,15}
4. Observe: Observe the client extending the elbow to just less than maximal range. The wrist and fingers remain relaxed (Figure 22-15, A).
5. Resist: Provide resistance at the distal end of the forearm into elbow flexion. Before resistance is given, be sure that the elbow is not locked.

Resistance to a locked elbow can cause joint injury (Figure 22-15, B).^{6,10}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with the humerus abducted to 90 degrees and in external rotation, the elbow fully flexed, and the forearm supinated. The therapist is standing next to the client, just behind the arm to be tested.¹⁰ An alternate position is with the client seated, shoulder abducted to 90 degrees in neutral rotation, elbow flexed, and forearm in neutral position, supported by the therapist.^{7,10,12}
2. Stabilize: Provide stabilization at the humerus by holding one hand over the middle or distal end to prevent shoulder motion.
3. Palpate: Palpate the triceps as described for the previous test.
4. Observe: Observe the client extending the elbow, moving the hand away from the head (Figure 22-15, C).

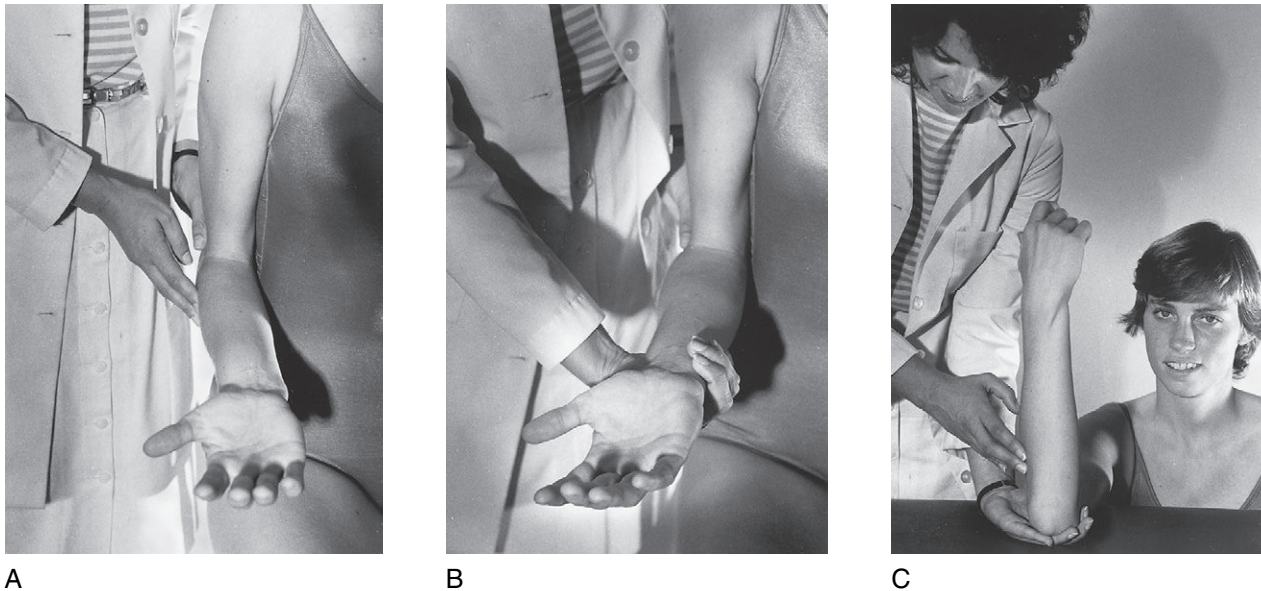

FIGURE 22-16 Forearm supination. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Finger and wrist extensors may substitute for weak elbow extensors. Observe for the presence of finger and wrist extension preceding elbow extension. When the client is upright, gravity and eccentric contraction of the biceps will effect elbow extension from the flexed position.¹⁵ Scapula depression with shoulder external rotation aided by gravity is another effective substitution pattern for elbow extension.⁶

Forearm Supination

Muscles ^{4,10,13}	Innervation ^{6,10,13}
Biceps brachii	Musculocutaneous nerve, C5,6
Supinator	Radial nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the humerus adducted, the elbow flexed to 90 degrees, and the forearm pronated. The therapist stands in front of the client or next to the client on the side to be tested.^{6,7,10,12,13}
2. Stabilize: Provide stabilization at the humerus just proximal to the elbow.^{6,10}
3. Palpate: Palpate the client over the supinator muscle on the dorsal-lateral aspect of the forearm, below the head of the radius. The muscle can be best felt when the radial muscle group (extensor carpi radialis and brachioradialis) is pushed up out of the way.⁴ The therapist may also palpate the biceps at the middle of the anterior surface of the humerus.^{6,7}
4. Observe: Observe the client supinating the forearm, turning the hand palm up. Because gravity assists

movement, after the 0-degree neutral position is passed, the therapist may apply slight resistance equal to the weight of the forearm (Figure 22-16, A).^{6,7}

5. Resist: Provide resistance by grasping around the dorsal aspect of the distal forearm with the fingers and heel of the hand, while turning the arm toward pronation (Figure 22-16, B).⁶

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, shoulder flexed to 90 degrees and the upper arm resting on the supporting surface, elbow flexed to 90 degrees; the forearm is in full pronation in a position perpendicular to the floor.^{6,7,20} The therapist stands next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the humerus just proximal to the elbow.⁶
3. Palpate: Palpate the supinator or biceps as described for the previous test.
4. Observe: Observe the client supinating the forearm, turning the palm of the hand toward the face (Figure 22-16, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: With the elbow flexed, external rotation and horizontal adduction of the humerus will effect forearm supination. With the elbow extended, shoulder external rotation will place the forearm in supination. The brachioradialis can bring the forearm from full pronation to mid-position. Wrist and thumb extensors, assisted by gravity, can initiate supination. The therapist should note any external rotation of the humerus, supination to midline only, and initiation of motion by wrist and thumb extension.^{10,13,15,20}

FIGURE 22-17 Forearm pronation. A, Palpate and observe. B, Resist. C, Gravity-minimized position.

Forearm Pronation

Muscles^{4,12,13,15}

Pronator teres

Pronator quadratus

Innervation^{12,14}

Median nerve, C6,7

Median nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated with the humerus adducted, the elbow flexed to 90 degrees, and the forearm in full supination. The therapist stands beside the client on the side to be tested.^{6,7,10,13}
2. Stabilize: Provide stabilization at the humerus just proximal to the elbow to prevent shoulder abduction.^{6,7,10,14}
3. Palpate: Palpate the pronator teres on the upper part of the volar surface of the forearm, medial to the biceps tendon and diagonally from the medial condyle of the humerus to the lateral border of the radius.^{7,10,14,15}
4. Observe: Observe the client pronating the forearm, turning the hand palm down (Figure 22-17, A).¹⁰ Slight resistance may be applied after the arm has passed midposition to compensate for the assistance of gravity after that point.⁶
5. Resist: Provide resistance by grasping over the dorsal aspect of the distal forearm, using the fingers and heel of the hand and turning toward supination (Figure 22-17, B).

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, shoulder flexed to 90 degrees, elbow flexed to 90 degrees, and the forearm in full supination. The upper arm is resting on the supporting surface, and the forearm is perpendicular

to the floor.²⁰ The therapist stands next to the client on the side to be tested.

2. Palpate: Palpate the pronator teres as described for the previous test.
3. Observe: Observe the client pronating the forearm, turning the palm of the hand away from the face (Figure 22-17, C).
4. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: With the elbow flexed, internal rotation and abduction of the humerus will produce apparent forearm pronation. With the elbow extended, internal rotation can place the forearm in a pronated position. Brachioradialis can bring the fully supinated forearm to midposition. Wrist flexion, aided by gravity, can effect pronation.^{6,7,10,12,13,15,20}

Wrist Extension With Radial Deviation

Muscles^{10,12,14}

Extensor carpi radialis longus (ECRL)

Extensor carpi radialis brevis (ECRB)

Extensor carpi ulnaris (ECU)

Innervation^{6,12}

Radial nerve, C5-7

Radial nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine with the forearm resting on the supporting surface in pronation, the wrist at neutral, and the fingers and thumb relaxed. The therapist sits opposite to or next to the client on the side to be tested.^{10,14}
2. Stabilize: Provide stabilization over the volar or dorsal aspect of the distal forearm.^{6,10,14}

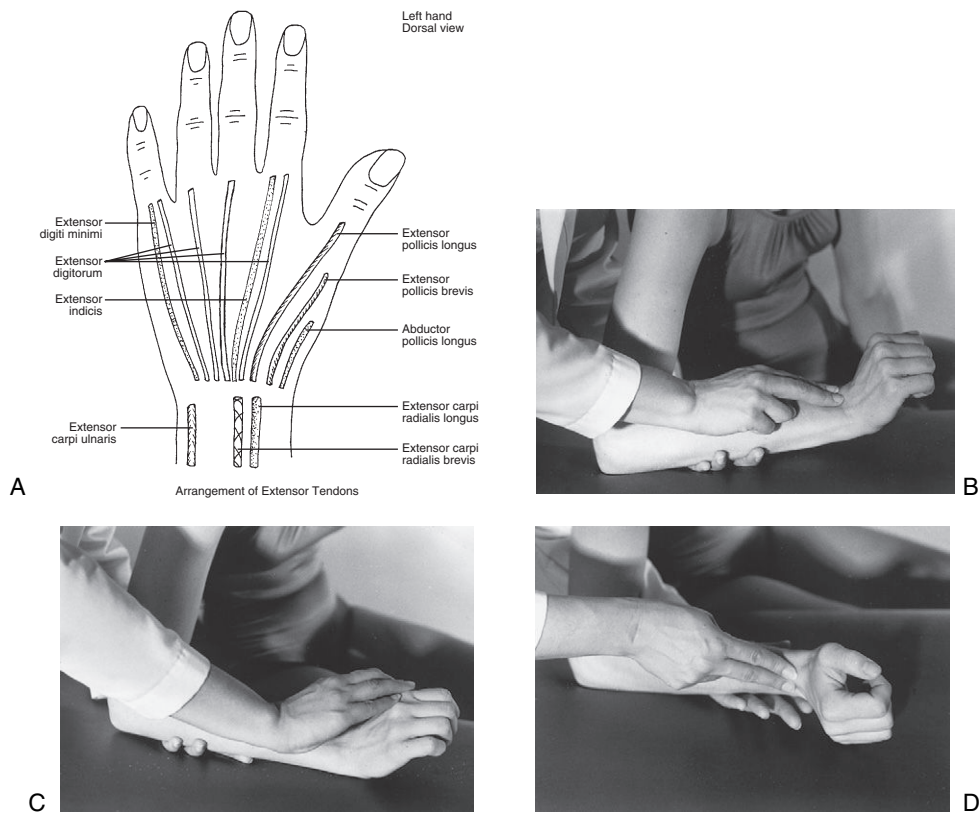

FIGURE 22-18 A, Arrangement of extensor tendons at wrist. B, Wrist extension with radial deviation. Palpate and observe. C, Resist. D, Gravity-minimized position.

3. Palpate: Palpate the ECRL and ECRB tendons on the dorsal aspect of the wrist at the bases of the second and third metacarpals, respectively.^{6,7,10} The tendon of the ECU may be palpated at the base of the fifth metacarpal, just distal to the head of the ulna (Figure 22-18, A).^{4,6,10,15}
4. Observe: Observe the client extending and radially deviating the wrist, while lifting the hand from the supporting surface and simultaneously moving it medially (to the radial side). The movement should be performed without finger extension, which could substitute for the wrist motion (Figure 22-18, B).^{6,10,15}
5. Resist: Provide resistance over the dorsum of the second and third metacarpals, toward flexion and ulnar deviation (Figure 22-18, C).^{6,10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is placed in the same manner as described for the previous test, except that the forearm is resting in midposition on its ulnar border.^{10,20}
2. Stabilize: Provide stabilization at the ulnar border of the forearm, supported slightly above the table surface.¹⁰
3. Palpate: Palpate radial wrist extensors as described for the previous test.

4. Observe: Observe client extending the wrist, moving the hand away from the body (Figure 22-18, D).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Wrist extensors can substitute for one another. In the absence of the extensor carpi radialis muscles, the extensor carpi ulnaris will extend the wrist, but in an ulnar direction. Combined extension and radial deviation will not be possible. The extensor digitorum communis muscle and the extensor pollicis longus can initiate wrist extension, but finger or thumb extension will precede wrist extension.^{6,7,12,13,15,20}

Wrist Extension With Ulnar Deviation

Muscles ^{10,12-14}	Innervation ^{10,14}
Extensor carpi ulnaris (ECU)	Radial nerve, C6-8
Extensor carpi radialis brevis (ECRB)	
Extensor carpi radialis longus (ECRL)	Radial nerve, C5-7

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, forearm pronated, wrist neutral, fingers and thumb relaxed, supported on a table. The therapist sits opposite or next to the client on the side to be tested.

FIGURE 22-19 Wrist extension with ulnar deviation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

2. Stabilize: Provide stabilization under the distal forearm.^{10,12-14}
3. Palpate: Palpate the ECU tendon at the base of the fifth metacarpal, just distal to the ulnar styloid,⁶ and the ECRL and ECRB tendons at the bases of the second and third metacarpals.
4. Observe: Observe the client extending the wrist and simultaneously moving it laterally (to the ulnar side). The therapist should observe that movement is not preceded by thumb or finger extension (Figure 22-19, A).^{6,10,12,13,15}
5. Resist: Provide resistance over the dorsal-lateral aspect of the fourth and fifth metacarpals toward flexion and radial deviation (Figure 22-19, B).^{6,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is placed in the same manner as that described for the previous test, except that the forearm is in 45 degrees of pronation and is supported on a table. The wrist is flexed and radially deviated, and the thumb and fingers are flexed.⁶
2. Stabilize: Provide stabilization under the distal forearm, supporting it slightly above the supporting surface.^{10,14}
3. Palpate: Palpate the extensor tendons as described previously.
4. Observe: Observe client extending the wrist and moving it ulnarly at the same time (Figure 22-19, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: In the absence of the ECU muscle, the ECRL and ECRB muscles can extend the wrist but will do so in a radial direction. The ulnar deviation component of the test motion will not be possible. Long finger and thumb extensors can initiate wrist extension, but the movement will be preceded by finger or thumb extension.^{6,7,12,13,15,20}

Wrist Flexion With Radial Deviation

Muscles ^{12,14}	Innervation ^{5,6,10}
Flexor carpi radialis (FCR)	Median nerve, C6-8
Flexor carpi ulnaris (FCU)	Ulnar nerve, C7-T1
Palmaris longus	Median nerve, C7-T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, with the forearm resting in nearly full supination on the supporting surface, fingers and thumb relaxed.^{7,12,15} The therapist is seated next to the client on the side to be tested.
2. Stabilize: Provide stabilization over the volar aspect of the midforearm.^{6,10,14}
3. Palpate: The FCR tendon can be palpated over the wrist at the base of the second metacarpal bone. The palmaris longus tendon is at the center of the wrist at the base of the third metacarpal, and the FCU tendon can be palpated at the ulnar side of the volar aspect of the wrist, at the base of the fifth metacarpal (Figure 22-20, A).⁴
4. Observe: Observe the client simultaneously flexing and radially deviating the hand. The therapist should observe that the fingers remain relaxed during the movement⁶ (Figure 22-20, B).
5. Resist: Provide resistance in the palm at the radial side of the hand, over the second and third metacarpals toward extension and ulnar deviation (Figure 22-20, C).⁶

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated with the forearm in midposition and the ulnar border of the hand resting on the supporting surface.^{10,20} The therapist sits next to the client on the side to be tested.
2. Stabilize: Provide stabilization under the ulnar border of the forearm, supporting the wrist slightly above the supporting surface.
3. Palpate: Palpate the wrist flexor tendons as described for the previous test.
4. Observe: Observe the client flexing and radially deviating the wrist. Movement should not be initiated with finger flexion (Figure 22-20, D).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Wrist flexors can substitute for one another. If the flexor carpi radialis is weak or nonfunctioning in this test, the flexor carpi ulnaris will produce wrist

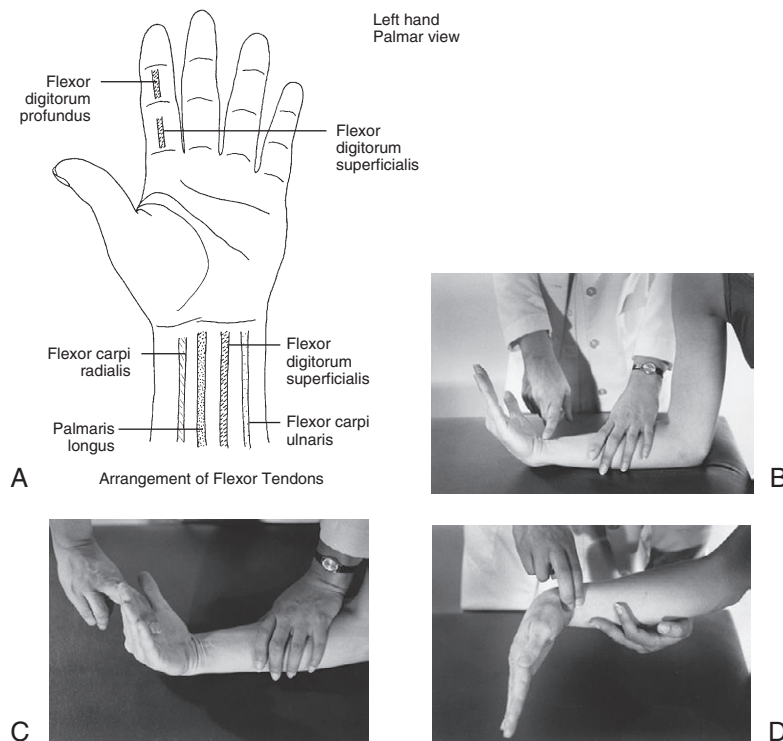

FIGURE 22-20 A, Arrangement of flexor tendons at wrist. B, Wrist flexion with radial deviation. Palpate and observe. C, Resist. D, Gravity-minimized position.

flexion, but in an ulnar direction, and radial deviation will not be possible. The finger flexors can assist wrist flexion, but finger flexion will occur before the wrist is flexed. The abductor pollicis longus, with the assistance of gravity, can initiate wrist flexion.^{6,7,15}

Wrist Flexion With Ulnar Deviation

Muscles ^{10,13}	Innervation ^{5,10,13}
Flexor carpi ulnaris (FCU)	Ulnar nerve, C7-T1
Palmaris longus	Median nerve, C7-T1
Flexor carpi radialis (FCR)	Median nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, with the forearm resting in nearly full supination on the supporting surface, fingers and thumb relaxed. The therapist is seated opposite or next to the client on the side to be tested.^{10,14}
2. Stabilize: Provide stabilization over the volar aspect of the middle of the forearm.^{10,14}
3. Palpate: Palpate the flexor tendons on the volar aspect of the wrist, the FCU at the base of the fifth metacarpal, the FCR at the base of the second metacarpal, and the palmaris longus at the base of the third metacarpal.⁴
4. Observe: Observe the client simultaneously flexing the wrist and deviating it ulnarly (Figure 22-21, A).

5. Resist: Provide resistance in the palm of the hand over the hypothenar eminence toward extension and radial deviation (Figure 22-21, B).^{6,7,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with the forearm in neutral rotation and resting in 45 degrees of supination on the ulnar border of the arm and hand.¹⁰ The therapist sits opposite or next to the client on the side being tested.
2. Stabilize: The client's arm can be supported slightly above the supporting surface and stabilized at the dorsal-medial aspect of the forearm to prevent elbow and forearm motion.
3. Palpate: Palpate the wrist flexor tendons as described for the previous test.
4. Observe: Observe the client simultaneously flexing and deviating the wrist toward ulnar side (Figure 22-21, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Wrist flexors can substitute for one another. If the FCU is weak or absent, the FCR can produce wrist flexion in a radial direction, and the ulnar deviation will not be possible. The finger flexors can also assist wrist flexion, but the motion will be preceded by flexion of the fingers.^{6,15,20}

FIGURE 22-21 Wrist flexion with ulnar deviation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-22 Metacarpophalangeal flexion with interphalangeal extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Metacarpophalangeal Flexion With Interphalangeal Extension

Muscles^{1,4}

Lumbricals 1 and 2

Lumbricals 3 and 4

Dorsal interossei

Palmar interossei

Innervation^{10,12}

Median nerve, C8,T1

Ulnar nerve, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with forearm in supination, wrist at neutral, resting on the supporting surface.⁸ The metacarpophalangeal (MP) joints are extended, and the interphalangeal (IP) joints are flexed.^{12,20} The therapist sits next to the client on the side being tested.
2. Stabilize: Provide stabilization over the metacarpals, proximal to the MP joints in the palm of the hand to prevent wrist motion.
3. Palpate: Palpate the first dorsal interosseous muscle just medial to the distal aspect of the second metacarpal on the dorsum of the hand. The remainder of these muscles are not easily palpable because of their size and deep location in the hand.^{15,20}
4. Observe: Observe the client flexing the MP joints and extending the IP joints simultaneously (Figure 22-22, A).^{12,14}

5. Resist: Provide resistance to each finger separately by grasping the distal phalanx and pushing downward on the finger into the supporting surface toward MP extension and IP flexion, or apply pressure first against the dorsal surface of the middle and distal phalanges toward flexion, followed by application of pressure to the volar surface of the proximal phalanges toward extension (Figure 22-22, B).¹⁴

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated or supine, with the forearm and wrist in midposition and resting on the ulnar border on the supporting surface. MP joints are extended, and IP joints are flexed.^{10,13} The therapist sits next to the client on the side being tested.
2. Stabilize: Provide stabilization at the wrist and palm of the hand.
3. Palpate: Palpate the client as described for the previous test.
4. Observe: Observe the client flexing the MP joints and extending the IP joints simultaneously (Figure 22-22, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Flexor digitorum profundus and superficialis may substitute for weak or absent lumbricals.¹² In this

FIGURE 22-23 Metacarpophalangeal extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

case, MP flexion will be preceded by flexion of the distal and proximal IP joints.^{15,20}

Metacarpophalangeal Extension

Muscles ^{10,13}	Innervation ^{10,13}
Extensor digitorum communis (EDC)	Radial nerve, C7,8
Extensor indicis	
Extensor digiti minimi (EDM)	

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the forearm pronated and the wrist in the neutral position, MP and IP joints relaxed in partial flexion.^{7,10,12} The therapist sits opposite or next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the wrist and metacarpals slightly above the supporting surface.^{10,12-14}
3. Palpate: Palpate the EDC tendons where they course over the dorsum of the hand.^{6,7,10} In some individuals, the EDM tendon can be palpated or visualized just lateral to the EDC tendon to the fifth finger. The extensor indicis tendon can be palpated or visualized just medial to the EDC tendon to the first finger.⁶
4. Observe: Observe the client extending the MP joints but maintaining the IP joints in some flexion (Figure 22-23, A).^{6,12}
5. Resist: Provide resistance to each finger individually on the dorsum of the proximal phalanx toward MP flexion (Figure 22-23, B).^{6,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The patient should be placed in a position similar to that described for the previous test, except that the client's forearm is in midposition and the hand and forearm are supported on the ulnar border.^{10,12}
2. Stabilize: Provide stabilization in the same manner as described for the previous test.
3. Palpate: Palpate the patient in the same manner as described for the previous test.

4. Observe: Observe the client extending the MP joints while keeping the IP joints somewhat flexed (Figure 22-23, C).
5. Grade: The patient is graded according to standard definitions of muscle grades.

Substitutions: With the wrist stabilized, no substitutions are possible. When the wrist is not stabilized, wrist flexion with tendon action can produce MP extension.^{6,7,10,13,15,20}

Proximal Interphalangeal Flexion, Second Through Fifth Fingers

Muscles ^{10,14}	Innervation ^{6,10,12}
Flexor digitorum superficialis	Median nerve, C7,8,T1 (FDS)

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the forearm supinated, wrist at neutral, fingers extended, and hand and forearm resting on the dorsal surface.^{6,10,12} The therapist sits opposite or next to the client on the side being tested.
2. Stabilize: Provide stabilization at the MP joint and the proximal phalanx of the finger being tested (Figure 22-24, A).^{6,7,14} If it is difficult for the client to isolate PIP flexion, hold all of the fingers not being tested in MP hyperextension and PIP extension. This maneuver inactivates the flexor digitorum profundus so that the client cannot flex the distal joint (Figure 22-24, B).^{4,6,12,20} Most individuals cannot perform isolated action of the PIP joint of the fifth finger, even with this assistance.¹⁵
3. Palpate: Palpate the FDS tendon on the volar surface of the proximal phalanx.⁶ A stabilizing finger may be used to palpate in this instance.¹⁵ The tendon supplying the fourth finger may be palpated over the volar aspect of the wrist between the flexor carpi ulnaris and the palmaris longus tendons, if desired.^{4,6}
4. Observe: Observe the client flexing the PIP joint while maintaining DIP extension (Figure 22-24, A).
5. Resist: Provide resistance with one finger at the volar aspect of the middle phalanx toward extension.^{6,10,14}

FIGURE 22-24 Proximal interphalangeal flexion. **A**, Palpate and observe. **B**, Position to assist with isolation of proximal interphalangeal joint flexion. **C**, Resist. Therapist checks for substitution by flexor digitorum profundus. **D**, Gravity-minimized position.

If the therapist uses the index finger to apply resistance, the middle finger may be used to move the DIP joint to and fro to verify that the flexor digitorum profundus (FDP) is not substituting (Figure 22-24, C).

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with the forearm in midposition and the wrist at neutral, resting on the ulnar border.^{12,20} The therapist sits opposite or next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the MP joint and proximal phalanx of the finger.^{10,14} If stabilization during the motion is difficult in this position, the forearm may be returned to full supination because the effect of gravity on the fingers is not significant.
3. Palpate and observe: The therapist palpates and observes the client in the same manner as described for the previous test, except that movement is performed in the gravity-minimized position (Figure 22-24, D).
4. Grade: The client is graded according to standard definitions of muscle grades. If the test for grades poor and below is done with the forearm in full supination, partial ROM against gravity may be graded poor.¹⁰

Substitutions: The FDP may substitute for the FDS. DIP flexion will precede PIP flexion.^{7,12,13,15,17,20} Tendon action of the long finger flexors accompanies wrist extension and can produce apparent flexion of the fingers through partial ROM.^{10,13,20}

Distal Interphalangeal Flexion, Second Through Fifth Fingers

Muscles ^{10,13}	Innervation ^{10,13}
Flexor digitorum profundus	Median and ulnar nerves (FDP) C8, T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the forearm supinated, the wrist at neutral, and the fingers extended.¹⁰ The therapist sits opposite or next to the client on the side being tested.¹²
2. Stabilize: Provide stabilization at the wrist in neutral and the PIP joint and middle phalanx of the finger being tested.^{6,20}
3. Palpate: Use the finger stabilizing the middle phalanx to simultaneously palpate the FDP tendon over the volar surface of the middle phalanx.^{6,10,15}
4. Observe: Observe the client flexing the DIP joint (Figure 22-25, A).
5. Resist: Provide resistance with one finger at the volar aspect of the distal phalanx toward extension (Figure 22-25, B).^{6,7,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is seated, with the forearm in midposition and with the wrist at neutral, resting on the ulnar border.^{12,20} The client may be positioned with the forearm supinated, if necessary.
2. Stabilize: The client is stabilized in the same manner as described for the previous test.
3. Palpate: The client is palpated in the same manner as described for the previous test.

FIGURE 22-25 Distal interphalangeal flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-26 Finger abduction. **A**, Palpate and observe. **B**, Resist.

4. Observe: Observe the client flexing the DIP joint (Figure 22-25, C).
5. Grade: The client is graded according to standard definitions of muscle grades, except that if the test for grades poor and below was done with the forearm in full supination, movement through partial ROM may be graded poor.¹⁰

Substitutions: None possible during the testing procedure if the wrist is well stabilized because the FDP is the only muscle that can act to flex the DIP joint when it is isolated. During normal hand function, however, wrist extension with tendon action of the finger flexors can produce partial flexion of the DIP joints.^{10,15,20}

Finger Abduction

Muscles^{10,12}

Dorsal interossei

Abductor digiti minimi

Innervation^{10,12}

Ulnar nerve, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, with the forearm pronated, wrist at neutral, and fingers extended and adducted. The therapist is seated opposite or next to the client on the side to be tested.^{10,13}
2. Stabilize: Provide stabilization at the wrist and metacarpals slightly above the supporting surface.
3. Palpate: Palpate the first dorsal interosseous muscle on the radial side of the second metacarpal or of the abductor digiti minimi on the ulnar border of the fifth metacarpal. The remaining interossei are not palpable.^{6,7,10}
4. Observe: Observe the client spreading the fingers, with abduction of the little finger, the ring finger toward the little finger, the middle finger toward the ring finger, and the index finger toward the thumb (Figure 22-26, A).¹²
5. Resist: Provide the first dorsal interosseous by applying pressure on the radial side of the proximal phalanx of the second finger in an ulnar direction (Figure 22-26, B); the second dorsal interosseous on the radial side of the proximal phalanx of the middle finger in an ulnar direction; the third dorsal interosseous on the ulnar side of the proximal phalanx of the middle finger in a radial direction; the fourth dorsal interosseous on the ulnar side of the proximal phalanx of the ring finger in a radial direction; and the abductor digiti minimi on the ulnar side of the proximal phalanx of the little finger in a radial direction.^{6,14} An alternative mode of resistance is to

FIGURE 22-27 Finger adduction. **A**, Therapist observes movement of fingers into adduction. Palpation of these muscles is not possible. **B**, Resist.

flick each finger toward adduction. If the finger rebounds, the grade is N (5).¹²

Procedure for Testing Grades P (2), T (1), and 0

Tests for these muscle grades are the same as described for the previous test.

1. Grade: Because the test motions were not performed against gravity, the therapist must exercise professional judgment when grading. For example, partial ROM in the gravity-minimized position may be graded poor and full ROM graded fair.^{10,13}

Substitutions: EDC can assist weak or absent dorsal interossei, but abduction will be accompanied by MP extension.^{6,15,20}

Finger Adduction

Muscles¹⁰⁻¹⁴ Palmar interossei, 1, 2, 3
 Innervation^{10,13} Ulnar nerve, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with forearm pronated, wrist in neutral, and fingers extended and abducted.^{10,13}
2. Stabilize: Provide stabilization at the wrist and metacarpals slightly above the supporting surface.⁶
3. Palpate: The condition is not palpable.⁶ The muscle cannot be palpated.
4. Observe: Observe the client adducting the first, fourth, and fifth fingers toward the middle finger (Figure 22-27, A).
5. Resist: Provide resistance at the index finger at the proximal phalanx by pulling it in a radial direction, with the ring finger at the proximal phalanx in an ulnar direction, and the little finger likewise (Figure 22-27, B).^{6,14} These muscles are very small, and resistance must be modified to accommodate their comparatively limited power. Fingers can be grasped at the distal phalanx and flicked in the direction of abduction. If the finger snaps back to the adducted position, the grade is N (5).¹²

Procedure for Testing Grades P (2), T (1), and 0

The test for these muscle grades is the same as described for the previous test. The therapist’s judgment must be used in determining the degree of weakness. Achievement of full ROM may be graded fair and partial ROM graded poor.^{10,12}

Substitutions: FDP and FDS can substitute for weak palmar interossei, but IP flexion will occur with finger adduction.^{13,15,20}

Thumb Metacarpophalangeal Extension

Muscles^{10,12-14} Extensor pollicis brevis (EPB)
 Innervation^{10,12-14} Radial nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, forearm in midposition, wrist at neutral, and hand and forearm resting on the ulnar border.^{6,10,13} The thumb is flexed into the palm at the MP joint, and the IP joint is extended but relaxed. The therapist sits opposite or next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the wrist and the thumb metacarpal.⁶
3. Palpate: Palpate the EPB tendon on the dorsoradial aspect of the base of the first metacarpal. It lies just medial to the abductor pollicis longus tendon on the radial side of the anatomical snuffbox, which is the hollow space created between the EPL and EPB tendons when the thumb is fully extended and radially abducted.^{4,6,7}
4. Observe: Observe the client extending the MP joint. The IP joint remains relaxed (Figure 22-28, A). It is difficult for many individuals to isolate this motion.
5. Resist: Provide resistance on the dorsal surface of the proximal phalanx toward MP flexion (Figure 22-28, B).^{6,10,12-14}

Procedure for Testing Grades (P), (T), and (0)

1. Position and stabilize: Positioning and stabilizing are the same as described for the previous test, except that the forearm is fully pronated and resting on the

FIGURE 22-28 Thumb metacarpophalangeal extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-29 Thumb interphalangeal extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

volar surface.²⁰ The therapist may stabilize the first metacarpal, holding the hand slightly above the supporting surface. The test may also be performed in the same manner as for grades normal to fair, with modified grading.¹⁰

2. Palpate and observe: The client is palpated and observed in the same way as described for the previous test. MP extension is performed in a plane parallel to the supporting surface (Figure 22-28, C).
3. Grade: The client is graded according to standard definitions of muscle grades. If midposition of the forearm was used, partial ROM is graded poor and full ROM is graded fair.^{10,12}

Substitutions: Extensor pollicis longus may substitute for extensor pollicis brevis. IP extension will precede MP extension.^{6,7,13,15,20}

Thumb Interphalangeal Extension

Muscles^{10,12-14}

Extensor pollicis longus (EPL)

Innervation^{10,12-14}

Radial nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, forearm in midposition, wrist at neutral, and hand and forearm resting on the ulnar border.^{6,10,13} The thumb is adducted, the MP joint is extended or slightly flexed, and the IP is flexed.⁶ The therapist sits opposite or next to the client on the side being tested.

2. Stabilize: Provide stabilization at the wrist in neutral position, the first metacarpal, and the proximal phalanx of the thumb.⁶
3. Palpate: Palpate the EPL tendon on the dorsal surface of the hand medial to the EPB tendon, between the head of the first metacarpal and the base of the second on the ulnar side of the anatomical snuffbox.^{4,6,10}
4. Observe: C extends the IP joint (Figure 22-29, A).
5. Resist: Provide resistance on the dorsal surface of the distal phalanx, down toward IP flexion (Figure 22-29, B).^{6,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position and stabilize: Positioning and stabilizing are the same as described for the previous test, except that the forearm is fully pronated.²⁰ The therapist may stabilize so that the client's hand is held slightly above the supporting surface. The test may also be performed in the same position as for grades normal to fair with modification in grading.
2. Palpate and observe: The patient is palpated and observed in the same manner as described for the previous test. IP extension is performed in the plane of the palm, parallel to the supporting surface (Figure 22-29, C).
3. Grade: The client is graded according to standard definitions of muscle grades. If the test was performed

FIGURE 22-30 Thumb metacarpophalangeal flexion. **A**, Palpate and observe. **B**, Resist.

with the forearm in midposition, partial ROM is graded P (2).¹⁰

Substitutions: A quick contraction of the flexor pollicis longus followed by rapid release will cause the IP joint to rebound into extension.⁶ IP flexion will precede IP extension.^{7,15} The abductor pollicis brevis, the flexor pollicis brevis, the oblique fibers of the adductor pollicis, and the first palmar interosseous can extend the IP joint because of their insertions into the extensor expansion of the thumb.^{14,20}

Thumb Metacarpophalangeal Flexion

Muscles^{10,12-14} Flexor pollicis brevis (FPB)
 Innervation^{10,12-14} Median and ulnar nerves, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, the forearm supinated, the wrist in neutral position, and the thumb in extension and adduction.^{6,12} The therapist is seated next to or opposite the client.^{7,10,14}
2. Stabilize: Provide stabilization at the first metacarpal and the wrist.¹²
3. Palpate: Palpate the client over the middle of the palmar surface of the thenar eminence just medial to the abductor pollicis brevis muscle.^{6,10} The hand that is used to stabilize may also be used for palpation.
4. Observe: Observe the client flexing the MP joint while maintaining extension of the IP joint (Figure 22-30, A).⁶ It may not be possible for some individuals to isolate flexion to the MP joint. In this instance, both MP and IP flexion may be tested together as a gross test for thumb flexion strength and graded according to the therapist's judgment.
5. Resist: Provide resistance on the palmar surface of the first phalanx toward MP extension (Figure 22-30, B).^{6,7,10,14}

Procedure for Testing Grades P (2), T (1), and (0)

Positioning, stabilizing, and palpating are the same as described for the previous test.

1. Observe: Observe the client flexing the MP joint so that the thumb moves over the palm of the hand.

2. Grade: Full ROM is graded fair; partial ROM is graded poor.^{10,13}

Substitutions: FPL can substitute for FPB. In this case, isolated MP flexion will not be possible and MP flexion will be preceded by IP flexion.^{7,12,13,15,20}

Thumb Interphalangeal Flexion

Muscles^{6,10,12} Flexor pollicis longus (FPL)
 Innervation^{10,13} Median nerve, C7-T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the forearm fully supinated, wrist in neutral position, and thumb extended and adducted.^{10,13} The therapist is seated next to or opposite the client.
2. Stabilize: Provide stabilization at the wrist, thumb metacarpal, and proximal phalanx of the thumb in extension.^{6,7,10,14}
3. Palpate: Palpate the FPL tendon on the palmar surface of the proximal phalanx.⁶ In this instance, the palpating finger may be the same one used for stabilizing the proximal phalanx.
4. Observe: Observe the client flexing the IP joint in the plane of the palm (Figure 22-31, A).^{10,12}
5. Resist: Provide resistance on the palmar surface of the distal phalanx, toward IP extension (Figure 22-31, B).^{6,10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

The test for these muscle grades is the same as that described for the previous test. The judgment of the occupational therapist must be used in determining the degree of weakness. Achievement of full ROM may be graded fair and partial ROM graded poor.^{10,13}

Substitutions: Quick contraction and release of the EPL may cause an apparent flexion of the IP joint. The therapist should observe for IP extension preceding IP flexion.^{6,7,12,13,15,20}

Thumb Palmar Abduction

Muscles^{13,14} Abductor pollicis brevis (APB)
 Innervation^{13,14} Median nerve, C8,T1

FIGURE 22-31 Thumb interphalangeal flexion. **A**, Palpate and observe. **B**, Resist.

FIGURE 22-32 Thumb palmar abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Procedure for Testing Grades Fair (F) to Normal (N)

1. Position: The client is seated or supine, forearm in supination, wrist at neutral, thumb relaxed in adduction against the volar aspect of the index finger. The OT sits opposite or next to the client on the side to be tested.^{6,7,10,12-14}
2. Stabilize: Provide stabilization at the metacarpals and wrist.
3. Palpate: Palpate the APB muscle on the lateral aspect of the thenar eminence, lateral to the flexor pollicis brevis muscle.¹⁰
4. Observe: Observe the client raising the thumb away from the palm in a plane perpendicular to the palm (Figure 22-32, A).^{6,14}
5. Resist: Provide resistance at the lateral aspect of the proximal phalanx, downward toward adduction (Figure 22-32, B).^{6,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is positioned in the same manner as described for the previous test, except that the forearm and hand are supported on the ulnar border.^{12,20}
2. Stabilize: Provide stabilization at the wrist and metacarpals.
3. Palpate: Palpate the APB muscle on the lateral aspect of the thenar eminence.
4. Observe: Observe the client moving the thumb away from the palm in a plane at right angles to the palm

of the hand and parallel to the supporting surface (Figure 22-32, C).

5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: APL can substitute for APB. Abduction will take place more in the plane of the palm, however, rather than perpendicular to it.^{13,15,20}

Thumb Radial Abduction

Muscles^{12,14}

Abductor pollicis longus (APL)

Innervation^{12,14}

Radial nerve, C6-8

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, forearm in neutral rotation, wrist at neutral, thumb adducted and slightly flexed across the palm. Hand and forearm are resting on the ulnar border.¹⁴ The therapist sits opposite or next to the client on the side being tested.
2. Stabilize: Provide stabilization at the wrist and metacarpals of the fingers.^{10,14}
3. Palpate: Palpate the APL tendon on the lateral aspect of the base of the first metacarpal. It is the tendon immediately lateral (radial) to the EPB tendon.^{4,6,10}
4. Observe: Observe the client moving the thumb out of the palm of the hand, abducting away from the index finger at an angle of about 45 degrees (Figure 22-33, A).⁶

FIGURE 22-33 Radial abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-34 Thumb adduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

5. Resist: Provide resistance at the lateral aspect of the thumb metacarpal toward adduction (Figure 22-33, B).^{6,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is positioned in the same manner as described for the previous test, except that the forearm is in supination.¹⁰
2. Stabilize: Provide stabilization at the wrist and palm of the hand.
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client moving the thumb out away from the palm of the hand in the plane of the palm (Figure 22-33, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: APB can substitute for APL. Abduction will not take place in the plane of the palm but rather in a more ulnar direction.^{15,20} EPB can substitute for APL. The

movement will be more toward the dorsal surface of the forearm.¹²

Thumb Adduction

Muscles^{10,12-14} Adductor pollicis (AP)
 Innervation^{10,12-14} Ulnar nerve, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, forearm pronated, wrist at neutral, thumb relaxed and in palmar abduction.^{10,13,20} The therapist is sitting opposite or next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the wrist and metacarpals by grasping the hand around the ulnar side and supporting it slightly above the resting surface.^{10,13}
3. Palpate: Palpate the AP on the palmar side of the thumb web space.^{6,15}
4. Observe: Observe the client adducting the thumb to touch the palm (Figure 22-34, A).^{10,12} (The palm is

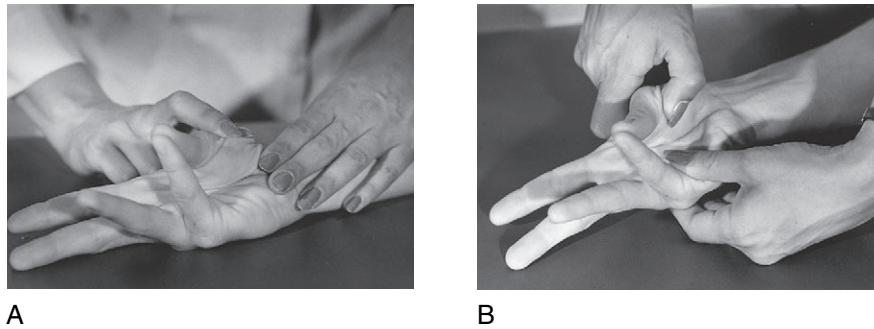

FIGURE 22-35 Thumb opposition. **A**, Palpate and observe. **B**, Resist.

turned upward in the illustration to show the palpation point.)

5. Resist: Provide resistance by grasping the proximal phalanx of the thumb near the metacarpal head and pulling downward, toward abduction (Figure 22-34, B).¹⁰

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is positioned in the same manner as described for the previous test, except that the forearm is in midposition and the forearm and hand are resting on the ulnar border.²⁰
2. Stabilize: Provide stabilization over the wrist and palm of the hand.
3. Palpate: Palpate the client in the same manner as described for the previous test.
4. Observe: Observe the client adducting the thumb to touch the radial side of the palm of the hand or the second metacarpal (Figure 22-34, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: FPL or EPL may assist weak or absent AP. If one substitutes, adduction will be accompanied by thumb flexion or extension preceding adduction.^{13,15,20}

Opposition of the Thumb to the Fifth Finger

Muscles ^{10,13}	Innervation ^{10,13}
Opponens pollicis	Median nerve, C8,T1
Opponens digiti minimi	Ulnar nerve, C8,T1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated or supine, with forearm supinated, wrist at neutral, thumb in palmar abduction, and fifth finger extended.^{6,7,10,14} The therapist sits opposite or next to the client on the side to be tested.
2. Stabilize: Provide stabilization at the forearm and wrist.
3. Palpate: Palpate the opponens pollicis along the radial side of the shaft of the first metacarpal, lateral to the APB; the opponens digiti minimi on the shaft of the fifth metacarpal.^{6,10,15}

4. Observe: Observe the client opposing the thumb to touch the thumb pad to the pad of the fifth finger, which flexes and rotates toward the thumb (Figure 22-35, A).^{6,7}
5. Resist: Provide resistance at the distal ends of the first and fifth metacarpals toward derotation of these bones and flattening of the palm of the hand (Figure 22-35, B).^{10,12}

Procedure for Testing Grades P (2), T (1), and 0

The procedure described for the previous test may be used for these grades, if grading is modified to compensate for movement of the parts against gravity. For example, movement through full ROM would be graded fair and through partial ROM would be graded poor.^{10,12}

Substitutions: APB will assist with opposition by flexing and medially rotating the CMC joint, but the IP joint will extend. The FPB will flex and medially rotate the CMC joint, but the thumb will not move away from the palm of the hand. The FPL will flex and slightly rotate the CMC joint, but the thumb will not move away from the palm, and the IP joint will flex strongly.^{15,20} The DIP joints of the thumb and little finger may flex to meet, giving the appearance of full opposition.^{7,12}

Manual Muscle Testing of the Lower Extremity

Hip Flexion

Muscles ^{4,7,10}	Innervation ^{4,6,10}
Psoas major	Lumbar plexus, L1-3
Iliacus	Femoral nerve, L2,3
Rectus femoris	Femoral nerve, L2-4
Tensor fasciae latae	Superior gluteal nerve, L4,5,S1
Sartorius	Femoral nerve, L2-S1
Pectineus	Femoral nerve, L2,3

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with knees flexed over the edge of the table and feet above the floor.¹² The therapist stands next to the client on the side being tested.⁷

FIGURE 22-36 Hip flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

2. Stabilize: Provide stabilization at the pelvis at the iliac crest on the side being tested. The client may grasp the edge of the table or fold arms across chest.^{6,7,10,12-14}
3. Palpate: The psoas and iliacus are difficult to palpate.⁶ The rectus femoris may be palpated on the middle anterior aspect of the thigh, just lateral to the sartorius muscle.^{4,15}
4. Observe: Observe the client flexing the hip so that the femur rises above the table surface (Figure 22-36, A).
5. Resist: Provide resistance just proximal to the knee on the anterior surface of the thigh, down toward the table into hip extension (Figure 22-36, B).^{6,7,10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client assumes a side-lying position. The therapist stands behind the client, supporting the upper leg in neutral rotation and slight abduction, with the knee extended.^{10,12,13} The lower leg (to be tested) is extended at the hip and knee.
2. Stabilize: The weight of the trunk may provide adequate stabilization, or the therapist may stabilize the pelvis.¹⁰
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client bringing the lower leg up toward the trunk, flexing the hip and knee (Figure 22-36, C).¹⁰
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Observe for internal rotation, external rotation, and abduction accompanying flexion as signs of substitution or muscle imbalance in this muscle group.^{6,7,13,14} The hip flexors can substitute for one another. If the iliacus and psoas major muscles are weak or absent, hip flexion will be accompanied by other movements: abduction and external rotation (sartorius), abduction and internal rotation (tensor fasciae latae), and adduction (pectineus).^{10,12,13} If the anterior abdominal muscles do not stabilize the pelvis, it will flex on the thighs; the hip flexors may hold against resistance but not at maximal ROM.¹⁴

Hip Extension

Muscles ^{6,12,14}	Innervation ^{10,13}
Gluteus maximus	Inferior gluteal nerve, L5-S2
Semitendinosus	Sciatic nerve, L5-S2
Semimembranosus	
Biceps femoris (long head)	Sciatic nerve, L5-S3

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the hip at neutral and the knee flexed to about 90 degrees. This position is used to isolate the gluteus maximus.^{6,12} The client may also be prone with the knee extended.¹² The therapist stands next to the client on the opposite side.¹⁴ Two pillows may be placed under the pelvis to flex the hips.^{6,7}
2. Stabilize: Provide stabilization over the iliac crest on the side being tested.^{10,12}
3. Palpate: Palpate the gluteus maximus on the middle posterior surface of the buttock.¹⁵
4. Observe: Observe the client extending the hip while keeping the knee flexed to minimize action of the hamstring muscles on the hip joint (Figure 22-37, A).
5. Resist: Provide resistance at the distal end of the posterior aspect of the thigh, downward, toward flexion (Figure 22-37, B).^{10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client assumes a side-lying position. The therapist stands in front of the client, supporting the upper leg in extension and slight abduction.¹⁰ The lower leg (to be tested) is flexed at the hip and knee.
2. Stabilize: Provide stabilization at the pelvis over the iliac crest.¹⁰
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client extending the hip, bringing the lower leg backward, while maintaining flexion of the knee (Figure 22-37, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

FIGURE 22-37 Hip extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-38 Hip abduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Substitutions: Elevation of the pelvis and extension of the lumbar spine can produce some hip extension. In the supine position, gravity and eccentric contraction of the hip flexors can return the flexed hip to extension.¹⁵ Hip external rotation, abduction, or adduction may be used to substitute.⁷

Hip Abduction

Muscles^{6,10,12}

Gluteus medius
Gluteus minimus

Innervation^{10,12-14}

Superior gluteal nerve, L4-S1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client assumes a side-lying position, with the upper leg (to be tested) with the knee extended and hip extended slightly beyond the neutral position and slight forward rotation of the pelvis¹²; the lower leg is flexed at the hip and knee to provide a wide base of support.⁷ The therapist stands behind or in front of the client.^{6,7,10,12-14}
2. Stabilize: Provide stabilization at the pelvis over the iliac crest.^{10,14}
3. Palpate: Palpate the gluteus medius on the lateral aspect of the ilium above the greater trochanter of the femur.^{6,10}
4. Observe: Observe the client abducting the hip, lifting the leg upward (Figure 22-38, A).

5. Resist: Provide resistance at the point just proximal to the knee in a downward direction, toward adduction (Figure 22-38, B).^{6,10,12}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with both legs extended and in neutral rotation. The therapist stands next to the client on the opposite side.¹⁰ The therapist may use one hand to support at the ankle and slightly lift the test leg off the surface, being careful to offer no resistance or assistance to the movement.¹²
2. Stabilize: Provide stabilization at the pelvis at the iliac crest on the side to be tested and at the opposite limb at the lateral aspect of the calf.¹⁰
3. Palpate: Use the hand stabilizing over the pelvis to palpate the gluteus medius muscle simultaneously by adjusting the position of the hand so that the fingers are touching the lateral aspect of the ilium, above the greater trochanter, as described for the previous test.
4. Observe: Observe the client abducting the hip, moving the free leg sideward, while maintaining neutral rotation during this movement (Figure 22-38, C).¹⁰
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Lateral muscles of the trunk may contract to bring the pelvis toward the thorax, effecting partial

FIGURE 22-39 Hip adduction. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

abduction at the hip.¹⁰ If the hip is externally rotated, the hip flexors may assist in abduction.^{6,7,10,15}

Hip Adduction

Muscles^{4,10,12}

Adductor magnus
Adductor brevis
Adductor longus
Gracilis
Pectineus

Innervation^{4,10,12}

Obturator L2-4

Femoral L2-4

Procedure for Testing Grades N (5) to F (3)

1. Position: The client assumes a side-lying position, with the test limb lowermost; the therapist supports the uppermost limb in 25 degrees of abduction and stands behind the client.¹² This test may also be done with the client in the supine position.^{6,8,10}
2. Stabilize: Support the client's upper leg in partial abduction while the client grasps the supporting surface for stability.^{5,6,10,14}
3. Palpate: Palpate any of the adductor muscles as follows: adductor magnus at the middle of the medial surface of the thigh; adductor longus at the medial aspect of the groin; gracilis on the medial aspect of the posterior surface of the knee, just anterior to the semitendinosus tendon.¹⁵
4. Observe: Observe the client adducting the hip by raising the lower leg from the table until it meets the upper leg. Observe that there is no rotation, flexion, or extension of the hip nor pelvic tilting (Figure 22-39, A).^{12,14}
5. Resist: Provide resistance over the medial aspect of the leg, just proximal to the knee, downward toward abduction or outward if tested in supine position (Figure 22-39, B).^{6,7,10,12-14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine; the limb to be tested is abducted to 45 degrees. The therapist stands next to the client on the opposite side.
2. Stabilize: Provide stabilization over the iliac crest on the side to be tested.¹⁰

3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client adducting the leg toward midline (Figure 22-39, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Hip flexors may substitute for adductors. The client will internally rotate the hip and tilt the pelvis backward. Hamstrings may be used to substitute for adduction. The client will externally rotate the hip and tip the pelvis forward.¹²⁻¹⁵

Hip External Rotation

Muscles^{10,12}

Quadratus femoris
Piriformis
Obturator internus
Obturator externus
Gemellus superior
Gemellus inferior

Innervation^{10,12}

Sacral plexus, L5,S1
Sacral plexus, S1,2
Sacral plexus, L5-S2
Obturator nerve, L3,4
Sacral plexus, L5-S2
Sacral plexus, L4-S1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with knees flexed over the edge of the table. A small pad or folded towel is placed under the knee on the side to be tested. The therapist stands in front of the client toward the side to be tested.^{6,10,12-14}
2. Stabilize: Provide stabilization at the lateral aspect of the knee on the side to be tested. The client may grasp the edge of the table to stabilize the trunk and pelvis.^{6,10,14}
3. Palpate: These deep muscles are difficult or impossible to palpate.⁶ Action of the external rotators may be detected by palpating deeply posterior to the greater trochanter of the femur.¹⁰
4. Observe: Observe the client rotating the thigh outwardly, moving the foot medially (Figure 22-40, A).
5. Resist: Provide resistance at the medial aspect of the lower leg, just proximal to the ankle in a lateral direction, toward internal rotation.^{6,7,10,12-14} Resistance should be given carefully and gradually, because use

FIGURE 22-40 Hip external rotation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

of the long lever arm can cause joint injury if sudden forceful resistance is given. Clients with knee instability should be tested in the supine position (Figure 22-40, *B*).^{7,10}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with hips and knees extended; the hip to be tested is internally rotated. The therapist is standing next to the client on the opposite side.^{10,12}
2. Stabilize: Provide stabilization at the pelvis on the side to be tested.
3. Palpate: Action of the external rotators may be detected by palpating deeply posterior to the greater trochanter of the femur.¹⁰
4. Observe: Observe the client externally rotating the thigh (roll laterally). Gravity may assist this motion once the client has passed the neutral position. The therapist may use one hand to palpate and the other to offer slight resistance during the second half of the movement to compensate for the assistance of gravity. If the range can be completed with slight resistance, a grade of poor can be given (Figure 22-40, *C*).¹⁰
5. Grade: The client is graded according to standard definitions of muscle grades for fair to normal muscles. Muscles are graded poor if ROM in the gravity-minimized position can be achieved against slight resistance during the second half of the ROM. A grade of trace can be assigned if contraction of external rotators can be detected by deep palpation, as described for the previous test, when movement is attempted in the gravity-minimized position.¹⁰

Substitutions: The gluteus maximus may substitute for the deep external rotators when the hip is in extension. The sartorius may substitute, but external rotation will be accompanied by hip flexion, abduction, and knee flexion.^{7,15}

Hip Internal Rotation

Muscles^{4,10,14}

Gluteus minimus

Gluteus medius

Tensor fasciae latae

Innervation^{10,14}

Superior gluteal nerve, L4-S1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated on a table, with the knees flexed over the edge and with a small pad placed under the knee. The therapist stands in front of or next to the client on the side to be tested.^{6,10} (The therapist is shown on the opposite side in the illustration so that palpation and stabilization will be apparent.)
2. Stabilize: Provide stabilization at the medial aspect of the knee. The client may grasp the edge of the table to stabilize the pelvis and trunk.^{6,10,14}
3. Palpate: Palpate the gluteus medius between the iliac crest and the greater trochanter.⁴
4. Observe: Observe the client internally rotating the thigh, moving the foot laterally. The therapist should observe that the client does not lift the pelvis on the side being tested (Figure 22-41, *A*).^{6,10}
5. Resist: Provide resistance at the lateral aspect of the lower leg, pushing the leg medially and, therefore, the thigh toward external rotation. Resistance is stressful to the knee joint. Clients with knee instability should be tested in the supine position as described for the next test (Figure 22-41, *B*).^{7,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with hips and knees extended; the hip to be tested is in external rotation. The therapist stands on the opposite side.^{10,12}
2. Stabilize: Provide stabilization over the iliac crest on the side to be tested.¹⁰
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client rotating the thigh inwardly or medially. As in external rotation, gravity may assist the motion once the neutral position is passed but to a lesser degree than in the test for external rotation (Figure 22-41, *C*).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Hip adduction and knee flexion may substitute; trunk medial rotation may cause some internal rotation of the hip.^{7,15}

FIGURE 22-41 Hip internal rotation. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

FIGURE 22-42 Knee flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Knee Flexion

Muscles^{4,10,14}

Biceps femoris
Semitendinosus

Semimembranosus (hamstrings)

Innervation^{4,10,12,13}

Sciatic nerve, L5-S2

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with knees and hips in extension and neutral rotation with the foot in midline and toes hanging over the end of the table.^{5,7,10,12-14} The therapist stands next to the client on the opposite side, or the same side, toward the lower end of the supporting surface.¹⁰
2. Stabilize: Provide stabilization firmly over the posterior aspect of the thigh, above the tendinous insertion of the knee flexors.^{6,10}
3. Palpate: For the biceps femoris tendon proximal to the knee joint, palpate on the lateral aspect of the popliteal fossa; for the semitendinosus tendon proximal to the knee joint, palpate medial to the popliteal fossa.^{4,6,15}
4. Observe: Observe the client flexing the knee to slightly less than 90 degrees (Figure 22-42, A).^{13,15}
5. Resist: Provide resistance over the posterior aspect of the ankle downward toward knee extension.^{6,10,13} Note that not as much resistance can be applied to knee flexion in this position as when tested in sitting position with the hip flexed (Figure 22-42, B).¹⁴

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client assumes a side-lying position, with knees and hips extended and in neutral rotation. The therapist stands next to the client and supports the upper leg in slight abduction to allow testing of the lower leg.¹⁰
2. Stabilize: Provide stabilization over the medial aspect of the thigh.
3. Palpate: Palpate the semitendinosus as described for the previous test.
4. Observe: Observe the client flexing the knee of the lower leg (Figure 22-42, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The sartorius may substitute or assist the hamstrings, but hip flexion and external rotation will occur simultaneously.^{10,12,13,15} The gracilis may substitute, causing hip adduction with knee flexion.¹² The gastrocnemius may assist or substitute if strong plantar flexion of the ankle occurs during knee flexion.^{10,12,13}

Knee Extension

Muscles¹⁰

Innervation¹⁰

The quadriceps group:

Rectus femoris
Vastus intermedius
Vastus medialis
Vastus lateralis

Femoral nerve, L2-4

FIGURE 22-43 Knee extension. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with knees flexed over the edge of the table and feet suspended off the floor. The client may lean backward slightly to release tension on the hamstrings and grasp the edge of the table for stability.^{6,10,12} The therapist stands next to the client on the side to be tested.^{6,12}
2. Stabilize: Provide stabilization at the thigh by holding hand firmly over it, or place one hand under the client's knee to cushion it from the edge of the table. The client may grasp the edge of the table.^{7,10,12-14}
3. Palpate: Any of the muscles in the quadriceps femoris group can be palpated as follows: the rectus femoris on the anterior aspect of the midthigh; the vastus medialis on the medial aspect of the distal thigh; and the vastus lateralis on the lateral aspect of the midthigh. The vastus intermedius cannot be palpated.^{6,15}
4. Observe: Observe the client extending the knee to slightly less than full ROM. Observe for hip movement that may betray evidence of substitutions (Figure 22-43, A).
5. Resist: Provide resistance on the anterior surface of the leg, just above the ankle, with downward pressure toward knee flexion.^{6,10,14} The client should not be allowed to lock the knee joint at the end of the ROM when full extension is achieved.^{7,10} Maintenance of a slight amount of knee flexion will prevent this condition. Resistance to a locked knee can cause joint injury (Figure 22-43, B).¹⁰

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client assumes a side-lying position on the side to be tested. The lower leg is positioned with the hip extended and the knee flexed to 90 degrees. The therapist stands behind the client.
2. Stabilize: Provide stabilization at the upper leg in slight abduction with one hand, with the other hand over the anterior aspect of the thigh on the leg to be tested.¹⁰

3. Palpate: Any of the muscles can be palpated, as described for the previous test, with the same hand used to stabilize the client's thigh. Then ask the client to straighten the leg, extending the knee. Observe for hip movements that may betray signs of substitution (Figure 22-43, C).
4. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: Tensor fasciae latae may substitute for or assist weak quadriceps. In this case, hip internal rotation will accompany knee extension.^{6,10,14}

Ankle Plantar Flexion

Muscles^{4,10,14}

Gastrocnemius

Soleus

Innervation¹⁴

Tibial nerve, S1,2

Tibial nerve, L5-S2

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is prone, with the hips and knees extended and the feet projecting beyond the edge of the table. The therapist stands at the lower end of the table, facing the client's feet.^{6,7,13,14}
2. Stabilize: The weight of the leg is usually adequate stabilization. The client may stabilize the leg proximal to the ankle.⁶
3. Palpate: Palpate the gastrocnemius on the posterior aspect of the calf of the leg or the soleus, which is slightly lateral to and beneath the lateral head of the gastrocnemius.¹⁵ The gastrocnemius tendon above the calcaneus may also be palpated.¹⁰
4. Observe: Observe the client flexing the plantar portion of the ankle. Observe for flexion of the toes and forefoot before movement of the heel, which may indicate substitutions (Figure 22-44, A).^{6,14,15}
5. Resist: Provide resistance on the posterior aspect of the calcaneus as if pulling downward and on the forefoot as if pushing forward.¹² If there is considerable weakness, pressure to the calcaneus may be sufficient (Figure 22-44, B).¹⁴

FIGURE 22-44 Ankle plantar flexion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client assumes a side-lying position on the side to be tested; the hip and knee of the lower limb are extended, and the ankle is in midposition. The upper limb may be flexed at the knee to keep it out of the way. The therapist stands at the lower end of the table.^{6,10}
2. Stabilize: Provide stabilization over the posterior aspect of the calf.¹⁰
3. Palpate: Palpate the client in the same manner as described for the previous test.
4. Observe: Observe the client pulling the heel upward, pointing the toes down. Observe for toe flexion and inversion or eversion of the foot, which may indicate substitutions (Figure 22-44, C).
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The flexor digitorum longus and flexor hallucis longus can substitute for plantar flexors, producing toe flexion and flexion of the forefoot, with incomplete movement of the calcaneus. Substitution by the peroneus longus and brevis will cause foot eversion, and substitution by the tibialis posterior will cause foot inversion. Substitution by all three will effect plantar flexion of the forefoot, with limited movement of the calcaneus.^{10,12,13,15}

Ankle Dorsiflexion With Inversion

Muscles^{6,10,12} Tibialis anterior
 Innervation^{6,10,14} Peroneal nerve, L4-S1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client is seated, with the legs flexed at the knees, over the edge of the table. The therapist sits in front of the client, slightly to the side to be tested.^{6,10,12-14}
2. Stabilize: Provide stabilization at the leg, just above the ankle. The client's heel can rest in the therapist's lap.^{6,12}
3. Palpate: Palpate the tibialis anterior tendon on the anterior medial aspect of the ankle joint.^{6,7,10} Muscle fibers may be palpated on the anterior surface of the leg, just lateral to the tibia.¹⁵

4. Observe: Observe the client dorsiflexing and inverting the foot, keeping the toes relaxed.¹² Watch for extension of the great toe preceding the ankle motion, which may be a sign of muscle substitution (Figure 22-45, A).¹²⁻¹⁴
5. Resist: Provide resistance on the medial dorsal aspect of the foot, toward plantar flexion and eversion (Figure 22-45, B).^{6,10,14}

Procedure for Testing Grades P (2), T (1), and 0

The same position and procedure described for the previous test may be used, with modified grading. The test may also be performed with the client in a side-lying or supine position.^{7,10}

1. Grade: If the against-gravity position is used in the procedure for grades P to 0, the therapist must exercise clinical judgment to determine muscle grades. Partial ROM against gravity can be graded poor.¹² If the test is performed in the supine position for these grades, standard definitions of muscle grades may be used.¹⁰

Substitutions: The extensor hallucis longus and extensor digitorum longus may assist or substitute. Movement will be preceded by extension of the great toe or of all toes.^{7,10,12-15}

Foot Inversion

Muscles^{10,14} Tibialis posterior
 Innervation^{7,8} Tibial nerve, L5,S1

Procedure for Testing Grades N (5) to F (3)

1. Position: The client assumes a side-lying position on the side to be tested, with the hip in neutral rotation, the knee slightly flexed, and the foot and ankle in a neutral position.⁶ The upper leg may be flexed at the knee to keep it out of the way. The therapist stands at the end of the table.
2. Stabilize: Provide stabilization at the leg to be tested above the ankle joint on the dorsal surface of the calf, being careful not to put pressure on the tibialis posterior muscle.^{6,10}
3. Palpate: Palpate the tendon of the tibialis posterior muscle between the medial malleolus and navicular

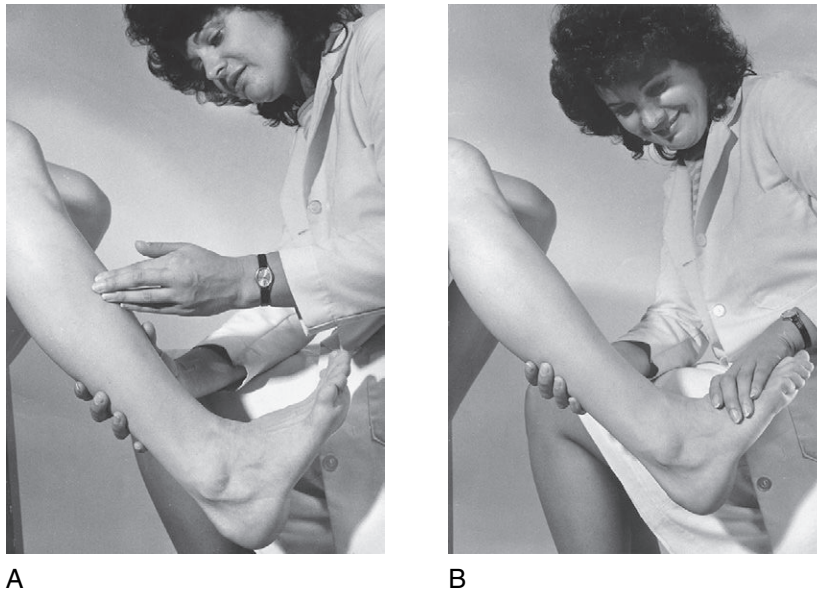

FIGURE 22-45 Ankle dorsiflexion with inversion. **A**, Palpate and observe. **B**, Resist.

FIGURE 22-46 Foot inversion. **A**, Palpate and observe. **B**, Resist.

bone, or above and just posterior to the medial malleolus.^{6,7,10}

4. Observe: C inverts the foot, keeping the toes relaxed. There normally will be some plantar flexion as well (Figure 22-46, A).^{10,14}
5. Resist: Provide resistance at the medial border of the forefoot toward eversion (Figure 22-46, B).^{6,7,10,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, with the hip extended and in neutral rotation, the knee extended, and the ankle in midposition.
2. Stabilize: The client is stabilized in the same manner as described for the previous test.
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client moving the foot inward (medially), inverting it while keeping the toes relaxed.
5. Grade: The client is graded according to standard definitions of muscle grades.

Substitutions: The flexor hallucis longus and flexor digitorum longus can substitute for the tibialis posterior. Movement will be accompanied by toe flexion, or toes will flex when resistance is applied.^{10,12,13}

Foot Eversion

Muscles^{10,14}

Peroneus longus
Peroneus brevis

Innervation^{10,14}

Peroneal nerve, L4-S1

Procedure for Testing Grades Normal (N) and Fair (F)

1. Position: The client assumes a side-lying position, with the lower leg flexed at the knee to keep it out of the way. The upper test leg is in hip extension with neutral rotation, knee extension, and ankle plantar flexion with foot inversion.⁶
2. Stabilize: Provide stabilization medially or laterally, above the ankle.⁶
3. Palpate: Palpate the peroneus longus over the upper half of the lateral aspect of the calf, just distal to the

FIGURE 22-47 Foot eversion. **A**, Palpate and observe. **B**, Resist. **C**, Gravity-minimized position.

head of the fibula. Its tendon can be palpated on the lateral aspect of the ankle, above and behind the lateral malleolus. The peroneus brevis tendon may be palpated on the lateral border of the foot, proximal to the base of the fifth metatarsal.^{6,10,15} Its muscle fibers can be found on the lower half of the lateral surface of the leg, over the fibula.¹⁰

4. Observe: Observe the client everting the foot. (Note that this movement is normally accompanied by some degree of plantar flexion.^{14,15}) Observe for dorsiflexion or toe extension, which may indicate substitutions (Figure 22-47, *A*).
5. Resist: Provide resistance against the lateral border and the plantar surface of the foot toward inversion and dorsiflexion (Figure 22-47, *B*).^{6,14}

Procedure for Testing Grades P (2), T (1), and 0

1. Position: The client is supine, hip extended and in neutral rotation.¹⁰ The knee is extended, and the ankle is in midposition.
2. Stabilize: Provide stabilization at the leg, under the calf.
3. Palpate: The client is palpated in the same manner as described for the previous test.
4. Observe: Observe the client everting the foot (Figure 22-47, *C*).
5. Grade: Grade according to standard definitions of muscle grades.

Substitutions: The peroneus tertius, while everting the foot, also dorsiflexes it. If it is substituting for the peroneus longus and peroneus brevis, dorsiflexion will accompany eversion. The extensor digitorum longus can substitute for the peroneals, and toe extension will precede or accompany eversion.^{7,15}

Summary

Many diseases and injuries result in muscle weakness. Screening tests can be used to assess the general level of strength available for the client to engage in ADLs; IADLs;

and sleep and rest, educational, work, and leisure occupations. These tests can also help determine which clients and muscle groups might require MMT.

MMT evaluates the level of strength in a muscle or muscle group. It is used with clients who have motor unit (lower motor neuron) disorders and orthopedic conditions. It does not measure muscle endurance or coordination, and it cannot be used accurately in upper motor neuron disorders when spasticity and or patterned/synergistic motion is present, or when selective motion is not present.

Accurate assessment of muscle strength depends on the knowledge, skill, and experience of the occupational therapist. Although there are standard definitions of muscle grades, clinical judgment is important in accurate evaluation.

Muscle test results are used to plan intervention strategies to improve occupational performance, compensate for muscle weakness, and increase strength. In some cases, muscle test results can also be used to track the expected course and progression of the disease or disorder, which can assist the OT practitioner when choosing intervention modalities and strategies, and when setting goals, as in the case of Sharon.

Review Questions

1. List three general classifications of physical dysfunction in which muscle weakness is a primary symptom.
2. List at least three purposes for assessing muscle strength.
3. Discuss five considerations and their implications in intervention planning that are based on the results of muscle strength assessment.
4. Define endurance.
5. How can muscle weakness be differentiated from joint limitation?
6. If there is joint limitation, can muscle strength be measured accurately? How is strength recorded when available ROM is less than normal?
7. What does MMT measure?
8. What are the limitations of MMT?

9. When is MMT contraindicated?
10. What are the criteria for determining muscle grades?
11. In relation to the floor as a horizontal plane, describe or demonstrate what is meant by the terms “with gravity assisting,” “with gravity minimized,” “against gravity,” and “against gravity and resistance.”
12. List five factors that can influence the amount of resistance against which a muscle group can hold.
13. Define the muscle grades: N (5), F– (3–), F (3), P (2), P– (2–), T (1), and zero (0).
14. Explain what is meant by substitution.
15. How are substitutions most likely to be ruled out in the muscle testing procedure?
16. List the steps in the muscle testing procedure.
17. Is it always necessary to perform MMT to determine level of strength? If not, what alternatives may be used to make a general assessment of strength?
18. List the purposes of screening tests.

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe how sensation is positioned within the Occupational Therapy Practice Framework-2 (OTPF-2).
2. Describe and compare the difference in sensory loss because of a cardiovascular accident versus a peripheral nerve repair.
3. Perform a sensory evaluation on a client with a peripheral nerve problem.
4. Instruct a client in an appropriate program for desensitization, describe ways to upgrade the program, and name the criteria that reflect client readiness to have the program upgraded.
5. Explain why people who lack protective sensation are at risk for serious injury and what types of injury are possible.
6. Identify whether a client is a candidate for protective sensory re-education or discriminative sensory re-education based on sensory evaluation findings.

Threaded Case Study Mary

Mary is a 48-year-old woman who recently underwent carpal tunnel release of her right dominant hand. She works as a customer service representative for a large insurance company. Her sensory loss is interfering with her ability to type, to manipulate small fasteners, and to quilt by hand. She lives alone and is particularly concerned about not being able to put on her earrings or a necklace. This is difficult because she cannot feel or manipulate earring backs or necklace hooks. She states that she is very independent and does not want to burden others by asking for help. Her hand surgeon has told her that she anticipates excellent sensory recovery.

Critical Thinking Questions

1. What sensory tests would be most appropriate for Mary?
2. Describe a sensory re-education program that would be appropriate for Mary.
3. What will you tell Mary regarding typical sensory recovery following carpal tunnel release?

People who have not experienced sensory problems probably take for granted all that sensation contributes to their daily occupational performance. By comparison, people with sensory dysfunction are likely to be acutely aware of the lost picture that normal sensation provides.¹¹

Sensation (also called sensibility) is a body function, a component of the client factors that influences both the motor and processing aspects of performance skills. For this reason, sensation and sensory dysfunction affect clients' performance in areas of occupation such as activities of daily living (ADLs) and education. For people with carpal tunnel syndrome, as in Mary's case, the sensory loss involves the thumb, index finger, long finger, and radial half of the ring finger. This distribution of sensory loss makes it difficult to pinch and manipulate small objects with a typical three-point or palmar pinch. It often forces people to oppose their thumb to the pad of their small finger instead.

All clients with sensory dysfunction, regardless of etiology, should be evaluated to determine the occupational impact of the loss. The specific sensory tests and interventions may vary according to the diagnosis and prognosis for recovery. The battery of tests selected depends on whether the diagnosis is either central nervous system (CNS) or peripheral nervous system (PNS) in origin. A person with CNS injury is more likely to have deficits in proprioception and stereognosis. A person with PNS injury is more likely to have deficits in touch pressure awareness and two-point discrimination. A client with a history of a cerebrovascular accident (CVA) who then sustains a wrist fracture should be evaluated for proprioception and stereognosis, as well as for pressure threshold and two-point discrimination.

Somatosensory System

The somatosensory system handles sensory input from superficial sources such as the skin and from deep sources such as the musculoskeletal system. Sensation is stimulated by receptors in the periphery of the body, and the sensory information then travels to the brain by way of the spinal cord.

Somatosensory receptors are specialized to respond to stimulation of a specific nature. These receptors are categorized as mechanoreceptors, chemoreceptors, and thermoreceptors. Mechanoreceptors respond to touch, pressure, stretch, and vibration and are stimulated by mechanical deformation. Chemoreceptors respond to cell injury or damage and are stimulated by substances that the injured cells release. Thermoreceptors respond to the stimulation of heating or cooling. Each of these three types of receptors has a subset called nociceptors, which sense pain when stimulated.¹⁰

Disturbances in somatosensation may be manifested as paresthesia, hyperalgesia, dysesthesia, or allodynia. Paresthesia is a tingling, electrical, or prickling sensation. Tapping the volar aspect of the wrist may elicit paresthesias in the distribution of the median nerve in a person who has carpal tunnel syndrome. When such tapping elicits paresthesia, it is referred to as a Tinel sign. Hyperalgesia is increased pain

and may occur during nerve regeneration. Hypersensitivity is increased sensory pain. Mary experienced hypersensitivity at her incision site following her surgery. Desensitization (discussed in detail later in this chapter) helps normalize the phenomenon of hypersensitivity. In clients with hypersensitivity, application of splint straps and desensitization intervention should be performed in the direction of arm hair growth, not against it, since hair follicle receptors sense hair displacement. Dysesthesia is an unpleasant sensation that may be spontaneous or stimulated. Allodynia is pain in response to a stimulus that is not normally painful.⁹ An example of allodynia would be seen when a person with complex regional pain syndrome (also referred to as reflex sympathetic dystrophy [RSD]) experiences pain with the mere movement of air wafting over the involved arm.

A dermatome is the area of skin supplied by one spinal dorsal root and its spinal nerve. The affected dermatome correlates with the level of the spinal cord lesion. However, some peripheral nerves have innervation patterns that differ from dermatome patterns. This is due to regrouping of sensory axons in the brachial plexus and in the lumbosacral plexus (Figure 23-1). The clinical significance of such regrouping is that sensory assessment along a dermatomal pattern is more appropriate in clients with CNS lesions, not PNS lesions. This is why clients with CNS lesions, such as CVA, are more likely to be tested for proprioception, stereognosis, and temperature whereas clients with PNS lesions are more likely to be tested for pain, pressure threshold, and two-point discrimination. Vibration testing is sometimes done with a tuning fork or with more

FIGURE 23-1 Cutaneous sensory distribution and dermatomes.

(From Lundy-Ekman L: *Neuroscience: Fundamentals for Rehabilitation*, ed 3, St. Louis, Mo, 2007, Saunders, p 109.)

sophisticated laboratory instruments. (For more information on vibration testing, see Bell-Krotoski, Weinstein, and Weinstein.³)

Neuropathy is defined as dysfunction of the peripheral nervous system. The typical order of sensory impairment associated with peripheral neuropathy is loss in the following sequence: light touch, cold, heat, and pain. This order is reversed for sensory recovery. Therefore, test for pain perception first and then heat, cold, and light touch.

Superficial Sensation

Pain, temperature, and touch are aspects of superficial sensation, also called cutaneous sensation. When compared with the more proximal body parts, the distal parts have a higher density of receptors and smaller receptive fields. This arrangement contributes to enhanced fingertip sensation, such as the ability to distinguish between one and two stimuli that are close together. The relevance of this in terms of daily occupations is that normal two-point discrimination enables a person to distinguish a dime from a penny without vision, as when one fingers the coins in a pocket or wallet. Figure 23-2 shows normal two-point discrimination values over different locations of the body.

Blisters, altered sweat patterns, calluses, shiny or dry skin, blanching of skin, scars, and wounds are indicators of possible sensory problems and indicate the need to instruct the client in the use of compensatory techniques such as vision during daily occupations. In people with sensory problems, healing is slowed because of decreased nutrition and vascularity. An absence of “wear” marks such as calluses or lack of dirt or grease stains on the hands of a mechanic, for example, may suggest that the hand is not being used. Lack of sweating correlates with lack of discriminative sensation. Nerve damage results in atrophy of soft tissue, which increases the tissue’s susceptibility to injury. Even pinprick testing (see the section on testing pain sensation) might elicit a drop of blood unexpectedly. Occupational therapists should follow universal precautions when performing this test.

Because upper extremity cutaneous sensory fibers and sympathetic nervous system fibers follow the same pathways, sympathetic phenomena may correlate with sensory function. In the upper extremity, the median nerve has more sympathetic fibers than the ulnar nerve, which may explain the increased risk for complex regional pain syndrome (RSD) in clients with median nerve injury. Therefore, it is important to assess Mary for vasomotor function such as blotching of the skin, sudomotor function such as abnormal sweating, pilomotor changes such as no goose bumps, and trophic changes such as atrophy of finger pulp or hair growth.

Before any sensory testing, a history should be obtained through client interview and review of medical reports. The history should include information on name, age, hand dominance, sex, occupation, date of injury, nature of injury, client description of the sensory problem,

FIGURE 23-2 Normal two-point discrimination values over different locations of the body.

(From Lundy-Ekman L: *Neuroscience: Fundamentals for Rehabilitation*, ed 3, St. Louis, Mo, 2007, Saunders, p 134).

screening of motor function, and grip and pinch tests if appropriate.

The most accurate sensory evaluation requires an environment free of background noise, good instruments, consistent testing techniques, cooperative clients, and competent testers. It is important to support the client’s hand fully with the examiner’s hand or by resting the client’s hand against putty to prevent it from moving because movement could provide sensory information that interferes with the test being administered (Figure 23-3). For all sensory testing, the client’s vision should be occluded. This is accomplished by asking the client to keep the eyes closed or by occluding the area with other means (Figure 23-4). A hand grid worksheet is used to record the findings (Figure 23-5).

Sensory screening is a time-saving method to determine some parameters of the sensory loss experienced. When screening the hand, specific sites can be used to reflect larger portions of the hand innervated by the same nerve. For screening Mary’s median nerve function, test the thumb tip, index tip, and index proximal phalanx. For screening ulnar

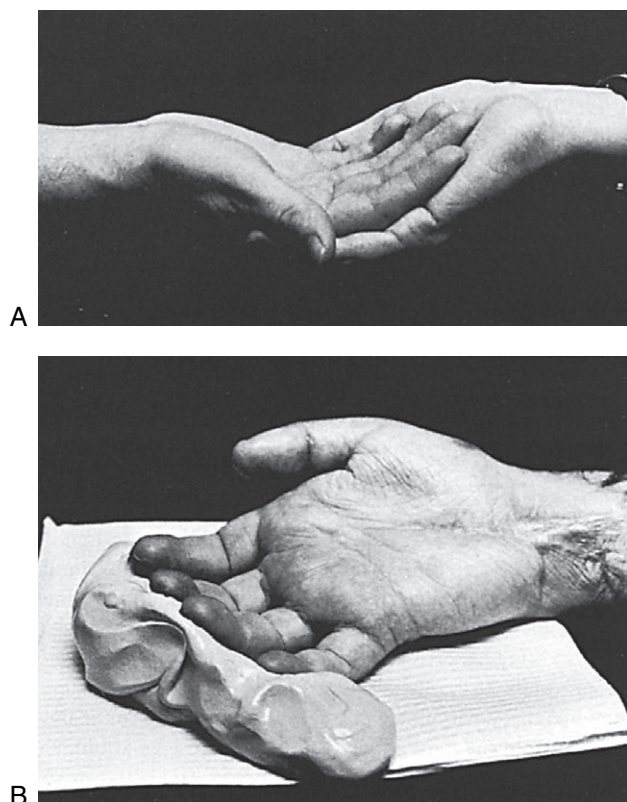

FIGURE 23-3 Ways to support the hand during sensory testing. **A**, In the examiner's hand. **B**, In putty.

(From Callahan AD: Sensibility assessment for nerve lesions-in-continuity and nerve lacerations. In Mackin EJ, Callahan AD, Skirven TM, et al, editors: *Rehabilitation of the hand and upper extremity*, ed 5, St. Louis, Mo, 2002, Mosby.)

nerve function, test the distal and proximal ends of the small finger and the proximal ulnar aspect of the palm. For screening the radial nerve, test the thumb web space.² (See [Figure 23-6](#) for a picture of the sensory distribution of the hand.)

Pain Sensation

Pain is an unpleasant sensory and perceptual experience that is associated with either actual or potential cellular damage. The experience of pain is subjective and multidimensional.⁷ Pain can be tested by pinching the digit firmly or by pinprick. Intact pain sensation is indicative of protective sensation. The pinprick test can be used to rule out a digital nerve laceration. Be sure to use universal precautions (see [Chapter 9](#)).

Test for Pain (Protective Sensation)

Procedure

- Using a sterilized safety pin, assess the amount of pressure required to elicit a pain response on the uninvolved hand. This is the amount of pressure that the examiner will use on the involved side.

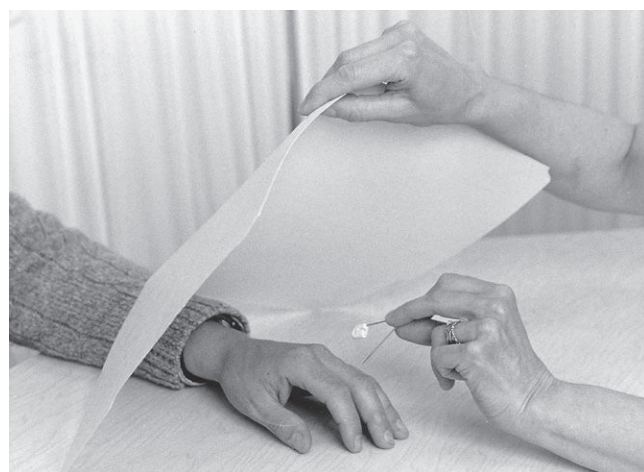

FIGURE 23-4 One method to occlude vision while performing sensory testing.

- Alternate randomly between the sharp and dull sides of the safety pin and ensure that each spot has one sharp and one dull application ([Figure 23-7](#)).

Response

- The client indicates “sharp” or “dull” following application.

Scoring

- A correct response to both sharp and dull indicates intact protective sensation.
- An incorrect response to both sharp and dull indicates absent protective sensation.

Temperature Awareness

Temperature awareness is a test for protective sensation. Thermal receptors detect warmth and cold. In the clinic, it is important to test temperature sensation before applying heat or cold modalities to avoid burn injuries. Thermal receptors are also critical for a person to be able to determine safe water temperature for bathing. A client who lacks temperature awareness must learn compensatory strategies such as testing the water temperature with an unaffected body part. Many clinicians use only the pinprick test as sufficient evidence of protective sensation.

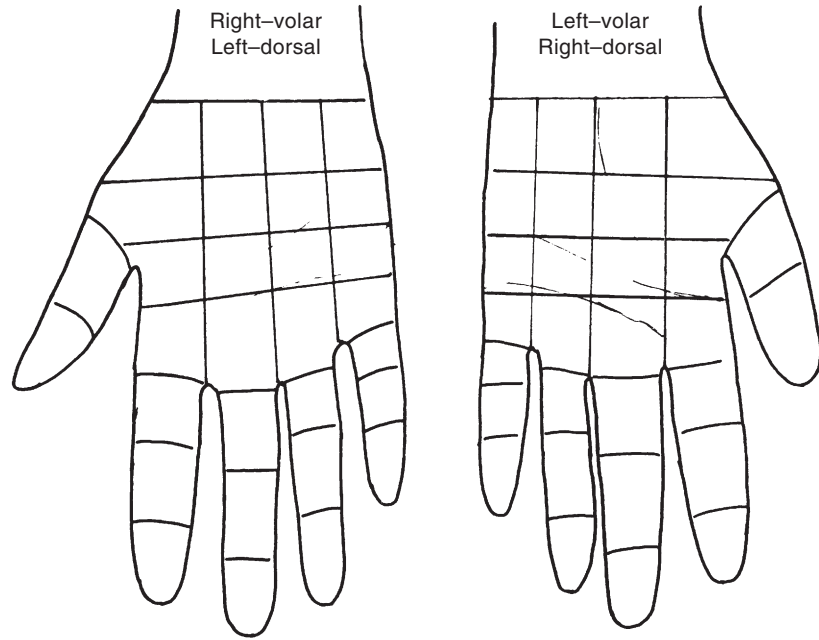

Test for Temperature Awareness (Protective Sensation)

Procedure

- Apply test tubes or metal cylinders filled with hot or cold fluid randomly to areas of the involved hand ([Figure 23-8](#)).

Response

- The client indicates “hot” or “cold” following application.

(From Trumble TE: *Principles of hand surgery and therapy*, ed 2, Philadelphia, 2000, Saunders, p 14.)

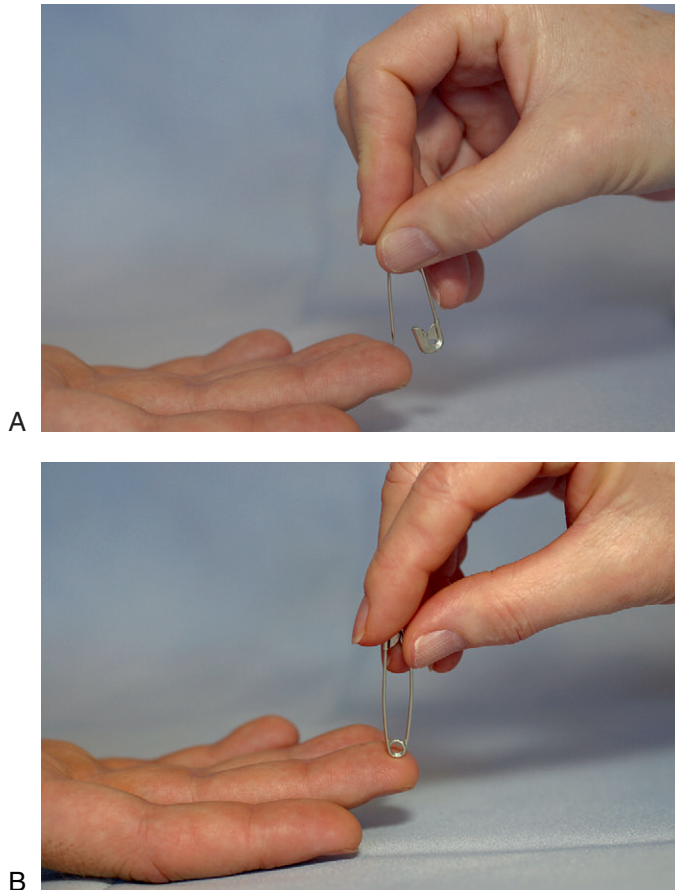

FIGURE 23-7 Sensory testing for sharp and dull. **A**, Sharp. **B**, Dull.

Scoring

- A correct response to both cold and hot indicates intact temperature awareness.
- An incorrect response to either or both indicates impaired temperature awareness.

Testing for Touch Sensation

Two-Point Discrimination

Two-point discrimination and touch pressure testing with monofilaments are tests of different aspects of sensation. Two-point discrimination is a test for receptor density and is a good test to use for mapping improvement following nerve repair. Moving two-point discrimination returns before static two-point discrimination and is an indicator of recovery that is typically noticed before static two-point discrimination improves. One criticism concerns potential variability in the force of application during testing. Nonetheless, good intertester reliability has been reported with the Disk-Criminator tool.¹³

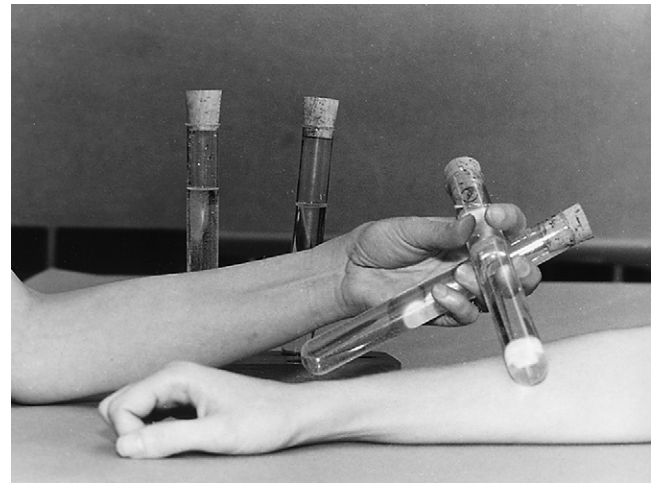

FIGURE 23-8 Test for temperature awareness.

Test for Static Two-Point Discrimination

Procedure

- Use a device such as the Disk-Criminator or Boley gauge with blunt testing ends (Figure 23-9).
- Test only the fingertips because this is the primary area of the hand used for exploration of objects.
- Begin with a distance of 5 mm between the testing points.
- Randomly test one or two points on the radial and ulnar aspects of each finger for 10 applications (Figure 23-10).
- Pressure is applied lightly; stop just when the skin begins to blanch.

Response

- The client will respond “one” or “two” or “I don’t know” following application.

Scoring

- The client responds accurately to 7 of 10 applications at that number of millimeters of distance between the two points.
- Norms are as follows:
 - 1 to 5 mm indicates normal static two-point discrimination.
 - 6 to 10 mm indicates fair static two-point discrimination.
 - 11 to 15 mm indicates poor static two-point discrimination.
- One point perceived indicates protective sensation only.
- No points perceived indicates an anesthetic area.

FIGURE 23-9 Boley gauge (A) and Disk-Criminator (B) for testing static and moving two-point discrimination.

FIGURE 23-10 Two-point discrimination testing.

Test for Moving Two-Point Discrimination

Procedure

- Begin with distance of 8 mm between points.
- Randomly select one or two points, and move proximal to distal on the distal phalanx parallel to the longitudinal axis of the finger so that the adjacent digital nerve is not stimulated (see Figure 23-10).
- The pressure applied is just enough for the client to appreciate the stimulus.

- If client responds accurately, decrease the distance between the points and repeat the sequence until you find the smallest distance that the client can perceive accurately.

Response

- The client states “one,” “two,” or “I don’t know.”

Scoring

- The client responds accurately to 7 of 10 applications.
- Norms are as follows:
 - 2 to 4 mm for ages 4 to 60 indicates normal moving two-point discrimination.
 - 4 to 6 mm for ages 60 and older indicates normal moving two-point discrimination.

Touch Pressure

Light touch is perceived by receptors in the superficial skin. Pressure (or deeper touch) is perceived by receptors in the subcutaneous and deeper tissues. Light touch is important for fine discriminatory hand use, whereas deep pressure is important as a form of protective sensation. Touch pressure testing examines the spectrum from light touch to deep pressure. Touch pressure testing is a good test to use for clients with nerve entrapment such as carpal tunnel

FIGURE 23-11 Application of a touch pressure monofilament to the client's fingertip.

syndrome. Many clinicians test two-point discrimination and the touch pressure of their hand therapy patients. Having intact light touch pressure awareness is an indicator of better sensation than having only intact deep touch pressure awareness. It is interesting to note that light touch pressure awareness has to be intact for two-point discrimination to be testable because the two-point discrimination test uses light touch.

Touch pressure is tested with a set of 20 monofilaments. These monofilaments are of varying thickness with numbers that represent a mathematic formula of the force required to bow them when applied perpendicularly. They are color-coded to correspond to five threshold categories. Clinicians will frequently use an abbreviated set of five monofilaments, one for each of these categories.

Test for Touch Pressure

Procedure

- Begin with monofilament 1.65.
- Apply the monofilament for 1 to 1.5 seconds at the pressure needed to bow the monofilament (applied perpendicularly) (Figure 23-11).
- Hold the pressure for 1 to 1.5 seconds.
- Lift the monofilament in 1 to 1.5 seconds.
- The proper amount of pressure is achieved when the filament bends.
- Repeat this three times in the same spot for monofilaments 1.65 to 4.08; monofilaments higher than 4.08 are applied only once.
- Randomly select areas of the hand to test, and change the interval of time between the application of monofilaments.
- If the client does not perceive the monofilament, proceed to the next (thicker) monofilament and repeat the sequence until monofilament 6.65.
- If the client does perceive the monofilament, record this number on the hand grid and proceed to the next area of the hand.

FIGURE 23-12 Testing proprioception of the finger.

Response

- The client says “touch” when he feels the monofilament.

Scoring

- The client responds to at least one of the three applications of the monofilament.
- Norms are as follows:
 - Green (1.65 to 2.83) indicates normal light touch.
 - Blue (3.22 to 3.61) indicates diminished light touch.
 - Purple (3.84 to 4.31) indicates diminished protective sensation.
 - Red (4.56 to 6.65) indicates loss of protective sensation.
 - Untestable indicates an inability to feel the largest monofilament.

Proprioception

Conscious proprioception derives from receptors found in muscles, tendons, and joints and is defined as awareness of joint position in space. It is through cerebral integration of information about touch and proprioception that objects can be identified by tactile cues and pressure. If proprioception is impaired, it may be difficult to gauge how much pressure to use when holding a paper cup.

Test for Proprioception

Procedure

- Hold the lateral aspect of the elbow, wrist, or digit.
- Move the body part into flexion or extension (Figure 23-12).

Response

- The client indicates whether the body part is being moved “up” or “down.”

Scoring

- An accurate response indicates intact proprioception.

The term *kinesthesia* is sometimes used interchangeably with the term *proprioception* but can also be defined as awareness of joint movement. Some therapists make a distinction between these two terms and test for kinesthesia by moving the unaffected limb into a certain posture and having the client copy the movement with the affected side while the eyes are closed.

Stereognosis

Stereognosis is the use of both proprioceptive information and touch information to identify an item with the vision occluded. Without stereognosis, it is impossible to pick out a specific object such as a coin or a key from one's pocket, use a zipper that fastens behind you, or pick up a plate from a sink of sudsy water.

The Dellon modification of the Moberg Pickup Test is a good test for stereognosis for clients with injuries involving the median and/or ulnar nerves. This test requires the client to have the ability to participate motorically, so motor loss or weakness should be factored into the choice of this assessment. This test is based on the Moberg Pickup Test, which is a timed motor test that does not require identification of objects.

The Dellon Modification of the Moberg Pickup Test**Procedure**

- Begin with a group of 12 standardized items: wing nut, large nut, hex nut, small square nut, screw, key, nickel, dime, washer, safety pin, paper clip, and nail.
- If the ulnar nerve is not involved, tape the ulnar two fingers to the client's palm if possible.
- Test 1
 - The client places the items one at a time into a box as quickly as possible (Figure 23-13).
 - Record the time for two trials.
- Test 2 (initiate test 2 only if the client's deficits do not appear to be too severe during test 1).
 - With client's vision occluded, the examiner places the items into the client's radial three digits one at a time.
 - The examiner records the time that it takes to identify each item, with a maximum of 30 seconds for each item.
 - Each item is placed in the client's hand two times.

Response

- Test 1: The client places the items in a box as quickly as possible with the radial three digits.
- Test 2: The client manipulates the objects and attempts to identify them as quickly as possible.

Scoring

- Test 1: the time that it takes to place all items in the box.
- Test 2: the time that it takes to identify all the items.

FIGURE 23-13 The Dellon modification of the Moberg Pickup Test.

(From Callahan AD: Sensibility assessment for nerve lesions-in-continuity and nerve lacerations. In Mackin EJ, Callahan AD, Skirven TM, et al, editors: *Rehabilitation of the hand and upper extremity*, ed 5, St. Louis, Mo, 2002, Mosby.)

Localization of Touch

Localization of touch is considered to be a test of functional sensation because there is high correlation between this test and the test for two-point discrimination. Localization of touch is an important test to perform following nerve repair since it helps determine the client's baseline and projected functional prognosis. This test can be done with a constant (static) touch or a moving touch. Localization of touch is thought by many to reflect a cognitive component of the client's abilities. Because it is considered to be a test of tactile discrimination that requires cortical processing, it is different from touch pressure testing.

Test for Localization of Touch**Procedure**

- Apply the finest monofilament that the client can perceive to the center of a corresponding zone on the hand grid.
- Once the client feels a touch, have him or her open his or her eyes and use the index finger to point to the exact area where the stimulus was felt.

FIGURE 23-14 Homunculus.

(From Lundy-Ekman L: *Neuroscience: fundamentals for rehabilitation*, ed 3, St. Louis, Mo, 2007, Saunders.)

- Place a dot on the hand grid for a correct response.
- Place an arrow from the site of the actual stimulation to the identified site if the stimulus is identified incorrectly.

Response

- The client attempts to identify the exact location of a stimulus.

Scoring

- Correct identification of the area within 1 cm of actual placement indicates intact touch localization.²

Somatotopic Arrangement

Sensory information is received and organized somatotopically in the primary somatosensory cortex. The homunculus (Figure 23-14) is a diagram that shows the arrangement and proportions of cortical areas representing the surface of the body. Areas with large cortical representation indicate a high density of sensory receptors. As indicated in Figure 23-14, somatotopic arrangement is such that axons providing

information from the index finger are situated closer to those from the thumb than to those from the foot. Elegant research studies have elucidated the relevance of somatotopic arrangement to therapeutic strategies for normalizing impaired sensation. These strategies are effective because of the brain's plasticity.¹⁶

Within the somatosensory cortex there is an inherent capacity for plasticity involving the circuitry.⁵ Topographic reorganization of the cerebral cortex occurs following injury and can be influenced by sensory input and by learning and experience. This has been described eloquently by the neurologist and author Frank R. Wilson as a dynamic interplay of the sensorimotor and cognitive worlds.¹⁹ Referred sensations and phantom pain (pain felt in a part removed from its point of origin) in amputees are examples of cortical reorganization.

Neuroplasticity

Our brain has the plasticity to mechanically induce neuronal reorganization. One aspect of this phenomenon, called neuroplasticity, includes the processes of habituation, learning, memory, and cellular recovery following an injury. Along with changes in synaptic connections, there are also changes in non-neuronal cells. Some concepts of neuroplasticity are as follows^{5,11}:

- Sensory perception is a dynamic process that is experienced by the CNS.
- Receptor morphology is affected by hand use. The axiom of “use it or lose it” is particularly applicable here. Immobilization or disuse (such as a casted fracture or a highly guarded upper extremity posture) contributes to retrogressive modifications in receptors. Conversely, promoting normal use may stimulate new receptors.¹⁵
- Because there is overlap of the receptive fields of various nerve fibers, a single stimulus can excite different receptors.

Neurons may die following CNS injuries such as spinal cord lesions and strokes. The nervous system accommodates for injuries with behavioral, physiologic, and anatomic changes. Over time, the CNS can adapt by altering the strength of neural transmission through modifications in the structure and function of neurons and synapses. It is very exciting clinically to realize that occupational therapists facilitate recovery through functional activities and involvement in occupation resulting in somatosensory reeducation.¹¹

Desensitization

The existence or persistence of hypersensitivity will often limit use of the affected body part and may prevent sensory re-education from proceeding, so it is important to address this problem early if possible. Desensitization for

FIGURE 23-15 Dowels with graded textures used for desensitization.

(From Stanley BG, Tribuzi SM, editors: *Concepts in hand rehabilitation*, Philadelphia, Pa, 1992, FA Davis.)

hypersensitivity is a form of treatment that aims to elicit habituation and thereby reduce the client's hypersensitivity and improve function. Habituation is a decrease in a response following repeated benign stimuli. There is a reduction in the excitatory neurotransmitters released, and if the stimulation continues over a prolonged period, a permanent change consisting of a reduction in the number of synaptic connections will occur.⁴

Desensitization uses graded stimulation with procedures and modalities that are slightly aversive but tolerable. The stimuli are upgraded to be slightly more noxious as the client's tolerance increases.¹⁸ Lois Barber, an occupational therapist and pioneer in hand splinting and hand therapy, developed a desensitization approach that exposes the hypersensitive area to textures such as sandpaper, contact particles such as rice, and vibration.¹ Treatment is performed for 10-minute intervals, three or four times a day (Figure 23-15). Clients can be very creative at incorporating desensitization into their daily routine. For example, they may find that rubbing the hand on their textured shirt or corduroy pants is desensitizing and can be performed easily throughout the day.

Sensory Re-education

Stimulation and use of a body part affect the cortical map.¹² Passage of time, use of the involved hand, and training all help promote improved functional sensibility.⁸ Children have greater capacity for neural regeneration and neuroplasticity than older people do. Motivation and the ability to concentrate enhance the results of sensory re-education.

Sensory re-education has been shown to improve the sensation of fingertip replantations even without repair of the nerves.¹⁴ Anne Callahan, an occupational therapist and prolific author in the field of hand therapy, has identified

two groups of clients for sensory re-education, with guidelines differing according to the group. The two groups are candidates for protective sensory re-education and candidates for discriminative sensory re-education.

Protective Sensory Re-education

People who lack protective sensation are at risk for serious injury since they cannot feel pinprick or hot or cold exposure. Blisters may develop after holding objects and people do not realize it until they visually examine the hand. Following a CVA, a person with left hemiparesis and left neglect may inadvertently move the left hand on top of a stove burner during a cooking task. If the client lacks protective sensation, he or she will be burned without feeling the painful sensory stimulus of the hot stove. The same frequently happens to individuals with C6 quadriplegia. Protective sensation in their thumb, index finger, and long finger may be intact, whereas sensation in their ring and little fingers is absent.

Callahan identified the following instructions for protective sensory re-education of these clients⁶:

- Protect from being exposed to sharp items or to cold or heat.
- Try to soften the amount of force used when gripping an object.
- Use built-up handles on objects whenever possible to distribute gripping pressure over a greater surface area.
- Do not persist in an activity for prolonged periods. Instead, change the tool used and rotate the work task often.
- Visually examine the skin for edema, redness, warmth, blisters, cuts, or other wounds. This is important because tissue heals more slowly when a nerve injury has occurred.
- If there is tissue injury or damage, be very careful in treating and try to avoid infection.
- Maintain skin suppleness as much as possible by applying moisturizing agents.

Discriminative Sensory Re-education

Clients are candidates for discriminative sensory training if they have intact protective sensation with recognition of at least 4.31 on the touch pressure monofilament test. A client who is not able to localize the stimulus but can feel it is still a candidate for discriminative sensory re-education. A client with a brain insult or nerve injury resulting in reduced discriminative sensation will be unable to fasten a bra in the back, braid her own hair, or locate a wallet in a bag or pocket with the vision occluded. Discriminative sensory re-education can be graded by initially using grossly dissimilar objects such as a spoon and a penny and progressing over time to more similar objects such as a dime and a penny.

When planning discriminative sensory re-education intervention, it works best to identify short-term goals that are achievable and that will enhance function despite the sensory loss. If the client has motor involvement and cannot

FIGURE 23-16 A, Different grades of sandpaper. B, Nuts and bolts used for graded discrimination sensory re-education.

(A, From Callahan AD: Therapist's management of peripheral injuries. manually manipulate the stimulus, the stimulus can be moved over the hand instead. Discriminative sensory re-education involves training in both localization and graded discrimination.

Localization

Localization of moving touch tends to return before localization of constant touch. Retraining is done for both. With the client's eyes closed, the eraser end of a pencil or the therapist's finger is used to touch the client's hand in the midline of one zone of the hand grid. This makes documentation easier and the intervention more accurate and consistent and minimizes afferent activity from adjacent areas of the skin. The stimulus is applied with either a moving or a constant touch. The client is told to open his or her eyes and point to the area that was touched. Interestingly, it has been shown that activity in the visual cortex is enhanced when touch of the hand is added to the visual stimulation, as long as the touch is provided on the same side as the visual stimulation.¹⁷ If the answer was incorrect, the process is repeated. The steps are repeated again with the eyes closed. The full process is then repeated in a new area. As the client improves, the stimulus is changed to a lighter and smaller touch.

Graded Discrimination

Stimulation is graded from that requiring gross discrimination to that requiring fine discrimination. Levels of difficulty in discrimination are represented by sequencing of the following three categories: (1) same or different, (2) how they are the same or different, (3) identification of the material or object.

The stimulus is applied to the skin in an area corresponding to the hand grid. Either the hand or the stimulus is moved

to provide input. As earlier, the eyes are closed, then opened, and then closed for the retraining steps. Various textures can be used, such as different grades of sandpaper fabric or objects such as nuts and bolts or coins (Figure 23-16).

Another version of discriminative training involves tracing a geometric shape or a letter or number on the fingertip or small area of the hand. This can be applied with a fingertip or the end of an instrument such as a small dowel or a pencil eraser. The client tries to identify the figure.

Difficulty is increased by adding the requirement of fingering for motor stimulation if appropriate and by occluding vision. Discriminative training can include identifying objects out of a box, retrieving objects from rice or sand, or performing ADLs with the eyes closed (Figure 23-17). Progress can be determined by improvement in the number of accurate responses, better mapping of areas of localization, increased speed of completing motor tasks, better status of two-point discrimination, and improved level of function involving ADLs overall.

Summary

The most appropriate sensory tests for Mary would be touch pressure, two-point discrimination, and the Dellon modification of the Moberg Pickup Test. Test for touch pressure first since light touch must be intact for two-point discrimination to be tested. The Dellon modification of the Moberg Pickup Test is particularly appropriate for Mary because it looks at sensory function of the digits that carpal tunnel syndrome is affecting. Mary is a good candidate for both desensitization of the hypersensitive incision scar and discriminative sensory re-education to stimulate neural recovery. For instance, Mary could practice putting her

earrings on in front of a mirror and grading the size of the earrings/fasteners. Tell Mary that typical recovery after successful carpal release includes decreased hypersensitivity as the desensitization program progresses. She should expect improving ability to feel and manipulate small objects as sensory recovery proceeds proximally to distally, with the fingertips being the last to recover. Deeper pressure will be felt before lighter pressure, and it will be easier to discern a nickel before she can discern a dime with vision occluded; this will progress as two-point discrimination improves.

Review Questions

1. What is the typical order of sensory recovery following peripheral nerve injury?
2. Explain why the fingertips have enhanced sensation when compared with more proximal body parts.
3. Name three signs that represent altered sympathetic nervous system status.
4. Explain how desensitization works.
5. What are the two categories of sensory re-education and how do they differ?

Acknowledgment

We thank Colleen G. West, MS, OTR/L, Genevieve Lebel, OTR/L, Shawn A. McGoogan, OTR/L, and Alex Pereda, MOT, OTR/L, for their review and feedback regarding this manuscript.

Evaluation and Treatment of Visual Deficits Following Brain Injury

MARY WARREN

■ Chapter Outline

Role of vision in the adaptation process

An overview of visual processing within the central nervous system

Framework for assessment and treatment of visual perceptual dysfunction

A hierarchic model of visual perceptual processing
Intervention

Occupational therapy evaluation

Occupational therapy intervention

Occupational therapy assessment and intervention for specific visual impairments

Visual acuity

Deficits in visual acuity

Disruption of the ability to focus an image on the retina

Disruption of the ability of the retina to process the image

Disruption of the ability of the optic nerve to send the retinal image

Occupational limitations caused by reduced visual acuity

Assessment of performance skills

Intervention

Increase background contrast

Increase illumination

Reduce background pattern

Enlarge objects or features that need to be seen

Organize

Access community services

Visual field

Visual field deficits

Occupational limitations caused by visual field deficits

Assessment

Intervention

Addressing limitations in mobility

Addressing limitations in reading

Visual attention and scanning

Deficits in visual attention and scanning

Occupational limitations caused by visual inattention

Assessment

Intervention

Oculomotor function

Deficits in oculomotor function

Occupational limitations caused by oculomotor deficits

Assessment

Intervention

Occlusion

Prisms

Eye exercises

Surgery

Complex visual processing

Summary

Review questions

■ Key Terms

Visual perception	Visual fields
Visual perceptual hierarchy	Visual acuity
Visual cognition	Visual field deficit
Visual memory	Hemi-inattention
Pattern recognition	Visual neglect
Visual scanning	Binocular vision
Search	Sensory fusion
Visual attention	Diplopia
Oculomotor control	

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the role that vision plays in enabling a person to complete daily occupations.
2. Describe how visual input is processed within the central nervous system to turn raw visual data into cognitive concepts of space and form through the process of visual perception.
3. Describe the concept and features of the visual perceptual hierarchy as a framework for assessment and treatment of visual perceptual dysfunction.
4. Describe how assessment is used to link visual performance and process deficits to limitations in daily occupations.
5. Describe how the sensory functions of visual acuity, visual field, oculomotor control, visual attention, and visual scanning change following brain injury.
6. Describe how the sensory functions of visual acuity, visual field, oculomotor control, visual attention, and visual scanning contribute to engagement in daily occupations.
7. Describe how to assess and develop intervention plans for deficits in visual acuity, visual field, oculomotor control, visual attention, and visual scanning.
8. Describe how to modify the client's environment to increase visibility and facilitate engagement in daily occupations.

Threaded Case Study | Penny, Part 1

Penny, age 70, sustained a right cerebrovascular accident (CVA). The stroke was caused by an occlusion in the right middle cerebral artery. The CVA resulted in left hemiparesis, a left visual field deficit (VFD), and hemi-inattention. Penny was hospitalized for 1 week and then transferred to a rehabilitation hospital, where she received 3 weeks of intensive inpatient rehabilitation, including twice-daily sessions of occupational and physical therapy.

Following inpatient discharge, she received an additional 6 weeks of therapy from both disciplines and was then discharged. It has now been 4 months since onset of the stroke. Penny was referred to the University Low Vision Rehabilitation Clinic by her primary care physician after complaining that she is still having difficulty reading and expressing a desire to resume driving. She was evaluated by a low-vision optometrist at the center and found to have normal visual acuity and contrast sensitivity function and complete left homonymous hemianopia. The optometrist also noted that Penny has a 5-year history of insulin-dependent diabetes. The optometrist referred Penny to the clinic's occupational therapy (OT) practitioner to address her reading limitations and other deficits in daily living activities and evaluate her potential to resume driving.

Before analyzing her occupational performance, the OT practitioner completed an occupational profile on Penny and gathered the following information. Penny has been married for 45 years. She has one grown, unmarried son who lives several states away and no other family in the area. Her husband Pot sustained a severe stroke 5 years earlier. He has right hemiplegia and global aphasia. He is able to ambulate short distances with a 3-point cane and requires assistance for completion of all basic and instrumental activities of daily living (ADLs). They live alone in a one-story home in a suburb. Penny is the primary caregiver for her husband. After her stroke, Penny hired a home care aide to assist in caring for Pot. The aide comes 3 days a week for 2 hours to help Pot with bathing and other personal ADLs. Penny is unable to afford more service. Penny is a retired art teacher and a well-known local artist, famous for her detailed ink drawings of local architecture. Penny describes herself as fiercely independent. Although her friends have been very kind, it has been extremely difficult to ask them for help, and she would prefer to find ways to accomplish tasks by herself. She expresses pride that she has been able to care for Pot even though her physicians advised her to place him in a nursing home. Although he does not comprehend language and

cannot speak, they have found a way to communicate through gestures, music, and art that they both find spiritually satisfying. She states openly that his needs come first.

Penny states that she is having difficulty reading because of the VFD and that it is particularly problematic in completing financial management tasks: paying bills and managing their retirement income. A friend now comes over once a month to proofread her checks and bank deposits and balance her checkbook. She also likes to read books to Pot because even though he does not understand the language, he enjoys the cadence and she feels that it is therapeutic. She also expresses a strong desire to resume driving so that she can run errands and take Pot to doctor appointments. There is no mass transit available in her suburb and she is reluctant to continuously ask friends. She states that she no longer sees well enough to complete her ink drawings and has not attempted to complete any art since she returned home, although she misses it a

great deal. She reports that she is independent in basic ADLs and completes meal preparation and home management activities independently but with difficulty. When shopping, Penny requires assistance from a friend for community mobility and locating items. She has difficulty locating objects and is fearful of collisions on the left side when moving about her environment.

Critical Thinking Questions

1. How does the presence of left homonymous hemianopia affect Penny's ability to read and perform other daily living activities?
2. Does Penny actually have hemi-inattention or does she have uncompensated left hemianopia?
3. What intervention approach will be most beneficial in increasing Penny's independence in daily occupations?

An understanding of visual perceptual dysfunction after a CVA and traumatic brain injury must be preceded by the realization that visual perception is a process used by the central nervous system (CNS) to adapt to context and complete daily occupations. Visual perception is not a series of discrete perceptual skills or the function of a single sensory modality, but rather a process that integrates vision with other sensory input for adaptation and survival.^{55,62,81,120} The activities that a person performs in a day dictates the visual perceptual processing needed. Whether a client has a visual perceptual deficit after a brain injury will depend on whether the ability to process visual information has been altered such that it prevents performance of a necessary daily activity or occupation.

Role of Vision in the Adaptation Process

According to Ayres,⁶ the overall function of the brain is to filter, organize, and integrate sensory information to make an adaptive response to the context surrounding the person. The brain or CNS receives a variety of sensory information, including visual, proprioceptive, tactile, vestibular, and auditory. Vision is used with information from these other sensory systems to adapt to the situational context—to act on it and to manipulate, mold, and improve it. In adapting, the CNS combines the isolated bits of sensory information that it receives and integrates them to form a picture. This picture, created by sensory input, becomes the context of a situation, and an individual uses this context to make decisions and formulate plans to respond to various situations.

Successful adaptation depends on the ability to anticipate situations and contexts. The key to survival is to stay

one step ahead of circumstances, whether working with clients or navigating rush-hour traffic. Anticipation enables an individual to plan for situations and increases the chance of a successful outcome. Anticipation and planning are driven by the sensory context of a person's circumstances, for example, "It looks like rain, so I'd better take an umbrella," or "It's dark in there, so I'd better take a flashlight." When visual input is present, it dominates the sensory context for the simple reason that vision takes us farther into the environment than any of our other senses do. We can see lightning before we hear thunder and see a car careening toward us before we hear the squeal of the tires or smell the exhaust. By warning us of changes in our environment, vision enables us to anticipate developing situations and formulate a plan to handle them. So when an object is unexpectedly flung in our direction, we duck, or when we see a banana peel on the floor, we walk around it.

The decision-making process guided by vision is not limited to avoiding objects. We also rely on vision to "size up" situations. We say to ourselves, "He looks harmless," or "That looks delicious." Our language is peppered with phrases that reflect the importance of vision in decision making, such as "I'll believe it when I see it," "I'll keep an eye out for it," or "I can see what you mean." Vision plays an important role in social communication by enabling a person to "read" and respond to the subtle gestures and facial expressions used to communicate emotional content in conversations. Vision also plays an important role in motor and postural accommodation by warning of upcoming challenges to postural control, such as the presence of a curb or a curb cut, and by alerting us to needed information, such as the "exit" sign.

Vision has the power to convey large amounts of detailed information in milliseconds. Although we are able to

instantly identify an object with vision, we would require many more milliseconds to identify the same object tactually or by hearing a verbal description of it. This explains the power of television as a medium for conveying information and why we rush to view the television when we hear about a significant event such as the fall of the World Trade Towers on September 11th, 2001, or the tsunami in Japan in 2011.

The speed of information processing supplied by vision also enables us to successfully adapt to dynamic environments. In contrast to static environments in which we are the only moving object, dynamic community environments often contain several objects moving independent of ourselves and each other. In these environments, to successfully adapt we must not only monitor our own movement but also adapt it to the movement of other objects to avoid collisions and potential harm.

Much of our success in adaptation depends on the rapid processing of information. It does no good to recognize the car after it has struck you; you must be ready for the event before it occurs. Only vision supplies us with sufficient information quickly enough to match our movement to the objects surrounding us. The daily occupations most affected by visual impairment take place in dynamic, unpredictable environments such as those found in the community and workplace. Reintegrating a person with a visual impairment into the stable environment of the home is a relatively easy process, but reintegrating a person into community environments is much more difficult.

Visual impairment can occur secondary to disease, trauma, and aging.^{8,36,71,106} Frequently, a combination of at least two of these causes is observed, especially in older clients. Visual impairment can alter the quality and amount of visual input into the CNS or alter how the CNS is able to process and use incoming visual input. Either way, the result is a decrease in the ability to use vision to perform daily occupations. Changes are observed in occupations dependent on vision. Clients with visual impairment may process visual information so slowly that they are unable to navigate a dynamic environment or play a card game with friends. Changes in decision making may be observed in which the client makes errors because insufficient visual information was received or because the information received was faulty. Because of the pervasive use of vision in adaptation, visual impairment has the potential to change the client's interaction with all aspects of the environment and the people and objects in it.

Recall, for example, the many daily activities that Penny is having difficulty completing both in the home and in the community. Yet despite its significance, the effect of visual impairment on occupational performance is often attributed to other causes because visual impairment is a hidden disability. Unlike a physical impairment, which can easily be observed, there are few outward signs of visual impairment. As a result, the limitations produced by visual impairment are often attributed to other causes such as motor or

cognitive impairment, especially when a brain injury has occurred.

An Overview of Visual Processing within the Central Nervous System

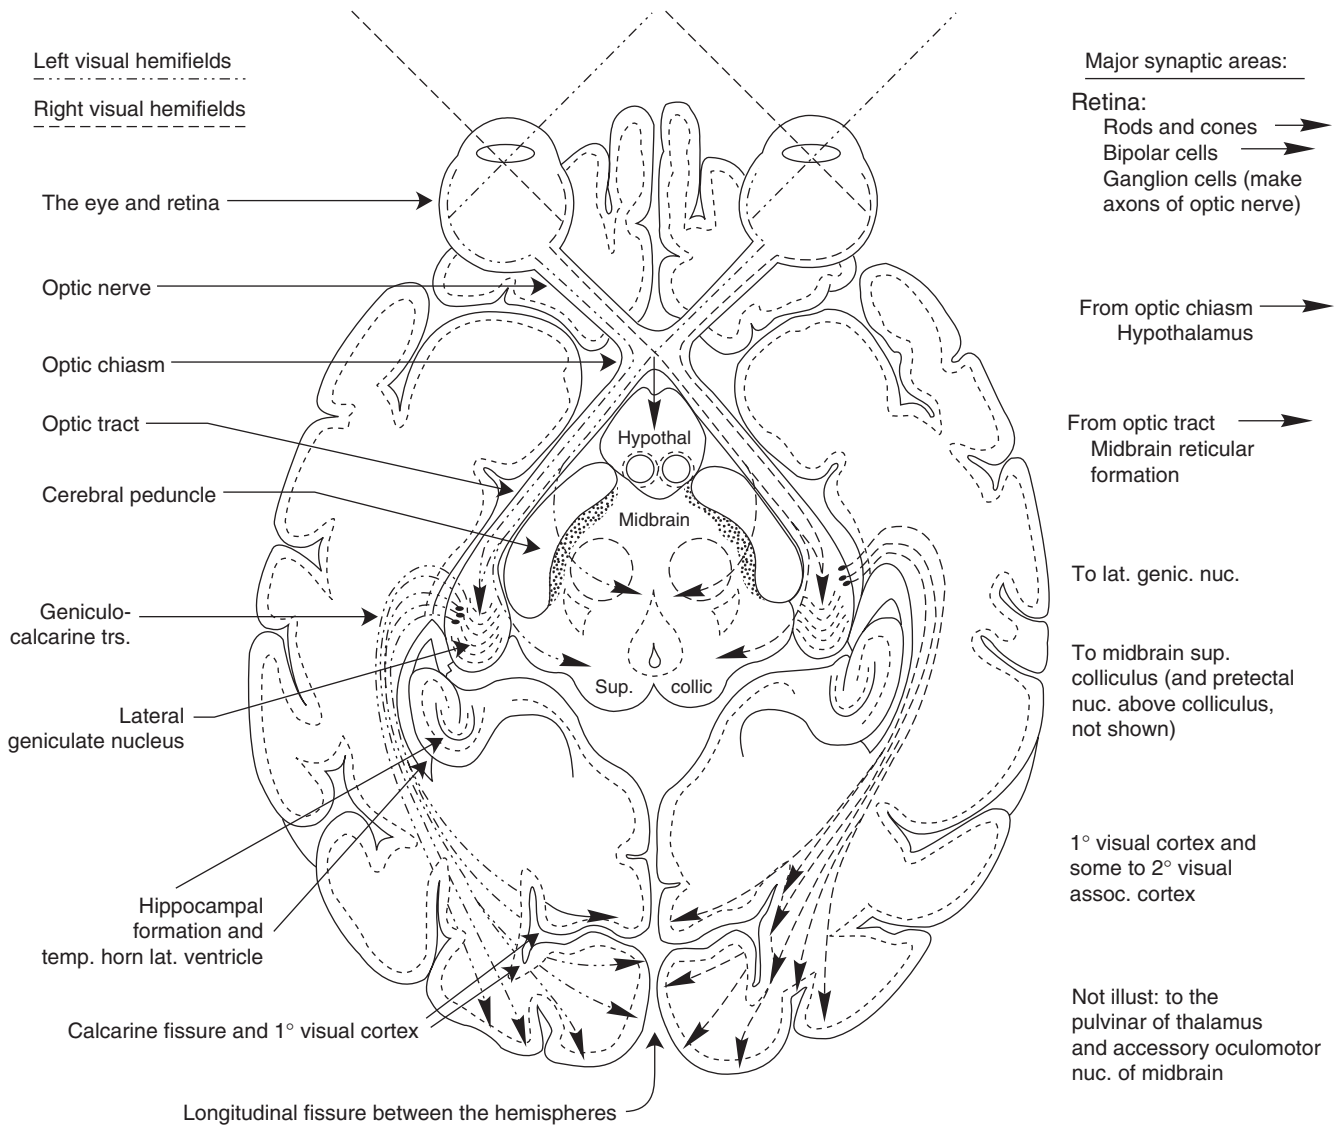

For vision to be used for occupation, the raw material of vision (i.e., the pattern of light that falls onto the retina) must be transformed into images of the surrounding environment that can be compared with stored memories, combined with other sensory input and knowledge, and then be used for decision making. The process is known as visual perception, and the journey encompasses many of the major structures of the CNS. The processing route is a circular one, with visual information transported from the retina in the anterior of the brain to the occipital pole in the posterior brain and then back again to the prefrontal cortex in the anterior brain. Along the way visual input is sorted out, fine-tuned, combined, and repackaged with other sensory input to provide a product that can be used for adaptation.^{17,55,81}

The process begins as light enters the eye and passes through the cornea and lens to focus on the retina. The retina conveys this information over the optic nerve and tract to the lateral geniculate nucleus (LGN) of the thalamus.⁵⁴ Because of crossing of retinal nasal fibers (of the optic nerve) at the optic chiasm, the LGN receives information from the retinal hemifields of both eyes.^{54,81} After synapsing in the LGN, visual information travels over the geniculocalcarine tracts (GCTs) to the V1 area of the visual cortex (found within the occipital lobe).⁵⁴ Figure 24-1 shows these pathways. The visual cortex sorts through the incoming visual information, sharpens and fine-tunes features such as orientation of line and color, and then disperses this information for cortical processing.^{54,55,128} From the visual cortex, visual information is processed by the temporal and parietal circuitry and eventually sent to the prefrontal circuitry to be used in decision making.⁵⁵ Before it can be used by the prefrontal areas, visual information must be combined (integrated) with other incoming sensory information to establish images and relationships between the body and the environmental surroundings.^{55,56,81}

To integrate vision with other sensory input, visual information is sent from the visual cortex to the prefrontal area over two routes: a “northern” or superior route, which takes it through the posterior parietal circuitry, and a “southern” or inferior route through the posterior temporal circuitry.^{44,55,56,81} This process is known as parallel-distributed sensory processing (Figure 24-2). Visual information traveling the southern route through the posterior temporal circuitry is combined with language and auditory input and processed for visual object information and recognition.^{55,81} The purpose of this processing is to identify objects and classify them. Neural processes in the posterior temporal lobe use precise visual input from the macular-foveal area

PARALLEL-DISTRIBUTED PROCESSING OF THE VISUAL SYSTEM-I

Schematic inferior view of a horizontal slice of the brain

The visual system is our most important sense in regard to:

- A. Learning, memory, and recall including our ability to see color and fine details as well as the visual surround and global relationships.
- B. Communication: use of symbolic language, speaking, and body language.
- C. Spatiotemporal orientation in concert with vestibular-proprioceptive systems.
- D. Early warning system to pleasure or danger, i.e., vision is our farthest reaching distance receptor and movement detector par excellence.
- E. Visual-manual and visual-motor activities.

1°, Primary.
2°, Secondary.

FIGURE 24-1 Pathways from the retina to the lateral geniculate nucleus to the visual cortex.

(Courtesy Josephine C. Moore, PhD, OTR.)

PARALLEL-DISTRIBUTED PROCESSING OF THE VISUAL SYSTEM

Two parallel routes carry visual information from the occipital lobe to the prefrontal lobe and frontal eye field (FEF). Fibers from these two routes distribute to many areas along each route (not illustrated) before terminating in the prefrontal cortex and FEF as illustrated.

(N) = “Northern” or superior route via parietal and frontal lobes.

(S) = “Southern” or inferior route via temporal and frontal lobes.

FIGURE 24-2 Visual input travels from the visual cortex through the parietal and posterior temporal circuitry to the prefrontal lobe to complete cortical visual processing.

(Courtesy Josephine C. Moore, PhD, OTR.)

of the retina to tune in to the visual details of objects. Processing by the posterior temporal circuitry is critical to the ability to distinguish discrete features of objects, such as the difference between the style of a can of diet Coke and regular Coke or particular facial features.⁵⁵

Visual information traveling simultaneously through the northern route to the prefrontal circuitry is processed in the posterior parietal lobe. The parietal lobe is a synthesizer of sensory information; it receives input from all of the sensory systems and integrates the input to create internal sensory maps that are used to orient the body in space.^{9,44,55,56,81,98,100} Visual information traveling through the parietal circuits is used to tune the CNS to the presence of objects surrounding the body and to determine the spatial relationship of these objects to the body and to each other. Visual information must be integrated with other sensory information to provide this orientation. Tactile, proprioceptive, kinesthetic,

vestibular, and auditory information is necessary, along with visual input, to accurately assess the relationship between the self and surrounding objects. The map created by information synthesized in the parietal circuitry is body centered and dynamic; it changes in shape and content as the body moves through space.^{9,44,79,81,98,100}

The posterior parietal circuitry in each hemisphere contains a map of the space on the contralateral side of the body. Thus, the right hemisphere contains a map of the left side of the body and surrounding space, and the left hemisphere contains a map of the right side of the body and surroundings.^{9,44,100} This map is not a detailed representation of space but provides a general impression of objects in space on that side of the body. The CNS relies on visual information from the peripheral areas of the retinal fields to create and maintain these maps. This area of the brain participates in directing general attention to and awareness of space.⁷⁹

The final destination for visual information traveling through the posterior temporal and parietal circuitry is the prefrontal area of the brain, where the information is used for cognitive processing to make decisions and formulate plans. This area, in conjunction with the premotor circuitry and other areas, is responsible for planning skilled body movements, including eye movements.^{43,44,55,81} Important visual structures located in the prefrontal lobes are the frontal eye fields, which are responsible for voluntary visual search of the space on the contralateral side of the body.^{11,44,92,101,103} The frontal eye fields in the right hemisphere direct visual search toward the left visual space, and vice versa. The frontal eye fields conduct a visual search based on an expectation of where visual information will be found in the environment.⁴² For example, if you were looking for a light switch in a room, you would direct your visual search toward the walls because that is where you expect to find a light switch. You would not waste time searching the floor or the ceiling. By directing visual search based on the expected location of crucial visual information, the CNS is able to process visual information quickly. This arrangement enables us to successfully engage in activities that require rapid visual processing, such as driving.

Not all visual information travels over the GCTs for cortical processing. Many neural pathways leave the optic nerve and tract and travel to subcortical areas, including the hypothalamus and brainstem.^{54,71,81} The brainstem contains important neural structures involved in visual processing. The superior colliculi, located in the midbrain of the brainstem, are the primary brainstem processing centers for visual input. The superior colliculi are responsible for the detection of moving visual stimuli appearing in the peripheral visual fields.^{44,54,71,77} When motion is detected, the colliculi automatically initiate eye movement toward the direction of the detected motion. In performing this function, the colliculi serve as an early warning system to prevent the CNS from being caught off guard by events occurring in the environment.^{44,90} The nuclei of cranial nerves III, IV, and VI, which control the extraocular muscles of the eyes, are also located in the brainstem, along with basic visual functions such as the light (pupillary) reflex and the accommodation reflex.⁵⁴

Many CNS areas are responsible for processing visual information, but all areas must work together for a person to make sense of what is seen and thus use this visual information to adapt.^{44,55,79,81,99} Millions of long and short neural fibers tie the various cortical and subcortical structures together to ensure effective and efficient visual processing. Like a car, in which the fuel injection system is as critical to performance as the spark plugs, the visual system will not run efficiently unless all of its components are working together. When brain injury or disease occurs, this communication system is disrupted and the organization of visual processing breaks down. Table 24-1 lists the effects of various CNS lesions on different aspects of the visual system. In reviewing the table, remember that a client will

exhibit limitations only in daily occupations that require the type of visual processing compromised by the lesion. For example, a deficit in the ability to process visual detail caused by a lesion in the left posterior temporal lobe would significantly affect the ability of a proofreader to return to work but might have little effect on a piano tuner's ability to return to work.

Penny's CVA occurred in the middle cerebral artery feeding the left hemisphere of the cortex and affected an area known as the internal capsule. As a result of the stroke, the temporal and parietal loops of the GCTs were damaged along with areas in the posterior parietal lobe and the motor strip controlling the left upper and lower extremities.

Framework for Assessment and Treatment of Visual Perceptual Dysfunction

A Hierarchic Model of Visual Perceptual Processing

The ability to use vision to adapt to the environment requires the integration of vision within the CNS to turn the raw data supplied by the retina into cognitive concepts of the perception of space and objects that can be manipulated and used for decision making. The process by which this occurs is known as visual perception. Visual perceptual function can be conceptualized as an organized hierarchy of processes that interact with and subserve each other.¹²⁰ Figure 24-3 illustrates this hierarchy. Within the hierarchy, each process is supported by the one that precedes it and cannot properly function without integration of the lower-level process. As Figure 24-3 shows, the visual perceptual hierarchy consists of the processes of visual cognition (visuocognition), visual memory, pattern recognition, visual

scanning, and visual attention. These perceptual processes are supported by three basic visual functions that form the foundation of the hierarchy: oculomotor control, visual fields, and visual acuity.

The ability to use visual perception to adapt to the environment is a result of the interaction of all of the processes in the hierarchy in a unified system. Although each perceptual process is discussed individually in this section, the reader should remember that the ability to adapt through vision is a result of the processes working in synergy. Although discrete perceptual processes can be identified, they do not operate independently of one another.

The highest-order visual perceptual process in the hierarchy is visual cognition. Visual cognition can be defined as the ability to manipulate and integrate visual input with other sensory information to gain knowledge, solve problems, formulate plans, and make decisions. In other words, visual cognition is the ability to use vision to complete cognitive processing. The development of visual cognition begins in childhood when we combine visual input with somatosensory input to develop such cognitive concepts as size constancy and permanence. We then apply these concepts to decision making. For example, if we see a 12-inch-tall adult, we assume that the adult must be some distance away because by applying size constancy we know that adults are not 12 inches high. Because visual cognition enables complex visual analysis, it serves as a foundation for

all academic endeavors, including reading, writing, and mathematics, as well as many vocations, such as artist, engineer, surgeon, architect, and scientist.

Visual cognition cannot occur without the presence of visual memory, the next process level in the hierarchy. Mental manipulation of visual stimuli requires the ability to create and retain a picture of the object in the mind's eye while the visual analysis is being completed. In addition to being able to store visual images temporarily in short-term memory, a person must also be able to store and retrieve images from long-term memory. For example, to interpret the illustration in Figure 24-4, one must be able to access visual memories of the shape of both a goose and a hawk. Adults and older children can easily resolve this illusion, but most toddlers cannot because they have not yet stored memories of the shapes of these birds.

Before a visual image can be stored in memory, an individual must recognize the pattern making up the image. Pattern recognition, which subserves visual memory in the hierarchy, involves identifying the salient features of an object and using these features to distinguish the object from its surroundings.³⁷ A salient feature is one that distinguishes a particular object from another. For example, the salient feature that differentiates an “E” from an “F” is the lower horizontal line on the “E.” Pattern recognition involves two abilities: the ability to identify the configural and holistic aspects of an object—to see its general shape,

FIGURE 24-4 Is this a goose or a hawk?

(From Warren M: A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, part I, *Am J Occup Ther* 47[1]:55, 1993.)

contour, and features—and the ability to identify specific features of an object, such as details of color, shading, and texture.¹⁸ Both aspects of recognition must occur for accurate identification.⁸

Pattern recognition cannot be accomplished without the next process in the hierarchy: organized and thorough scanning of the visual array. Visual scanning or search is accomplished through the use of saccadic eye movements. A saccade is a movement of the eye toward an object of interest in the environment. The purpose of a saccade is to focus on the object with the fovea, the area of the retina with the greatest ability to process detail.⁴² In scanning a visual array, the eyes selectively focus on the elements that are critical for accurately interpreting the array.^{35,48,83,95} The most important details are re-examined several times through a series of cyclic saccades to ensure that correct identification is made. Unessential elements in the scene are ignored.^{35,95,131}

Visual scanning is actually a product of visual attention.^{35,45,48,90} The saccadic eye movements observed in scanning reflect the engagement of visual attention as it is shifted from object to object. Visual search occurs on two levels: an automatic or reflexive level largely controlled by the brainstem and a voluntary level driven by the cortical processes of cognition.⁷⁹ On a reflexive level, visual attention (and therefore visual search) is automatically engaged by any novel object moving or suddenly appearing in the peripheral visual field, such as a flash of light.^{54,77} This response serves to protect an individual from unexpected intrusions in the environment. Voluntary visual search, directed by the cortex, is completed for the explicit purpose of gathering information. Visual search is purposefully and consciously driven by a desire to locate certain objects in the environment, such as a misplaced set of keys, or to obtain certain information, such as where an exit is located.^{35,79}

Visual attention is a critical prerequisite for visual cognitive processing. If and how a person attends to an object or information determines whether and how that visual input

is analyzed by the CNS, which becomes the basis for decision making. People who do not attend to visual information do not initiate a search for visual information, do not complete pattern recognition, do not lay down a visual memory, and cannot use this visual input for decision making. Likewise, those who attend to visual information in a random and incomplete way often do not have sufficient or accurate information on which to base a decision.

The type of visual attention engaged by the CNS depends on the type of visual analysis needed. For example, the type of attention needed for awareness that a chair is in the room is different from the type needed to identify the style of the chair. The first instance requires a global awareness of the environment and the location of objects within it; the second requires selective visual attention to the details of the chair to identify its features. In addition, it is necessary to be able to use more than one type of visual attention at the same time. When crossing a crowded room to talk to a friend, a person must be aware of the movement of people and the placement of obstacles in the room to avoid collisions while at the same time focusing on the friend (or target). The CNS uses several types of visual attention simultaneously and shifts constantly between types and levels of attention.⁷⁹ Because a large amount of neural processing is devoted to directing visual attention, visual attention can easily be disrupted by brain injury, but at the same time it is a highly resilient visual perceptual process.⁷⁹

Engagement of visual attention and the other higher-level processes in the hierarchy cannot occur unless the CNS is receiving clear, concise visual information from the environment.^{21,120} Visual input is provided through the visual functions of oculomotor control, visual field, and visual acuity. Oculomotor control enables eye movements to be completed quickly and accurately and ensures perceptual stability. The visual fields register the visual scene and ensure that the CNS receives complete visual information. Visual acuity ensures that the visual information sent to the CNS is accurate. Without these prerequisite visual functions, an inadequate image is generated, thereby preventing the engagement of higher-level visual perceptual processing.

Brain injury or disease can disrupt visual processing at any level in the hierarchy. Because of the unity of the hierarchy, if brain injury disturbs a lower-level process or function, the processes above it will also be compromised. When this occurs, the client may appear to have a deficit in a higher-level process even though the deficit has actually occurred at a lower level in the hierarchy. For example, a client who is unable to complete an embedded figures test appears to have a deficit in the visual cognitive process of figure-ground perception. In fact, this client may be experiencing inaccurate pattern recognition caused by an asymmetric scanning pattern that results from visual inattention, compounded by a VFD. Treatment of the higher-level process (figure-ground imperception) will not be successful unless the underlying deficits in visual attention and visual

field are addressed first. This effect is similar to that observed in the motor system following brain injury. The high-level deficit observed is that the client cannot use the hand to pick up an object. The underlying deficits are reduced muscle tone and sensation and muscle weakness. Use of the hand for manipulation will not be possible until the deficits in muscle tone, strength, and sensation are addressed by intervention.

Left homonymous hemianopia was diagnosed in Penny. Because of this deficit, she does not see objects in the left half of her visual field. This visual field defect compromises her ability to attend to objects on her left side, and she fails to search for objects on her left side. Failure to search for objects on her left side limits her ability to complete pattern recognition and form visual memory of objects on her left side. Because she has no visual memory of objects on the left side, she is more likely to experience disorientation and collide with objects on the left when navigating environments.

OT Practice Notes

Effective assessment and treatment of visual perceptual dysfunction require an understanding of how brain injury affects the integration of vision at each level of the process and how the levels interact to enable visual perceptual processing.

Intervention

When working with a client with visual impairment following brain injury, the OT practitioner often encounters and works closely with two medical disciplines: ophthalmology and optometry. Specialists in both these eye care fields diagnose, manage, and treat visual impairment, and both may serve as a referral source to OT practitioners. However, there are distinctions between the two professions that OT practitioners must be aware of to collaborate effectively and benefit from their input. Ophthalmologists are medical doctors who complete a residency in ophthalmology. As physicians, ophthalmologists are primarily responsible for diagnosing and treating medical conditions that cause visual impairment. Neuro-ophthalmologists are board-certified in this specialty and often treat the largest number of persons with visual impairment as a result of brain injury. Consequently, they often work with OT practitioners and serve as referral sources and consultants to OT practice.

Optometrists are independent health care providers who have a doctorate in optometry from a postgraduate university program. Like OT practitioners, optometrists specialize in a variety of areas following training, including neuro-rehabilitative, developmental, and behavioral optometry. Although they are not medical doctors, they also diagnose and treat medical conditions causing vision loss and provide nearly two thirds of primary eye care in the United States.

Neither discipline, at this time, routinely serves as a member of the rehabilitation team, and both provide mainly consultative services. Which specialty the team uses depends primarily on availability and reimbursement.

Occupational Therapy Evaluation

To develop an intervention plan, the OT practitioner must link limitations in activity and participation to the presence of a visual impairment. Establishing this relationship is the purpose of assessment of visual performance by an OT practitioner. This process is also known as establishing “medical necessity,” which is the prerequisite to receiving third party reimbursement for OT services. To achieve the link, the practitioner must be able to identify the limitation in occupation and then connect it to the presence of a visual impairment. This frequently requires that the OT practitioner also perform assessments to identify visual impairment. However, whereas an ophthalmologist or optometrist evaluates visual impairment for the purpose of diagnosing a visual disorder, OT practitioners assess visual impairment to explain the presence of a limitation in occupation and participation.

OT Practice Notes

Occupational therapy assessment has three purposes: (1) to identify the limitation in activity or occupation, (2) to link that limitation to the presence of a visual impairment, and (3) to develop an appropriate intervention plan based on the results of the assessment. In addressing evaluation and intervention, it is important to remember that a client’s visual performance is significant not in terms of how it deviates from an established norm but in how it interferes with occupational performance. A client is considered to have a visual impairment that requires intervention if the impairment interferes with performance of a necessary daily occupation.

In an ideal treatment setting, the OT practitioner would work in partnership with an ophthalmologist or optometrist to identify the client’s visual impairment. These eye care professionals would serve as members of the rehabilitation team and screen the client’s vision at several intervals during the recovery period. They would provide the other rehabilitation professionals on the team information regarding the health of the eyes and the status of visual acuity, visual field, and oculomotor control, along with information on prognosis and medical and optical management. In reality, these two eye care specialists are rarely integrated into rehabilitation teams, and the process of obtaining a referral to either one is time-consuming and difficult.

To succeed, the OT practitioner must often first convince the physician or case manager overseeing the client’s

recovery that a visual deficit exists and is limiting occupational performance. This requires the OT practitioner to be well versed in completing basic visual assessments such as acuity, contrast sensitivity function, and visual field to screen for visual impairment. The eye care specialist would use the information obtained from these evaluations to diagnose the client's visual impairment, whereas the OT practitioner would use the information to justify referral to these specialists and to link the presence of an occupational limitation to visual impairment.

Several tests are available to OT practitioners for assessment of visual performance. Subtests from the Brain Injury Visual Assessment Battery for Adults (biVABA) developed by the author are used in this chapter to describe assessment techniques.¹²¹ The biVABA was designed specifically as a tool to assist OT practitioners in developing effective intervention plans for adults with visual impairment caused by brain injury. The biVABA consists of 17 subtests designed to measure visual processing ability. The assessments include evaluation tools used by ophthalmologists and optometrists to measure basic visual function, along with subtests designed specifically for OT practitioners.

Occupational Therapy Intervention

The focus of OT intervention is to change the outcome in the categories of visual disability and visual handicap. Two primary approaches are used in providing intervention. A remediation approach may be used in which intervention attempts to establish or restore the client's ability to complete visual processing by improving aspects of visual performance such as increasing the efficiency of visual search or improving visual attention. A compensatory approach is also used in which the emphasis of intervention is on changing the context of the environment or task to enable the client to successfully use his or her current level of visual processing. These two approaches may be used alone or together, depending on the needs of the client. Education of the client and family is always used in conjunction with the two approaches to increase their insight into how the client's visual processing has changed and how it has affected occupational performance. Education is a critical component of the intervention process because insight is crucial to the ability to learn compensatory strategies.^{1,110}

Occupational Therapy Assessment and Intervention for Specific Visual Impairments

The concept of a visual perceptual hierarchy provides the framework for the discussion of assessment and intervention. It is assumed that many changes in visual perceptual function occur after brain injury because of the alteration in lower-level processes within the perceptual hierarchy,

including visual acuity, visual field, oculomotor control, and visual attention and scanning. Deficits in these functions prevent the CNS from accurately carrying out complex visual processing and using vision for adaptation. Identification of deficiencies in these processes, followed by treatment to remediate the deficits, enables the CNS to process visual input more efficiently and facilitates adaptation. This section focuses on assessment and intervention for these processes within the visual perceptual hierarchy and examines how brain injury disrupts the functioning of each process, how the process is assessed, and how the implementation of intervention is provided.

Visual Acuity

Visual acuity is the ability to see small visual detail. Acuity contributes to the capability of the CNS to recognize objects. The dictionary defines acuity as "keenness or sharpness," and with regard to vision, acuity ensures that clear and precise visual information is provided to the CNS for processing.^{2,109} The greater the quality of the visual input, the more precise the image created by CNS processing. The more precise the image, the faster and more accurate the ability of the CNS to recognize the object and discriminate it from other features in the environment. Good acuity therefore enables speed and accuracy of information processing and facilitates decision making.

Acuity occurs through a multistep process that begins with focusing of light onto the retina. Light rays enter the eye through the pupil and are focused on the retina by the anterior structures of the eye: the cornea, lens, and optic media (Figure 24-5).¹⁰⁹ The retina, acting like film in a camera, processes the light and records a "picture" that is relayed to the rest of the CNS via the optic nerve and pathway.⁵⁵ Although the concept is simple, the process is complex and involves many factors, including the ability to focus light precisely onto the retina, the ability to maintain sharp focus over various focal distances, the ability to obtain sufficient illumination of the retina to capture a quality image, and the ability of the optic nerve to transmit the image through the CNS for perceptual processing.^{54,55} Any compromise of the structures involved in this process will result in degradation of the image and reduced acuity.¹⁰⁶

Visual acuity is most commonly measured by having the client read progressively smaller optotypes on a chart. The optotypes may be letters, numbers, or symbols. The most common acuity measurement unit used in the United States is the Snellen fraction (20/20, 20/50, etc.).¹⁷ The fraction represents a ratio of distance to size of the optotype.²⁶ In layman's terms, a measurement of "20/20" means that when standing at a distance of 20 feet, the viewer can see the letter that a person with normal vision can see at 20 feet, and 20/200 would indicate that a person standing at a distance of 20 feet can see a letter that a person with normal vision could identify at 200 feet. In reality, 20/20 means that a person can identify an optotype that subtends 1 minute of arc at a distance of 20 feet, whereas 20/200 means that a

FIGURE 24-5 Anterior structures of the eyeball. Light passes through these transparent structures to focus on the receptor cells of the retina. (Courtesy Josephine C. Moore, PhD, OTR.)

person can identify an optotype that subtends 10 minutes of arc at the same distance.

Visual acuity is typically associated with the ability to see high-contrast, black-on-white optotypes. However, visual acuity is actually a continuum of visual function ranging from the ability to detect high-contrast features on one end of the continuum to the ability to detect low-contrast features (such as beige on white) on the other end.⁵⁰ Low-contrast acuity, known as contrast sensitivity function (CSF), is the ability to detect the borders of objects reliably as they decrease in contrast (rather than size) from their backgrounds.⁵⁰ CSF makes it possible to distinguish and identify faint features of objects, such as the curve of a concrete curb or protrusion of the nose on the face.⁵⁰ Because much of the environment is made up of low-contrast features (gradations of colors between objects rather than stark contrasts), CSF is a critical visual function underlying the ability to negotiate an environment safely.⁵⁰

For example, curbs and steps are routinely the same color throughout; without CSF, it would not be possible to see the depth in the curb or step. Carpets, walls, doors, door frames, and furniture are also often monochromatic in color; without the ability to distinguish low-contrast features, it would not be possible to locate the door or avoid

the chair jutting out into the pathway in monochromatic environments. One of the most common low-contrast objects is the human face. Human faces contain very little differentiation in contrast between the facial features. That is, the nose is the same color as the forehead, cheeks, and chin, and eye and hair color are designed to blend with skin tones. To see the unique features of a human face requires very good CSF. Research has shown that CSF can be impaired in clients even when their high-contrast acuity is within normal limits.^{16,19,48} Therefore, both forms of acuity (high and low contrast) must be measured to obtain an accurate assessment of acuity function.

Two forms of high-contrast visual acuity are measured: distance acuity and reading (near) acuity. Distance acuity is the ability to see objects at a distance. Near acuity is the ability to see objects clearly as they come close to the eye. Near acuity is most accurately called “reading acuity” because reading is the primary activity enabled by near acuity. Reading acuity is measured by having the client read sentences in progressively smaller sizes of print. Reading acuity is dependent on the brainstem neural process of accommodation. Accommodation enables the eye to maintain clear focus on objects as they come closer.⁴² When an object approaches the eye, its point of focus on the retina is pushed

farther back, which eventually causes the image to go out of focus. The CNS adjusts for this situation through the three-step process of accommodation. As the object comes closer, (1) the eyes converge (turn inward) to ensure that the light rays entering the eye stay parallel and in focus, (2) the crystalline lens of the eye thickens to refract the light rays more strongly and shorten the focal distance, and (3) the pupil constricts to reduce scattering of the light rays. These three steps enable objects to stay in focus in the near-vision range (distances between 3 and 16 inches from the eyes).

The accommodative process is controlled by the third cranial nerve (the oculomotor nerve), whose nucleus is located in the midbrain portion of the brainstem.⁴² Brain injuries that affect the brainstem or this nerve can disrupt the accommodative process. A person experiencing such disruption may demonstrate normal distance acuity (which does not require accommodation) and impaired reading acuity. Accommodation can also be affected by a normal by-product of aging called presbyopia. Until the fourth decade of life the accommodation process works efficiently to ensure equal acuity when an individual is viewing objects both up close and at a distance. As a person approaches the age of 50, the lens of the eye gradually becomes less flexible, thereby reducing its ability to keep images in focus as they come closer and creating presbyopia.¹⁰² Persons with this condition frequently complain of difficulty reading small print. Presbyopia is corrected either by using reading glasses to magnify print or, if the person already wears eyeglasses, by adding a magnifying lens or “reading ad” to the base of the lenses to create a bifocal. Because of the influence of accommodation, both forms of acuity, reading and distance, must be measured to obtain an accurate assessment of acuity function in some clients.

Deficits in Visual Acuity

In the normal eye, most deficiencies in visual acuity are due to defects in the optical system (the cornea or lens or even the length of the eyeball), which cause images to be focused poorly on the retina.¹⁰² The three most common optical defects that reduce acuity are myopia (nearsightedness), hyperopia (farsightedness), and astigmatism. In myopia, the image of an object is focused at a point in front of the retina and is therefore blurred when it reaches the retina. Myopia is corrected by placing a concave lens in front of the eye. In hyperopia the image comes into focus behind the retina, which causes the image to remain out of focus on the retina. Hyperopia is corrected by placing a convex lens in front of the eye. [Figure 24-6](#) illustrates these defects. In astigmatism, light is focused differently by two meridians 90 degrees apart. A cornea that is not perfectly spherical and smooth but is more spoon shaped or dimpled usually causes this defect. It results in blurring of the image because both meridians cannot be focused on the retina. Astigmatism is corrected by placing a cylindrical lens in front of the eye.

Visual acuity deficits primarily occur as a result of impairment in three areas of visual processing: disruption of the

ability to focus light onto the retina, inability of the retina to accurately process the image, and inability of the optic nerve to transmit the information to the rest of the CNS for processing.¹⁰⁶ These impairments may be the direct result of a brain injury, a disease process, or a change in the eye occurring incidental to the injury. It is not possible to describe all of the conditions that can result in reduced acuity after brain injury, but the most common are described in the sections that follow.

Disruption of the Ability to Focus an Image on the Retina

Sharp focusing of an image on the retina depends largely on the transparency of the intervening structures between the outside of the eye and the retina and on the ability of these structures to focus the light rays entering the eye. Light entering the eye passes through four transparent media: the cornea, aqueous humor, crystalline lens, and vitreous humor. An opacity or irregularity in these structures will prevent light from properly reaching the receptor cells in the retina. Conditions that can occur in conjunction with head trauma include corneal scarring, trauma-induced cataract, and vitreous hemorrhage.¹⁰⁶ Corneal scarring may result from direct trauma to the eye sustained during an assault to the head. The inner layers of the cornea are damaged and scar as they heal, which creates an irregular surface that refracts the light unevenly. The person experiences blurred vision similar to that created by astigmatism. Trauma to the crystalline lens may cause displacement or result in the subsequent development of a cataract that clouds the lens and reduces acuity. Trauma to the eye can also result in bleeding into the vitreous humor. Because blood is an opaque medium, light cannot pass through it, and the client experiences floaters, shadows, and episodes of darkness as the blood passes in front of the retina. Of these conditions, only vitreal hemorrhage is temporary and resolves without treatment.

Impairment of accommodation is another condition that affects the focusing ability of the eye. This condition is associated with brainstem injury, either from head trauma or from stroke.^{53,71,72,102,106} As stated previously, brainstem injury can affect the functioning of one or all of the components of accommodation: convergence of the eyes, thickening of the lens, and pupillary constriction. When accommodation is impaired, the client has difficulty achieving and sustaining focus during near-vision tasks. The most frequent complaint voiced by the client is difficulty maintaining focus during reading, which may cause the print to blur and swirl on the page.²⁵

Disruption of the Ability of the Retina to Process the Image

The health and integrity of the retina also influence the quality of the image sent to the CNS. The receptor cells of the retina can be damaged directly by injury or disease, thereby preventing them from responding to light. Diseases that affect retinal function, such as macular degeneration

FIGURE 24-6 Normal, myopic, and hyperopic optical refraction of light coming into the eye and the type of lens used to correct myopic and hyperopic optical refractive errors.

(Courtesy Josephine C. Moore, PhD, OTR.)

and diabetic retinopathy, are associated with age and significantly increase in incidence in the seventh and eighth decades of life.³⁶ With damage to the retina (especially the macular area), both high- and low-contrast visual acuity is diminished, thus making accurate identification of features and objects difficult. It is estimated that approximately one in four persons older than 80 years has a visual impairment that affects the retina significantly enough to prevent reading standard print. It is not uncommon for an older adult who has been referred for treatment of a CVA (such as stroke) to also demonstrate reduced visual acuity secondary to eye disease. Too often the visual loss resulting from the disease is either overlooked or misdiagnosed as an impairment in attention or cognition associated with the CVA.

Disruption of the Ability of the Optic Nerve to Send the Retinal Image

The most common cause of optic nerve damage in brain injury is trauma.⁵³ Damage can occur from a direct penetrating injury to the nerve, such as a missile wound to the head from a gunshot.⁵³ Indirect trauma can also occur from an optic canal fracture associated with facial or blunt forehead fractures. These fractures are most common in children and young adults and usually result in unilateral injuries.⁵³ Severe closed head injuries can cause stretching or tearing of the optic nerve and result in significant and generally bilateral damage to the nerves. Bilateral optic nerve injury can also result from compression of the nerves secondary to intracranial swelling or hematoma.⁵³

Other common conditions that can cause optic nerve damage are glaucoma and multiple sclerosis. Glaucoma typically damages the optic nerve fibers carrying peripheral visual field input but can also affect the central visual field and reduce visual acuity. Multiple sclerosis can cause plaques to develop along the optic nerve, which results in optic neuritis, a condition accompanied by reduced visual acuity, VFD, and sensitivity to light (photophobia).¹⁰⁶

Occupational Limitations Caused by Reduced Visual Acuity

Reduced visual acuity can cause limitations in a significant number of daily occupations. The severity of the limitation depends on the extent of the loss in acuity and whether there has been a loss of central acuity, peripheral acuity, or both. Loss of central acuity results in an inability to discriminate small visual details and to distinguish contrast and color. Activities dependent on reading, writing, and fine motor coordination (e.g., reading recipes and labels on foodstuffs, dialing a telephone, writing a check, paying a bill, applying makeup, shaving, identifying money, and shopping) will be affected. When peripheral acuity is reduced, as occurs with a VFD, mobility will be affected. The client may be unable to identify landmarks, see obstacles in the path of travel, or accurately detect motion, which may impair his or her ability to ambulate safely and maintain orientation in the environment. This may reduce independence in driving, shopping, and participation in community activities.

Assessment of Performance Skills

All assessment of performance skill begins with observation of the client's performance in daily activities. Clients with deficits in visual acuity often complain of an inability to read print and may state that the print is too small or too faint to read. Complaints that print is distorted, that parts of words are missing, or that the words run together and swirl on the page are also common. Clients with deficits in CSF may complain of an inability to see faces clearly. These clients may also be unable to distinguish between colors of similar hue, such as navy blue and black, or to detect low-contrast substances such as water spilled on the floor.

If a decrease in visual acuity is suspected, a screening is completed to determine how the acuity has changed. To obtain a complete picture of the client's visual acuity, both high- and low-contrast acuity are measured. High-contrast acuity is measured both for distance, using a test chart at a distance of 1 m or greater, and for reading, using a text card at 40 cm (16 inches). When measuring visual acuity, the practitioner must be sure that the chart is well illuminated and held at the specified distance from the client. Adequate illumination is important because as illumination decreases, so does acuity (no one can read a letter chart in the dark). Because acuity is depicted as a fraction of distance over letter size (e.g., 20/20 or 20/200), the measurement is not accurate unless the viewing distance is accurate. All test charts

specify a distance at which they are to be used, and this should not be altered.

The client's acuity level is determined by the smallest line of optotypes that can be read with good accuracy. The client is instructed to read the optotypes on the chart out loud, beginning with the largest line and continuing to lower lines until the print is too small to see. Clients with brain injury may have deficits in cognition, language, and perception that interfere with the ability to provide an accurate and timely response in a testing situation. Extra time may be needed for the client to locate the optotype, process the image, and respond. Slowness in responding therefore does not necessarily indicate that the client lacks the acuity to identify the optotype. If the client struggles with the identification of optotypes on each line but is accurate, the test should proceed until a line is reached on which the client can no longer accurately identify the majority of the optotypes.

The most useful chart for the OT practitioner is one that measures visual acuity as low as 20/1000 so that significant reductions in acuity can be measured. Standard charts measure visual acuity primarily in the range that can be compensated for with eyeglasses and measure nothing below 20/200 Snellen acuity. When acuity is below that level, the client is referred to a low-vision specialist for evaluation. Because some conditions such as optic nerve damage or macular diseases can result in profound vision loss (less than 20/400 acuity), it is important for a practitioner to be able to measure acuity in the lower ranges so that appropriate referral and modifications can be made. The LeaNumbers Low Vision Test Chart and the Warren Text Card from the biVABA are examples of test charts that measure visual acuity in the low-vision ranges.

CSF is also assessed by viewing optotypes printed on a chart that is held at a specified distance from the client. However, for this type of testing the optotypes (which may be letters, numbers, symbols, or sine wave gratings) remain the same size but diminish in contrast as one proceeds down or across the chart. The client is asked to identify as many optotypes as possible. There are many forms of CSF tests. The least expensive and most portable test charts are those designed by Dr. Lea Hyvarinen and include the LeaNumbers Low Contrast Screener (part of the biVABA), the LeaSymbols Low Contrast Screener, and the LeaNumbers and LeaSymbols Low Contrast Tests. When CSF is measured, the client is asked to read down the chart as far as possible until the optotype is too faint to be identified. As with high-contrast acuity testing, the test chart must be held at a specific distance and must be well illuminated to obtain an accurate measurement.

In assessing visual acuity, the OT practitioner is not responsible for diagnosing the cause of the deficiency, but rather linking the presence of the deficiency to a limitation in occupational performance. This is a subtle but important distinction that affects the assessment procedure. When a client has reduced visual acuity, the ophthalmologist or

optometrist uses the results of the assessment to determine the cause of the reduction (e.g., damage to the retina or cornea or the presence of a refractive error). With this information, the eye care specialist determines how to manage the condition to restore optimum sight with optical devices (glasses or contact lenses), a surgical procedure, or medication prescription. In contrast, when an OT practitioner determines that a client has reduced visual acuity, the information is used to modify activities and the environment so that the client can compensate for the loss and successfully complete daily activities. For example, if a client cannot read the size of print on a medication label, the OT practitioner determines whether the print can be enlarged to a size that the client can read or determines another way for the client to identify the medication bottle.

Intervention

If a significant reduction in visual acuity is noted, the client should be referred to an ophthalmologist or optometrist to determine the nature and cause of the visual loss and whether vision can be restored. Referring clients to specialists can take days, weeks, and even months to complete. The client's intervention program cannot be placed on hold while the referral is being processed; therefore, the OT practitioner uses the information obtained from the assessment to modify the environment and activities and enable the client to use his or her remaining visual acuity. This is achieved by increasing the visibility of the environment and tasks through manipulation of physical context.

Increase Background Contrast

Changing the background color to contrast with an object can help the client see objects more clearly. Application of this technique can be as simple as using a black cup for milk and a white cup for coffee. In cases in which the background color cannot be changed, such as on carpeted steps, color can be applied to provide a marker. For example, a line of bright fluorescent tape can be applied to the end of each step riser on the carpeted stairs to distinguish between them.³³

Increase Illumination

Increasing the intensity and amount of available light enables objects and environmental features to be seen more readily and reduces the need for high contrast between objects. For example, facial features can be identified more easily if a person's face is fully illuminated. The challenge in providing light is to increase illumination without increasing glare. Halogen, fluorescent, and full-spectrum lights provide the best sources of bright illumination with minimum glare and are generally recommended over standard incandescent lighting for both room and task illumination. Lighting should be strategically placed to provide full, even illumination without areas of surface shadow. For example, if a 50-W halogen lamp is used for reading, it should be positioned behind the client's shoulder so that

the page of print is fully illuminated without the light shining directly in the client's eyes.

Reduce Background Pattern

Patterned backgrounds have the effect of camouflaging the objects lying on them. The detrimental effect of pattern on object identification can be minimized by using solid colors for background surfaces such as bedspreads, place mats, dishes, countertops, rugs, towels, and furniture coverings. Objects in the environment also create a background pattern. Cluttered environments with haphazardly placed objects create challenges, even for persons with good acuity. If possible, the number of objects in the environment should be reduced and those remaining arranged in an orderly fashion. Closets, drawers, shelves, and countertops should be reorganized and simplified, as should such areas as sewing baskets, desks, and refrigerators.

Enlarge Objects or Features That Need to Be Seen

When possible, objects should be enlarged to make them more visible. Instructions can be reprinted in larger print, medications and other items relabeled, and calendars enlarged. The last line of print that is easily read on the reading acuity test card indicates the minimum size that print should be enlarged for the client. Contrast should also be increased because it does little good to enlarge print if the print is faint. Black on white or white on black print is usually more visible than any other color combination. Many items are now manufactured with larger print, including calculators, clocks, watches, telephones, check registers, glucose monitors, scales, playing cards, games, and puzzles. These items can be purchased through specialty catalogs.

Organize

Items used daily should be arranged on accessible shelves in single rows. Rarely used items should be stored on upper and lower shelves or removed. Commercially available organizing systems can be used to store similar items together to create workstations. Once closets and shelves are rearranged and simplified, every effort should be made to keep them organized. Putting items back where they belong and maintaining organization reduce frustration and facilitate independence. Establishing routines for tasks such as filing nails and paying bills prevents these tasks from becoming overwhelming. Task steps requiring vision to complete can be eliminated by using such items as pre-chopped and pre-measured food ingredients, wrinkle-free clothing, electronic funds transfer, and voice-activated telephone dialing.

Access Community Services

In addition to environmental modification, the client may benefit from the variety of services available to assist persons with vision loss. These services are generally free of charge and can be found in the resource section of the public library or by contacting an advocacy organization such as the American Foundation for the Blind (www.afb.org)

FIGURE 24-7 Visual field chart illustrating the divisions of the visual field related to visual acuity. (Courtesy Josephine C. Moore, PhD, OTR.)

or the Lighthouse Information and Resource Center (www.lighthouse.org). The following are some examples of available services:

1. The National Library Service for the Blind and Physically Handicapped offers books, magazines, and music on cassette tape through its Talking Books program.
2. Most states offer radio reading services in conjunction with a university-sponsored public radio station.
3. Local telephone companies often offer free directory assistance to persons with disabilities; most pharmacies will provide large-print medication labels, and many businesses will provide large-print bills.

Visual Field

The visual field is the external world that can be seen when a person looks straight ahead. It is analogous to the dimensions of a picture imprinted on the film in a camera (with the retina representing the film). The normal visual field extends approximately 60 degrees superiorly, 75 degrees inferiorly, 60 degrees to the nasal side, and 100 degrees to the temporal side.^{3,106} As shown in Figure 24-7, most of the visual field is binocular and is seen by both eyes. A small

Threaded Case Study Penny, Part 2

The location of Penny's stroke in the middle cerebral artery would not cause a change in visual acuity. However, Penny's medical condition of insulin-dependent diabetes may cause diabetic retinopathy and other eye conditions that can result in significant visual loss. After learning that she was a diabetic, the optometrist carefully evaluated the health of Penny's eyes and checked her acuity. The optometrist saw changes on the retina indicating that Penny has early-stage background diabetic retinopathy. The disease has not yet caused a reduction in visual acuity. The optometrist reinforced to Penny that she must maintain her blood glucose at the level prescribed by her physician, monitor her diet, and check her blood glucose levels several times a day. The optometrist conveyed this information to the OT practitioner and instructed the practitioner to assess Penny's ability to compensate for her VFD in completing diabetes self-management, including drawing insulin, using a glucometer to monitor blood glucose levels, and completing meal preparation according to her prescribed meal plan.

portion of the peripheral temporal field in each eye is monocular and can be seen by only one eye because the bridge of the nose occludes vision in the other eye. At the very center of the retinal visual field is the fovea, an area approximately 8 to 10 degrees in diameter that records the visual details for identification of objects. The fovea is located in the macular area of the field, also referred to as the central visual field (Figure 24-7). This area, which is packed with cone receptor cells, is approximately 20 to 30 degrees in diameter and is used for identification of objects.^{81,109} The rest of the visual field is the peripheral field. The peripheral visual field is composed of rod receptor cells that detect general shapes and movement in the environment. On the border between the central and peripheral visual fields on the temporal side is the blind spot, so called because the optic disc pierces the retina here and there are no sensory receptor cells.

Visual Field Deficits

Damage to receptor cells in the retina or to the optic pathway that relays retinal information to the CNS for processing results in a VFD.^{3,54,80,106,129} Figure 24-1 illustrates this pathway as it changes from the optic nerve to the optic tract to the GCTs. The location and extent of the VFD depends on where the damage occurs on the pathway. Although any type of VFD is possible after brain injury, homonymous hemianopia resulting from a lesion along the GCTs is the most commonly occurring deficit.¹³⁴ Hemianopia (hemi = half, anopia = blindness) means that there has been loss of vision in half of the visual field in the eye. Homonymous means that the deficit is the same in both eyes. A lesion along the GCTs in the right hemisphere causes left homonymous hemianopia; a lesion along the GCTs in the left hemisphere causes right homonymous hemianopia. In stroke, most hemianopias are caused by occlusion of the posterior cerebral artery,^{40,134} although a middle cerebral artery stroke such as that experienced by Penny in the case example can also cause this deficit.

Occupational Limitations Caused by Visual Field Deficits

Although a VFD is often considered a mild impairment in comparison to the dramatic loss of use of the limbs, it can create changes in visual processing that significantly limit daily performance.⁴⁰ The most important change occurs in the search pattern used by a person with a VFD to compensate for the blind portion of the visual field. Instead of spontaneously adopting a wider search strategy (turning the head farther to see around the blind field), the person tends to narrow the scope of scanning.^{89,132} The person typically turns the head very little and limits visual search to areas immediately adjacent to the seeing side of the body. The reason for this odd strategy is the influence of a visual process known as perceptual completion.^{48,73,91,99,105} Perceptual completion is a process whereby the CNS samples a visual array and internally completes a visual scene based on an expectation of the visual information that would be

FIGURE 24-8 Example of perceptual completion. A person exercising perceptual completion is able to perceive the border of the solid white triangle in the center of this illustration even when no contrast exists between the border and the background to define the triangle. This perception is based on juxtaposition of the circles and black lines, which “suggests” the presence of the white triangle.

(From Schuchard RA: Adaptation to macular scotomas in persons with low vision, *Am J Occup Ther* 49:873, 1995.)

found in the array, as illustrated in Figure 24-8. The perceptual outcome of this process is that the viewer perceives that he or she is seeing a complete visual scene, even though part of the visual information in the scene was not recorded.^{55,105}

Perceptual completion provides speed in information processing by enabling an individual to construct a complete visual scene based on partial visual input. Accordingly, it plays an important role in the person’s ability to adapt to fast-paced and dynamic environments. However, in the case of significant visual field loss, the presence of perceptual completion makes it difficult for the client to determine how his or her visual field has changed.^{73,99} Because of perceptual completion, a client with a VFD is not immediately aware of the absence of vision after onset of the deficit.^{71,73,105} He or she perceives the presence of a complete visual field without gaps or missing information. However, the CNS cannot place objects in a visual scene that it does not actually see. Therefore, the client may not be aware of unanticipated objects on the blind side. As a result, the client may run into a recently placed chair or other obstacles on the blind side or may not be able to find items placed within the blind field. Until the client becomes aware of the VFD, he or she will have the odd perception of a complete visual scene in which objects always seem to be appearing, disappearing, and reappearing, without warning, on the affected side. Uncertainty regarding the accuracy of visual input on

the affected side causes the client to adopt a protective strategy in which he or she attends only to visual input from the intact visual field.^{89,132} This creates a narrowed scope of scanning restricted to the midline of the body and seeing side. The restriction creates significant limitations in occupations that require monitoring of the entire visual field, such as driving a car or traversing a busy environment.

Even when the person becomes aware of the presence of a VFD, visual search into the blind field is often slow and delayed.^{51,78,89,132} Again, the culprit is perceptual completion, which eliminates the presence of a marker to indicate the boundary between the seeing and nonseeing fields. Unable to determine the actual border of the seeing field or where a target might be within the nonseeing field, the client naturally slows down when scanning toward the blind field. The slow visual search toward the affected side increases the difficulty that the client has navigating and finding objects within the environment and also reduces reading speed.

If the hemianopia affects the macular portion of the visual field, especially the fovea, a client may miss or misidentify visual details when viewing objects because part of the object falls into the blind area of the field. This can create significant challenges in reading.^{13,18,29,30,32,68,69,114,133-135} Normal readers view words through a “window” or perceptual span that allows them to see approximately 18 characters (letters) with each fixation of the eye.¹³³ The reader typically moves from word to word by using a series of consecutive saccadic eye movements to cross the line of print. The presence of hemianopia can reduce the width of the perceptual span from 18 characters to as few as 3 to 4. This may cause the client to view only part of a word during fixation and even skip over small words, which often results in misidentification and omission of words.

For example, a client with left hemianopia may read the sentence “She should not shake the juice” as “He should make juice,” with “she” transformed into “he” and “shake” into “make” and leaving out “not” and “the.” Errors such as these cause the client to have to stop and reread sentences, thereby reducing reading speed and comprehension. Accuracy in reading numbers generally creates more challenge for the client than reading words does. Whereas context alerts the client to an error when reading sentences (the sentence does not make sense), numbers appear without precise context, which causes mistakes to go unnoticed. For example, a bill for \$28.00 may be misread as \$23.00 and the error missed until a notice of insufficient payment is received. Clients making these kinds of errors quickly lose confidence in their ability to pay bills and manage their checkbook and turn over these important daily occupations to someone else.

If the VFD has occurred on the same side as the dominant hand, the client may have difficulty visually guiding the hand in fine motor activities. The most common functional change is a reduction in writing legibility. The client often cannot visually locate and maintain fixation on the

tip of the writing instrument as the hand moves into the blind visual field, which causes the handwriting to drift up and down on the line. Writing over something that was just written and improperly positioning handwriting on a form are also common mistakes. Quilting, hand sewing, pouring liquids, and other fine motor activities are likewise frequently impaired.

The changes described (narrow scope of scanning, slow scanning toward the blind side, missing or misidentified visual detail, and reduced visual monitoring of the hand) contribute to a variety of limitations in performance. The primary activities affected include mobility, reading, writing, and the daily occupations dependent on these skills. Such occupations include personal hygiene and grooming, medication management, financial management, meal preparation, clothing selection and care, meal preparation, home management, telephone use, and yard work. In general, the more dynamic the environment where the occupation is completed and the wider the field of view required to perform the task, the greater the limitation. Therefore, only minor limitations are generally experienced in basic ADLs, as opposed to significant limitations in shopping and driving.

Persons with a VFD commonly face significant emotional challenges in adapting to this considerable visual loss. For example, clients with a VFD regularly report feeling a sense of anxiety when moving in unfamiliar environments. Sometimes the anxiety can be so severe that clients experience an autonomic nervous system reaction in which they become nauseated and short of breath and break out into a sweat in crowded environments. One individual with a VFD described this sensation as “crowditis” and reported that he became physically ill if he had to go into a department store or other crowded environment. This anxiety can become debilitating and lead to withdrawal from community activities and social isolation. Other clients report a tremendous loss of self-confidence because of the numerous mistakes that they make during the course of a day, and many state that they experience depression because of their limitations, especially in the ability to drive a car and read accurately.

Assessment

The process of measuring the visual field is known as perimetry.³ Several types of perimeters are available. They range from simple bedside assessments (such as the confrontation test), which give a gross indication of field loss, to the very precise imaging of a scanning laser ophthalmoscope (SLO).^{3,46,102,105,116} The perimetry test selected depends on the availability and cost of the test and the ability of the client to participate in testing. For example, confrontation testing does not incur any expense and can be performed nearly anywhere, whereas imaging with an SLO must be completed by a specially trained technician in a center that has purchased the \$120,000 instrument. In between these two extremes are the tangent screen, Damato Campimeter,

Threaded Case Study | Penny, Part 3

Penny reported to the OT practitioner that she is able to successfully complete basic ADLs but has difficulty completing several instrumental ADLs. She has difficulty reading and states that she reads very slowly and makes frequent mistakes, especially when reading numbers. Because of these deficiencies, she has difficulty reading bills and financial statements and disclosed that she did not pay her Visa bill correctly one month and was charged a financing fee. She also has difficulty reconciling her checkbook because she may read entries incorrectly and then be unable to find her errors. She estimates that it takes her approximately three times as long to pay bills as it did before her visual loss and that she always has a headache when she is finished. Her difficulty reading numbers also creates other challenges when renewing prescriptions for herself and for Pot. She frequently gives the wrong number to the pharmacist and consequently can no longer use the automated renewal line and must wait until she can get someone in person. This is very embarrassing. She also misread her blood glucometer incorrectly once and injected insulin when she did not need it, which caused a reaction lasting several hours. She was an avid newspaper reader and read the metro and sports pages to Pot daily, an activity that they both enjoyed because he would recognize some of the names of local teams and players. She can no longer do this, nor can she read novels to him, which she believed was very therapeutic.

She reports that she is able to complete meal preparation, although she spends a great deal of time scanning shelves trying to locate items. She also has difficulty seeing well enough to pour and measure items and will sometimes misread a

recipe or set the microwave at the wrong time setting. She recalled a time when she was melting chocolate to put in a cake batter and set the microwave on 8 minutes rather than 3 and burned the chocolate.

She reports that her greatest limitations revolve around mobility. She is unable to drive and must depend on others for transportation. When a friend takes her on a shopping outing, she has difficulty locating the items that she needs and reading the labels. Because she does not want to inconvenience her friend and slow her down, she often comes home with the wrong item or without items because she could not find them. She also admits to feeling very uncomfortable in crowded environments, especially with people moving on her left side. She states that her heart pounds and she feels an overwhelming desire to leave. She is afraid that she will collide with someone; she has experienced several such episodes and also at times experiences disorientation. She and Pot attended church services regularly before her stroke and the deacons will provide transportation, but she feels too uncomfortable to go.

She did not bring up her art but when asked about it, she became very quiet and finally stated that she felt that was behind her now. She stated that she had tried drawing again but could not see well enough and could not find the supplies that she needed and was very frustrated. She does not want to resume drawing if she cannot do it well.

When asked to prioritize her goals for therapy, she stated driving as the number one goal and reading as the second goal. She also wanted to accurately complete financial management, meal preparation, and diabetes self-management.

manual bowl perimeters (the Goldmann), and automated bowl perimeters (the Humphrey), ranging in cost from \$100 to \$20,000. In general, the more expensive the apparatus, the more precise the measurement provided.

All perimetry testing involves three parameters: fixation on a central target by the client while the testing is performed, presentation of a target of a specific size and luminosity in a designated area of the visual field, and acknowledgment of the second target without breaking fixation on the central target.³ Testing is done with either static or kinetic presentation of the target. In static presentation, the target appears in a specified area of the visual field without being shown moving to that location. In kinetic testing the target moves in from the periphery until it is identified.^{3,102}

The most accurate perimetry test available to clinicians is computerized, automated perimetry, which is completed by either an ophthalmologist or optometrist.³ During automated perimetry, the client places his or her chin on a chin rest and fixates on a central target inside a bowl-shaped device. As the person fixates on the central target, lights are displayed inside the bowl in varying locations and intensities. The client responds to each seen light by pushing a

small button. The test can be very thorough, with lights presented in more than a hundred locations within the field and the intensity of the light increased in a step threshold sequence if the target is not appreciated the first time. The result is an accurate measurement of the areas of absolute loss (no response) and relative loss (decreased retinal sensitivity) within the field. An ophthalmologist or optometrist may also use a simpler screening test, the tangent screen, to assess the integrity of the central visual field. The tangent screen consists of a black felt screen with a grid stitched into the felt in black thread so that the grid is visible only to the examiner.³ The client sits directly in front of the screen at a distance of 1 m. The client is instructed to fixate on the center of the screen as the examiner moves or places a white target attached to a black wand in a certain area of the screen. Without breaking fixation on the center of the screen, the client indicates when the target is seen. If the client does not see the target when it is presented, that point in the visual field is recorded as a loss. The examiner uses the grid to determine the location of the field deficit.

OT practitioners can screen for a VFD by using simple perimetry testing in combination with careful observation of client performance of daily occupations. Confrontation

testing is a bedside examination that provides a crude indication of visual field loss.^{102,116} To complete a static confrontation test, the examiner sits in front of the client at a meter distance and has the client fixate on a centrally placed target (the examiner's eye). The examiner then holds up two targets in each of the four quadrants of the visual field (right upper, right lower, left upper, and left lower). The client indicates whether the targets are seen.^{57,102,106} For a kinetic test the examiner stands behind the client and moves a target (generally a penlight) in from the periphery while the client fixates on a central target. The client indicates as soon as the target is noticed. Standardized versions of these tests are included in the biVABA. Because confrontation testing has been shown to be unreliable in detecting all but gross defects, OT practitioners using this form of testing must be careful to correlate their findings with observations of client performance.¹¹⁶ If the confrontation test shows no deficit but clinical observations suggest that a deficit is present, the clinical observations should carry the greater weight in deciding whether a deficit exists.

Assessment using perimetry devices such as the Damato 30-Point Multifixation Campimeter (biVABA) enables OT practitioners to obtain a more accurate measurement of central visual field function. The Damato Campimeter, shown in Figure 24-9, is a portable test card that provides a precise measurement of the central 30 degrees of the visual field. The test grid consists of 30 numbered targets that place the test stimulus at known points in the visual field by moving the eye rather than the target. The test stimulus is a 6-mm black circle that is shown in the center part of the card. The client is instructed to fixate on one of the numbered targets. The test stimulus is then shown in the central window, and the client indicates whether the circle is seen. If the client does not see the black circle, that point in the visual field is recorded as a loss. The test proceeds

FIGURE 24-9 Position of the examiner and client for completion of perimetry testing with the Damato 30-point Campimeter from the Brain Injury Visual Assessment Battery for Adults.

(Courtesy Precision Vision, LaSalle, Ill.)

with the client successively moving the eye to view the numbered targets until the entire field is mapped out.

Clinical observation of the client's behavior is especially important to confirm the presence of a VFD because of the limitations of perimetry testing.¹⁰² Clients with fluctuating or limited attention, language, and cognition may give unreliable perimetry results. It may also be difficult to distinguish between a VFD and a deficit in visual attention. However, the client's performance of daily activities will strongly indicate the presence of a VFD. For example, the presence of a VFD may be indicated if any of the following are observed: the client changes head position when asked to view objects placed in a certain plane, the client consistently bumps into objects on one side, the client misplaces objects in one field, or the client makes consistent errors in reading.

Perimetry tests establish only whether a VFD is present and the size and location of the deficit. To determine whether intervention is needed, the practitioner must determine whether the client is able to compensate for the VFD in performing daily activities, as well as the quality and consistency of that compensation. The presence of a VFD can cause significant limitations in daily occupations. The level of impairment will depend on whether the VFD occurs alone or in conjunction with visual inattention. An analysis of occupational performance should be completed to identify limitations in basic and instrumental ADLs. If the client demonstrates difficulty completing an activity, the visual requirements of the activity should be analyzed to determine whether the VFD is interfering with performance. For example, if the client is unable to locate a toothbrush during grooming, is it because the toothbrush is stored on the side of the client's field deficit?

Reading is another daily activity often affected by a VFD. The Visual Skills for Reading Test (VSRT) provides an effective way to measure interference of the VFD in reading performance. The VSRT is designed to assess the influence of a scotoma (or field loss) in the macula on the visual components of reading, including visual word recognition and control of eye movement.¹²⁴ The client is asked to read single letters and words printed on a card. Three different versions of the test card in four font sizes are included in the test to accommodate clients with low vision and to permit retesting. The words are not in context and are designed so that they can be misread and still make sense (e.g., "shot" can be mistakenly read as "hot"). The test measures reading accuracy and corrected reading rate and provides information on the prevalent types of reading errors made by the client. The client's performance on the letter and reading charts used to measure visual acuity may also indicate the influence of a VFD on reading performance. Because of the wider visual field, a client with a VFD may have more difficulty reading the larger symbols and words on the chart and may be able to read faster and more accurately as the optotypes (and field) decrease in size. Telephone Number Copy, part of the biVABA, provides

information about the client's accuracy in reading numbers. In this test the client is required to copy down telephone numbers that include numbers easily misread by persons with a VFD, such as 6, 8, 9, and 3.

To effectively compensate for the VFD, the client must execute an organized and thorough search of the blind field by using the seeing portion of the visual field. This means that a client with a left VFD must use the right visual field to search both the left and right fields. Clients with a VFD demonstrate difficulty searching both peripersonal space (the space immediately around the body) and extrapersonal space (the space extending from the body into the environment). Deficiencies in searching the peripersonal space affect the performance of basic ADLs such as grooming, dressing, reading, and writing, as well as instrumental ADLs requiring monitoring of a wider visual field, such as meal preparation or leisure activities. Deficiencies in searching the extrapersonal space have a pronounced impact on mobility and affect activities in outside and community environments, such as driving, shopping, and mowing the yard.

To navigate dynamic community environments, the client must use a wide scanning strategy that is initiated on the side of the deficit and executed quickly and efficiently. The client must also be able to shift attention and search rapidly between the central visual field and the peripheral visual field. A variety of observational tests can be used to measure the ability to compensate for the VFD during mobility. An objective assessment of the client's ability to execute compensatory search strategies can be made with the Dynavision 2000, an apparatus increasingly used in rehabilitation to assess and train visual motor performance (Figure 24-10).⁶³⁻⁶⁶ OT practitioners without access to a Dynavision can use a laser pointer to observe the client's search capability. The beam of light from the pointer is projected onto various areas of a blank white wall, and the client is instructed to locate and touch the projected red dot. The strategy used by the client to locate the dot and the efficiency of the strategy are noted. Integration of visual scanning with ambulation is the final component of the mobility assessment and must be completed to determine whether the client will be able to compensate for the deficit during body movement. This can be assessed by using tests such as the ScanCourse from the biVABA. To complete a ScanCourse, the client is instructed to walk through a course and identify targets placed in various locations on the left and right sides. The client's ability to locate the targets on each side during ambulation is noted.

Intervention

The performance limitations experienced by persons with a VFD generally fall into two categories: difficulty with mobility and difficulty with reading. Because of the mobility limitation, clients will experience limitations in daily occupations that must be performed in dynamic environments, such as shopping and participating in community

Threaded Case Study Penny, Part 4

Penny's left hemianopia was identified by the optometrist with a Humphrey Visual Field Analyzer. This perimetry test showed that Penny has complete left hemianopia in both eyes affecting both the central and peripheral fields. Of particular importance is the finding that the border of the hemianopia comes into the fovea and splits this area of the field. This observation indicates to the OT practitioner that Penny's perceptual span for reading has probably been significantly reduced on the left side, which causes her to miss words and letters on the left. The practitioner confirms this by using the VSRT, which shows that Penny does miss both letters and words on the left, with her reading accuracy reduced to 83%. Her corrected reading rate is also significantly reduced, 32 words per minute, thus indicating that she reads text at a rate of about 51 words per minute (people read approximately 1.6 times faster). Because of her stated difficulty reading numbers accurately, Penny was also administered the Telephone Number Copy test from the biVABA. She misread three numbers on this test, misidentifying 3 as 8, 4 as 1, and 9 and 5 as 8. She was able to find her errors on the test and correct her mistakes.

The Dynavision 2000 was used to observe Penny's ability to search for targets in her visual field. Analysis of her Dynavision performance showed that Penny demonstrated a reaction time of 2.35 seconds to locate targets in the left half of the board versus 1.1 seconds in the right half of the board. In observing her locate targets on the board, the OT practitioner noted that Penny moved her head very slowly to the left side of the board to locate targets and did not turn her head far enough to see the lighted targets on the outer ring of lights. Penny also completed a ScanCourse. On the first pass through the course, she missed 4 of 10 targets located on the left side (60%) but easily identified 10 of 10 targets on the right side (100%). After receiving feedback on her performance, on the second pass through the course (going in the reverse direction) she identified 9 of 10 targets (90%) on the left and 10 of 10 targets (100%) on the right.

events. Resumption of driving may or may not be a goal, depending on the driving statutes of the state in which the client resides. Some states do not specify a minimum degree of visual field for licensure. In these states a client may be able to safely resume driving if given the proper training. Challenges in reading will cause difficulty completing such activities as financial management and meal preparation.

Although a limited body of research shows that some restitution of the visual field may be possible with intensive rehabilitation,^{7,58,59,86} return of visual field function is unlikely.¹⁰⁶ Therefore, the major focus of intervention is to improve compensation for the visual field loss. Compensation for the VFD requires adopting a conscious, cognitive strategy of using head movement to search and broaden the visual field. Because the CNS exercises perceptual

FIGURE 24-10 Example of a visual search task using the Dynavision 2000. The lights on the board are illuminated one at a time in random patterns. The client must locate the illuminated light and press it to turn it off. As a light is pressed, another light is illuminated. The client strikes as many lights as possible within a specified time. The activity can be used to teach and reinforce efficient search patterns to compensate for visual field deficits and visual inattention.

(Courtesy Dynavision 2000, manufactured by Performance Enterprises, Ontario, Canada.)

completion, the client often lacks insight into the extent and boundaries of the field deficit. Successful compensation requires the client to firmly believe that the deficit exists and that the visual input from the blind side cannot be trusted. A client able to develop this level of insight will usually learn to effectively compensate for the deficit. Every effort must be made through activities and educational materials to make the client aware of the location and extent of the deficit.

Addressing Limitations in Mobility

The limitations experienced in mobility occur primarily because the client does not turn his or her head far enough, fast enough, or often enough toward the blind field to take in the information needed for safe mobility in the allotted time. If the inferior visual field has been affected, as occurs with hemianopia, the client may also experience difficulty monitoring the support surface on the side with the deficit. This can result in hesitancy in walking and a tendency to keep the head down and the eyes fixed on the floor directly in front of the client. Although this strategy may keep the client from colliding with objects, it also prevents the client from monitoring the surrounding environment and can cause disorientation during ambulation.

A combination of remediation and compensation strategies is used to address these deficiencies in mobility. Remediation strategies focus on increasing the speed, width, and

organization of the search pattern.^{49,61,63,66,104,115} The client must learn to quickly turn the head and completely search the blind visual field. The desired outcome behaviors include the following:

1. Initiation of a wide head turn toward the blind field
2. An increase in the number of head and eye movements toward the blind field
3. Faster completion of head and eye movement toward the blind field
4. Execution of an organized and efficient search pattern that begins on the blind side
5. Attention to and detection of visual detail on the blind side
6. Ability to quickly shift attention and search between the central visual field and the peripheral visual field on the blind side

To achieve these outcomes, the client must complete activities in which these skills are required during the performance of an occupation. This is difficult to achieve in the restricted environment of the clinic. The Dynavision 2000 apparatus has been shown to be effective in teaching these components of effective search patterns and is strongly recommended as an intervention tool.⁴³

OT Practice Notes

Other therapeutic activities that may facilitate the development of these performance skills include the following:

1. Ball games in which balls are passed quickly from player to player
2. Balloon batting
3. Projection of light from a laser pointer onto various locations on a white wall for the client to search and find
4. Adhesive stick-on notes with numbers and letters printed on them, widely scattered over a wall for the client to search and find
5. Use of the strategy in completion of daily activities such as finding clothes in a closet or locating items needed for meal preparation

As the basic components of the search strategy are developed, they should be incorporated into activities that require combining search with ambulation. Indoor activities can include completing scan courses using cards with letters taped onto walls in various locations along hallways. Two examples are activities such as “find red,” where the client points out every red item while walking toward a destination within the rehabilitation center, and “narrated walks,” where the client points out landmarks and changes in the environmental surroundings while ambulating toward a destination. These activities reinforce keeping the head up

during ambulation and thereby improve orientation. As skill is developed, practice in dynamic and in unfamiliar environments should be incorporated. The client completes activities in stores and malls, where he or she identifies the number of persons standing in an aisle or inside a store on the blind side while ambulating by, and locates stores within a mall and specific items within stores by using landmarks and organized search strategies.

Integrated into the intervention plan is instruction in compensatory strategies. The client is taught to identify features in the environment that could cause harm, such as steps, curb cuts, and other changes in the support surface. The client is also taught to be more observant of landmarks such as a picture on a wall or a change in wall color to assist in maintaining orientation.

Addressing Limitations in Reading

The client’s primary challenges in reading occur because his or her present saccade strategy does not match the new restricted size of the perceptual span. That is, the client is trying to read with a saccade strategy designed for a wider unrestricted perceptual span. To improve reading speed and accuracy, the client must learn how to adapt a saccade strategy to the new perceptual span. This requires significant practice and can be extremely frustrating for the client. To address this, a remediation approach is used. Prereading exercises, such as those designed by Warren¹²³ or by Wright and Watson,¹³⁰ and commercially available word and number searches are used to provide the practice that the client needs to learn to make the precise eye movements required to see words completely again. These exercises are designed so that the client searches for specified letters, numbers, or words on worksheets (Figure 24-11). As the client’s performance skill improves, large-print books of familiar stories are used to provide the needed practice and transition the client into reading continuous text.

A compensatory intervention approach is also used to address reading and writing challenges. Clients with left hemianopia often have difficulty accurately locating the next line of print on the left margin of the reading material and lose their place. Drawing a bold red line down the left margin provides the client with a visual cue to use as an “anchor” to find the left margin.¹²⁵ The same technique used on the right margin helps a client with a right VFD who may be uncertain about the location of the end of the line of print. If the client has difficulty staying on line or moving from line to line, a ruler or card can be used to underline the line of print and keep the client’s place.

Difficulty staying on line when writing is addressed by teaching the client to monitor the pen tip and maintain fixation as the hand moves across the page and into the side with field loss. Activities that require the client to trace lines toward the side of the VFD are effective in re-establishing eye-hand coordination. Practice in completing blank checks, envelopes, and check registers is also helpful.

FIGURE 24-11 Example of a prereading exercise. The client is instructed to cross out all of the double numbers on the page. (From Warren M: *Prereading and writing exercises for persons with macular scotomas*, Birmingham Ala, 1996, visAbilities Rehab Services.)

Occupational performance can be enhanced by increasing the visibility of tasks and environments. Adding color and contrast to the key structures in the environment needed for orientation (e.g., door frames and furniture) will help the client locate these structures. Using black felt-tipped pens can heighten the contrast in writing materials, and bold-lined paper can be used to help the client monitor handwriting. The simple addition of more light often increases reading speed and reduces errors. Reducing patterns in the environment by reducing clutter and using solid-colored objects enhances the client’s ability to locate items.

Visual Attention and Scanning

Visual attention is the ability to observe objects closely and carefully to discern information about their features and their relationship to oneself and other objects in the environment. It requires the ability to ignore irrelevant sensory

Threaded Case Study | Penny, Part 5

Penny underwent 10 sessions of outpatient OT intervention lasting 1 hour per session over a 10-week period. To address her limitations in reading, Penny was given prereading exercises involving letters, numbers, and words to help her modify her saccade strategy to match her reduced perceptual span. She did the exercises at home for 45 minutes a day. During therapy sessions, she performed timed reading drills that showed the OT practitioner how she was progressing in speed and accuracy on the prereading exercises. The VSRT was repeated at 5 weeks and showed that her reading accuracy had increased to 92% and her reading rate increased to 72 words per minute. The Telephone Number Copy test was also repeated with 100% accuracy. Penny was progressed to reading large-print books with familiar content. Penny and Pot were fans of the Sue Grafton alphabet murder mysteries, so Penny's friend took her to the local library to check out a large-print copy of one of the books that she had read before. She read the book to Pot for an hour daily. At discharge, the VSRT was repeated and Penny demonstrated 100% accuracy with a reading rate of 124 words per minute.

To address mobility and driving, the OT practitioner began by having Penny complete a succession of exercises on the Dynavision for the first 20 minutes of each treatment session. The exercises focused on increasing the speed and efficiency of the search pattern that she executed to the left and on her ability to shift attention between the center and peripheral areas of the board and complete the scanning with cognitive distractions. Scan courses involving targets taped along the hallways of the center were used together with “find red” and narrated scanning. As Penny improved on indoor activities, the OT practitioner moved outdoors and had Penny navigate sidewalks and areas adjacent to the clinic. Before navigating an unfamiliar environment she was instructed to consciously turn her head widely and survey her surroundings to locate any potential obstacles and identify landmarks. As her comfort in these environments increased, she was taken on a community outing to her local grocery store to practice the skills that she had learned and to receive instruction in how to quickly and efficiently scan shelves to locate needed items. Additional community outings were completed in her local mall and in her church.

Two weeks before discharge, Penny excitedly reported that she and Pot had attended church and lunch with friends afterward with no difficulty. Three weeks after therapy was initiated, the OT practitioner made a home visit to assess Penny's environment and to meet Pot. Penny's friend and fellow artist who had been taking her to therapy also attended the session. The home assessment showed that Penny's home generally had sufficient lighting, contrast, and organization. However, the small kitchen had only a single small round ceiling light that left the countertops and work surfaces poorly lit. In addition, she had deep cupboards packed with food and cookware, and her countertops were also cluttered. Penny's studio, located in a bedroom, was cluttered and had only overhead lighting and a small table lamp.

Following the assessment, the OT practitioner suggested replacing the overhead lighting fixture in the kitchen with a large fluorescent fixture, adding fluorescent lighting under the cupboards, and reorganizing the shelves and countertops to remove rarely used items.

Although Penny was still resistant to resuming her art, suggestions were made to improve the lighting in her studio by adding a 50-W halogen task lamp on her work table along with increasing organization and decreasing clutter. A low-power magnifying lamp was also recommended to assist her in seeing details more clearly. Penny was initially resistant to these suggestions because she did not think that she could complete them, but her friend stated that she would help her, and within 2 weeks all recommendations were implemented.

The friend was also very interested in getting Penny to resume her art and asked for suggestions on how to accomplish this. The OT practitioner suggested that if the detailed drawings that Penny had previously completed were still too difficult even with the studio modifications, perhaps she could explore other forms of artistic expression that were not so visually demanding. The next week Penny reported in therapy that she and her friend had attended an art fair on the weekend and that she thought she might experiment with watercolor landscapes, something she had done early in her career. Her friend was coming over to assist her that week.

Driving was addressed throughout this intervention period. The Dynavision exercises that Penny performed were designed to improve the visual skills needed for driving, especially speed, flexibility, and width of the search strategy to the left. Limitations experienced by drivers with a VFD were discussed in conjunction with strategies to compensate for these limitations and vehicle modifications. When Penny had shown sufficient improvement, the 4-minute test on the Dynavision was administered. This test has been shown to be predictive of performance behind the wheel.⁶⁵ A person scoring higher than 195 on the test is likely to successfully complete an on-road driving assessment. Penny scored 230 on the test and was referred to a driver's program for assessment with an OT practitioner credentialed as a certified driver rehabilitation specialist (CDRS). Penny passed the driving assessment and was released to resume driving during daylight hours over familiar routes.

Penny's ability to complete meal preparation, financial management, and diabetes self-management was addressed through improvement in reading and visual search skills, task and environmental modification, and adaptive equipment. A talking calculator to verify numbers assisted her in reconciling her checkbook. Because of the critical need for accuracy in drawing insulin and monitoring blood glucose levels, she was trained to use a nonvisual adaptive device to draw her insulin and a talking glucometer. The environmental modifications implemented following the home assessment greatly improved her ability to complete meal preparation, along with instruction in how to increase contrast.

input and random thought processes and to sustain focus for several seconds to several minutes. Visual attention also entails being able to shift visual focus from object to object in an organized and efficient manner. Engagement of visual attention is accomplished through visual scanning or search (these two terms are used interchangeably). Although these two processes are separated within the visual perceptual hierarchy to assist in understanding them, they cannot be separated in assessment and treatment of the client. Any change in visual attention will be observed in the client as a change in the scanning pattern used for visual search.

Visual attention can be divided into two categories: focal, or selective, visual attention and ambient, or peripheral, visual attention.^{37,55,85,94} Focal attention is used for recognition and identification of objects. Visual input from the macular area of the retina is used to complete this processing. Focal, or selective, attention enables an individual to accurately distinguish visual details such as differences between letters, numbers, and faces. Ambient, or peripheral, attention is concerned with the detection of events in the environment and their location in space and proximity to the person. It relies on input from the peripheral visual field. Peripheral attention ensures that a person is able to move safely through space and maintain orientation in space. Without peripheral attention, collisions with objects and disorientation when moving would be the norm. To have a fully operational and efficient visual system, these two modes of visual attention must work together. The contribution of each is equally important to perceptual processing.

In adults without brain injury, visual search is completed by using an organized, systematic, and efficient pattern.^{34,38,48,90,122,126} The type of search pattern used depends on the demands of the task. In reading English, for example, a left-to-right and top-to-bottom linear strategy is used. In scanning an open array (such as a room), a circular, left-to-right strategy is generally used, following either a clockwise or a counterclockwise pattern.

Deficits in Visual Attention and Scanning

Studies have shown that disruption of the normal visual search strategy can occur after brain injury. The characteristics of the disruption vary, depending on which hemisphere was damaged. Visual search deficits associated with right hemisphere injury are characterized by avoidance in searching the left half of the visual space.^{10,22,24,37,38,45,47,90} This condition is known as hemi-inattention. Instead of initiating the normal left-to-right visual search pattern, clients with right hemisphere injuries often begin and confine the search to the right side of a visual array. This creates an asymmetric search pattern instead of the normal symmetric pattern. The client misses visual information on the left side and, as a result, may be deprived of the information needed to make accurate identification and decisions.

Hemi-inattention is associated with injuries to the right hemisphere and probably occurs because of a difference in the way that the hemispheres are programmed to direct visual attention.^{47,107} As illustrated in Figure 24-12, the left hemisphere directs attention toward the right half of the visual space surrounding the body. In contrast, the right hemisphere directs visual attention toward both the right and left halves of the space surrounding the body. If a lesion occurs in the left hemisphere, visual attention and search toward the right side are diminished, but some attentional capability is still provided by the right hemisphere. A similar lesion in the right hemisphere may completely eliminate attentional capability toward the left because there is no other area directing attention toward the left side.

Hemi-inattention is often confused with the presence of a left VFD in the client. Although both conditions may cause the client to miss visual information on the left side, they are distinctly different conditions and do not have the same effect on performance. When a left VFD occurs, the client attempts to compensate for the loss of vision by engaging visual attention.^{10,11,51,75} The client directs eye movements toward the blind left side in an attempt to gather visual information from that side. Because of the field deficit, however, the client may not move the eyes far enough to acquire the needed visual information from the left side and as a result may appear inattentive. In contrast, a client with hemi-inattention has lost the attentional mechanisms in the CNS that drive the search for visual information on the left. No attempt will be made by the inattentive client to search for information on the left side of the visual space, and no eye movement or head turns will be observed toward the left side.^{22,51} The most significant change in visual search takes place when the two conditions occur together in a client.^{10,20} In this case the client is not receiving visual input from the left side because of a VFD and does not compensate for the loss of visual input by directing attention toward the left side. The combination of hemi-inattention and left VFD creates severe inattention, often called visual neglect. Clients with this condition show exaggerated inattention toward the left half of the visual space surrounding the body and often do not move the eyes past midline toward the left or turn the head toward the left side. Visual neglect may be compounded by neglect of the limbs on the left side of the body or neglect of auditory input from the left side.^{45,61} The presence of neglect is consistently associated with poor rehabilitation outcomes.⁵¹

Another change in visual search associated with right hemisphere lesions is a tendency to fixate first on the most peripheral visual stimuli occurring in the right visual field.⁴⁵ If two visual stimuli simultaneously appear in the right visual field, the client will attend first to the most peripheral stimulus.³¹ A client with this tendency makes frequent head turns to attend to events occurring in the right peripheral field, thus giving the impression of being distractible. Yet another change in visual search is a reluctance to rescan for additional information once an area has been viewed,

an organized and efficient visual search strategy. Research has shown that when persons with brain injuries are asked to search complex visual arrays for specific targets, they have difficulty maintaining attention on the salient features of the target and mistakenly select targets with similar features.^{93,126} They also demonstrate an inability to superimpose an organized, efficient structure for visual scanning when asked to search an array of randomly displayed objects. For example, if asked to locate a certain individual seated among others on rows of benches (a structured visual array), the injured person would be able to accomplish the task. However, if asked to find the same individual standing in a jumbled crowd of persons (a random visual array), the injured person would display a random approach to searching the array and would probably miss the target.

Occupational Limitations Caused by Visual Inattention

Disruption of visual attention creates asymmetry and gaps in the visual information gathered through visual search. The quality of an individual's adaptation to the environment decreases because the CNS is not receiving complete visual information in an organized fashion and is therefore unable to effectively use this information to make appropriate decisions. A reduction in visual attention will affect all aspects of the performance of daily occupations. However, the most affected activities will be those that require inspection and integration of significant amounts of visual detail and those completed in dynamic environments. Driving and reading are two diverse examples of tasks often significantly affected by inattention.

Because visual attention is modulated through an extensive neural network involving the entire CNS, some capacity for visual attention is generally retained even in individuals with severe brain trauma.⁸¹ Conversely, because so many neural structures contribute to attention, changes in visual attention occur even with mild injuries.⁹⁹ Whether a change in visual attention affects occupational performance depends on the task to be completed. Tasks such as reading can require enormous amounts of selective visual attention if an individual is reading a highly technical textbook and less selective attention if the individual is reading an advertisement. The task of driving requires continuous global attention to monitor the speed and position of other vehicles and objects and sporadic selective attention to landmarks, street signs, and traffic lights. Whether a deficiency in visual attention occurs after brain injury depends on the circumstances and requirements of the tasks that the client completes.

Assessment

As a process found at the intermediate level of the visual perceptual hierarchy, visual attention can be affected by deficits in lower-level visual functions (visual acuity, oculomotor function, and visual field). Therefore, these functions should be assessed before visual attention is measured. The presence of aphasia and motor impairment can also affect

performance on assessments for visual attention. How efficiently and completely a person attends to and takes in visual information determines the ability to use the information for adaptation. Therefore, the emphasis in assessment is on observing how a client initiates and carries out visual scanning to complete a task requiring visual search. During the assessment the OT practitioner should answer the following questions: Does the client initiate an organized search strategy? Can the client carry out the search strategy in an organized and efficient manner? Does the client obtain complete visual information from a visual search? Is the client able to identify visual detail correctly? Does the client's ability to search for information decrease as the visual complexity of the task increases?

Research has shown that persons with good visual attention demonstrate specific characteristics of search patterns that make them effective in obtaining visual information.^{48,122,131} These characteristics include strategies that are organized, symmetric, thorough, resilient, and consistent. Use of these strategies generally results in good accuracy and speed in completion of visual search tasks. In contrast, persons with a significant VFD or inattention often have ineffective search strategies. These individuals demonstrate incomplete or abbreviated patterns in which only a portion of the visual array is searched, usually in a random, unpredictable fashion.^{15,23,37,48,51,74,78,93,126} The organization and accuracy of the pattern often break down when the person is challenged to search more complex visual arrays. [Figure 24-13](#) provides examples of some of the ineffective search strategies used on the visual search subtests of the biVABA by persons with brain injury. A client using ineffective search strategies may not acquire sufficient visual information to complete perceptual processing accurately. The client may acquire the information in such a way that it cannot be used to complete perceptual processing, or the person may not acquire the information rapidly enough to enable adaptation. The subsequent disruption of perceptual processing may cause errors in decision making and adversely affect performance of a variety of ADLs.

When measuring visual attention, the OT practitioner must be aware that visual search can be significantly affected by the presence of both a VFD and hemi-inattention. Because a VFD and hemi-inattention are not the same condition, it is necessary to distinguish between the two to establish an effective intervention plan. This can be difficult, both because similar errors are observed with the two conditions on search tasks and because the two can also occur together in the same client. However, differentiation can be accomplished by observing the strategies used by the client to complete visual search tasks such as those on the biVABA ([Figure 24-13](#)). Although both VFDs and hemi-inattention can result in decreased accuracy in identifying targets on a visual search task, the characteristics of the search deficiencies are different.^{10,22,27,28,41,51}

For example, a client with left hemianopia may demonstrate a left-to-right linear search pattern that is abbreviated

A

NAME: C.T. DATE: _____

FIGURE 24-13 Examples of ineffective search patterns used by clients to complete two visual search subtests of the Brain Injury Visual Assessment Battery for Adults. **A**, An abbreviated search pattern used by a client with left hemianopia when crossing out the letters P and F on the subtest. The client executed an organized left-to-right linear search pattern but failed to locate the beginning of the line on the left side and as a result failed to cross out targets on that side (the *circled letters*). **B**, An asymmetric and abbreviated search pattern executed by a client with hemi-inattention and left hemianopia. The client was asked to number the circles consecutively in any pattern desired. The client began numbering the circles from the right rather than the left and failed to number circles on the left side of the array.

RANDOM PLAIN CIRCLES-SAMPLE ©1997, visABILITIES Rehab Services Inc.

B

on the blind side. The search pattern is organized but results in a number of errors on the left because the client did not see that side of the array. In contrast, a client with hemi-inattention may demonstrate an asymmetric pattern in which visual search is initiated and confined to the right side with a disorganized and random search pattern. The pattern also results in a large number of errors on the left. Although accuracy in the search task may be similar for these two clients, the cause of the errors is different. By observing the strategy used by the client to complete the search task, it is possible to distinguish between the two conditions. Table 24-2 compares the characteristics of search patterns used by persons with hemianopia and those with hemi-inattention. When the two conditions occur

together, it is important to determine the severity of the inattention because this will determine whether the client is able to learn the strategies needed to compensate for the VFD.

The visual search tests that have been described are pencil-and-paper tasks presented in a restricted and well-defined personal space. Determining how the client applies a search strategy to the broader extrapersonal space requires the use of a test such as the ScanBoard described by Warren.¹²² The test, part of the biVABA, consists of a large (20 by 30 inch) board with a series of 10 numbers displayed in an unstructured pattern. The board is placed at eye level and centered at the client's midline. The client is asked to scan the board and point out all of the numbers that he or

■ **TABLE 24-2** | Comparison of Search Patterns: Persons with a Visual Field Deficit vs. Persons with Hemi-inattention

Visual Field Deficit	Hemi-inattention
Search pattern is abbreviated toward the blind field	Search pattern is asymmetric; initiated/ confined to the right side
Attempts to direct search toward the blind side	No attempt to direct search toward the left side
Search pattern is organized and generally efficient	Search pattern is random and generally inefficient
Client rescans to check accuracy of performance	Client does not rescan to check accuracy of performance
Time spent on task is appropriate to the level of difficulty	Client completes the task quickly; the level of effort applied is not consistent with the difficulty of the task

From Warren M: *Brain Injury Visual Assessment Battery for Adults Test Manual*, Hoover, Ala, 1998, visAbilities Rehab Services.

she sees. The examiner records the pattern that the client follows in identifying the numbers. Research using this test has shown that adults with normal visual search use an organized, sequential search pattern, beginning on the left side of the board and proceeding in either a clockwise or counterclockwise fashion until all of the numbers are identified. In contrast, adults with deficits in visual attention demonstrate disorganized, random, and often abbreviated search strategies, with numbers frequently being missed on one side of the board. Those with hemi-inattention often show an asymmetric pattern, with visual search initiated and confined to the right side of the board. Clients with a VFD may miss numbers on the blind side but demonstrate an organized search strategy.

Intervention

Information gathered from observing the client complete visual search tests should reveal specific deficiencies in the scanning pattern that the client uses to acquire visual information during the performance of daily tasks. For example, it may be observed that the client does not search toward the left side of visual arrays. If this deficiency is significant, similar performance should be observed when the client completes a daily activity. This could be an inability to locate items placed on the left side of the sink while grooming or a tendency to begin reading a recipe in the middle of the line of print instead of at the left margin.

Depending on the severity of the deficit, some clients with inattention are able to complete basic and habitual

 **Threaded Case Study**
Penny, Part 6

The physician referring Penny to the low-vision center noted that she had hemi-inattention in addition to the left hemianopia. Because hemi-inattention can significantly interfere with performance of ADLs, especially driving, it was important to determine how much, if any, of Penny's difficulty scanning was due to inattention.

To assess this, Penny was administered the visual search subtests from the biVABA. On three of the subtests involving searching for letter and words, she missed several of the targets located on the left side, a finding indicative of an abbreviated search pattern toward the left. However, on each of the seven subtests she consistently used an organized left-to-right and top-to-bottom search strategy. She also carefully looked at each target and rechecked her work for accuracy. These observations suggested normal attentional capability, which was verified by her performance on other assessments. For example, although she made mistakes in copying numbers on the Telephone Number Copy test, she was able to search for and correct her mistakes without assistance. She also missed targets on the left side during her first pass through the ScanCourse, but after receiving feedback, she made no errors during her second trial on the course. On the Dynavision assessment, she was also able to switch attention easily between the left and right sides of the board, and her ability to search the left side of the board rapidly improved with practice.

After analyzing Penny's performance on these assessments, the OT practitioner concluded that because of the severity of her VFD, Penny may have appeared to be inattentive toward the left side during the first several weeks after her stroke when she was unaware of the VFD. However, as she gained awareness of the deficit, she was able to use attention to help compensate for the loss of vision on the left. If Penny's performance had suggested the presence of hemi-inattention, it would not have been appropriate to set a goal of resuming driving, and it would have been necessary to explore alternative forms of transportation.

daily activities and experience difficulty only with tasks that are unfamiliar or require search of a complex visual array.⁷⁶ Others, especially those with neglect, may have difficulty with such a simple task as finding all the food on their plate. By combining information from visual search tests with that gained from observation while performing ADLs, it is possible to determine whether and how the client's performance of daily activities has been affected by the impairment in visual search. The goals on the intervention plan should be worded to reflect the specific daily activities compromised by the inattention. For example, the intervention plan could include such goals as "The client will be able to complete grooming independently" or "The client will be able to prepare a simple meal independently."

The goals established for independent performance of ADLs are achieved by ensuring that the client learns to take in visual information in a consistent, systematic, and organized manner. Before clients can learn to reorganize a visual search, they must understand how their visual search and attention have changed. To facilitate development of this insight, the OT practitioner should carefully review the results of the client's performance on the visual search tests and show the client how his or her search pattern differed from the norm and caused errors. If after receiving this feedback the client wishes to retake one of the tests, he or she should be allowed to do so. If the client's performance improves on the retest, this is an indication of the capability of benefiting from therapy intervention and serves as a justification for intervention. Likewise, if the client's performance does not improve, this helps verify the significance of the deficit and also may indicate reduced rehabilitation potential.

The intervention plan should incorporate compensatory strategies and environmental modification. The primary compensatory strategy taught to a client with hemi-inattention is to reorganize the scanning pattern to begin visual search on the left side of a visual array and progress from left to right.^{5,28,88,125,127} Use of this pattern will counteract the client's tendency to restrict all visual search to the right side and will increase the symmetry of the search pattern. Clients with left hemisphere injuries do not demonstrate asymmetry in visual search but often fail to notice details when searching visual arrays. These clients should be taught to initiate careful item-by-item search of visual arrays. Two scanning strategies are taught to all clients: a left-to-right linear pattern for reading and inspection of small visual detail and a left-to-right clockwise or counterclockwise pattern for viewing unstructured and extrapersonal visual arrays.⁴ Activities should be selected that encourage and reinforce the use of these patterns.

Compensatory strategies can be taught more effectively if intervention activities are designed in accordance with the following guidelines:

1. Intervention activities should require the client to scan as broad a visual space as possible. Most daily activities require orientation to a broad visual space. To help the client complete a wide visual search, the working field of the activity should be large enough to require the client either to turn the head or to change body positions to accomplish the task.¹²⁷ Many activities and games can be enlarged to require head turning for scanning. For example, a deck of playing cards can be laid out, facing up, in rows 2 to 3 feet wide. The client is given another deck of playing cards and instructed to match the cards in hand to the cards on the table. The practitioner ensures that the client initiates a left-to-right, top-to-bottom, organized scanning pattern when searching for the matching cards to complete the task.
2. Intervention activities will be more effective if the client is required to interact physically with the target once it is located. Research has shown that a stronger mental representation of a visual image is formed if what is seen is verified by tactual exploration.^{4,67} Whenever possible, the intervention activity should be designed to be interactive. Games such as solitaire, dominoes, and ball games or activities such as putting together large puzzles are examples of activities with interactive qualities.
3. Intervention activities should emphasize conscious attention to visual detail and careful inspection and comparison of targets. Because complex visual processing is dependent on initiation of the item-by-item search strategy of selective visual attention, it is important to include scanning activities that require discrimination of subtle details and matching. Clients should be taught consciously to study objects for their relevant features, with emphasis placed on attending to detail in the impaired space. Many games such as solitaire, double solitaire, Concentration, Connect Four, checkers, Scrabble, and dominoes have these qualities. Large 300- to 500-piece puzzles, word or number searches, crossword puzzles, and needlecrafts such as latch hook also require these performance skills. Throughout performance of these tasks, clients should be encouraged to recheck their work to make sure that critical details are not missed.
4. Facilitate attention to the left half of the visual space by occluding vision in the right half of the visual space. Occlusion of the right half of the visual field has been shown to be effective in increasing the client's attention toward the left.¹⁴ The occluder, made by placing opaque tape over the right side of a pair of safety lenses, is worn while the client completes a therapeutic activity to facilitate attention. The lenses are removed once the activity is completed.
5. Practice the search strategy within context to ensure carryover of application to ADLs. Clinic activities provide a starting place to begin teaching the strategies needed for successful visual perceptual processing. Research has shown, however, that clients with brain injury often do not spontaneously transfer skills from one learning situation to the next. Toglia¹¹³ suggested that having the client apply the learned strategy in different contexts of daily living can facilitate transfer of learning. For example, the client can be required to use a left-to-right search strategy when selecting clothes from a closet, searching for items in a refrigerator, or shopping for groceries. The more often the strategy is repeated under varied circumstances, the more the skill is generalized and transferred to new situations. There is no substitute in therapy for the practice of real-life situations to help the client develop insight into abilities and

compensation for limitations. Cafeterias, gift shops, and office areas within the hospital and fast-food restaurants and shops surrounding the hospital can be used to expose the client to more realistic and demanding visual environments.

Insight on the part of the client into the nature of the visual deficit and how it has affected functional performance is critical to learning compensation.¹¹⁰⁻¹¹² According to Toglia,¹¹³ one of the reasons that clients with brain injury do not spontaneously recognize their limitations and the need to compensate is that their concept of their capabilities is based on premorbid experiences. This causes these clients to overestimate their abilities after injury. Without a realistic understanding of limitations, the client may be unwilling to use compensatory strategies. To increase insight, Abreu and Toglia¹ advocate teaching a client to monitor and control his or her performance by learning to recognize and correct for errors in performance. Giving the client immediate feedback about the performance and pointing out deficiencies facilitate this process of error detection. The process can also be facilitated by teaching the client to use self-monitoring techniques such as activity prediction, in which the client predicts how successfully an activity will be performed and identifies the aspects of the activity in which errors are likely to occur. The client then compares actual performance with predicted performance. This technique helps the client develop anticipatory skills and increase awareness of how the deficit affects functional capabilities. The use of video feedback has also been shown to be useful in enabling clients to understand how their neglect behavior affects occupational performance.¹¹²

Some clients, because of the severity of their deficits, lack the cognition to benefit from training in compensatory strategies. Although treatment intervention is limited, such clients may benefit from a modification of the environment to help the client use his or her limited attentional capabilities. The environment can be made more visible and “user-friendly” by reducing factors that place stress on visual processing. Suggested environmental modifications include the following:

1. Reduce the background pattern so that objects in the foreground can be seen more easily. The more densely packed the background pattern, the greater the amount of selective attention needed to locate the desired object. Clients with severe brain injuries may not be able to sustain the effort needed to complete this level of processing and may view their environments as being filled with “visual noise” rather than meaningful objects. Backgrounds can be simplified by eliminating patterned designs and using solid colors on surfaces. Eliminating superfluous objects such as knickknacks and old magazines and organizing frequently used items on shelves and in containers also simplify the background. As a general

rule, environments should be sparse and contain only the items needed by the client for completion of daily activities. Items that contain a lot of intrinsic pattern, such as reading material, can be enlarged to decrease the density of the pattern.

2. Ensure that room and task illumination is adequate. Both too little and too much illumination can impair visual processing. However, environments usually contain too little rather than too much light. The type of lighting used should provide bright, even illumination without glare.
3. Increase contrast between background and foreground objects to enhance the visibility of items in the environment that need to be noticed. For example, the edge of a white plate placed on a black place mat is more visible than it would be if placed on a white place mat, and milk is more visible in a black cup than in a white cup. The use of glass or clear plastic items should be avoided because these items reduce contrast by absorbing whatever pattern or color is around them.

Oculomotor Function

The purpose of oculomotor function is to achieve and maintain foveation of an object.⁴² That is, oculomotor function ensures that the object that the person wishes to view is focused on the fovea of both retinas (to ensure a clear image) and that focus is maintained as long as needed to accomplish the desired goal. This is a daunting task because human beings interact within dynamic, moving environments. An image focused on the fovea is always in danger of slipping off as the head or object is moved. Foveation is achieved and maintained by eye movements that keep the target stabilized on the retina during fixation, gaze shift, and head movement.^{42,70,77,97}

Another function of oculomotor control is to provide binocular vision. Binocular vision ensures perception of a single image even though the CNS is receiving two separate visual images (one from each eye). The process of combining two visual images into one is called sensory fusion. For sensory fusion to occur, corresponding points (or receptor cells) on the two retinas must be stimulated with the same image. If the retinas are thus stimulated and if the images match in size and clarity, the CNS is able to fuse the two images perceptually into one. If the eyes do not align with each other or if there is a significant difference in acuity between the eyes, a double image (diplopia) may occur.^{42,71,119}

Deficits in Oculomotor Function

Deficits in oculomotor control following brain injury generally result from either of two types of disruption: specific cranial nerve lesions causing paresis or paralysis of one or more of the extraocular muscles that control eye movements or disruption of central neural control of the extraocular muscles affecting the coordination of eye

movements.^{5,60,72,74,96,97} In the first case, the message to the extraocular muscles through the cranial nerve is blocked; in the second case, the message comes through but is scrambled. In both cases, the functional results are decreased speed, control, and coordination of eye movements. Three pairs of cranial nerves control the extraocular muscles: the oculomotor nerve (III), the trochlear nerve (IV), and the abducens nerve (VI). Among them, these nerves are responsible for controlling seven pairs of striated muscles that surround and attach to the two eyeballs.

When a cranial nerve lesion is sustained, the muscles controlled by that cranial nerve are weakened or paralyzed, a condition known as paralytic strabismus.^{82,119} As a result, the eye is unable to move in the direction of the paretic muscles and may even be unable to maintain a central position in the eye socket (i.e., it drifts in or out). Because the eyes must always move in synergy and line up evenly to maintain a single visual image, an individual sees a double image when the movement of one eye is impeded or when the eye's position changes and does not match that of the other. This condition, diplopia or double vision, is the primary functional disruption observed in individuals with cranial nerve lesions.^{82,119}

Occupational Limitations Caused by Oculomotor Deficits

The presence of diplopia creates perceptual distortion, which may affect eye-hand coordination, postural control, and binocular use of the eyes. The limitations in performance experienced by the client depend on where the diplopia occurs within the focal range (the range in which a person can keep objects in focus). Diplopia occurring within 20 inches of the face will disrupt reading and activities requiring eye-hand coordination, such as pouring liquids, writing, and grooming. Diplopia occurring at a distance (greater than 4 feet) will affect walking, driving, television viewing, and playing sports such as golf and tennis.

To eliminate the double image, the client will often assume a head position that avoids the field of action of the paretic muscle.^{8,72,119} For example, a client with a left lateral rectus palsy (cranial nerve VI) will turn the head toward the left to avoid the need to abduct the eye. A client with paralysis of the right superior oblique muscle (cranial nerve IV) will tilt the head to the right and downward to avoid the action of that muscle.⁸ Unless oculomotor function is carefully assessed, these alterations in head position may be interpreted as resulting from changes in muscle tone in the neck rather than as a functional adaptation purposely assumed to stabilize vision.

Often it is not the cranial nerves that are damaged during brain injury but the neural centers that coordinate their actions. These structures are scattered throughout the brainstem and communicate extensively with cortical, cerebellar, and subcortical areas of the CNS and the spinal cord.^{52,77} In cases of traumatic brain injury, diffuse damage may take place throughout the brainstem and affect these control

centers. If the centers are damaged, the person will have difficulty executing eye movements even though the cranial nerves are intact.^{72,96,97,107} Disconjugate eye movements may occur and cause the client to have difficulty using the eyes together in a coordinated fashion. Dysmetric eye movement, in which the eye undershoots or overshoots a target, may also be observed.¹⁰⁶

Damage to the pretectal nuclei in the brainstem can cause convergence insufficiency, a condition in which the client is unable to obtain or sustain convergence of the eyes.^{25,72} Convergence is the muscle action of moving the eyes inward in adduction. It is one of the three components of accommodation, the process that keeps objects in focus as they come into close view. When convergence insufficiency occurs, clients have difficulty obtaining or sustaining adequate focus during near-vision tasks (tasks within 20 inches of the face). Clients with this condition often complain of fatigue, eye pain, or headache after a period of sustained viewing in near tasks such as reading. As the eye muscles fatigue from the exertion of sustaining convergence during reading, clients may begin to complain that the print is swirling and moving on the page. The condition is frequently overlooked in evaluation because cranial nerve function is usually intact and clients' complaints are instead attributed to inattention, lack of effort, or dyslexia.^{25,72}

These disturbances in ocular motility can create a variety of functional deficits for the client.^{72,84} The speed and range of eye movement may be diminished. This will reduce the speed at which the client is able to scan the environment and take in visual information, thereby causing delays in responding to the environment. The client may have difficulty maintaining a clear image and may experience doubling and blurring of visual images.^{53,72} There may be difficulty focusing at different distances from the body. Depth perception may be diminished. These conditions will create significant visual stress for the client and reduce concentration and endurance for activities. The client may respond to this increased stress by becoming agitated and uncooperative in therapy sessions or by complaining of headaches, eyestrain, or neck strain.

Because a number of factors can disrupt the control of eye movements, much skill and expertise are needed to accurately diagnose the oculomotor deficit and design an appropriate treatment intervention. Practitioners who treat this type of dysfunction should do so under the guidance of an optometrist or ophthalmologist who specializes in visual impairment caused by neurologic conditions.^{39,84}

Assessment

The purpose of an assessment completed by the OT practitioner is to determine whether the client is experiencing limitations in daily occupations because of dysfunction within the oculomotor system. It is not to determine whether the oculomotor dysfunction is the result of a cranial nerve lesion, brainstem injury, or other conditions. Determining the etiology of the dysfunction is the responsibility

of the ophthalmologist or optometrist. However, the OT practitioner is often one of the first members of the rehabilitation team to observe that the client may have an oculomotor impairment affecting occupational performance. This frequently places the OT practitioner in the position of requesting further evaluation by an eye care specialist. To make an appropriate referral, it is necessary to perform a screening to identify patterns of oculomotor dysfunction that may account for the functional limitations observed in the client.

In assessing the client, a “listen and look” approach is used wherein the practitioner listens to the complaints being voiced by the client or the rehabilitation staff working with the client and looks for deviations in oculomotor control that may be contributing to these complaints. This approach is described in the biVABA, and the following steps in evaluation are from that assessment.

The first step in assessment is to obtain a visual history from the client. The history is necessary because adults with childhood histories of oculomotor dysfunction or reduced acuity often display oculomotor abnormalities that do not affect functional performance. These individuals frequently wear eyeglasses to correct for the deficiencies; in this case the eyeglasses must be worn during the assessment to obtain accurate results. Areas addressed in this part of the evaluation include whether the client had good vision before the brain injury, whether the client wears eyeglasses, and whether the client has a history of conditions that may affect oculomotor control, such as congenital strabismus, lazy eye, or amblyopia.

Next, the client is asked whether he or she is experiencing diplopia. If the response is affirmative, the client should be questioned about the characteristics of the diplopia. Does the diplopia disappear when one eye is closed? This indicates impairment of the extraocular muscles. Do objects double side to side or on top of one another? Is the diplopia present at near distances or at far distances? Is there any area within the range of focus at which the client is able to achieve single vision? The answers to these questions may suggest which cranial nerve has been injured (Table 24-3) and can also supply important information about

limitations that the client may experience in daily activities. The OT practitioner concludes the interview by identifying activities that the client has difficulty performing that could be caused by oculomotor dysfunction. The practitioner should look for a pattern in the client’s response, such as difficulty with activities that require sustained focus in near space (reading, writing, and quilting). The practitioner should pay attention to whether the client’s visual difficulty seems to change with the focal length of the task and whether the client’s fatigue and reduced concentration appear to be related to activities requiring sustained focusing.

The next part of the assessment is observing the client’s eyes and eye movements for deficiencies. First, the eyes are evaluated for asymmetries in pupil size, eyelid function, and eye position as the client focuses on a distant object. Asymmetries such as a dilated pupil in one eye or a droopy eyelid (ptosis) may indicate cranial nerve involvement and suggest difficulty adjusting to light (light sensitivity) and reading. Next, movement of the eyes is observed by asking the client to track a moving object (such as a penlight) through the nine cardinal directions of gaze plus convergence.⁸⁷ This test can be thought of as an active range-of-motion test of the eyes because the nine cardinal directions represent the directions through which the eyes move. The test is used to determine whether there are deviations in strength and function of the extraocular muscles and is completed by observing the eyes move in a binocular test.

During the test, the OT practitioner observes the following: (1) symmetry of eye movement, (2) whether the eyes move the same distance in each direction, (3) whether the eyes are able to stay on target with a minimum of jerking movements, and (4) whether the client is able to hold the eyes in a deviated position at the end of the range for 2 to 3 seconds. Restriction of eye movement in a specific direction or difficulty moving the eyes in a specific direction may indicate impaired oculomotor function.⁸² Observing the eyes as they track an object moving toward the bridge of the nose tests convergence. Most adults can maintain focus and track an object to a distance of approximately 3 inches from the bridge of the nose. At that point one eye usually

■ **TABLE 24-3** | Summary of Oculomotor Deficits Associated with Cranial Nerve Lesions

Oculomotor Nerve III	Trochlear Nerve IV	Abducens Nerve VI
Impaired vertical eye movements	Impaired downward and lateral eye movements	Impaired lateral eye movements
Lateral diplopia for near-vision tasks	Vertical diplopia for near-vision tasks	Lateral diplopia for far-vision tasks
Dilation of pupil and impaired accommodation	With bilateral lesion assumes downward head tilt	
Ptosis of eyelid		

breaks fixation and moves outward. The point at which convergence is broken is known as the near point of convergence.⁸²

Although the near point of convergence is 2 to 3 inches from the bridge of the nose, few adults ever view objects that closely. Therefore, limitations in convergence are not generally functionally significant unless the client is unable to converge the eyes and easily maintain convergence to a distance of 12 to 16 inches from the bridge of the nose. An inability to converge the eyes to this distance and maintain convergence for several seconds while focusing on an object may cause the client to have difficulty performing tasks in near vision that require sustained focus. Observation of convergence insufficiency may explain complaints made by the client regarding such tasks as reading, writing, quilting, or sewing.

The final component of the assessment is diplopia testing, which is completed only if the client is complaining of diplopia.¹⁰⁶ Diplopia testing is used to determine the severity of the diplopia and whether it is caused by a “tropia” or a “phoria.” Tropia is the suffix applied when there is a noticeable deviation of the position of one eye in relation to the other when the client is viewing an object.^{106,119} Phoria is the suffix used when there is a deviation of the eye that is held in check by fusion and is therefore not noticeable when the client is focusing on an object. These terms are used in conjunction with a prefix describing the direction of the deviation. Four prefixes are used: “eso,” meaning turning in of the eye; “exo,” turning out of the eye; “hypo,” turning downward of the eye; and “hyper,” turning upward of the eye. Esotropia therefore describes an observable, inward deviation of the eye commonly described as “crossed eyes,” whereas esophoria indicates that the eye drifts inward when the client is not focusing on an object but is held in check when the client is focusing on an object.⁷²

Diplopia testing is based on the principle that when an eye is required to fixate on an object, it will do so with the fovea. If an eye that is not fixating on a target is suddenly required to foveate, it will achieve foveation by making a saccade toward the target. By requiring the client to fixate with both eyes on a target and then covering one of the client’s eyes during fixation, the examiner can determine whether both eyes are aligned in focusing on the target and, if not, which eye is the deviant (strabismic) one.^{87,118} Two tests are used: a cover/uncover test, which is completed when a tropia is suspected, and a cross or alternate-cover test, which is completed when a phoria is suspected.^{87,118} If both eyes are aligned equally and fixating on the target, no movement of either eye will be observed when one is covered. If the eyes are not aligned, the deviating eye will move to take up fixation when the nonaffected eye is covered. Clients with tropias generally complain of constant diplopia when viewing objects and must have one eye occluded to eliminate the diplopia. Clients with phorias often complain of diplopia only intermittently, usually when fatigued or stressed by sustained viewing of a target.

Although a phoric client may complete most activities without diplopia, he or she may experience significant visual stress, which can be manifested as headaches, eye strain, or decreased concentration.

The information gathered from the assessment should be compared with the client’s visual complaints and observations of his or her occupational performance to determine whether the oculomotor dysfunction is contributing to the client’s functional limitations. For example, the presence of convergence insufficiency may help explain the difficulty that the client is having in maintaining concentration when reading. As another example, the observation of downward movement of the left eye during the cover/uncover test may explain why the client complains of feeling off balance and unsure when descending stairs. If oculomotor deficiencies are observed that appear to limit occupational performance, referral should be made to an ophthalmologist or optometrist for further evaluation to determine the cause of the deficiency, the prognosis for improvement, and treatment options.

Intervention

The presence of oculomotor dysfunction does not usually prevent the completion of daily occupations; however, it does make completion of daily activities both tedious and fatiguing. The client may express reluctance to perform some activities or even stop performing them because of the constant visual stress. Motor and postural control may also be compromised and consequently reduce safety when navigating the environment. For these reasons, oculomotor dysfunction must be addressed during intervention, although it is not specifically identified as a goal on the intervention plan. That is, the goal remains a functional one such as safe and accurate completion of meal preparation, shopping, or bill paying, and management of the oculomotor dysfunction becomes one of the methods used to achieve the goal.

Intervention can be divided into four types: occlusion, application of a prism, eye exercises, and surgery.^{12,19,108,119} The last three interventions are used to re-establish fusion and binocularity and are performed only by ophthalmologists or optometrists. OT practitioners, under the direction of a physician, may apply occlusion. Most oculomotor dysfunction clears up without intervention within 6 to 12 months after the brain injury.^{97,119} Accordingly, ophthalmologists do not generally believe that it is necessary to provide any intervention other than eliminate the diplopia for the client’s comfort during the recuperation period. If the diplopia persists and becomes chronic, surgery can be used to re-establish fusion. Optometrists often choose a remediation approach and prescribe eye exercises to re-establish binocularity, in addition to using occlusion and a prism.^{12,102} Brief descriptions of these interventions follow. The treatment option selected for a client depends on the prognosis for recovery, the client’s ability to participate in therapy, family and financial resources, and the eye specialist providing consultation.

Occlusion

The presence of diplopia causes perceptual distortion. This distortion creates confusion for the client and limits participation in daily activities. Therefore, diplopia must be eliminated if the client is to fully benefit from rehabilitation. Diplopia is eliminated by occluding the image presented to one eye. Occlusion can be achieved by assuming a head position or by covering one eye. Because assuming a deviant head position often affects motor and postural control, the preferred method is to cover one eye. Occlusion of the eye can be achieved through either full or partial occlusion.^{12,19,102,108,119}

With full occlusion, vision is completely occluded in one eye by the application of a “pirate patch,” a clip-on occluder, or opaque tape. The challenge with complete occlusion is that it eliminates peripheral visual input, which disrupts normal CNS mechanisms for control of balance and orientation to space. This often causes the client to feel off balance and disoriented and reduces depth perception. Another challenge is that the client cannot generally tolerate long periods of occlusion of an eye, especially of the dominant eye. Therefore, for the comfort of the client, the period of occlusion is alternated between the eyes every hour. Alternating occlusion between the eyes also reduces the likelihood of the development of secondary contracture of the muscles antagonistic to the paretic muscle.

For partial occlusion, a strip of opaque material (such as 3M Transpore surgical tape) is applied to a portion of the eyeglass lens to block visual stimulation in the central visual field, with the peripheral visual field being left unoccluded (Figure 24-14). The client is instructed to view a target within the diplopic field. Tape is applied from the nasal rim toward the center of the lens until the client reports that the diplopia is gone when viewing the target. The tape is applied to the nondominant eye for the greater comfort of the client. The width of the tape is gradually reduced as the muscle paresis resolves. An advantage of partial occlusion is that the client is more comfortable and therefore compliance is increased. Another advantage is that peripheral vision is left intact and available for use in orientation to space and balance. The main disadvantage of this type of occlusion is that the client must either wear prescription

FIGURE 24-14 Example of partial occlusion to eliminate diplopia. Translucent tape is applied to the nasal portion of the eyeglass lens on the side of the nondominant eye.

(From Warren M: *Brain Injury Visual Assessment Battery for Adults Test Manual*, Hoover, Ala, 1998, visAbilities Rehab Services.)

lenses or have tape applied to a pair of frames with plano (nonrefractive) lenses.

Prisms

Ophthalmologists and optometrists may use a prism to re-establish single vision in the primary directions of gaze: looking straight ahead and looking down. Application of a prism displaces the image and causes the disparate images created by the strabismus to fuse into a single image.^{12,19,102}

The prism can be ground into the eyeglass lenses worn by the client or temporarily applied to the lens of the glasses, as with a plastic Fresnel press-on prism. A prism is used only as long as it is needed to maintain fusion. If the paresis is resolving, the client is gradually weaned from the prism by reducing the dioptic strength of the prism over a period of time commensurate with the rate of recovery.

Eye Exercises

There has yet to be objective research unequivocally demonstrating that the use of eye exercises will restore binocular function following paretic strabismus. Eye exercises do not appear to adversely affect muscle function, however, and the use of eye exercises can empower the client by increasing his or her participation in the recovery process. An optometrist directs the use of eye exercises in this aspect of the rehabilitation program.¹⁰²

Surgery

Surgery is recommended when the degree of strabismus is too large to be overcome consistently and easily by fusional effort or when the client has a significant strabismic condition that does not resolve in 12 to 18 months.¹¹⁹ The general approach in surgery is to make the action of one of the extraocular muscles either weaker or stronger by changing the position of its attachment on the eyeball. The position of the eye in the socket is changed by the procedure, and the image is realigned. Surgery is performed by an ophthalmologist specially trained in strabismus surgery.

Because Penny sustained a posterior cerebral artery occlusion, the lesion was confined to the right cerebral hemisphere. Subsequently, she did not experience any oculomotor deficits.

Complex Visual Processing

The processes of pattern recognition, visual memory, and visual cognition involve complex processing and integration of vision with other sensory information, past experiences, and cognitive function. To complete this sophisticated level of processing requires not only organized, high-quality sensory input but also good cognitive ability such as the ability to categorize information and complete abstract reasoning. Complex visual processing, like other cognitive functioning, is elicited by the demands of a particular event. It is a learned skill established by one’s experiences in mastering the environment. With few exceptions, complex visual processing is always applied within the context used to

solve a problem, formulate a plan, or make a decision regarding a specific situation. Because of the contextual nature of complex visual processing, the best way to assess it is not to ask the client to complete some abstract, two-dimensional visual task but rather to observe the client complete daily tasks requiring this level of processing. For example, if the client is an architect planning to return to work, his or her ability to design and execute building plans or other aspects of the job should be assessed, preferably at the client's place of employment. If the client wants to return to driving, his or her ability to handle complex traffic situations should be assessed with a behind-the-wheel assessment.

Visual input that is of poor quality or is incomplete or inaccurate will affect the ability to perform complex visual processing. Therefore, visual acuity, visual field, oculomotor control, and visual attention and search should be assessed first to determine whether deficits exist that might be contributing to deficiencies in complex processing. If deficits are identified, their effect on the client's performance of daily occupations requiring complex visual processing should be observed. For example, after having determined that a client has a left VFD and an incomplete search pattern indicative of hemi-inattention, the OT practitioner should observe the client complete a daily occupation requiring attending, planning, and decision making. The activity may be preparing a meal, sorting and doing laundry, shopping for groceries, measuring the oil level in the car, or completing a job-related task. In observing the client, the practitioner should make special note of how the client's visual deficit affects his or her ability to process the more complex visual information needed to complete the task. If the client has difficulty successfully completing the task and if the visual deficit appears to be the cause, the practitioner should determine whether it is possible to improve the client's performance by treatment of the visual deficit.

Summary

The CNS relies on visual information to anticipate and plan adaptation to the environment and perform daily occupations. Brain injury or disease disrupts the processing of visual information, thereby creating gaps in the visual input sent to the CNS. The quality of a person's occupational performance decreases because the CNS does not have sufficient or accurate visual information to make decisions. Penny's left hemianopia, for example, caused her to misread words and sentences because she did not always see letters and words on the left side; she also collided with persons and objects and experienced disorientation because of missing information on the left side. Whether a person's deficit in visual perceptual processing necessitates therapeutic intervention depends on the person's lifestyle and whether the visual deficit prevents successful completion of ADLs. In Penny's case, as the primary caregiver for an ailing husband, she needed to be able to complete the family finances, drive, and shop; if her husband had been fit, she may not have needed to perform these activities.

The framework for assessment and intervention rests on the concept of a hierarchy of visual perceptual processing levels that interact with and subserve one another. Because of the unity of the hierarchy, a process cannot be disrupted at one level without an adverse effect on all perceptual processing. Assessment must be directed at measuring function at all process levels, with particular emphasis placed on the foundation of visual functions and visual attention and scanning. The absence of visual input on the left side caused Penny to appear to ignore visual stimuli on the left, which gave the impression of hemi-inattention. Assessment demonstrated that she has normal attentional capability but had not yet learned to compensate for the hemianopia.

Intervention focuses on increasing the accuracy and organization of visual input into the system through manipulation of the environment and by providing the client with strategies to compensate for or minimize the effect of the deficit in daily occupations. Penny benefited from a variety of compensatory and remediation strategies aimed at improving her ability to use her remaining right visual field to compensate for the left VFD and to adapt her environment to assist her in using her remaining vision to complete daily activities.

Review Questions

1. What determines whether treatment intervention is needed for a client with a visual impairment?
2. What three aspects of environments/tasks can be modified to increase their visibility for a client with visual impairment?
3. What prevents a client from automatically compensating for a VFD by turning the head farther to see around the blind field?
4. What kind of protective behaviors do persons adopt following onset of a VFD? Why do they adopt these strategies?
5. What is the normal search pattern executed by most adults when viewing an unstructured visual array? A structured array?
6. What is the primary compensatory strategy taught to the client with hemi-inattention?
7. What is the most crucial lower-level visual process contributing to the ability to complete visual cognitive processing?
8. What changes occur in the visual search pattern of a client with hemi-inattention?
9. When would partial occlusion be used for the client? Describe the technique used to apply partial occlusion.
10. How does convergence insufficiency affect reading performance?

Assessment and Intervention for Perceptual Dysfunction

25

SHAWN C. PHIPPS

■ Chapter Outline

General principles of the OT assessment
General approaches to OT intervention
Remedial approaches
Adaptive approaches for perceptual dysfunction
Assessment and intervention of specific perceptual impairments
Visual perception disorders
Visual-spatial perception disorders
Tactile perception disorders
Motor perception disorders
Behavioral aspects of perceptual dysfunction

■ Key Terms

Perception	Right-left discrimination
Adaptive approaches	Stereopsis
Remedial approaches	Stereognosis
Agnosia	Astereognosis
Color agnosia	Graphesthesia
Color anomia	Agraphesthesia
Metamorphopsia	Body scheme
Prosopagnosia	Finger agnosia
Simultanagnosia	Praxis
Visual-spatial perception	Apraxia
Figure-ground discrimination	Ideational apraxia
Form constancy	Ideomotor apraxia
Spatial relations	Dressing apraxia
	Constructional disorder

■ Learning Objectives *After reviewing this chapter, the student or practitioner will be able to do the following:*

1. Describe how perceptual dysfunction affects participation in occupational performance.
2. Identify standardized and functional assessments for visual perception, visual-spatial perception, tactile perception, body schema perception, and perceptual motor skills.
3. Differentiate between remedial and adaptive approaches to intervention for perceptual dysfunction and how they facilitate engagement in occupation.
4. Describe specific occupational therapy interventions for targeted perceptual motor deficits that facilitate improved performance skills, client factors, and participation in occupation.

Threaded Case Study Walt, Part 1

Walt is a 38-year-old male who sustained a traumatic brain injury from a motor vehicle accident, resulting in right frontal, parietal, temporal, and occipital lobe damage. His occupational profile included a rich occupational history that consisted of full-time work as a graphic artist in a prestigious marketing firm. Walt is a husband and father of two young children, as well as an accomplished painter.

After the brain injury, Walt's roles as worker, husband, father, and artist were affected because of impairments with motor and process performance skills and client factors, such as perceptual and cognitive dysfunction. Walt was unable to participate in his most valued areas of occupation, including painting, using a computer, sketching, and playing catch with his children. His visual foundation skills, including visual acuity, oculomotor control, and visual field function, were found to be intact during the evaluation process. However, he demonstrated difficulty initiating motor actions when playing with his children and interpreting visual information for meaningful visual-spatial relationships when painting, sketching, or using the computer. In addition, he exhibits clinical signs of unilateral neglect to the left half of his body and is unable to discriminate between different types of materials through touch alone.

During the initial assessment, the occupational therapist elected to use the Canadian Occupational Performance Measure⁶⁴ to obtain client-centered goals that would assist Walt in achieving his occupational performance goals. Walt identified his primary goals in occupational therapy: to submit a painting to a local art gallery, to play with his children, to drive, and to regain computer skills in preparation for resumption of part-time work as a graphic artist.

Critical Thinking Questions

1. How would you best assess Walt's occupational performance?
2. How would you best assess Walt's perceptual dysfunction?
3. How would you assist Walt in achieving his occupational performance goals using remedial and adaptive approaches for his perceptual dysfunction?

“Perception is the gateway to cognition.”¹⁵

Perception is the mechanism by which the brain interprets sensory information received from the environment. This perceived information is then processed by the various cognitive centers in the brain (described in [Chapter 26](#)). The individual may then choose to respond with a motor act or a verbal expression. For example, when waiting in a checkout line in a grocery store, a person may observe the array of brightly wrapped candy lining the aisle, may remember the sweet taste of the chocolate, may remember a recent resolution to lose weight, and may choose to resist

adding any candy bars to the grocery cart. The person may look over to the next aisle, recognize a neighbor, and begin a conversation. In a few minutes, the person may notice that another register has a shorter line and may choose to move over to that line to be able to complete grocery shopping in a shorter amount of time. Perception of the environment provides the information to enable these response options.

In early development, tactile, proprioceptive, vestibular, and visual perception provide an internalized sense of body scheme, which is basic to all motor function.^{7,69,109} Highly developed spatial skills are critical to the successful occupational performance of an architect, plumber, designer, or artist.⁴⁰ The process of interpreting visual stimuli is a learned skill, as evidenced by blind individuals who, when sight is restored later in life, have difficulty interpreting what they see.⁹⁰

Acquired perceptual deficits are noted in persons with cerebrovascular accident (CVA), traumatic brain injury (TBI), and other neurologic disorders, such as multiple sclerosis and Parkinson's disease.^{65,82} Spatial disorders and apraxia of a progressive nature are also seen in Alzheimer's disease.^{6,14}

Severe perceptual deficits, frequently combined with cognitive impairments, can affect every area of occupation (e.g., activities of daily living [ADLs], instrumental activities of daily living [IADLs], education, work, play, leisure, and social participation) and can present with grave safety concerns.⁵⁶ For example, an individual who is not able to judge distance and the spatial relationship of his foot to the top step of a stairwell may be in danger of a serious fall. Another person who cannot judge the position of the dial on the stove when preparing a meal may cause a fire. It is often the occupational therapy practitioner's role to evaluate safe and independent functioning in valued occupations and to assess visual and perceptual skills using both standardized instruments along with observations of occupational performance in context.

This chapter describes the client factors of visual perception, visual spatial perception, tactile perception, body schema perception, motor perception, and the potential deficits in occupational performance that result from impairment to these client factors. Suggestions for standardized and functional testing are provided. General occupational therapy (OT) approaches to intervention are reviewed, and suggestions for treatment are presented.

General Principles of the Occupational Therapy Assessment

When assessing perceptual skills, several assessment tools may be required. The optimal battery of standardized assessments includes tools that require a verbal response (e.g., naming a picture) or a motor response (e.g., drawing or constructing) or have flexible response requirements of

either mode (multiple choice indicated by verbalizing the number or letter or by pointing to the chosen item). This enables the OT practitioner to assess visual perceptual dysfunction in a client with severe limitations in cognitive or communication ability. With a variety of such assessments, the OT practitioner is able to gather information to discriminate between an impairment in the reception of information and an impairment in the motor or verbal output.²⁵ This, in turn, influences the occupational therapy intervention approach. Observation of occupational performance in context and the analysis of the perceptual-motor demands of functional activities further complement the analysis of perceptual dysfunction via standardized assessment tools and enable the determination of underlying causes of deficits in occupational performance. Assessment methods should be conducted in the specific context of the occupation being performed.

Warren emphasized the importance of using a bottom-up approach to evaluate impairments in visual foundation skills,^{99,100} such as visual acuity, oculomotor function, visual field function, visual attention, and visual scanning prior to evaluating the higher-level perceptual skills covered in this chapter. For example, a deficit in visual acuity could be the underlying cause of poor performance on a test of perceptual processing. The normal aging process also results in impairments related to visual foundation areas, and a variety of age-related eye diseases such as macular degeneration, glaucoma, diabetic retinopathy, and cataracts can affect visual acuity or visual field function.⁶² It is also possible that performance on global perceptual tests may be affected by deficits in cognitive areas such as attention, memory, or executive function (see Chapter 26). For example, an individual with severely limited attention is unlikely to perform well on many standardized assessments, regardless of the modality or nature of the task. Tsurumi and Todd also analyzed the cognitive skills involved in the commonly used assessments of visual perceptual functions and warn that an individual's performance using two-dimensional representations of visual stimuli may not predict the person's performance in a dynamic three-dimensional world.⁹⁸

Arnadottir recommended the use of ADLs to assess neurobehavioral dysfunction, including perceptual dysfunction and its effect on the performance of tasks essential to functional independence.⁵ She maintained that it is preferable for occupational therapists to assess neurobehavioral deficits directly from the ADL evaluation. She developed the Arnadottir OT-ADL Neurobehavioral Evaluation (A-ONE), which evaluates perceptual and perceptual-motor dysfunction in the context of ADL and functional mobility tasks, including ideational apraxia, ideomotor apraxia, unilateral neglect, body scheme disorders, organization/sequencing dysfunction, agnosias, and spatial dysfunction.³⁻⁵

Toglia's Multicontext Treatment Approach focuses on remediating and compensating for perceptual and cognitive impairments by promoting generalization of functional skills across multiple contexts.⁹⁶ Visual processing strategies,

task analysis, incorporation of the specific learning needs of the client, establishment of criteria for the transfer of learning, metacognitive training, and practice in multiple environments are key components of Toglia's approach. This approach also assists the client with TBI to gain self-awareness of perceptual and cognitive strengths and weaknesses to promote the use of strategies for remediation or compensation of skills across multiple contexts.⁹⁷ Toglia's Dynamic Object Search Test is one assessment that can be utilized to assess visual processing, visual scanning, and visual attention.⁹⁶

Another occupation-based assessment tool that can be used to assess the impact of deficient performance skills on functional tasks is the Assessment of Motor and Process Skills (AMPS).³⁸ This standardized assessment evaluates the performance skills necessary for engagement in areas of occupation by assessing 16 motor skills and 20 process skills (e.g., temporal organization, organizing space and objects). Each performance skill is evaluated in the context of client-identified and culturally relevant IADLs from a list of standardized activities at various levels of difficulty. The AMPS has a high rate of reliability and validity, and the evaluator must be an occupational therapist who has received advanced training and certification to administer this assessment.

The Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)⁵⁷ and Rivermead Perceptual Assessment Battery^{32,103} provide a comprehensive profile of visual perceptual and motor skills and involve both motor-free and constructional functions. Various other assessment tools require either a verbal or a simple pointing response. The Motor-Free Visual Perceptual Test-Revised (MVPT-R)^{24,70} assesses basic visual perceptual abilities. An alternative version of the test presents the multiple choices in a vertical format (MVPT-V) to reduce the interference of hemianopsia or visual inattention.⁷³ The MVPT-V has been shown to be predictive of on-the-road driving performance and can be used as a screening tool to identify persons who would not be safe drivers.⁷¹ The Test of Visual Perceptual Skills-Upper Level (TVPS-UL)⁴² also provides a multiple-choice format and has been normed for adults. Test items require a higher level of visual analysis compared with the MVPT, and the test is untimed.¹⁶⁻¹⁸ The Hooper Visual Organization Test⁵³ requires that the individual mentally assemble fragmented drawings of common objects. The Minnesota Paper Form Board Test⁶⁶ is a high-level assessment of visual organization, requiring mental rotation of fragmented geometric shapes.

General Approaches to Occupational Therapy Intervention

An underlying assumption about perceptual-motor function is that perceptual deficits will adversely affect occupational performance. Further, it is assumed that remediation

of or compensation for perceptual deficits will improve occupational performance.⁷⁴ In her critical analysis of approaches to treatment for perceptual deficits, Neistadt described two general classifications of approaches: the adaptive and the remedial.⁷⁴ Adaptive approaches provide training in occupational performance to facilitate the client's adaptation to unique contextual environments.² In contrast, the remedial approaches seek to produce some change in central nervous system (CNS) functions.⁷⁴ The effectiveness of the various approaches to the remediation of perceptual deficits has not been well documented and requires further scientific investigation.^{33,74,89}

The OT practitioner may use one approach or a combination of approaches when designing an intervention plan to address the effects of perceptual dysfunction. The remedial and adaptive approaches can be used along a continuum, beginning with remediating basic visual perceptual skills and gradually incorporating compensatory techniques as the deficits persist.⁵⁸ The occupational therapy literature suggests specific activities for the intervention of perceptual deficits, but protocols for the use of such activities require further research.¹⁰⁹ For measuring the effectiveness of occupational therapy intervention, criteria are needed for successful performance, task grading, objective methods of evaluating performance, and guidelines for task modification.⁷⁵ In the absence of such objective criteria, the occupational therapist relies on empirical methods to measure and document functional improvement. Several studies have demonstrated the relationship between perceptual deficits and functional performance.^{8,32,88,89}

Remedial Approaches

Remedial, or transfer of learning, approaches assume that multiple practice opportunities with a particular perceptual skill produce carryover of performance to similar activities or tasks requiring comparable perceptual skills.⁷⁴ For example, practice in reproducing pegboard designs for spatial relations training could carry over to dressing skills that require spatial judgment (such as orienting a blouse sleeve to an arm and discriminating between right and left shoes). The capacity for persons to improve their performance on perceptual tests following perceptual training has been documented.⁴⁷ However, additional research has also shown that remedial strategies for optimizing perceptual skills may not be as effective as using occupation-based interventions in context to promote changes in perceptual awareness and abilities.^{33,68,76,77,109}

Adaptive Approaches for Perceptual Dysfunction

Adaptive approaches are characterized by the repetitive practice of targeted occupational performance tasks that help the person with neurologic dysfunction gain independence by utilizing alternate strategies to compensate for perceptual impairments.⁷⁴ The therapist does not retrain specific

perceptual skills when utilizing an adaptive approach. Rather, the person is made aware of the problem and is instructed on adaptive strategies for the perceptual deficit during occupational performance. For example, if the client has difficulty with dressing because of a body schema perceptual impairment, the therapist may set up a regular dressing routine and provide cues with repetitive practice on how to compensate for the perceptual challenges in context. With these adaptations, the client may learn to dress independently. Adaptation of the physical environment or the specific activity demands (e.g., objects used in the environment and their properties) is another way to compensate for a perceptual deficit. For example, if an individual has difficulty discriminating a white shirt against the white sheets of the bed, the therapist may encourage the person to select a patterned shirt or may lay the white shirt on a colored towel or bedspread to provide a contrasting background.

Assessment and Intervention of Specific Perceptual Impairments

Visual Perception Disorders

Walt has difficulty recognizing the faces of his two children and identifying the difference between the brushes he uses for painting. He requires verbal cues to identify the unique features that distinguish the faces of his two children and to identify the appropriate painting utensil to use during an art project. He also has difficulty identifying and recognizing the significance of various traffic signs, which would prevent him from driving safely.

Walt presents with a visual perception disorder, which impairs the person's ability to recognize and identify familiar objects and people.¹⁰⁸ Although these individuals may have intact visual anatomic structures, objects and people may appear distorted, or larger or smaller than they actually are. These individuals also have difficulty interpreting the meaning of objects in their environment, such as signs and maps. In addition, they can have difficulty recognizing, identifying, or remembering the names of colors in their environment. These visual perception disorders can lead to safety problems in dynamic environments and may affect social skills, as the person has difficulty recognizing family members, friends, and coworkers.

Agnosia

Visual object recognition refers to the ability to verbally identify objects via visual input. An impairment in this area is called agnosia, and it is caused by lesions in the right occipital lobe or posterior multimodal association area.^{54,65}

The individual with agnosia can demonstrate normal visual foundation skills. The inability to name objects is not caused by a language deficit in naming the object, as noted in aphasic disorders. Rather, the person is unable to recognize and identify an item using only visual means. If the person holds the object, he or she can identify that object

via tactile input, or by olfactory means if the object has a distinguishable odor, such as a flower or an onion.⁹¹

Assessment of agnosia is performed by asking the individual to identify five common objects by sight, such as a pencil, comb, keys, a watch, and eyeglasses. If the client demonstrates word-finding difficulties, offer the client a choice of three answers. Ask the client to indicate the correct choice through a head nod (yes or no). If the client is unable to name four out of the five objects, visual agnosia may be indicated.

OT intervention for visual agnosia will focus on adaptive or compensatory methods of keeping frequently used objects, such as a hairbrush, in consistent locations, and teaching the client to rely more heavily on intact sensory modalities, such as stereognosis and tactile discriminatory touch, to seek and find desired items for functional use.⁵⁴ Remediative approaches can include having the client practice identifying objects that are needed for occupational performance, such as a paintbrush for Walt, or using non-verbal, tactile-kinesthetic guiding during occupations.¹⁰⁸ Following the activity, have the client practice naming the items that were used. Current research has found that efforts to remediate object recognition have met with limited success.⁵⁵

Color Agnosia and Color Anomia

Color agnosia refers to the client's inability to remember and recognize the specific colors for common objects in the environment.⁵⁰ For example, Walt was unable to recognize the color of the paints he was using during his landscape painting. He confused the green paint he was using to paint the grass with the blue paint he intended to use for the sky. Alternatively, color anomia refers to the client's inability to name the color of the objects. Although these clients understand the differences between the different colors of objects, they are unable to name the object accurately. For example, Walt was able to recognize the color red but was not able to name it as such.

To assess color agnosia, present the client with two common objects that are accurately colored and two objects that are not accurately colored. Ask the client to pick out those common objects that are not accurately colored. If the client is unable to choose the objects that are inaccurately colored, color agnosia may be clinically present.

To assess color anomia, ask the client to name the color of various objects in his or her environment. If the patient has aphasia, ask him or her to nod yes or no after offering the patient choices of colors. If the client is unable to correctly name the colors of various objects, color anomia may be present.

OT intervention for color agnosia and color anomia will focus on providing the client with opportunities to recognize, identify, and name various colors of objects in his or her environment. Intervention is best provided in a familiar context and can be incorporated functionally during occupational performance. For example, while Walt is painting

a landscape, the therapist would provide verbal cues that assist him in recognizing, identifying, and naming the various colors of paint he is using.

Metamorphopsia

Metamorphopsia refers to the visual distortion of objects, such as the physical properties of size and weight.¹⁰⁸ For example, when Walt was playing sports with his two children, he could not distinguish between the basketball, the football, the baseball, or the volleyball. Each of the balls appeared heavier, lighter, larger, or smaller than they actually were, making it difficult to distinguish the differences between them through observation alone.

Assessment for metamorphopsia includes presenting the client with various objects of different weights and sizes (e.g., balls, drinking glasses filled with water, puzzle pieces). Ask the client to place each object in order according to size or weight through observation alone. Metamorphopsia may be indicated if the client is unable to determine the weight and size of the various objects.

OT intervention for metamorphopsia includes providing the client with opportunities to practice distinguishing objects in the natural environment through intact sensory modalities (e.g., tactile-kinesthetic-proprioception). The functional use of objects during occupational performance will provide the client with feedback about the sizes and shapes of different objects. The therapist should also provide specific verbal descriptors of the object when using this approach. Other treatment modalities include puzzles, board games, and computer games that help the client to gain experience distinguishing the sizes and shapes of different objects.

Prosopagnosia

Prosopagnosia refers to an inability to recognize and identify familiar faces caused by lesions of the right posterior hemisphere.^{19,54,91} The individual with prosopagnosia may have difficulty recognizing his or her own face, faces of family members and friends, or of recognizable public figures because the person cannot recognize the unique facial expressions that make each face different. When attempting to identify family members and acquaintances, the person will tend to compensate by relying on auditory cues such as the sound of the family member's voice or a distinctive feature such as long, wavy hair.

Brain lesions can also impair the ability to interpret facial expressions, which can have significant social consequences.^{21,106} For example, one client tended to be very suspicious of others. He was observed to have difficulty describing the expressions of various persons depicted in photographs. Because he had immigrated to the United States from another country, his difficulty was originally thought to be a result of cultural differences. He was asked to bring in a newspaper that he regularly received from his native country. The captions of the photographs were occluded, and he was asked to describe the emotional

expressions of the persons shown. He was then asked to translate the photo captions and became aware that he was unable to discriminate the emotions apparent on the faces.

A standardized Test of Facial Recognition¹² is available, which presents a multiple-choice matching of faces presented in front view and side view and under various lighting conditions. Informal functional assessments could include having the client identify the names of the people in photographs, with family members at a dinner table (e.g., Walt's two children side by side), or by having the client identify his or her own face in a mirror. Photographs of famous public figures could also be used during assessment. If aphasia is present, have the client communicate through gestures, such as head nodding (e.g., yes or no) in response to multiple choices. If the client is unable to identify him or herself or family members, prosopagnosia may be present. A formal test of facial expression discrimination is not available in the literature,⁶⁵ but an informal assessment is possible using pictures and photographs of familiar people.

OT interventions for prosopagnosia include remedial approaches such as providing face-matching exercises.¹⁰⁸ Adaptive approaches include providing pictures of family members and famous people with names and assisting the client to associate the family member's face with other unique characteristics and features, such as weight, height, mannerisms, accents, and hairstyle.

Simultanagnosia

Simultanagnosia refers to the inability to recognize and interpret a visual array as a whole, and it is caused by lesions to the right hemisphere of the brain.³⁵ Clients with simultanagnosia are able to identify the individual components of a visual scene, but are unable to recognize and interpret the gestalt of the scene. For example, Walt is able to identify the flowers and the trees in one of his paintings, but he is not able to recognize and interpret this painting as the landscape surrounding the family home where he grew up.

Assessment includes presenting the client with a photograph with a detailed visual array (e.g., Walt's family photograph at the beach), asking the client to describe the scene in detail, and assessing whether or not the client can describe the scene as a whole. Many clients will be able to identify specific features of the visual array (e.g., the sand castle) but cannot describe the context or meaning of the whole scene (e.g., a family trip to the beach). Simultanagnosia is clinically significant when the client cannot recognize and interpret a visual array as a whole.

OT intervention will focus on helping the client to construct meaning of a visual array through verbal cues and therapeutic questions to facilitate abstract reasoning. Intervention is best provided in familiar contexts, such as a client's home, work setting, or during a community outing to the shopping mall.

Visual-Spatial Perception Disorders

Walt presents with difficulty distinguishing the right and left side of his body and often confuses right and left when given directions. He often gets lost and requires a family member to be with him at all times when he is in unfamiliar community environments. When painting, Walt has also been observed to have difficulty with distinguishing the foreground and the background in his paintings and is unable to determine the differences between the amounts of paint in each of the cups next to him. In addition, he is often observed missing the canvas in front of him when attempting to apply the paint.

Walt presents with visual-spatial perception dysfunction. Visual-spatial perception refers to the capacity to appreciate the spatial arrangement of one's body, objects in relationship to oneself, and relationships between objects in space. Various efforts have been made to subdivide spatial skills into components, but recent authors acknowledge that spatial skills cannot be isolated easily from one another.²² It is generally acknowledged that the right hemisphere, which controls spatial abilities, tends to function in the gestalt (whole), whereas the left hemisphere, tends to focus on discrete details.⁶⁵

Visual-spatial perception occurs instantaneously. Because of this rapid processing of spatial information it is possible to react quickly to another driver's actions to avoid a collision when operating a motor vehicle. An individual with a mild visual-spatial perception impairment may need additional time to perform a task but processes the information correctly, possibly by compensating with verbal analysis of the perceptual components. Severe impairment may result in the incorrect response despite additional time used in attempting to solve the problem.

Visual-spatial skills are not limited to the visual domain.⁶³ Sounds can be localized in space, and the mobility and daily occupations of blind individuals are heavily dependent on the tactile appreciation of the spatial arrangements of objects.⁸³ For example, a blind person's ability to navigate through a familiar room requires awareness of the layout of each piece of furniture in the physical environment and continual shifting of the individual's "cognitive map" while changing positions in the room.

As a pencil rolls across a desktop, it is the skill of visual-spatial perception that enables a person to appreciate the relative orientation of the pencil to the table surface as the pencil nears the edge and is about to fall to the floor. [Figure 25-1](#) illustrates the complexity of visual-spatial perceptual function.

Figure-Ground Discrimination Dysfunction

Figure-ground discrimination allows a person to perceive the foreground from the background in a visual array.¹⁰⁸ For example, Walt is unable to locate a particular painting utensil from the other writing utensils in the pencil holder,

FIGURE 25-1 Visual-spatial functions in real life. Note that all components of spatial functions can be found in this scene.

thereby demonstrating difficulty with distinguishing the targeted object from the background.

Figure-ground discrimination can be assessed functionally in a variety of contexts. During a dressing activity, you may ask the client to identify the white undershirt that is located on top of his or her white sheets. In the kitchen, you can ask the client to pick out all of the spoons from a disorganized utensil drawer. Figure-ground discrimination dysfunction may be indicated if the client is unable to discriminate the foreground from the background in a complex visual array.

Using a remedial approach, intervention for figure-ground discrimination dysfunction should focus on challenging the client to localize objects of similar color in a disorganized visual array.¹⁰⁸ The task could be incorporated contextually into meaningful occupation. For example, the therapist working with Walt may have him localize the exact pencil he would like to use for his sketch drawings. The task can be downgraded by making the visual array less complex and upgraded by making the visual array more complex.

An adaptive approach to intervention would focus on modifying the environment to increase the organization of common functional objects (e.g., placing only the most necessary objects needed for self-care), decreasing the complexity of the visual array that the client has to discriminate (e.g., have only one paintbrush in front of Walt at a given time), or marking common objects with colored tape so that objects are easily distinguished from one another, particularly when the objects are of a similar color.¹⁰⁷

Toglia's multicontextual approach may be used to help the client gain self-awareness of his or her figure-ground discrimination dysfunction and develop effective organizational and visual scanning strategies for discriminating the foreground and background in the environment.⁹⁶ This intervention approach also focuses on the generalization of skill to multiple functional contexts by using strategies that the client has identified as effective in locating objects in the environment.

Form-Constancy Dysfunction

Form constancy is the recognition of various forms, shapes, and objects, regardless of their position, location, or size.¹⁰⁸ For example, a person can perceive all of the pencils on a desk, in various sizes or in various positions in the pencil holder.

To assess form constancy, ask the client to identify familiar objects in his or her environment through observation alone when those objects are placed upside down or on their side. For example, in the kitchen, you may ask Walt to identify a cup that is turned upside down or a toaster oven that is placed on its side. Form-constancy dysfunction may be indicated if the client is unable to identify objects in a position that varies from the norm.

Intervention for form-constancy dysfunction would include using tactile cues to feel objects in various positions so that the client learns their constancy despite their position, size, or location. Activities can be graded from positioning all objects in an upright position to placing objects

in odd positions. Intervention is best provided with common objects that the client utilizes in everyday occupational performance.

Position in Space

Position in space, or spatial relations, refers to the relative orientation of a shape or object to the self. It is this component of perception that allows a person to recognize that the tip of the pencil is pointed away from him, and so directs the hand to effectively grasp the pencil.

To assess position in space, have the client place common objects in relation to the self or other objects using the following directional terms: top/bottom, up/down, in/out, behind/in front of, and before/after. For example, ask Walt to place his paintbrush on top of his computer or his basketball behind his back. Position in space dysfunction may be indicated if the client is unable to discern the relationships of objects to the self or other objects through directional terms.

Intervention for position in space includes providing the client with opportunities to experience the organization of objects in the environment to the self. For example, Walt could practice placing various objects in relation to one another in a graphic design program on the computer so that directional concepts of up/down, in/out, behind/in front of, and before/after can be reinforced.

Right-Left Discrimination Dysfunction

Right-left discrimination is the ability to accurately use the concepts of right and left.¹⁰⁸ An individual with right-left discrimination dysfunction may confuse the right and left side of his or her body or confuse right and left in directional terms when navigating through the environment.

To assess right-left discrimination, ask the client to point to various body parts (e.g., left ear) or assess the client's ability to accurately navigate the environment through verbal commands using right and left (e.g., turn right at the end of the hallway). Right-left discrimination dysfunction may be indicated if the client is unable to differentiate between right and left in relation to his or her body and the environment.

Intervention for right-left discrimination will focus on assisting the client to practice reciting right and left while interacting with his or her own body (e.g., "I am now placing my right arm into the shirt sleeve") or the environment (e.g., "I am now turning left at the stop sign"). Remediation of right-left discrimination can significantly improve topographic orientation as the client learns to navigate in a more dynamic home and community environment.

Stereopsis

Stereopsis is the inability to perceive depth in relation to the self or in relation to various objects in the environment.¹⁰⁸ Depth perception is critical to function in a three-dimensional world and to safety in driving and community mobility. Clients with visual dysfunction in one eye or who

wear an eye patch to compensate for double vision may demonstrate stereopsis because binocular visual input from both eyes is required to perceive depth.

To assess depth perception, place a variety of common objects on a table surface and ask the client to identify which object is closer and which object is farther away. In a community context, the client may also be assessed functionally by asking him or her to identify buildings or landmarks that are closer or farther away. Stereopsis may be indicated if the client is unable to judge the distance between objects in the environment.

Computer-assisted software has been developed that can help the client with developing depth perception by judging the relative distance of objects in relation to one another on a computer screen.¹⁰⁸ Tactile-kinesthetic approaches also help the client judge distances through the use of tactile input.¹

Tactile Perception Disorders

Walt is unable to identify the objects he uses for painting by touch alone. He is unable to discriminate between different types of materials or different forms and shapes by tactile means and must compensate visually to determine the objects he is using during occupational performance.

Walt presents with an impairment in tactile perception, which involves tactile discriminative skills of the second somatosensory area of the parietal lobes.⁷² These skills require a higher level of synthesis than the basic tactile sensory functions of light touch and pressure described in [Chapter 23](#).

Astereognosis

Stereognosis, also known as tactile gnosis,²⁷ is the perceptual skill that enables an individual to identify common objects and geometric shapes through tactile perception without the aid of vision. It results from the integration of the senses of touch, pressure, position, motion, texture, weight, and temperature and is dependent on intact parietal cortical function.⁴⁴ Stereognosis is essential to occupational performance because the ability to "see with the hands" is critical to many daily activities. It is the skill that makes it possible to reach into a handbag and find a pen and to find the light switch in a dark room. Along with proprioception, stereognosis enables the use of all fine-motor activities without the need to concentrate visually on the objects being manipulated. Examples of stereognosis are knitting while watching television, reaching into a pocket for house keys, and using a fork to eat while engaged in conversation.

A deficit in stereognosis is called astereognosis. Persons who have astereognosis must visually monitor the use of their hands' during activities. Thus, they must be very slow and purposeful in their movements and tend to be generally less active.

The purpose of a stereognosis test is to assess a client's ability to identify common objects and perceive their tactile properties.^{10,26,49,60} A means to occlude the person's vision is

needed, such as a curtain, patch, or folder as described in Chapter 23. Typical objects that could be used for identification include a pencil, pen, a pair of sunglasses, a key, nail, safety pin, paper clip, metal teaspoon, quarter, nickel, and a button. Any common objects may be used, but it is important to consider the client's social and ethnic background to ensure that he or she has had previous experience with the objects. Three-dimensional geometric shapes (e.g., a cube, sphere, or pyramid) can also be used to test shape and form perception.

The test should be conducted in an environment that has minimal distractions. The therapist should sit across from the client being tested. The client's vision is occluded, with the dorsal surface of the hand resting on the table. Objects are presented in random order. Manipulation of objects is allowed and encouraged. The therapist assists with the manipulation of items in the client's hand if the person's hand function is impaired. The client should be asked to name the object, or, if he or she is unable to name the object, to describe its properties. Clients with aphasia may view a duplicate set of test objects after each trial and point to a visual choice. The person's response to each of the items presented is scored. The therapist notes if the object is identified quickly and correctly, if there is a long delay before the identification of the object, or if the individual can describe only properties (e.g., size, texture, material, and shape) of the object. The therapist also notes if the person cannot identify the object or describe its properties.

A graded intervention program for astereognosis has been described by Eggers.³⁴ Initially, the client manipulates the object while looking at it and making noise with the object such as tapping it on the tabletop. This approach allows the client to see and hear an object while feeling it for the benefit of intersensory facilitation; then vision is occluded during the tactile exploration. Finally, a pad is placed on the tabletop so that both auditory and visual clues are eliminated and the person relies on tactile-kinesthetic input alone. The program for tactile-kinesthetic reeducation begins with gross discrimination of objects that are very dissimilar—for example, smooth and rough textures or round and square shapes. Next, the client is asked to estimate quantities (such as the number of marbles in a box) through touch. Then the client must discriminate between large and small objects hidden in sand and progress to discriminating between two- and three-dimensional objects. Finally, the client is required to pick a specific small object from among several objects.

Farber also described a treatment approach to retrain stereognosis for adults and children with central nervous system dysfunction.³⁷ First, the client is allowed to examine the training object visually as it is rotated by the therapist. The client is then allowed to handle the object in the less affected hand while observing the hand. In the next step, the client is allowed to manipulate the object with both hands while looking. Then the object is placed in the affected hand and the client manipulates the object while

looking at it. The individual may place the hand in a mirrored, three-sided box to increase visual input during these manipulations. This sequence is then repeated with the client's vision occluded. Once several objects can be identified consistently, two of the objects may be hidden in a tub of sand or rice. The client is then asked to reach into the tub and retrieve a specific object. If the sensation of the sand or rice is overstimulating or disturbing, the objects can be placed in a bag.³⁷

Agraphesthesia

An additional test of tactile perception that measures parietal lobe function is the test for graphesthesia, or the ability to recognize numbers, letters, or forms written on the skin.^{23,44,80} The loss of this ability is called agraphesthesia. To test graphesthesia, the examiner occludes the client's vision and traces letters, numbers, or geometric forms on the fingertips or palm with a dull-pointed pencil or similar instrument. The client tells the therapist which symbol was written.⁸⁰ If the client has aphasia, pictures of the symbols may be provided for the individual to indicate a response after each test stimulus. Agraphesthesia is clinically indicated if the client is unable to state or identify the symbol written on the palm of the hand.

OT intervention for agraphesthesia will focus on providing the client with opportunities for tactile discrimination through the use of his or her hands. The therapist can grade the intervention from tracing letters and numbers to words and geometric forms on the palm of the hand. With vision occluded, client can also practice writing his or her name in the opposite palm.

Body Schema Perception Disorders

Walt demonstrates unilateral inattention to the left side of his body and his environment. He demonstrates asymmetrical visual scanning to the left side of his environment, misses details in his drawings on the left, and routinely neglects the functional use of his left upper extremity during functional tasks. He often states that his left arm is owned by someone else and has difficulty holding a painting utensil because of impairments with spatial relationships between his fingers.

Following a CVA or TBI, a person's sense of his or her body's shape, position, and capacity frequently is distorted. This is known as a disorder of body schema, or autotopagnosia.¹¹ This can be noted in attempts to draw a human figure (Figure 25-2) or in a person's unrealistic expectations of performance abilities.⁶⁵ For example, an individual with left hemiplegia after a TBI expressed his intention to return to his previous manual labor job of installing garage doors. The disorder can affect egocentric perception of one's own body or allocentric orientation of another person's body.^{79,82} A person may neglect one side of the body or demonstrate generally distorted impressions of the body's configuration. The person may confuse his or her body with that of another, such as the person who thought that her wedding

FIGURE 25-2 Example of a body schema perception disorder. Drawing on the left is the person's first attempt to draw a face. The occupational therapist asked the person to try again. The second effort is the drawing on right.

ring had been stolen by the therapist, not realizing that the hand she was viewing was her own. Finger agnosia, or the inability to discriminate the fingers of the hand, can also be part of the disorder.¹¹ An impaired body scheme will also affect participation in occupation and performance skills.⁸⁹

Body schema perception disorders can be assessed by asking the individual to draw a human figure (Figure 25-2) or point to body parts on command (e.g., “Touch your left hand” and “Touch your right knee”). Finger agnosia is evaluated by occluding the person's vision and asking him or her to name each finger as the therapist touches it. Unilateral body neglect can be observed functionally during occupational performance as the client ignores the affected limb or states that a body part is not his or her own. A body schema perception disorder may be clinically indicated if the client is unable to correctly identify parts of his or her body.

A remedial approach to intervention for body schema perception disorders should focus on providing the client with opportunities to reinforce body knowledge through tactile and proprioceptive stimulation.¹⁰⁸ For example, while Walt is dressing or painting, have him incorporate his affected left upper extremity into the activity and verbally acknowledge that this is in fact his left arm and hand being used. Tactile-kinesthetic guiding or constraint-induced movement therapy strategies can also be used if the client has difficulty initiating the use of the affected limb. As the client incorporates the use of the affected limb into occupational performance, the client will begin to gain perceptual awareness of his or her body and the relationship between various body parts.

Motor Perception Disorders

When given a shirt to don, Walt attempts to put his legs through the sleeves of the shirt. During drawing and painting activities, he seems to hesitate and is unable to initiate a motor plan without physical cues. He knows that he is

painting and knows what he would like to paint, but is unable to translate this idea into a motor action. Walt is also unable to operate the mouse on the computer for a graphic design activity because of his difficulty with motor planning. In addition, when given a three-dimensional craft project, he is unable to use effective problem-solving strategies during the construction of the design.

Praxis is the ability to plan and perform purposeful movement. Walt presents with a motor perception disorder that affects his motor planning. Apraxia has been classically defined as a deficit in “the execution of learned movement which cannot be accounted for by either weakness, incoordination, or sensory loss, or by incomprehension of or inattention to commands.”⁴³ The disorder can result from damage to either side of the brain or to the corpus callosum,^{51,105} but it is more frequently noted with left hemisphere damage.⁵² Apraxia is often seen in persons with aphasia; however, not all aphasic persons are apraxic, nor are all apraxic persons aphasic.^{48,51} This type of dysfunction may occur after CVA or TBI. Progressive apraxia is also noted with degenerative disorders such as Alzheimer's disease.^{45,51,81} (See also Chapters 33, 34, and 35.)

Apraxia has been strongly correlated with dependence in areas of occupation.^{93,101} For example, in a severe case of apraxia, an individual referred to as Ms. S initially required total assistance with basic activities of daily living (BADLs). Ms. S was fully cognizant of ongoing events but could not direct her arm and leg movements in a way that would assist the nursing staff during dressing. When asked to pick up a pencil, Ms. S walked around all four sides of the table in an attempt to position her hand correctly to grasp the object. She could describe the desired action in words (“I want to pick up the pencil between my thumb and index finger, with the lead point of the pencil close to the tips of my fingers”) but reported after returning to her seat that her hand never “looked like it was in the right position” to take hold of the pencil.

The categories of apraxia are difficult to differentiate, and authors differ in their use of terms.⁹⁴ The principal types recognized in the literature are ideational apraxia, ideomotor apraxia, dressing apraxia, and constructional disorder. Because the distinction between ideational and ideomotor apraxia is often perplexing, some authors recommend simply using the term apraxia.^{61,65}

Ideational Apraxia

Ideational apraxia is a conceptual deficit, seen as an inability to use real objects appropriately.^{28,31,48} More recent authors suggest the use of the term *conceptual apraxia*.^{52,81} The individual also may have difficulty sequencing acts in the proper order,⁵¹ such as with folding a sheet of paper and inserting it into an envelope. The individual may use the wrong tool for the task or may associate the wrong tool with the object to be acted on, such as by attempting to write with a spoon.⁵¹ This deficit has significant functional implications in a variety of areas of occupation.

Ideomotor Apraxia

Ideomotor apraxia is an inability to carry out a motor act on verbal command or imitation. However, the person with ideomotor apraxia is able to perform the act correctly when asked to use the actual object.^{30,51,84} For example, a person is unable to mime the action of brushing his teeth on request but is observed using a toothbrush correctly when he is performing grooming activities in context. Observation of the person in areas of occupation is critical to the identification of ideomotor apraxia. Impairments are demonstrated only in the testing environment and appear to have little functional impact, as compared with ideational apraxia.⁹⁴

Dressing Apraxia

Another category of motor perception disorders recognized in the literature is dressing apraxia. Dressing apraxia contributes to the inability to plan effective motor actions required during the complex perceptual task of dressing one’s upper and lower body. The classification of dressing impairment as a form of apraxia has been questioned in recent years because the difficulties in ADLs are considered to be caused by perceptual or cognitive dysfunction^{20,101,109} (if apraxia is not noted in other activities) or are seen as an extension of an ideational or ideomotor apraxic disorder.

General Principles in the Assessment and Treatment of Apraxia

It is important that assessments of sensory function, muscle strength, and dexterity are completed before the test of praxis because deficits in these areas would complicate any assessment of apraxia. If a person has a hemiplegia, the unaffected hand is used for testing. Input from the speech-language pathologist is important for establishing an individual’s capacity for basic comprehension via words or gestures. Because of the frequent association of apraxia with aphasia and left hemisphere brain damage, an apraxia screening is included as a part of many aphasia batteries⁹⁴ used by speech-language pathologists.

The literature²⁰ offers several apraxia assessments used in research, such as the Florida Apraxia Screening Test (FAST),^{87,88} the Movement Imitation Test,^{29,30} and the Use of Objects Test.²⁹ The Loewenstein Occupational Therapy Cognitive Assessment (LOTCA)⁵⁷ includes a praxis subsection, as does the Rivermead Perceptual Assessment Battery,¹⁰³ both of which serve as screening tools for the disorder. The Santa Clara Valley Medical Center Praxis Test and the Solet Test for Apraxia are two additional evaluation tools developed by occupational therapists.¹⁰⁸

A thorough assessment includes functional items presented, such as those shown in Table 25-1,⁵¹ and involves both transitive movements (action involving both tool and use, such as writing with an imaginary pen) and intransitive movements (movements for communication, such as waving farewell). Lists of gestures used in assessment are noted in several studies.^{20,51,85,87,104}

TABLE 25-1 Elements of a Comprehensive Apraxia Assessment

Test Condition	Example
Gesture to command	“Show me how you would take off your hat.” (transitive) “Show me how you would throw a kiss.” (intransitive)
Gesture to imitation	“Copy what I do.” <i>Therapist shrugs shoulders.</i> (intransitive) <i>Therapist flips an imaginary coin.</i> (transitive)
Gesture in response to seeing the tool	“Show me how you would, seeing the tool, use this object.” <i>Therapist provides screwdriver for display.</i>
Gesture in response to seeing the object upon which the tool works	“Show me how you would use this object.” <i>Therapist provides screwdriver and block of wood with screw partially inserted.</i>
Actual tool use	“Show me how you would use this object.” <i>Therapist provides screwdriver for use.</i>
Imitation of the examiner using the tool	“Copy what I do.” <i>Therapist makes stirring motion, using a spoon.</i>
Discrimination between correct and incorrect pantomimed movements	“Is this the correct way to blow out a match?” <i>Therapist pantomimes holding a match in an unsafe manner (e.g., match held upside down, with the head of the match near the palm of hand).</i>
Gesture comprehension	“What object am I using?” <i>Therapist pantomimes by shaving face with a razor.</i>
Serial acts	“Show me how you would open an imaginary can of soda, pour it into a glass, and take a drink.”

From Heilman KM, Rothi LJG: Apraxia. In Heilman KM, Valenstein E, editors: *Clinical neuropsychology*, New York, 1993, Oxford University Press.

Returning to the case of Ms. S, who has severe apraxia, she was first treated by practicing basic motor movements, then she followed a developmental sequence to more advanced functional motor activities. For example, following repetition of basic movement patterns, the client with apraxia progressed to coloring geometric shapes on note cards (felt-tip markers were initially placed in a vertical stand for easy grasp) and gradually to writing exercises.

Independent telephone use was important to Ms. S, so a large calculator was used for keystroke practice. She gradually progressed to a disconnected telephone and then to a functional telephone. By the termination of the intervention program, Ms. S was independent in most areas of occupation, although additional time was needed for each activity.

For another client with apraxia, the clinical reasoning process was used in planning the treatment, beginning with spoken instruction for each sequence in the task, written or pictorial instructions, and visual monitoring of her limbs throughout each aspect of the task.²⁰ Another case study of apraxia treatment involved conductive education—that is, breaking the task into smaller units and verbally guiding the sequence.⁷⁶ The individual improved on targeted tasks, but minimal generalization was noted in everyday occupations across various contexts.

OT interventions for dressing apraxia involves problem solving with the client on effective dressing strategies, such as distinguishing from right and left or from front to back on specific clothing items. An effective strategy is to have the client position the garment the same way each time (e.g., positioning a shirt with the buttons face-up and pants with the zipper face-up). Labels, small buttons, or ribbons can be used as cues to differentiate the front from the back of the garment.^{108,109}

Constructional Disorder

The term *constructional disorder* is now favored over the previously used term of two- and three-dimensional constructional apraxia since the deficit does not clearly fall within the definition of apraxia.^{13,20,65} Many occupations depend on visuoconstructional skills, or the ability to organize visual information into meaningful spatial representations. Constructional deficits refer to the inability to organize or assemble parts into a whole, as in putting together block designs (three-dimensional) or drawings (two-dimensional). Constructional deficits can result in significant dysfunction in occupations that require constructional ability, such as dressing, organizing food in a refrigerator, following instructions for assembling a toy, and loading a dishwasher.^{78,95} Figure 25-3, which shows evidence of left inattention, also demonstrates constructional deficits. An individual acts on his or her contextual environment based on the information he or she perceives. Therefore, deficits in perception become more apparent when a person interacts with the environment in maladaptive ways.

Traditional tests of constructional abilities in a two-dimensional mode are the Test of Visual-Motor Skills for Adults,⁴¹ the copy administration of the Benton Visual Retention Test,⁹² and the Rey Complex Figure assessment.⁶⁵ The latter two tests also are used to evaluate visual memory skills. Use of the Rey Complex Figure has been suggested for a quick screening of visual perceptual function.⁶⁷ The Three-Dimensional Block Construction⁸ involves the use of

FIGURE 25-3 Example of a two-dimensional constructional disorder and left-sided inattention in a drawing of a house by a retired architect who suffered a right CVA.

various blocks to copy a design from a three-dimensional model. Nonstandardized tests that may be used are drawing, constructing matchstick designs, assembling block designs, or building a structure to match a model.¹⁰⁸ In daily living, occupations such as dressing or setting the table require constructional skills. To perform such tasks successfully, an individual must have integrated visual perception, motor planning, and motor execution.^{9,46,75,102,109}

Several studies have gathered data on the constructional skills of unimpaired subjects for use as a normative reference for persons with CVA and TBI.^{36,75} In a study of constructional abilities in the well elderly, Fall demonstrated that results are influenced by the type of test administration.³⁶ Subjects tended to score higher on tests that used three-dimensional models as guides for construction than on those that used photographs or drawings. The implications of this finding for occupational therapists are that (1) the type of test administration affects scores, and (2) in teaching persons with constructional disorders, models or demonstrations of desired performance are likely to produce better results than would photographs or drawings.³⁶

The remedial approach to intervention involves the use of perceptual tasks such as paper and pencil activities, puzzles, and three-dimensional craft projects to improve constructional skills. The adaptive approach would include participation in occupational performance and developing compensatory approaches to the functional performance skill impairments. Many areas of occupation are suitable for treatment of constructional deficits, such as folding towels, setting the dinner table, and weeding the garden.

Behavioral Aspects of Perceptual Dysfunction

Some degree of accurate self-awareness and recognition of the effect of the disability on one's functioning is needed if the person is to invest energy in the therapy process.³⁹ An individual who is unaware of perceptual deficits may be a serious safety risk and may attempt occupations that are well beyond present physical abilities. Denial is often noted in early stages of recovery from CVA or TBI and may serve as a protective coping mechanism that allows the individual to gradually absorb the effect of the injury on his or her functioning. A person's innate trust of the accuracy of perceptions often is a basis for unrealistic self-confidence; demonstrating to the individual that his or her perceptions are now distorted and no longer trustworthy can profoundly affect the person's sense of self. A therapist needs to respect and be sensitive to the individual's sense of self and be prepared to aid the client in understanding the changes in perceptual capacity and in reestablishing an accurate sense of self. Several questionnaires are available to assess an individual's self-awareness.⁵⁹ The questionnaires typically are issued to the person with deficits as well as to a family member or close acquaintance. The discrepancies in the two questionnaires are used as a measure of the accuracy of the individual's insight and serve as the basis for intervention. The individual's behavior may also be the result of a disorder in executive function.⁵⁹ See Chapter 26 for additional discussion of this possibility.

An individual who has some degree of awareness of the disability often is depressed, which seems an appropriate response given the effect of perceptual impairments on participation in occupational role performance. The therapist needs to recognize and appreciate this emotional response and assist the individual in achieving an emotional balance to reestablish quality of life through celebrating progress in therapy while acknowledging the impact of the perceptual impairments on participation in occupation.^{39,86} (See also Chapter 6 on social and psychological aspects.)

Review Questions

1. Describe the effects of visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception on occupational performance.
2. Compare the advantages and disadvantages of formal perceptual testing and functional assessment in the context of occupational performance.
3. Describe one assessment used to test perceptual impairments in the following areas: visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception.
4. Describe the two approaches to treatment of perceptual deficits, and give one example of an occupational therapy intervention for each.

Threaded Case Study Walt, Part 2

1. How would you best assess Walt's occupational performance?
Walt's performance in his most valued occupations has been affected because of perceptual impairment. A combination of skilled observation and formal assessments, such as the A-ONE³⁻⁵ and the AMPS,³⁸ could be used to assess Walt's occupational performance in a variety of functional contexts. In addition to assessing occupational performance, these assessments can also assess Walt's specific perceptual functioning. The COPM⁶⁴ can also be used to evaluate the client's primary goals in occupational therapy and set the stage for an occupation-based and client-centered approach to intervention.
2. How would you best assess Walt's perceptual function?
Throughout the chapter, a variety of assessment tools have been presented to evaluate visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception. In addition, other comprehensive perceptual tests—such as the MVPT-R,²⁴ the Dynamic Object Search Test,⁹⁶ the TVPS-UL,⁴² the Lowenstein Occupational Therapy Cognitive Assessment,⁵⁷ the Rivermead Perceptual Assessment Battery,^{32,103} the Minnesota Paper Form Board Test,⁶⁶ and the Hooper Visual Organization Test⁵³—could be used to assess global areas of visual processing and perceptual functioning.
3. How would you assist Walt in achieving his occupational performance goals using remedial and adaptive approaches for his perceptual dysfunction?
To assist Walt in achieving his occupational performance goals of submitting a painting to a local art gallery, playing with his children, driving, and regaining computer skills in preparation for resumption of part-time work as a graphic artist, the therapist would need to use a combination of remedial and adaptive approaches to treat his perceptual impairments. This chapter outlines a variety of intervention possibilities for Walt. The evidence shows that the most successful outcomes for treating perceptual impairments are through occupation-based activities that have meaning and offer the client the opportunity to generalize functional skills to multiple contexts through the remediation and adaptation of perceptual dysfunction.^{33,68,76,77,109}

5. Describe an intervention for each of the following types of perceptual dysfunction: visual perception, visual-spatial perception, tactile perception, body schema perception, and motor perception.

Semantic memory

Short-term memory

Sustained attention (vigilance)

Working memory

■ Chapter Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Understand the interplay between cognition and performance in areas of occupation.
2. Choose appropriate standardized, reliable, and ecologically valid tools to measure baseline status and client progression.
3. Understand the impact of impaired client factors and performance skills on performance in areas of occupation.
4. Develop an evidence-based treatment plan to maximize participation in chosen occupations for those with cognitive dysfunction.

Threaded Case Study Jane, Part I

Jane is a 28-year-old woman who is enrolled in graduate school and 6 months away from completing her masters degree in social work. She was recently married and lives in a ranch-style house in the suburbs. Approximately 1 week ago she told her husband that she was feeling “off” and later reported having the worst headache of her life (sometimes referred to as a “thunderclap headache”) and began vomiting, and her husband reported that she became confused. On arrival at the hospital, the medical team determined that Jane suffered a subarachnoid hemorrhage secondary to a ruptured cerebral aneurysm. Jane was rushed to the operating room where she underwent a craniotomy and clipping of the aneurysm. On postoperative day 8 she was transferred to the brain injury rehabilitation unit at the same hospital. Jane’s occupational profile was determined the first day on the rehabilitation unit via an interview with Jane (who was quite drowsy and distracted), Jane’s husband (Gary), and Jane’s sister (Paula). In addition to “being a grade A graduate student,” it was determined that Jane shared housekeeping responsibilities with Gary, maintained the family garden, was an avid reader of fiction, was responsible for paying the monthly bills online, and loved to cook. Jane was most looking forward to graduating on time. She had spent a tremendous amount of time and money getting through graduate school. Since high school she has been a volunteer working with impoverished children in urban areas. Gary stated that Jane was pursuing her social work degree to build her skills and “give her credibility” so that she could continue to serve this population. Gary and Paula expressed concern that Jane did not know what day it was, did not remember who had visited earlier in the day, and was slow to respond to questions and reported that her answers were inaccurate at times. Jane spent a large part of the time sleeping and did not know why she could not “just go home.”

Critical Thinking Questions

1. How would you structure Jane’s initial evaluation? What assessments would you choose and how would you prioritize them?
2. What are appropriate goals for Jane?
3. What interventions would you use to ensure that Jane meets her initial goals?

therapists (OTs) as the *process of improving function and quality of life for individuals with cognitive impairments*. In terms of maintaining this unique focus, the reader should consider the following points related to the process and domain of the practice of occupational therapy as it relates to this area of practice:

- Evaluations/assessment should be focused on clients performing relevant occupations. Simultaneously (as will be described later), the OT documents what impairment or patterns of impairment in client factors and performance skills are interfering with performance and participation.¹⁰
- Goals should be related to improving performance in areas of occupation, as described by the second edition of the Occupational Therapy Practice Framework.³
- Interventions should consist of primarily graded relevant occupations being performed in natural contexts.
- Finally, the outcomes of occupational therapy intervention for this population should document improved performance in areas of occupation.

Although these points may seem obvious, until recently this area of occupational therapy practice has focused primarily on impairments in client factors, and the focus of intervention involved the use of contrived “cognitive tasks” to treat this population. Outcomes were then measured on the basis of tests of cognition that were not related to function. It was assumed that remediation of an identified impairment or impairments would generalize into the ability to perform meaningful, functional activities. In general, this assumption has not been supported by empiric research.⁴¹ It has become clear that this approach is not consistent with present approaches to occupational therapy.³ Current practice embraces interventions that focus on strategies for living independently, with a purpose, and with improved quality of life despite the presence of cognitive impairments. Likewise, outcome measures that focus on documenting improved functioning outside a clinic environment and those that include test items focused on performing functional activities are being embraced.⁴¹ The remainder of this chapter focuses on areas of occupation, client factors, and performance skills³ and their relationships (Table 26-1).

Cognition and Occupational Therapy

Occupational therapy is one of several professions (e.g., psychology, psychiatry, neuropsychology, speech-language pathology, neurology) involved in the arena of working with those who are cognitively impaired. However, the approach of occupational therapy to this area of practice is unique and differentiated from other disciplines. The clinical focus of what most professions call *cognitive rehabilitation* or *working on cognition* is better described by occupational

Overview of Models That Guide the Practice of Occupational Therapy

Various models that guide this practice area have been described in the literature. The reader is referred to Katz for a comprehensive description of these models.⁵⁰ The following paragraphs are examples and summaries of commonly used approaches. A common theme used for this area of practice is maintaining a client-centered approach when providing rehabilitation services “which embraces a

■ **TABLE 26-1** | **Summary of the American Occupational Therapy Association Practice Framework, ed. 2, Related to Cognition and Occupation**

Domain	Examples
Performance in areas of occupation	Activities of daily living, instrumental activities of daily living, education, work, play, leisure, rest and sleep, social participation
Client factors (body functions)	<p><i>Specific Mental Functions:</i></p> <p>Higher-level cognitive: judgment, concept formation, metacognition, cognitive flexibility, insight, attention, awareness</p> <p>Attention: sustained, selective, and divided</p> <p>Memory: short-term, long-term, working memory</p> <p>Perception: discrimination of sensations</p> <p>Thought: recognition, categorization, generalization, awareness of reality, logical/coherent thought, and appropriate thought content</p> <p><i>Global Mental Functions:</i></p> <p>Consciousness: level of arousal, level of consciousness</p> <p>Orientation: orientation to person, place, time, self, and others</p> <p>Temperament and personality: emotional stability</p>
Performance skills	<p><i>Cognitive skills</i> (actions or behavior that a client uses to plan and manage performance of activity)</p> <p>Examples include judging, sequencing, organizing, prioritizing, and multitasking.</p>

From American Occupational Therapy Association: Occupational therapy practice framework: domain and process, *Am J Occup Ther* 62(6):625-683, 2008.

philosophy of respect for, and partnership with, people receiving services. Client-centered service fosters an active partnership where the client joins with the OT to design and implement an intervention program to best meet the client's unique needs."⁵⁶

van den Broek specifically recommends using a client-centered approach as a way to enhance rehabilitation outcomes and states that treatment failure may be secondary to clinicians focusing interventions on what they *believe* the client needs rather than what the client *actually* wants.¹¹⁰ Another argument for using a client-centered approach to guide the focus of intervention for this population is that the interventions typically used for those with cognitive dysfunction are notoriously difficult to generalize to other real-world settings and situations. For example, strategies

that are taught to accomplish a specific task (e.g., using an alarm watch to maintain a medication schedule for those with memory loss) will not necessarily generalize or “carry over” to another task such as remembering therapy appointments. Finally, there are a large number of clients whose level of brain damage precludes them from generalizing learned tasks.⁶⁹ This issue of task specificity related to treatment interventions must always be considered by clinicians working with this population. A client-centered approach will help ensure that the outcomes, goals, and tasks used as the focus of therapy are at least relevant, meaningful, and specific to each *client*, as well as the *caretaker* or *significant others*, despite the potential lack of being generalizable for a segment of the population affected by various cognitive impairments.

Dynamic Interactional Approach

The Dynamic Interactional Approach views cognition as a product of the interaction among the person, activity, and environment.¹⁰⁶ Therefore, performance of a skill can be promoted by changing either the demands of the activity, the environment in which the activity is carried out, or the person's use of particular strategies to facilitate skill performance. Toglia describes several constructs associated with this model, including the following:

- Structural capacity or physical limits in the ability to process and interpret information
- Personal context or characteristics of the person, such as coping style, beliefs, values, and lifestyle
- Self-awareness or understanding your own strengths and limitations, as well as metacognitive skills such as the ability to judge demands of tasks, evaluate performance, and anticipate the likelihood of problems
- Processing strategies or underlying components that improve the performance of tasks, such as attention, visual processing, memory, organization, and problem solving
- The activity itself with respect to its demands, meaningfulness, and how familiar the activity is
- Environmental factors such as the social, physical, and cultural aspects.

Toglia summarizes that “to understand cognitive function and occupational performance, one needs to analyze the interaction among person, activity, and environment. If the activity and environmental demands change, the type of cognitive strategies needed for efficient performance changes as well. Optimal performance is observed when there is a match between all three variables. Assessment and treatment reflect this dynamic view of cognition.” This approach may be used with adults, children, and adolescents.

Toglia used the Dynamic Interactional Model to develop the Multicontext Treatment Approach.^{106,107} Combining both remedial and compensatory strategies, this approach focuses on teaching a particular strategy to perform a task

and practicing this strategy across different activities, situations, and environments over time. Toglia summarizes the components of this approach to include the following:

- Awareness training or structured experiences should be used in conjunction with self-monitoring techniques so that clients may redefine their knowledge of their strengths and weaknesses.
- Use a personal context strategy. The choice of treatment activities is based on the client's interests and goals. Particular emphasis is placed on the relevance and purpose of the activities. Managing monthly bills may be an appropriate activity for a single person living alone, whereas crossword puzzles may be used as an activity for a retiree who previously enjoyed this activity.
- Processing strategies are practiced during a variety of functional activities and situations. Toglia defines processing strategies as strategies that help a client control cognitive and perceptual symptoms such as distractibility, impulsivity, inability to shift attention, disorganization, attention to only one side of the environment, or a tendency to overly focus on one part of an activity.
- Activity analysis is used to choose tasks that systematically place increased demands on the ability to generalize strategies that enhance performance.
- Transfer of learning occurs gradually and systematically as the client practices the same strategy during activities that gradually differ in physical appearance and complexity.
- Interventions occur in multiple environments to promote generalization of learning.

Quadrasonic Approach

The Quadrasonic Approach was developed by Abreu and Peloquin for use with those who are cognitively impaired after brain injury.¹ This approach is described as including both a “micro” perspective (i.e., a focus on the remediation of subskills such as attention, memory, etc.) and a “macro” perspective (i.e., a focus on functional skills such as activities of daily living [ADLs], leisure, etc.). The approach supports the use of remediation, as well as compensatory strategies.

The micro perspective incorporates four theories:

1. Teaching-learning theory is used to describe how clients use cues to increase cognitive awareness and control.
2. Information-processing theory describes how an individual perceives and reacts to the environment. Three successive processing strategies are described, including detection of a stimulus, discrimination and analysis of the stimulus, and selection and determination of a response.
3. Biomechanical theory is used to explain the client's movement, with an emphasis on integration of the

central nervous system, musculoskeletal system, and perceptual-motor skills.

4. Neurodevelopmental theory is concerned with quality of movement.

The macro perspective involves the use of narrative and functional analysis to explain behavior based on the following four characteristics:

1. Lifestyle status or personal characteristics related to performing everyday activities
2. Life stage status such as childhood, adolescence, adulthood, and marriage
3. Health status such as the presence of premorbid conditions
4. Disadvantage status or the degree of functional restrictions resulting from impairment

Cognitive-Retraining Model

The Cognitive-Retraining Model is used for adolescents and adults with neurologic and neuropsychologic dysfunction.¹¹ Based on neuropsychologic, cognitive, and neurobiologic rationales, this model focuses on cognitive training by enhancing clients' remaining skills and teaching cognitive strategies, learning strategies, or procedural strategies.

Neurofunctional Approach

The neurofunctional approach is applied to those with severe cognitive impairments secondary to brain injuries.³⁷ The approach focuses on training clients in highly specific compensatory strategies (not expecting generalization) and specific task training. Contextual and metacognitive factors are specifically considered during intervention planning. The approach does not target the underlying cause of the functional limitation but focuses directly on retraining the skill itself.

Task-Oriented Approach

Though usually discussed in relation to motor control dysfunction, the Task-Oriented Approach has potential application to this population as well.⁷⁸ Mathiowetz has discussed this approach in detail.⁶⁴ Summary points related to the adoption of a framework for evaluation with this approach include evaluating the following areas in the described order^{64,65}:

1. Role performance (social participation): Identify past roles and whether they can be maintained or need to be changed; determine how future roles will be balanced.
2. Occupational performance tasks (areas of occupation).
3. Task selection and analysis: What client factors, performance skills and patterns, and/or contexts and activity demands limit or enhance occupational performance?
4. Person (client factors, performance skills and patterns): Cognitive—orientation, attention span,

memory, problem solving, sequencing, calculations, learning, and generalization; psychosocial; and sensorimotor.

5. Environment (context and activity demands): Including physical, socioeconomic, and cultural.

In terms of intervention, Mathiowetz and Bass Haugen⁶⁵ and Mathiowetz⁶⁴ recommend the following:

- Help patients adjust to their role and limitations in performing tasks.
- Create an environment that uses the common challenges of everyday life.
- Practice functional tasks or close simulations to find effective and efficient strategies for performance.
- Provide opportunities for practice outside therapy time.
- Remediate a client factor (impairment).
- Adapt the environment, modify the task, or use assistive technology.

Choosing Appropriate Assessments

It is important to reiterate that occupational therapy outcomes should be focused on areas of occupation. The following paragraphs will focus on Jane's case to illustrate this point.

Potential (noninclusive) outcomes for Jane based on the practice framework may include the following³:

- Outcome 1: Following occupational therapy, Jane has improved her scores on a standardized memory scale (decreased impairment in client factors), but the changes are not detected on measures of instrumental activities of daily living (IADLs) and quality of life (stable performance in areas of occupation).
- Outcome 2: Following occupational therapy, Jane has no detectable changes on the standardized memory scale (stable impairment in client factors), but changes are detected on measures of IADL and quality of life (improved performance in areas of occupation).
- Outcome 3: Following occupational therapy, Jane has detectable changes on the standardized memory scale (decreased impairment in client factors), as well as changes detected on measures of IADL and quality of life (improved performance in areas of occupation).

Of the three outcome scenarios, outcome 1 is the least desirable. In the past this type of outcome may have been considered successful (i.e., "Jane's memory has improved"). This outcome may be indicative of an intervention plan that is overly focused on attempts to remediate memory skills (e.g., memory drills, computerized memory programs) without consideration of generalization to real-life scenarios. If a change at the impairment level of function does not translate or generalize to improved ability to engage in meaningful activities, participate successfully in life roles, or enhance quality of life, the importance of the intervention

needs to be reconsidered. Outcomes 2 and 3 are more clinically relevant and arguably more meaningful to Jane and her family and represent more optimal results of structured occupational therapy services. Outcome 2 may have been achieved by focusing interventions on Jane's chosen tasks. Interventions such as teaching compensatory strategies, including the use of assistive technology, may have been responsible for this outcome. Jane is able to engage in chosen tasks despite the presence of stable impairments in memory.

Finally, outcome 3 represents improvement (decreased impairment, improved performance of activities, and improved quality of life) across multiple health domains. Although this outcome may be considered the most optimal, the relationships among the three measures are not clear. Clinicians may assume that the improved status detected by the standardized measure of memory was also responsible for Jane's improved ability to perform household chores and child care. This reasoning is not necessarily accurate, however. The changes within the health domains may in fact be independent of each other. In other words, Jane's improved ability to manage her household after participating in treatment may be related to the fact that the interventions specifically included teaching Jane strategies to manage her household. Similar to outcome 2, this positive change may have occurred with or without a documented improvement in memory skills.

When choosing assessments, particular emphasis should be placed on the *ecologic validity* of an instrument. This term refers to the degree to which the cognitive demands of the test theoretically resemble the cognitive demands in the everyday environment, sometimes termed *functional cognition*. A test with high ecologic validity identifies difficulty performing real-world functional and meaningful tasks. Ecologic validity also refers to the degree to which existing tests are empirically related to measures of everyday functioning via a statistical analysis.²¹

In terms of a starting point (i.e., which areas of occupation should serve as the basis for assessment), as stated earlier, a client-centered approach is necessary. This can be assessed formally by using the Canadian Occupational Performance Measure⁵⁶ or informally via an interview with the client/significant others. The clinical context must also be considered. OTs working in an acute care setting may be focused on areas such as basic mobility (moving in bed and transfers), bedside self-care, IADLs that can be performed at the bedside (e.g., money management, medication management), and sedentary leisure activities (e.g., reading fiction, doing crosswords). Those working in the home setting may focus on intervention related to community reintegration, more complex IADLs, and returning to work. The OT uses observation skills to determine which underlying cognitive (and other) deficits are interfering with functional performance by using error analysis. In other words, errors in performance ("occupational errors" as per Árnadóttir⁷) are allowed to occur as long as they are safe and not

severe enough to halt performance. Árnadóttir gives the following example of this technique related to observing errors during grooming and hygiene⁸ (pp. 478-479):

Dysfunctions of global and specific mental functions with an effect on grooming and hygiene tasks include ideational apraxia, organization and sequencing problems related to activity steps, impaired judgment, decreased level of arousal, lack of attention, distraction, field dependency, impaired memory, and impaired intention. Ideational apraxia may appear during grooming and hygiene activities; an individual may not know what to do with the toothbrush, toothpaste, or shaving cream or may use these items inappropriately (e.g., smear toothpaste over the face or spray the shaving cream over the sink). An individual with organization and sequencing difficulties only may have the general idea of how to perform but may have problems timing and sequencing activity steps. Such a patient may not complete one activity step before starting another or may perform activities too quickly as a result of problems in timing activity steps, resulting in a poor performance.

Lack of judgment may appear as an inability to make realistic decisions based on environmental information, providing that perception of those impulses is adequate. An individual so affected may leave the sink area without turning off the water taps or may leave the wash cloth in the sink, not noticing that the water level is increasing and threatening to overflow.

Field dependency has an attention component and a perseveration component. Individuals with this dysfunction may be distracted from performing a particular task by specific stimuli that they are compelled to act on or incorporate into the previous activity. For example, if an individual with field dependency sees a denture brush while washing the hands, that person may incorporate the brush into the activity and scrub the hands with the denture brush.

An individual with short-term memory problems may not remember the sequence of activity steps or instructions throughout activity performance. The therapist may have to remind an individual several times to comb the hair, even though the individual does not have comprehension problems.

Lack of initiation may occur during performance of grooming and hygiene tasks; the individual may sit by the sink without performing, even after being asked to wash. With repeated instructions to begin, the individual may indicate that the activity is about to start, yet nothing happens. After several such incidents and if the therapist asks for a plan, the individual may state a detailed plan of action in which the water will be turned on, the washcloth will be picked up and put under the running water, soap will be put on the cloth, and washing will begin. The individual has a plan of action but cannot start the plan. This impairment may be associated with ideational problems as well.

Traditionally, clinicians and researchers involved in working with those who are cognitively impaired use

standardized measures of cognitive impairment (i.e., standardized tests to determine impairments in attention, memory, executive functions, etc.) as the primary outcome measure to document the effectiveness of interventions. These measures tend to be categorized as “pen-and-paper” or “tabletop” assessments and have low ecologic validity, as opposed to assessments that use relevant occupations in naturalistic contexts. Although this is one important level of measurement, it is critical that clinical programs and research protocols not only include but also *focus on* measures of activity, participation, and quality of life as a key outcome. As stated, positive changes in these measures are more relevant than an isolated change in an impairment measure; the change in impairment must be associated with a change in other health domains. Individuals receiving services, family members, and third party payers alike are likely to be more satisfied with changes in these arguably more meaningful levels of function. Table 26-2 suggests instruments to document successful clinical and research outcomes related to improving function in those with functional limitations secondary to the presence of cognitive impairments. For a thorough review of performance-based measures, refer to Law and associates.⁵⁷

It also is clinically useful to use self-report or caregiver report measures for this population. The rationale for this type of assessment is multifold:

1. Comparing self-reports with observed performance provides the OT with critical information on awareness of the severity of impairment and functional status.
2. Comparing self-reports and caregiver reports is helpful in getting a “snapshot” of how clients perform in their own environments, which may or may not be congruent with observed performance in an occupational therapy clinic.
3. It is important that clients and caregivers see benefit from the occupational therapy services provided. It is problematic if the OT is documenting improvements that cannot be detected by those to whom we provide services (Table 26-3).

Returning to the case study, the OT had access to Jane’s acute care medical record. He noted that the day before transfer to the inpatient rehabilitation unit, the neurology resident administered the Mini-Mental State Examination (a brief 30-item questionnaire used by multiple disciplines to screen for cognitive impairment). She scored 20 of 30, which is indicative of moderate cognitive impairment. Jane had difficulty on the specific items of orientation, attention and calculation, and recall. An assessment required in most inpatient rehabilitation units is the Functional Independence Measure (FIM). This tool measures the client’s ability to complete specific self-care and mobility tasks, and scoring is based on caregiver burden related to these tasks. The FIM provides information related to *what* tasks Jane requires

■ **TABLE 26-2** | Examples of Instruments to Document Improved Function in Those with Functional Limitations Secondary to the Presence of Cognitive Impairments

Instrument	Description
Standardized, valid, and reliable measures of quality of life	Measures life satisfaction and well-being. Examples include the Medical Outcomes Study 36-Item Short-Form Health Survey, World Health Organization Quality of Life Scale, and Reintegration to Normal Living.
Standardized, valid, and reliable measures of areas of occupation (e.g., BADLs, IADLs, leisure, work)	Measures performance in areas of occupation. Examples include the Functional Independence Measure, the Barthel Index, and the Lawton Instrumental Activities of Daily Living Scale.
Standardized, valid, and reliable measures of participation	Measures involvement in life situations. Examples include the Activity Card Sort, Community Integration Questionnaire, and the Canadian Occupational Performance Measure.
Comprehensive Measures That Simultaneously Assess Activity/Participation and Underlying Impairments or Subskills	
Árnadóttir OT-ADL Neurobehavioral Evaluation, more recently referred to as the ADL-Focused Occupation-Based Neurobehavioral Evaluation (A-ONE) ⁷⁻¹⁰	A performance-based tool that uses structured observations of upper and lower body dressing, grooming, hygiene, feeding, transfers, mobility, and communication to detect the underlying impairments that interfere with function. Examples of impairments include decreased organization and sequencing, short- and long-term memory loss, decreased alertness and arousal, impaired attention, performance latency, confusion, perseveration, distractibility, impaired initiation, insight, judgment, etc.
Assessment of Motor and Process Skills (AMPS) ³²	A client-centered performance assessment of both BADLs and IADLs with emphasis on IADL tasks. The AMPS entails the client choosing to perform 2 or 3 tasks in collaboration with a therapist from a list of more than 80 standardized tasks. It evaluates motor and processing skills that affect function. Process skills are observable actions that a person uses to (1) select, interact with, and use tools and materials; (2) carry out individual actions and steps; and (3) modify performance when problems are encountered. Process skills should not be confused with cognitive skills
Brief Measure of Cognitive Functional Performance	
Kettle Test ⁴⁷	Provides a brief performance-based assessment of an IADL task designed to tap into a broad range of cognitive skills. The task consists of making two hot beverages that differ in two ingredients (one for the client and one for the therapist). The electric kettle is emptied and disassembled to challenge problem-solving skills and safety/judgment, and additional kitchen utensils and ingredients are placed as distracters to increase demands on attention
Assessing Impairments in Executive Function	
Executive Function Performance Test (EFPT) ¹³	Assesses deficits in executive function during the performance of real-world tasks (cooking oatmeal, making a phone call, managing medications, and paying a bill). The test uses a structured cueing and scoring system to assess initiation, organization, safety, and task completion and develop cueing strategies.

assistance with. Jane's OT used this opportunity to also document *why* Jane requires assistance with the FIM tasks. He used the error analysis approach described earlier and objectified his findings with the ADL-Focused Occupation-Based Neurobehavioral Evaluation (A-ONE). Jane required minimal physical assistance to *initiate* each FIM task but needed consistent verbal cues to *organize and sequence* the FIM tasks. Additional verbal cues were required to maintain *alertness*, to stay on task secondary to *distractibility*, and to compensate for *short-term memory deficits*, most notably keeping in mind and remembering the tasks that the OT asked her to demonstrate.

Managing Cognitive Dysfunction That Limits Occupational Performance: Assessment and Interventions

Awareness Deficits Having an Impact on Daily Function

Management of deficits in awareness may be considered a foundational intervention for this population.⁴¹ Findings from standardized assessments of awareness may dictate the overall management of a client's functional limitations, as discussed later. Different terminology and definitions

■ **TABLE 26-2** | **Examples of Instruments to Document Improved Function in Those with Functional Limitations Secondary to the Presence of Cognitive Impairments—cont'd**

Instrument	Description
Calendar Planning Test ¹⁰⁹	The calendar planning activity is a higher-level simulated IADL task that involves entering 17 appointments and errands into a weekly schedule. It was designed to be sensitive to the effects of executive dysfunction in that it requires planning, organization, and multitasking abilities. In addition to entering appointments, the person must monitor time, keep track of rules, inhibit distractions, and deal with schedule conflicts
Multiple Errands Test ^{2,26,54,94}	A multitasking assessment that challenges multiple executive functions. Tasks include purchasing three items, picking up an envelope from reception, using a telephone, posting the envelope, writing down four items (e.g., price of a candy bar), meeting the assessor, and informing the assessor that the test is completed
Executive Function Route-Finding Task ¹⁷	Uses naturalistic observations of route finding to detect dysexecutive symptoms
Behavioural Assessment of the Dysexecutive Syndrome (BADS) ¹¹⁷	The battery is designed to assess capabilities that are typically required in everyday living. It includes six subtests that represent different executive abilities, such as cognitive flexibility, novel problem solving, planning, judgment and estimation, and behavioral regulation. It uses <i>simulated</i> everyday tasks
Assessing Memory Loss	
Rivermead Behavioral Memory Test—Third Edition ¹¹⁹	Ecologically valid test of everyday memory. Uses <i>simulations</i> of everyday memory tasks. Modifications are available for those with perceptual, language, and mobility impairments
Cambridge Behavioural Prospective Memory Test/Cambridge Prospective Memory Test ⁴⁴	Objective test of prospective memory
Assessing Impairments in Attention	
Test of Everyday Attention ⁸⁸	Considered an ecologically valid test for various types of everyday attention such as sustained attention, selective attention, attentional switching, and divided attention. Includes several subtests. It is one of the few tests of attention that <i>simulates</i> everyday life tasks. The test is based on the imagined scenario of a vacation trip to the Philadelphia area of the United States
Moss Attention Rating Scale ^{46,116}	An observational test of disordered attention that includes 22 items at present. It produces three factor scores and a total score
Rating Scale of Attentional Behaviour ⁷⁶	This short assessment of attention-based impairments is rated via clinicians' observations of behavior

BADLs, basic activities of daily living; IADLs, instrumental activities of daily living.

related to limited self-awareness are used in the literature, including lack of insight, lack of/impaired self-awareness or unawareness, anosognosia, and denial. Nonimpaired self-awareness has been defined as “the capacity to perceive the self in relatively objective terms, while maintaining a sense of subjectivity.”⁸¹⁻⁸³ The terms *impaired self-awareness* and *anosognosia* are used interchangeably and are defined as follows: the clinical phenomenon in which a person “does not appear to be aware of impaired neurological or neuropsychological function, which is obvious to the clinician and other reasonably attentive individuals. The lack of awareness appears specific to individual deficits and cannot

be accounted for by hyperarousal or widespread cognitive impairment.”⁸⁰

Other authors reserve the term *anosognosia* for describing unawareness of physical deficits only (i.e., not including cognitive impairments), such as “anosognosia for hemiplegia” or “anosognosia for hemianopia.”

Although impaired self-awareness and anosognosia have clearly been used as overlapping terms in the literature, the term *denial* must be considered separately. Psychologic denial has been defined as “a subconscious process that spares the patient the psychological pain of accepting the serious consequences of a brain injury and its unwanted

■ **TABLE 26-3** | Examples of Self-Report and/or Caregiver Report Measures

Instrument and Author	Instrument Description
Attention Rating and Monitoring Scale ²²	Self-report measure of the frequency of everyday problems related to impairments in attention
Cognitive Failures Questionnaire ¹⁸	Self-report measure of the frequency of lapses in attention and cognition in daily life. Includes items related to memory, attention, and executive dysfunction
Prospective Memory Questionnaire ⁴⁵	Behaviorally anchored self-rated evaluation of prospective memory
Comprehensive Assessment of Prospective Memory ^{89,112}	Assessment of prospective memory related to BADLs and IADLs
Everyday Memory Questionnaire ^{91,102,103}	Subjective report of everyday memory. A metamemory questionnaire. Self-report or via proxy
Prospective and Retrospective Memory Questionnaire ^{52,96}	Measure of prospective and retrospective failures in everyday life. Self-rated or proxy rated. Published norms
Dysexecutive Questionnaire (part of the Behavioral Assessment of the Dysexecutive Syndrome [BADS] test battery) ^{19,118}	A 20-item questionnaire sampling everyday symptoms associated with impairments in executive functions. Self-rating and ratings by significant others' versions available
Behavior Rating Inventory of Executive Function—Adult Version ⁹⁰	A measure that documents an adult's executive functions or self-regulation in his or her everyday environment. Includes both a self-report and an informant report

BADLs, basic activities of daily living; IADLs, instrumental activities of daily living.

effects on his or her life.”²⁵ Complicating the matter is that impaired self-awareness and denial may occur together. Differentiation between denial (a psychological method of coping) and lack of awareness that is neurologically based is difficult because some individuals have both types of clinical manifestations.⁸²

The pyramid model of self-awareness was developed by Crosson and colleagues.²⁵ This model includes three interdependent types of awareness:

1. *Intellectual awareness*: The ability to understand at some level that a function is impaired. At the lowest level, one must be aware that one is having difficulty performing certain activities. A more sophisticated level of awareness is to recognize commonalities between difficult activities and implications of the deficits. It refers to knowing that you have a problem. In terms of the case study, Jane was demonstrating substantial impairment in intellectual awareness on the acute service. Her family reported that she kept repeating, “Why can't I go home? I am fine.” The OT on the rehabilitation service noted that Jane consistently reported that she understood that she had a “stroke.” In addition, Jane was reporting that “simple” tasks seemed to take a long time and that she keeps “losing her train of thought.” Jane is showing signs of emerging (albeit still severely impaired) intellectual awareness.
2. *Emergent awareness*: The ability to recognize a problem when it is actually happening. Intellectual awareness is considered a prerequisite to emergent awareness in this model because one must first recognize that a problem exists (knowing that you are experiencing a problem when it occurs). Emergent awareness is included in the concept of online awareness or monitoring of performance during the actual task.
3. *Anticipatory awareness*: The ability to anticipate that a problem will occur as the result of a particular impairment in advance of actions. Anticipatory awareness is included in the concept of online awareness.

Those with brain injury or cognitive deterioration may be impaired across all three awareness domains⁷⁰ or may have better skills in one or more domains of awareness. Crosson and associates further applied this model to the selection of compensatory strategies and categorized compensations appropriate to each type of awareness.²⁵ They classified compensatory strategies according to the way that their implementation is triggered:

- *Anticipatory compensation*: Applied only when needed. This term refers to implementation of a compensatory technique by anticipating that a problem will occur (i.e., requires anticipatory awareness). An example is a person who needs groceries for the week and is aware that busy environments present a greater challenge to existing memory and attention deficits decides to defer shopping until 7 p.m. when the local store is not as busy.
- *Recognition compensation*: Also applied only when needed. This term refers to strategies that are triggered and implemented because a person recognizes that a problem is occurring (i.e., requires emergent awareness).

An example is asking a person to speak slower because you realize that you are not processing information quickly enough and are having difficulty following the conversation.

- *Situational compensation*: Applies to compensatory strategies that can be triggered by a specific type of circumstance in which an impairment may affect function. These strategies are taught to be used consistently every time that a particular event occurs. An example is a student who because of impairments in memory after a traumatic brain injury (TBI) tape-records all lectures in class. Although recording may not be necessary at times (e.g., a particularly slow-moving lecture with limited content), the strategy is used anyway because this type of compensation does not rely on the judgment of the client. Intellectual awareness is necessary to use this strategy because one must be aware that a deficit exists to integrate a strategy for overcoming it.
- *External compensation*: Triggered via an external agent or involves an environmental modification. Examples include alarm watches, posted lists of steps related to meal preparation, and so on.

This pyramid model was constructively criticized and expanded on by Toglia and Kirk.¹⁰⁸ Their model, the Dynamic Comprehensive Model of Awareness, suggests a dynamic rather than a hierarchic relationship. The model proposes a dynamic relationship among knowledge, beliefs, task demands, and the context of a situation based on the concept of metacognition. This model differentiates between metacognitive knowledge or declarative knowledge and beliefs about your abilities before performing the task (incorporating aspects of intellectual awareness) and online monitoring and regulation of the performance of a task (i.e., during task performance), which integrates aspects of emergent and anticipatory awareness.

Finally, Fleming and Strong discuss a three-level model of self-awareness³⁴:

1. Self-awareness of the injury-related deficits themselves such as cognitive, emotional, and physical impairments (i.e., knowledge of deficits)
2. Awareness of the functional implications of deficits for independent living
3. The ability to set realistic goals; the ability to predict one's future state and prognosis

Most authors recommend that self-awareness be evaluated before initiating an intervention program focused on retraining living skills. The findings from standardized evaluations of self-awareness will clearly guide choices of intervention. For example, a person who exhibits insight into an everyday memory deficit may be a candidate for teaching compensatory strategies such as using a diary or notebook (see later). However, a person who does not realize that he or she has severe unilateral neglect (a lateralized attention

deficit) may not be able to learn compensatory strategies and thus may require environmental modifications (e.g., all clothing hung on the right side of the closet) to improve everyday function. In addition, ascertaining the level of insight into a disability is one factor that may determine how motivated one is to participate in the rehabilitation process. In the most simplistic interpretation, one must be aware and concerned about a deficit in everyday function to be motivated to participate in what may be a long and difficult rehabilitation process. Returning to the case study, Jane has goals of returning to school and engaging in complex ADLs on returning home. It is imperative that Jane continue to gain insight so that she can implement strategies to compensate for her persistent deficits. Examples of strategies to return to school may include tape-recording lectures, having a “note taker” assigned so that Jane can fully attend to the lecture, switching to a part-time school schedule, and using electronic aids to organize her day, assignments, etc.

A variety of assessment measures are typically recommended for ascertaining a person's level of self-awareness, including questionnaires (self or clinician rated); interviews; rating scales; functional observations; comparisons of self-ratings and ratings made by others such as significant others, caretakers, or rehabilitation staff; and comparisons of self-ratings and ratings based on objective measures of function or cognitive constructs. No method is universally accepted for assessing the construct of awareness or lack thereof. In addition, naturalistic observations can provide further information related to how decreased awareness is interfering with the performance of everyday tasks. See Table 26-4 for examples of standardized assessments of awareness.

Although most researchers and scholars agree that interventions focused on improving awareness are critical for maximizing rehabilitation and that greater awareness of deficits is associated with better treatment outcomes,⁷¹ others have documented functional changes via task-specific treatment without concurrent improvement in awareness. Overall, there is a lack of empiric studies that have examined the effectiveness of various interventions aimed at improving awareness. In addition, many of the published studies have not included functional outcomes. As a starting point in managing awareness, the entire team should encourage clients to predict their level of performance before any observed performance in areas of occupation. Those with brain injury or cognitive deterioration most often *underestimate* their level of cognitive impairment and *overestimate* their level of function. Clinicians should leave time at the end of each session to compare actual performance with predicted performance. This comparison of predicted versus actual performance is critical and should be done with all functional tasks. Examples of predictions include questions such as “How long will the task take?”, “How many times will you need to ask for help?”, “How many times will the therapist need to physically help you?”,

■ **TABLE 26-4** | Examples of Standardized Tests of Awareness

Instrument	Brief Description
Self Awareness of Deficits Interview ³⁴	This interviewer-rated structured interview is used to obtain quantitative and qualitative data on the status of self-awareness after brain injury. Specifically, it assesses a client's level of intellectual awareness (the ability to understand that a function is decreased from the premorbid level and to recognize implications of the deficits)
Self-Regulation Skills Interview ⁷³	This semistructured clinician-rated interview is based on the model by Crosson and associates ²⁵ discussed earlier. The tool includes six questions that assess metacognitive or self-regulation skills
The Patient Competency Rating Scale (PCRS) ⁷⁹	This tool evaluates self-awareness following traumatic brain injury. It is a 30-item self-report instrument that uses a 5-point Likert scale (1 = can't do and 5 = can do with ease) to self-rate the degree of difficulty in a variety of tasks and functions. More recently, Borgaro and Prigatano ¹⁶ developed a modified yet still psychometrically sound version of the PCRS for use in an acute, inpatient neurorehabilitation unit. This version retains 13 items from the original PCRS
Awareness Questionnaire ⁹⁵	This is a measure of impaired self-awareness after traumatic brain injury. The instrument consists of three forms (one form is completed by the client, one by a significant other, and one by a clinician). The self-rated and family/significant others forms contain 17 items, and the clinician form contains 18 items. The client's ability to perform various tasks after the injury as compared with before the injury is rated on a 5-point scale
Awareness Interview ⁶	This tool is used to evaluate awareness of cognitive and motor defects after cerebral infarction, dementia, or head trauma. Operationally, the authors defined unawareness as a discrepancy between the client's opinion of his or her abilities in the interview and his or her abilities as measured by neuropsychologic and neurologic examinations
Assessment of Awareness of Disability ⁵⁵	This is an assessment based on a semistructured interview that is used in conjunction with the Assessment of Motor and Process Skills (AMPS). It consists of general and specific questions related to the activity of daily tasks, and the interview is conducted after performance of the AMPS

and “How many times will the therapist need to verbally help you?” The goal is to decrease the discrepancy between the two levels of performance.

It is important for the OT to remember that the verbal or physical cues used to support participation in meaningful occupations are not provided simply to support the completion of tasks. Cues are used to facilitate insight and to encourage the client to solve problems by developing new strategies to overcome deficit areas (Table 26-5).

Tham and colleagues developed an intervention to improve awareness related to the effect of neglect (a lateralized attention deficit) on functional performance.¹⁰⁴ Purposeful and meaningful (for the participant) daily occupations were used as therapeutic change agents to improve awareness of disabilities. Specific interventions included encouraging participants to choose motivating tasks as the modality of intervention and discussions about task performance. Examples include the following:

- Encouraging participants to describe their anticipated difficulties
- Linking their earlier experiences of disability to new tasks
- Planning how they would handle new situations

- Asking participants to evaluate and describe their performance
- Asking participants to think about whether they could improve their performance by performing the task in another way
- Providing feedback about the difficulties observed, including verbal feedback, discussion, and the use of compensatory techniques that could improve performance of the task
- Providing opportunities for further practice of the task by using newly learned compensatory techniques
- Using video feedback to improve awareness
- Using interviews to reflect on and heighten awareness

With this approach, awareness of disabilities and ADL ability improved in all four participants, unilateral neglect decreased in three participants, and sustained attention improved in two participants. The authors concluded that training to improve awareness of disabilities might improve the ability to learn the use of compensatory techniques for performing ADLs by clients with unilateral neglect.

Fleming and coworkers completed a pilot study examining the effect of an occupation-based intervention program on the self-awareness and emotional status of four men after

■ **TABLE 26-5** | **Prompting Procedures to Promote Awareness of Errors during Functional Activities**

Prompts	Rationale
“How do you know this is the right answer/procedure?” or “Tell me why you chose this answer/procedure.”	Refocuses the client’s attention to task performance and error detection. Can the client self-correct with a general cue?
“That is not correct. Can you see why?”	Provides general feedback about error but is not specific. Can the client find error and initiate correction?
“It is not correct because...”	Provides specific feedback about error. Can the client correct error when it is pointed out?
“Try this [strategy]” (e.g., going slower, saying each step out loud, verbalizing a plan before starting, or using a checklist).	Provides the client with a specific, alternative approach. Can the client use the strategy given?
The task is altered. “Try it another way.”	Modifies the task by one parameter. Can the client perform the task? Begin again with grading of prompting described previously

From Brockmann-Rubio K, Gillen G: Treatment of cognitive-perceptual impairments: a function-based approach. In Gillen G, Burkhardt A, editors: *Stroke rehabilitation: a function-based approach*, ed 2, St. Louis, Mo, 2004, Mosby, pp. 427-446. Modified from Toglia JP: Attention and memory. In Royeen CB, editor: *AOTA self-study series: cognitive rehabilitation*, Rockville, Md, 1993, American Occupational Therapy Association; Toglia JP: Generalization of treatment: a multicontext approach to cognitive perceptual impairment in adults with brain injury, *Am J Occup Ther* 45:505, 1991.

acquired brain injury.³³ Each participant received an individualized program that focused on the performance of three client-chosen occupations (e.g., writing a job application, budgeting, meal preparation, playing lawn bowling, cooking with one hand) for which they had decreased awareness according to significant others. The intervention was based on Toglia’s multicontextual approach described earlier.¹⁰⁵ Techniques included providing a nonthreatening environment to build positive therapeutic alliances; having the participants analyze their underlying skills, self-predict, and self-evaluate before and after the occupation; setting “just the right challenge”; supported and structured occupational performance; education on brain injury; timely and nonconfrontive verbal feedback in a sandwich format

(negative comments are preceded and followed by positive feedback); and video feedback.

Repeated measures of participants’ self-awareness and emotional status were performed before and after intervention and analyzed descriptively. The authors found that their results indicated preliminary support for the effectiveness of the program in facilitating participants’ self-awareness, although baseline and follow-up data indicated a complex and inconsistent picture. Of note is that slightly increased anxiety was found to accompany improvements in participants’ self-awareness in all four cases and slight increases in depressive symptoms were noted in three participants. These findings are consistent with the literature discussed earlier focused on the relationships between emotional status and awareness, as well as the interconnections between denial and self-awareness (Box 26-1).

Jane’s OT administered the Self Awareness of Deficits Interview. Gary was present for this session. Jane reported that she was not any different now from what she was like before her hospitalization, her brain injury has not had any effect on everyday life, and she hopes to be ready to graduate and look for her first job as a social worker in the next 6 months. The findings and ratings were indicative of severely limited self-awareness. The OT consistently used the time needed to complete a task as the prediction that Jane would make before each task. The OT chose time as the predictor because Jane had poor initiation, was disorganized, and repeated steps of the tasks. Such behavior increased the amount of time needed to complete tasks. Jane consistently predicted length of time based on her preinjury status. When the OT compared the predicted time with the actual time, Jane reacted with disbelief. As sessions progressed, Jane began to increase her accuracy in reporting the time needed for each task (increased awareness). As her awareness increased, the OT noted that Jane was frequently teary. The OT notified the team that although Jane was developing a better understanding of her current functional status, she required increased emotional support from the team, as well as monitoring for increased levels of depression and anxiety.

Attention Deficits Having an Impact on Daily Function

Attention in its various forms is one of the most important and basic functions of the human brain, and it constitutes the basis for other cognitive processes. Integrity of the attention system is considered a prerequisite for all other higher cognitive systems such as memory, executive functions, and so on.⁷⁵ In particular, basic memory functions such as working memory are dependent on intact attention processes.²² If one does not attend to incoming information and cannot hold information in mind, information will not be remembered and cannot be used to guide appropriate behavior or successfully complete daily activities.⁶⁷ It comes to follow that attention skills serve as a cognitive foundation and are a prerequisite to engage in most if not all

Box 26-1

Other Suggestions for Improving Awareness

Have clients perform tasks of interest and then provide them with feedback about their performance. The goal is to have clients monitor and observe their behavior more accurately so that they can make more realistic predictions about future performance, as well as gain insight into their strengths and weaknesses.

Encourage self-questioning during a task and self-evaluation after a task (e.g., “Have I completed all of the steps needed?”).

Provide methods of comparing functioning before and after injury to improve awareness.

Use prediction methods. Have the client estimate various task parameters such as difficulty, time needed for completion, number of errors, and/or amount of assistance needed before, during, or after a task and compare with the actual results.

Help clients develop and appropriately set their personal goals.

Allow clients to observe their own performance during specific tasks (i.e., via videotape) and compare actual performance with what they state that they can do.

Group treatments and peer feedback may be used because one person can receive feedback on performance from multiple individuals.

Use role reversals. Have the therapist perform the task and make errors, and have the client detect the errors.

The development of a strong therapeutic alliance is critical in managing both denial and lack of self-awareness. This alliance should be open and based on trust. Coach clients to make better choices and understand how defensive strategies affect daily function.

Use familiar tasks that are graded to match the person's cognitive level (“just the right challenge”) to develop self-monitoring skills and error recognition.

Provide education related to deficit areas for clients, as well as families.

Integrate experiential feedback experiences. This method has been called “supported risk taking” and “planned failures” and is used during daily activities to gently demonstrate impairments. High levels of therapist support are mandatory during this intervention.

Monitor for increased signs of depression and anxiety as awareness increases.

Increase mastery and control during performance of daily tasks to increase awareness.

Use emotionally neutral tasks to increase error recognition.

Use tasks that offer “just the right challenge” to increase error recognition/correction.

Provide feedback in a sandwich format (negative comments are preceded and followed by positive feedback).

Data from Fleming JM, Strong J, Ashton R: Cluster analysis of self-awareness levels in adults with traumatic brain injury and relationship to outcome, *J Head Trauma Rehabil* 13(5):39-51, 1998; Klonoff PS, O'Brien KP, Prigatano GP, et al: Cognitive retraining after traumatic brain injury and its role in facilitating awareness, *J Head Trauma Rehabil* 4(3):37-45, 1989; Lucas SE, Fleming JM: Interventions for improving self-awareness following acquired brain injury, *Aust Occup Ther J* 52(2):160-170, 2005; Prigatano GP: Disturbances of self-awareness and rehabilitation of patients with traumatic brain injury: a 20-year perspective, *J Head Trauma Rehabil* 20(1):19-29, 2005; Sherer M, Oden K, Bergloff P, et al: Assessment and treatment of impaired awareness after brain injury: implications for community re-integration, *NeuroRehabilitation* 10:25-37, 1998; Tham K, Tegner R: Video feedback in the rehabilitation of patients with unilateral neglect, *Arch Phys Med Rehabil* 78(4):410-413, 1997; Toglia J: A dynamic interactional approach to cognitive rehabilitation. Adapted from Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

meaningful activities and that any impairment in attention processes will result in observable difficulties in everyday life, which may in fact decrease quality of life. Terminology related to attention impairments is summarized in Table 26-6.

During performance of a task, impaired attention results in increased rates of off-task behavior (e.g., looking up and away from the task at hand, engaging in unsolicited conversations) in comparison to controls. Those with impairments in attention are markedly less attentive than controls both in the presence of distractions (noise, movements) and in their absence.¹¹⁴ Further compounding this problem is a relationship between attention impairment and awareness of errors. McAvinue and colleagues investigated the processes of error awareness and sustained attention in those with TBI.⁶⁶ They found the following:

- In comparison to controls, participants with TBI displayed reduced sustained attention and awareness of error.
- The degree of error awareness was strongly correlated with sustained attention capacity, even when the severity of injury was controlled for.
- Error feedback significantly reduces errors.
- TBI leads to impaired sustained attention and error awareness.

The finding of a significant relationship between these two deficits in clients with TBI suggests that there may be a link between these two processes.

Posner and Peterson proposed the existence of three main functionally and anatomically distinct attentional control subsystems⁷⁷:

■ TABLE 26-6 | Terminology Related to Impairments in Attention

Attention Component	Definition	Functional Examples
Attention	Voluntary control over more automatic brain systems to be able to select and manipulate sensory and stored information briefly or for sustained periods ⁷⁴	See later for examples of the specific components of attention
Arousal	A state of responsiveness to sensory stimulation or excitability ¹¹⁵ Dependent on a widely distributed neural network, including the prefrontal areas and neurotransmitter systems ¹⁰⁸	Decreased responsiveness to incoming visual, auditory, or tactile cues during performance of a task Requires noxious or extreme sensory stimuli (e.g., a cold washcloth applied to the face) to elicit a behavioral response
Selective attention	The type of attention involved in the processing and filtering of relevant information in the presence of irrelevant stimuli; ⁸⁷ The efficiency with which people can search and focus on specific information while ignoring distracters ⁸⁸ Because selective attention is critical for encoding information into memory, retaining and manipulating information in working memory, and successfully executing goal-directed behavior, a deficit in selective attention could contribute to the numerous cognitive deficits observed in those with neurologic impairments ⁸⁷ This skill is linked to the prefrontal and underlying anterior cingulate areas	Attending to one conversation during a party Studying outside with the noise of traffic and children playing Attending to a therapist's instructions and cues in a crowded therapy clinic Making dinner while the children are watching TV in the background Attending to a board game during recess
Sustained attention (vigilance)	Used to support tasks that require vigilance and the capacity to maintain attention over time ⁵ Many times this construct is measured by time spent on task ¹¹⁴ In adults this attention component is linked to prefrontal function in the right hemisphere, as well as white matter damage ⁸⁸	Being able to attend to long conversations, instructions, class lessons, television shows, or movies Attending to playing a game of chess Balancing a checkbook Watching your child on the playground
Attentional switching or alternating attention	The ability to switch attention flexibility from one concept to another. Related to cognitive flexibility The ability to change attentive focus in a flexible or adaptive manner ⁴ The ability to move between tasks with different cognitive requirements This skill appears to be a function of the prefrontal cortex, as well as the posterior parietal lobe, thalamus, and midbrain ⁶⁸	While typing a paper, a friend comes into your room to discuss a completely different topic; when the conversation is over, you return to typing Cooking, taking care of a crying child, then returning to cooking A unit clerk at the hospital alternating between flagging orders on the medical chart, answering the phone, and writing down phone messages
Divided attention	Dividing attention between two or more tasks simultaneously Dual tasking or multitasking The capacity to attend to two competing stimuli simultaneously ⁵ Deficits occur when limited attentional resources are divided between two sources	Making toast and tea at the same time Texting while carrying on a conversation Playing cards while discussing the events of the day

Continued

■ **TABLE 26-6** Terminology Related to Impairments in Attention—cont'd

Attention Component	Definition	Functional Examples
Distractibility	A breakdown in selective attention An inability to block out environmental or internal stimuli when one is trying to concentrate on performing a particular task A symptom of prefrontal damage, particularly the dorsolateral cortex ⁶³	Noise in the hallway takes away your attention while taking notes during a class Inability to attend during a therapy session because of being distracted by watching someone else's session
Field-dependent behavior	Distracted by and acting on an irrelevant impulse that interferes with performance of an activity and takes over goal-directed activity Includes both an attention and perseveration component ⁸	While performing oral care, a person becomes distracted by a light switch; the person then stops the oral care activity while turning on and off the light switch (i.e., not relevant to the task at hand)
Unilateral neglect (a lateralized attention deficit)	See Chapter 33	See Chapter 33

Adapted from Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

1. An orienting system related to sensory events that relies on the posterior brain areas (superior parietal lobe and temporoparietal junction, in addition to the frontal eye fields). This system is involved in the selection of relevant sensory information. This subsystem brings attention to a specific location in space and generates perceptual awareness. It reflects involuntary orienting or automatic processing. The performance of this system is determined by the reaction time in responding to the detection of stimuli.
2. An executive system focused on selection and involving multiple structures (anterior cingulate, lateral prefrontal cortex, and basal ganglia). This system is responsible for exercising control over lower-level cognitive functions and resolving conflicts. The system is prominent in detecting signals for focal or conscious attention. Breakdown in this system results in difficulty managing tasks that require divided attention, screening out interfering stimuli, and responding to novelty.
3. An alerting or sustained attention system involving the frontoparietal regions that is responsible for achieving and maintaining sensitivity to incoming stimuli. Impairments related to this system result in short attention spans.

Dockree and colleagues summarize the following²⁷:

- Attention deficits are among the most commonly observed deficits following brain injury.
- Damage to the frontal lobes of the brain, particularly the white matter connecting the frontal, parietal, and striatal regions, is in part responsible for these deficits.
- Frontal lobe damage in brain-injured clients results in a tendency to drift from intended goals and increases the frequency of action slips that were unintended.

- Self-reports from clients with TBI reveal that problems with attention and concentration rate among the highest complaints in this group of clients.

The usual and customary tests of attention include pen-and-paper measures or laboratory-type tasks, such as the Paced Auditory Serial Addition Test, Trail Making Test Part A, and Wisconsin Card Sorting Task. As discussed earlier, when using these measures the question of ecologic validity arises as regards difficulty generalizing the results to everyday living tasks. Suggested assessments are described in [Tables 26-2 and 26-3](#). Impairments in attention are manifested as observable errors during performance of tasks and should be documented as such (see [Table 26-4](#)).

In their meta-analysis of attention rehabilitation after an acquired brain injury, Park and Ingles examined two approaches to treating attention deficits⁷⁴:

1. *Directly retraining the damaged cognitive function or direct cognitive retraining.* This approach is used under the assumption that practice of carefully selected exercises promotes recovery of damaged neural circuits and restores function in the impaired attentional processes themselves, along with a further assumption that the tasks mediated by those circuits are then performed in a way that is similar to non-brain-damaged individuals. Intervention is then based on a series of repetitive exercises or drills in which clients respond to visual or auditory stimuli. This intervention has received the most attention in the literature with respect to interventions for those with impairments in attention.
2. *Attempts to assist people with attention deficits by having them learn or relearn how to perform specific skills of functional significance (i.e., specific skill training).* The

premise here is that through carefully structured practice of a specific skill that is impaired as a result of brain damage, it is possible for individuals to compensate and develop alternative neuropsychologic processes that rely on preserved brain functions (i.e., individuals learn to perform the skill in a way that is different from non-brain-damaged individuals). In terms of intervention, attention is trained either concurrently with or in the context of the specific skills. In addition, this approach applies behavioral principles and an understanding of how the impairment in attention affects the various skills.

Park and Ingles concluded that specific skills training significantly improved the performance of tasks requiring attention.⁷⁴ In comparison, the cognitive-retraining methods (i.e., those focused on improving impairments in attention out of context) included in the meta-analysis did not significantly affect outcomes. Further analysis revealed that overall performance improved in 69% of the participants who received specific skills training (e.g., driving, ADLs) whereas performance improved in only 31% of those not so trained. In terms of effect size, the improvements in cognitive functions after direct retraining were small, whereas the improvements in performance after specific skills training were medium or large. Their findings demonstrate that acquired deficits in attention are treatable by specific skills training. The authors also proposed clinical implications of their study, including the following:

- The learning that occurs as a function of training is specific and does not tend to generalize or transfer to tasks that differ considerably from those used in training. This specificity of improvement was demonstrated in both the cognitive-retraining studies and the specific functional skill-retraining studies.
- Performance of a task after training will improve to the extent that the processing operations required to complete that task overlap with the processes engaged during training (i.e., performance will improve after training if the training task is similar to the targeted outcome measure).
- Many survivors of brain injury are impaired when performing controlled cognitive processes but not when performing automatic processes. Controlled processing is heavily involved in the early stages of learning a skill and is less involved as a skill becomes more routine with practice. Therefore, training programs that reduce the requirement for controlled processing during learning may be the most effective. Examples of reducing the demands of controlled processing include breaking down a complex functional skill into simpler components, providing practice on these components, and structuring training in such a way that performance feedback can be more easily interpreted. The authors recommend the technique of “shaping” as a way to train people with controlled processing deficits because

shaping links the difficulty of a task to the person’s performance. As a result of using the technique of shaping, the person may make fewer errors and be able to interpret feedback more easily.

- Rehabilitation procedures are to be based on a set of learning principles.

Strategies aimed at modification of task and environments have proved to be beneficial for this population (Box 26-2). Specific strategies include the following:

- Time pressure management (TPM). Fasotti and colleagues noted that following severe closed head injury, deficits in speed of processing information are common and result in a feeling of “information overload” when performing daily tasks.³¹ The authors tested TPM as an approach for managing slow information processing. TPM uses alternative cognitive strategies to support participation in real-life tasks. The overall focus is to teach people to give themselves enough time to deal with life situations. Specific strategies used to prevent or manage time pressure

□ Box 26-2

**Managing Deficits in Attention:
Strategies for Clinicians and Caretakers**

- Avoid overstimulating/distracting environments.
- Face away from visual distracters during tasks.
- Wear earplugs.
- Shop or go to restaurants at off-peak times.
- Use filing systems to enhance organization.
- Label cupboards and drawers.
- Reduce clutter and visual distracters.
- Use self-instruction strategies.
- Use time pressure management strategies.
- Teach self-pacing strategies.
- Control the rate of incoming information.
- Self-manage effort and emotional responses during tasks.
- Teach monitoring or shared attentional resources when multitasking.
- Manage the home environment to decrease auditory and visual stimuli. Keep radios and phones turned off. Close doors and curtains. Keep surfaces, cabinets, closets, and refrigerators organized and uncluttered.
- Use daily checklists for work, self-care, and instrumental activities of daily living.

Data from Cicerone KD: Remediation of “working attention” in mild traumatic brain injury, *Brain Inj* 16(3):185-195, 2002; Fasotti L, Kovacs F, Eling Paul ATM, et al: Time pressure management as a compensatory strategy training after closed head injury, *Neuropsychol Rehabil* 10(1):47-65, 2000; Michel JA, Mateer CA: Attention rehabilitation following stroke and traumatic brain injury, a review, *Eura Medicophys* 42(1):59-67, 2006; and Webster JS, Scott RR: The effects of self-instructional training on attentional deficits following head injury, *Clin Neuropsychol* 5(2):69-74, 1983.
From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

- include the following: enhancing awareness of errors and deficient performance, self-instruction training (e.g., trying to focus, not getting distracted by outside sounds and other information, not getting distracted by irrelevant thoughts, and trying to imagine things that are being said), optimizing planning and organization, rehearsing task requirements, modifying the task environment, and using an overall strategy of “Let me give myself enough time.”
- Self-instruction statements.¹¹² Such statements can be suggested to improve listening and to ask for repetition if attention strays and include the following:
 - “To really concentrate, I must look at the person speaking to me.”
 - “I must also focus on what is being said, not on other thoughts that may want to intrude.”
 - “I must concentrate on what I am hearing at any moment by repeating each word in my head as the person speaks.”
 - “Although it is not horrible if I lose track of a conversation, I must tell the person to repeat the information if I have not attended to it.”

A case study by Webster and Scott demonstrated positive effects of this approach both immediately after treatment and at 18 months’ follow-up as the client demonstrated improved attention, which resulted in increased recall, increased sexual function, and improved job performance.¹¹³

- Self management strategies. Sohlberg and Mateer suggest the use of three self-management strategies⁹⁹:
 1. *Orienting procedures.* Encourage clients to consciously monitor activities to avoid/control a

lapse in attention. Clients are taught to ask themselves orienting questions at various intervals (possibly reminded by an alarm watch). These include “What am I currently doing?”, “What was I doing before this?”, and “What am I supposed to do next?”

2. *Pacing.* Pacing is used to decrease task demands. Scheduling uninterrupted work times is an example. Sohlberg and Mateer give examples such as setting realistic expectations, building in breaks, and self-monitoring fatigue and attention.
3. *Key ideas log.* Clients are taught to quickly write or tape-record questions or ideas to address later so that the task at hand is not interrupted.

Strategy training is considered a practice standard for the postacute period of rehabilitation by the American Congress of Rehabilitation Medicine.²³ Intervention should focus on strategy training to compensate for attention deficits in functional situations.

Memory Deficits Having an Impacting on Daily Function

Memory impairment is one of the most common consequences of brain injury and degenerative cognitive disorders. The severity and type of memory loss vary according to the structures affected. Human memory is composed of multiple and distinct systems that are required to support daily activities and participate in the community (Table 26-7).¹⁰¹ Examples include remembering your significant other’s birthday, remembering to take your medications, remembering to feed the dog, remembering how to type, remembering events that occurred during a vacation, and

■ **TABLE 26-7** | Terminology Related to Impairments in Memory

Term	Definition	Examples of Everyday Behavior
Anterograde amnesia	A deficit in new learning. An inability to recall information learned <i>after</i> acquired brain damage. An inability to form new memories after brain damage occurs	Not able to recall staff names, easily gets lost secondary to topographic disorientation, not able to recall what occurred in therapy this morning, difficulty learning adaptive strategies to compensate for loss of memory
Retrograde amnesia	Difficulty recalling memories formed and stored <i>before</i> the onset of disease. May be worse for recent events as opposed to substantially older memories	Inability to remember autobiographic information (address, social security number, birth order), not able to remember historical events (war, presidential elections, scientific breakthroughs) and/or personally experienced events (weddings, vacations)
Short-term memory	Storage of limited information for a limited amount of time	Difficulty remembering instructions related to the use of adaptive equipment, not able to remember the names of someone just introduced at a dinner party, not able to remember “today’s specials” in a restaurant

■ **TABLE 26-7** | Terminology Related to Impairments in Memory—cont'd

Term	Definition	Examples of Everyday Behavior
Working memory	Related to short-term memory and refers to actively manipulating information that is in short-term storage via rehearsals	While playing a board game, unable to remember and use the rules of the game; not able to perform calculations mentally while balancing the checkbook; difficulty remembering and adapting a recipe
Long-term memory (LTM)	Relatively permanent storing of information with unlimited capacity	May affect declarative memory of knowledge, episodes, and facts or nondeclarative memories such as those related to skills and habits
Nondeclarative/ implicit or procedural memory	Knowing <i>how</i> to perform a skill, retaining previously learned skills, and learning new skills. Form of LTM	Driving, playing sports, hand crafts, learning to use adaptive equipment or a wheelchair for activities of daily living
Declarative/ explicit memory	Knowing that something was learned, verbally retrieving a knowledge base such as facts, and remembering everyday events. Includes episodic and semantic information. Form of LTM (see the following)	See episodic and semantic memory
Episodic memory	Autobiographic memory for contextually specific events, personally experienced events. Form of declarative LTM	Remembering the day's events, what one had for breakfast, occurrences on the job, the content of therapy sessions
Semantic memory	Knowledge of the general world and facts, linguistic skill, and vocabulary. (Note: may be spared after injury.) Form of declarative LTM	Remembering the dates of holidays, the name of the president, dates of world events
Explicit memory	Explicit memories consist of memories of events that have occurred in the external world. Information stored in explicit memory is about a specific event that happened at a specific time and place	Remembering places and names and various words. See declarative memory
Implicit memory	Does not require conscious retrieval of the past. Knowledge is expressed in performance without the person being aware of possessing this knowledge. Consists of memories necessary to perform events and tasks or to produce a specific type of response	Memory of skills, habits, and subconscious processes. See nondeclarative memory
Prospective memory	Remembering to carry out future intentions	Remembering to take medications, return phone calls, buy food, pick up the children from school, mail the bills. A critical aspect of memory to support everyday living
Metamemory	Awareness of your own memory abilities	Knowing when you need to compensate for memory capacity (making a list of errands or a shopping list, writing down a new phone number or driving directions), recognizing errors in memory, etc.

Data from Baddeley AD: The psychology of memory. In Baddeley AD, Kopelman MD, Wilson BA, editors: *The essential handbook of memory disorders for clinicians*, Hoboken, NJ, 2004, John Wiley; Bauer RM, Grande L, Valenstein E: Amnesic disorders. In Heilman KM, Valenstein E, editors: *Clinical neuropsychology*, ed 4, New York, NY, 2003, Oxford University Press; Markowitsch HJ: Cognitive neuroscience of memory, *Neurocase* 4(6):429-435, 1998; and Sohlberg MM, Mateer CA: Memory theory applied to intervention. In Sohlberg MM, Mateer CA, editors: *Cognitive rehabilitation: an integrative neuropsychological approach*, New York, NY, 2001, Guilford Press.

so on. Even this “simple” list of memory tasks requires intact functioning of multiple memory systems and includes knowledge of facts and events, procedures, and future intentions. Clearly, memory serves as a key cognitive support to facilitate independent living.

The steps or stages of memory have been well documented.^{12,99} The flow of these stages follows (Table 26-8):

Attention → Encoding → Storage → Retrieval

Traditional measures of memory have tended to tabletop laboratory-style tools. Contrived tasks commonly used are remembering a string of numbers, a list of words, or the details of a drawn figure and/or paired associate learning (i.e., requiring a person to recognize or recall recently presented material). How the results of these tests relate to everyday memory function is not clear, and associations between scores on this type of test and reports of everyday memory failure are not strong.¹⁰² Similarly, functional gains do not always correlate with improvement in memory processes based on objective testing.⁸⁵

A comprehensive evaluation of how impairments in memory affect everyday function includes the use of standardized assessments, nonstandardized observations, standardized self-reports, and standardized reports of caregivers and significant others. Tables 26-2 and 26-3 include descriptions of recommended assessments. The Contextual Memory Test is a useful screening tool.¹⁰⁵ It allows clinicians to objectify three aspects of memory and screen for possible further evaluation:

1. Awareness of memory: via general questioning before the assessment, predicting performance before

assessment, and estimating memory capacity following performance.

2. Recall of 20 line-drawn aspects: immediate and delayed (15 to 20 minutes) recall.
3. Strategy use: probes the use of memory strategies and determines the ability to benefit from strategy recommended by the clinician.

Interventions focused on those with memory deficits can be categorized as restorative approaches to improve underlying memory deficits, strategy training, use of nonelectronic memory aids, and use of electronic memory aids or assistive technology. Techniques aimed at improving the underlying memory impairment such as memory drills have been unsuccessful in terms of generalization to meaningful activities. In other words, an improvement may be detected on a laboratory-based measure of memory without a corresponding change in daily function or subjective memory reports.

The most promising interventions to improve function in those with memory deficits rely at least partially on compensatory techniques (Box 26-3). When using a compensatory approach, choosing the correct system of compensation is critical. Kime suggests a comprehensive evaluation that includes the following⁵³:

- Severity of the injury
- Severity of the impairment in memory
- Presence of comorbid conditions, including physical impairments, language deficits, and other cognitive deficits
- Social supports
- Client needs (e.g., will the system be used for work, home management, or other occupations)

■ TABLE 26-8 | Stages of Memory

Stage of Memory	Description	Neuroanatomic Area of Function
Attention	The processes that allow a person to gain access to and use incoming information. Inclusive of alertness, arousal, and various attention processes such as selective attention	Brainstem Thalamic structures Frontal lobes
Encoding	How memories are formed. An initial stage of memory that analyzes the material to be remembered (visual vs. verbal characteristics of information). Correct analysis of information required for proper storage of the information	Dorsomedial thalamus Frontal lobes Language system (e.g., Wernicke’s area) Visual system (e.g., visual association areas)
Storage	How memories are retained Transfer of a transient memory to a form or location in the brain for permanent retention/access	Hippocampus Bilateral medial temporal lobes
Retrieval	How memories are recalled Searching for or activating existing memory traces	Frontal lobe

Data from Sohlberg MM, Mateer CA: Memory theory applied to intervention. In Sohlberg MM, Mateer CA, editors: *Cognitive rehabilitation: an integrative neuropsychological approach*, New York, NY, 2001, Guilford Press.

■ Box 26-3

Suggestions for Working with Those with Deficits in Working Memory

- Shorten the length of directions and instructions.
- Use real-world functional tasks for training (e.g., adding monthly bills as opposed to practice of rote strings of numbers).
- Avoid fast speaking rates.
- Place stress on target words during training to help the person realize the key part of the instruction. In addition, place key information at the beginning and end of sentences.
- Increase the automaticity of responding by extra practice and rehearsal such as learning to transfer from a wheelchair to a bed.
- Use part-whole learning or break the task down into components to promote overlearning of the components.
- Teach rehearsal strategies.

Data from Parente R, Kolakowsky-Hayner S, Krug K, et al: Retraining working memory after traumatic brain injury, *NeuroRehabilitation* 13(3):157-163, 1999.

Specific evidenced-based interventions include the following:

- *Memory notebooks and diaries.* Use of this strategy has been documented to improve orientation, as well as support everyday living tasks such as morning ADLs and simple IADLs.⁹² Sohlberg and Mateer published a systematic, structured training sequence for teaching individuals with severe impairments in memory to independently use a compensatory memory book.^{97,98} The training sequence that they proposed incorporates principles of learning theory, as well as procedural memory skills, which may be preserved in many clients with even severe impairments in memory. Donaghy and Williams suggested that the diary or notebook include a pair of pages for each day of the week.²⁸ The notebook is set up to aid scheduling things to do in the future and record activities done in the past. Within each pair of pages the left-hand page contains two columns, one with a timetable for the day and the other for to-do items. The right-hand page contains the memory log. A “last week” section at the back stores previous memory log entries. A full year calendar allows appointments to be recorded. Ownsworth and McFarland compared two approaches to memory diary training⁷²:
 - *Diary-only training.* This approach focuses on functional skill building and compensation-based task-specific learning. The subjects were taught a behavioral sequence consisting of making a diary entry, checking it, and using the information as needed.
 - *Diary and self-instructional training.* This approach emphasizes training of the subject’s capacity for the higher-level cognitive skills of self-regulation and

■ TABLE 26-9 | List and Purpose of Memory Notebook Sections

Notebook Section	Purpose
Daily log	Used to record, store, and retrieve information about daily activities; forms contained for charting hourly information and scheduling appointments; forms contained for prioritizing a list of tasks
Calendar	Used for recording appointments and retrieving information about important meetings and upcoming events
Names	Used to record, store, and retrieve identifying information and “name drawings” of new people
Current work	Used for recording specific procedures about work assignments that may be needed at a later date
Personal notes	Used for recording important personal information such as personal goals or autobiographic information; also used for recording addresses, birthdays, etc.

From Schmitter-Edgecombe M, Fahy JF, Whelan JP, et al: Memory remediation after severe closed head injury: notebook training versus supportive therapy, *J Consult Clin Psychol* 63(3):484-489, 1995.

self-awareness. The subjects were taught a WSTC strategy:

- W:** What are you going to do?
- S:** Select a strategy for the task.
- T:** Try out the strategy.
- C:** Check how the strategy is working.

The authors found that during the treatment phase, those who were in the diary and self-instruction training group consistently made more diary entries, reported fewer memory problems, compensated better via use of strategies, and made more positive ratings associated with the efficacy of treatment. Potential sections of a memory notebook are included in Table 26-9.

Errorless Learning

Errorless learning is a learning strategy that is in contrast to trial-and-error learning or errorful learning. Interventions using an errorless learning approach are based on differences in learning abilities. It is typical for people with impairments in memory to more successfully remember their own mistakes as results of their own action than they remember corrections of their mistakes occurring via explicit means (e.g., a therapist’s cue). In other words, people may remember their mistakes but not the correction. With errorless learning a person learns something by saying or doing it

Box 26-4

Assistive Technology for Those with Memory Loss

Hand-held computers
 Smart phones
 Paging systems
 Voice recorders
 Personal data assistants
 Alarm watches
 Electronic pill box
 Microwave with preset times
 Adaptive stove controls to turn off an electric stove after a certain period or when the heat becomes excessive
 A phone with programmable memory buttons (affix pictures to the buttons)
 A phone with buttons that are programmed to speak the name of the person being called
 A key locator attachment
 Recording used to cue a behavioral sequence such as morning care

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

rather than being told or shown by someone. A meta-analysis of errorless learning for treating memory loss conducted by Kessels and de Haan documented a large and statistically significant effect size for errorless learning treatment.⁵¹ In addition, no significant effect size was demonstrated for the vanishing cues method (i.e., teaching a skill by fading cues over time). It should be noted that the majority of studies that were analyzed used laboratory-type impairment measures such as word lists, face-name associations, and the like.

Assistive Technology

The literature focused on using technology to improve daily function in those with memory loss is substantial and consistently documents improvement in specifically trained tasks (managing medication, morning routines, IADLs, etc.). A variety of devices have been used (Box 26-4). Equipment that used to be specialized (paging systems, hand-held computers, etc.) continues to become commonplace; therefore, there is a larger population who may be amenable to using devices to compensate for memory loss. Typical smart phones have endless possibilities in terms of being used to cue performance of tasks in those with impaired memory. Examples include calendar functions, alarm functions, shopping list applications, dictation systems, map functions, contact lists, and others.

Mnemonics

Mnemonics is a broad term that refers to any strategy used to remember something, including rhymes, poems, acronyms, and imagery techniques. Examples include “Thirty

days hath September...” (rhymes or poems to remember how many days are in each month), the acronym ROYGBIV to remember the colors of the spectrum, and imagining placing the items you want to remember in specific locations in a room with which you are familiar (method of loci).

Hux and colleagues assessed the effectiveness of three frequencies of intervention sessions focused on using mnemonics and visual imagery strategies to recall names of people: once per day, two times per week, and five times per day.⁴⁹ Subjects included seven male TBI survivors ranging in age from 28 to 40 years. The results showed that sessions held daily and twice a week were more effective than sessions held five times per day. Mnemonics and visual imagery strategies were effective for four of the seven participants, regardless of the frequency of intervention sessions. More research is required to determine whether mnemonic strategies are generalizable to untrained tasks, as well as to provide information related to who is an appropriate candidate. At this point it seems that mnemonics are best suited for remembering specific and limited types of information (e.g., staff names).

Task-Specific Training

A series of experiments by Giles and colleagues documented improved daily function in those with severe memory loss via the following:

- An intervention program consisting of chaining nine discrete activities (shaving, oral care, etc.) by using linking phases. The phrases linked the performed activity to the one that immediately followed (e.g., “teeth cleaned, now shave”). The person was then asked to repeat the phrase as a cue to initiate the activity, which was followed by the behavioral techniques of verbal praise and a tangible reward.³⁸
- An intervention that consisted of a cued ADL sequence that was determined by the client’s preinjury habits and responsiveness to cueing. Washing and dressing were conceptualized as a 16-step program in which the staff would cue the next step if behavior compatible with the next step in the sequence was not evident within approximately 5 seconds of completion of the previous step or if behavior incompatible with production of the next step in the behavioral chain was demonstrated. Although the client’s physical and cognitive status remained unchanged during the program, which lasted for 12 treatment days, he did become independent in washing and dressing. Initially requiring between 25 and 30 instructions, as well as physical assistance, to perform the tasks, the client progressed to independence. Independence was maintained at the 6-month follow-up.⁴⁰

Similarly, Giles and associates present further support for these specific retraining protocols. Four clients were treated with the aforementioned washing and dressing protocol.³⁹ Three sustained TBI, and one had brain injury after cerebral

bleeding. All had moderate to severe memory loss. The training program consisted of behavioral observation, task analysis, consistent practice, and cue fading. The Adaptive Behavior Scale was used to measure change in behavior. The authors found that three subjects achieved rapid independence in washing and dressing (requiring 20 days, 37 days, and 11 days of treatment) and one did not show significant clinical improvement. Of note was that all clients admitted to the facility during a 3-year period and who required retraining in washing and dressing were treated with the same protocol. The authors further concluded that the consecutive series design prevented researchers from selecting clients whom they believed were good treatment candidates; therefore, the findings support the general applicability of the training program. See Box 26-5 for strategies for significant others.

Executive Dysfunction Having an Impact on Daily Function

Executive functions is an umbrella term that refers to complex cognitive processing requiring the coordination of several subprocesses to achieve a particular goal.²⁹ This term has been defined as “a product of the coordinated operation of various processes to accomplish a particular goal in a flexible manner”³⁶ or “those functions that enable a person to engage successfully in independent, purposive, self-serving behavior.”⁶¹ These higher-order mental capacities allow one to adapt to new situations and achieve goals. They include multiple specific functions such as decision making, problem solving, planning, task switching, modifying behavior in light of new information, self-correction, generating strategies, formulating goals, and sequencing complex actions. Unfortunately, there is a lack of consistency in the published literature related to whether a particular function is executive. Table 26-10 gives an in-depth list of the 20 most commonly reported dysexecutive symptoms, as well as the reported frequencies of these symptoms. Clearly, these executive functions support engagement in daily life activities and participation in the community, most important during new, nonroutine, complex, and unstructured situations (Table 26-11).

Indeed, recent studies examining meal preparation abilities in those with frontal lobe involvement support this hypothesis. Godbout and associates examined executive functions and ADLs in 10 clients with excised frontal lobe tumors and 10 normal controls by means of a neuropsychologic test battery, a script generation task, and a complex multitask ADL (planning and preparing a meal).⁴² The clients manifested numerous basic executive deficits on the pen-and-paper tests, were unimpaired on the script generation task (despite an aberrant semantic structure), and demonstrated marked difficulties in the meal preparation task. They concluded that the difficulties observed related to performing a lengthy complex multitask ADL can be explained by impairment of several executive functions, generalized slowness in performance, and paucity

Box 26-5

Strategies for Significant Others of Those with Memory Loss

- Understand that in many cases this impairment may not be reversible.
- Become very familiar with the specific type of compensatory memory strategies that have been prescribed.
- Keep daily schedules as consistent as able. Stick with habits and routines.
- Simplify the environment by decreasing clutter and keeping the living areas organized.
- Decrease excessive environmental stimuli.
- Help by organizing calendars and having clocks and reminders arranged around the house.
- Be proactive in identifying potential safety issues.
- Use short and direct sentences.
- Make sure that the most important information comes at the beginning of the sentence.
- Highlight, cue, and emphasize key aspects of communication (i.e., repeat, point, etc.)
- Avoid conversations that rely on memory (i.e., keep conversations in the present).
- Repetition of sentences may be inevitable.
- Summarize conversations.
- Remember that in many cases, intelligence may remain intact.
- Keep “a place for everything and everything in its place.”
- Use photographs, souvenirs, and other appropriate items to help access memories.
- Understand that fatigue, stress, sleep disorders, and depression can exacerbate memory loss.
- Keep back-up items (glasses, spare keys, etc.).
- Help create to-do lists. Remind loved ones to check it off or highlight the item when the task is completed.
- Label items, drawers, and shelves.

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

of behavior. Similarly, Fortin and colleagues investigated executive functions in performing ADLs in 10 clients with frontal lobe lesions after a mild to severe closed head injury (CHI) versus 12 normal controls by means of a neuropsychologic test battery, a script recitation task, and simulation of a complex multitask ADL.³⁵ The authors found that the groups did not differ on any neuropsychologic test by non-parametric testing. However, the clients with CHI manifested marked anomalies in the meal preparation task. Although small sequences of actions were easily produced, large action sets could not be executed correctly. They concluded that an outstanding deficit in strategic planning and prospective memory appears to be an important underpinning of the impairment in ADLs observed in CHI clients with frontal lobe lesions. Similarly, it has been found that components of executive functioning such as

■ TABLE 26-10 | Frequency of Reporting Dysexecutive Symptoms*

Symptom	Clients Reporting Problem (%)	Caregivers Reporting Problem (%)	Rank of Disagreement [†]	Scaled Disagreement in Rank [‡]
Poor abstract thinking	17	21	16.5	-9
Impulsivity	22	22	19.5	-10
Confabulation	5	5	19.5	+3
Planning	16	48	1	+8
Euphoria	14	28	5	+7
Poor temporal sequencing	18	25	15	-8
Lack of insight	17	39	3	+5
Apathy	20	27	13	-5
Disinhibition (social)	15	23	13	-3
Variable motivation	13	15	18	-7
Shallow affect	14	23	10.5	+1
Aggression	12	25	6	+6
Lack of concern	9	26	4	+9
Perseveration	17	26	10.5	-1
Restlessness	25	28	16.5	-6
Can't inhibit responses	11	21	9	+4
Know-do dissociation	13	21	13	-2
Distractibility	32	42	8	+1
Poor decision making	26	38	7	-3
Unconcern for social rules	13	38	2	+10

*Only ratings of 3 or 4 (out of a maximum of 4) for each item on the Dysexecutive Questionnaire were considered to indicate a problem. These correspond to classification of the symptom as "often" or "very often" observed. These results are based on data gathered as part of the study by Wilson and colleagues.

[†]This number represents the rank size of the disagreements (in proportions reporting the symptom) between clients and controls, in which 1 = the largest disagreement; that is, 1 means that caregivers reported this symptom much more often than clients did.

[‡]This number reflects the relative disagreement in rank frequency of reporting between clients and controls, scaled from -10 to +10, with 0 being absolute agreement in rank position of that symptom. On this scale, -10 means that this was a commonly reported symptom by clients, but not by caregivers, and +1 means that caregivers reported this symptom frequently, but it was relatively uncommon for clients to report it.

From Burgess PW, Simons JS: Theories of the frontal lobe executive function: clinical applications. In Halligan PW, Wade DT, editors: *Effectiveness of rehabilitation for cognitive deficits*, Oxford, UK, 2005, Oxford University Press.

categorization and deductive reasoning ability in persons with brain injury are good predictors of IADL functional performance.⁴³

Lezak classified the various forms of executive disorders listed previously in a four-part schema^{60,61}:

1. *Volition and goal formulation*: Including self-awareness, initiation, and motivation
2. *Planning*: Including the ability to conceptualize change, be objective, conceive alternatives, make choices, develop a plan, and sustain attention

3. *Purposive action*: To implement plans for achieving goals, including productivity, self-regulation, switching, and sequencing of actions
4. *Performance effectiveness*: Including quality control, self-correction, monitoring, and time management

Cicerone and associates also presented a schema based on executive functions. It includes four domains based on anatomy and evolutionary development²³:

1. *Executive cognitive functions* (dorsolateral prefrontal cortex): Involved in the control and direction

■ **TABLE 26-11** | Examples of Executive Functions Related to Everyday Living: Preparing a Salad

Executive Function	Associated Tasks
Initiation	Starting the task at the appropriate time without overreliance on prompts
Organization	Organizing the work space and performing the task efficiently (e.g., gathering the necessary vegetables at the same time from the refrigerator)
Sequencing	Sequencing the steps of the task appropriately (e.g., gather tools and vegetables, wash vegetables, chop and slice vegetables, mix in bowl, add dressing)
Problem solving	Solving the problem of a using a knife that is too dull to slice

From Gillen G: *Cognitive and perceptual rehabilitation: optimizing function*, St. Louis, Mo, 2009, Mosby.

(planning, monitoring, activating, switching, inhibiting) of lower-level functions. Working memory and inhibition mediate executive functions.

2. *Behavioral self-regulatory functions* (ventral/medial prefrontal area): Involved in emotional processing and behavioral self-regulation when cognitive analysis, habit, or environmental cues are not sufficient to determine the best adaptive response.
3. *Activation-regulating functions* (medial frontal areas): Activation via initiative and energizing behavior. Pathology results in decrease in activation and drive, also known as apathy and abulia.
4. *Metacognitive processes* (frontal poles): Personality, social cognition, and self-awareness as reflected by accurate evaluation of one's own abilities, as well as behavior, versus objective evaluation or reports by significant others.

People with impairments in executive functions, or *dys-executive syndrome*, have impaired judgment, impulsiveness, apathy, poor insight, and lack of organization, planning, and decision making, as well as behavioral disinhibition and impaired intellectual abilities. Specific behavioral characteristics include impulsivity, poor attention, erratic response, lack of flexibility, and poor self-control.^{84,100} Of note is that people with impaired executive function may perform normally on pen-and-paper tests of cognition but unfortunately are found to have catastrophic everyday problems that are particularly evident in situations requiring multi-tasking and planning.⁹⁴

■ **Box 26-6**

Categories of Interventions for Those with Impairments in Executive Functions

Environmental modifications: Examples include using antecedent control, manipulating the amount of distractions and structure in the environment, organizing work and living spaces, and ensuring balance of work, play, and rest, among others.

Compensatory strategies: Examples include the use of external cueing devices such as checklists, electronic pagers, use of reminder systems, organizers, etc.

Task-specific training: Training of specific functional skills and routines, including task modifications.

Training in metacognitive strategies to promote a functional change by increasing self-awareness and control over regulatory processes. Such strategies include self-instruction strategies, teaching problem solving, and goal management training.

Data from Cicerone KD, Giacino JT: Remediation of executive function deficits after traumatic brain injury, *NeuroRehabilitation* 2(3):12-22, 1992; Sohlberg MM, Mateer CA: Management of dysexecutive symptoms. In Sohlberg MM, Mateer CA, editors: *Cognitive rehabilitation: an integrative neuropsychological approach*, New York, NY, 2001, Guilford Press; and Worthington A: Rehabilitation of executive deficits: the effect on disability. In Halligan PW, Wade, DT, editors: *Effectiveness of rehabilitation for cognitive deficits*, Oxford, UK, 2005, Oxford University Press.

The usual and customary tests of executive dysfunction include pen-and-paper measures or laboratory-type tasks, such as the Wisconsin Card Sorting Task, Trail Making Test, and Stroop Test, among others. As discussed earlier, the question of ecologic validity arises when using these measures, in addition to difficulty generalizing the results to everyday living tasks. These measures have only a low to moderate relationship to everyday skills.

Additionally, the standard clinical tests used to assess executive impairments are considered too structured and rater led; therefore, they fail to capture the common problems of initiation, planning, and self-monitoring. Recommended instruments are summarized in Tables 26-2 and 26-3.

Interventions for dysexecutive syndrome (Box 26-6) continue to be tested empirically.

Because executive functions act as a manager of other cognitive processes such as attention, memory, and language,⁶² some of the interventions previously described in this chapter are appropriate for those with dysexecutive symptoms, including TPM,³¹ self-instruction training,²⁴ WSTC strategy,⁵⁸ external cueing devices (paging system, recorded instructions, checklists, etc.),^{20,30,93} and manipulation of environmental variables with a focus on level of distraction.⁴⁸ Other examples of specific interventions that have been tested and shown to be effective are described in the following sections.

Problem-Solving Training

The aim of this intervention is to substitute a participant's impulsive approach to problem solving with a verbally mediated systematic analysis of the goal and the means by which it may be achieved.¹¹¹ Participants were encouraged to act in the manner attributed to an intact executive system with a focus on five aspects of problem solving:

1. Problem orientation or identifying and analyzing. The difficulty in general recognition of a task or situation as a problem was the focus. The participant's tendency to oversimplify problems and neglect relevant information was addressed.
2. Problem definition and formulation. Participants learned to survey information by reading and rereading directions and formulated questions to augment their understanding of the problem. Main and relevant points were written down. A focus was to teach participants to discriminate between relevant and irrelevant information.
3. Generating alternatives and solutions. Participants were asked to generate as many solutions as possible for a given problem. This was done individually, followed by the participants sharing solutions. The goal was to make participants aware that there were more solutions available than they had originally thought.
4. Decision making. Solutions were discussed and the pros and cons of the solutions were weighed. The feasibility of the solutions was also considered.
5. Solution verification and evaluation. Participants learned to recognize faulty solutions, self-correct errors, and return to other hypotheses. The focus here was on increased sensitivity to errors and discrepancies.

Others have recommended using problem-solving strategies such as stop and think; asking clear thinking questions; thinking your way through each step; defining the problem; using clear thinking questions to produce, evaluate, and examine the utility of as many alternative solutions as possible; and emotional self-regulation strategies.⁸⁶ These problem-solving skills are then reinforced via role playing and practice of demanding real-life examples.

Goal Management Training

This intervention is aimed at decreasing disorganized behavior and improving one's ability to maintain intentions in goal-directed behavior (goal management).⁵⁹ Such disorganization results in one neglecting daily goals, such as never cleaning the house, forgetting to pack a lunch, or never getting around to making a shopping list, all of which compromise functional independence. Goal management training entails five stages that correspond to key aspects of goal-directed behavior:

- *Stage 1:* Orienting and assessing the current state. Stop current activity and direct awareness toward the task.

- *Stage 2:* Select the main goal.
- *Stage 3:* Partition the goals and make subgoals.
- *Stage 4:* Rehearse the steps necessary to complete the task. Encode, rehearse, and retain goals and subgoals.
- *Stage 5:* Monitor the outcome. Compare the outcome of action with the stated goal.

These steps are taught by using errorless techniques, and the cues for each stage are gradually faded to make sure that the person maintains nearly perfect performance.

Metacognitive Training

Birnboim and Miller tested the effectiveness of a metacognitive therapeutic approach¹⁴ in 10 people with multiple sclerosis and executive dysfunction.¹⁵ The approach focuses on the metacognitive aspects of behavior and assumes that metacognitive aspects can and should be learned explicitly via a structured process. Phases of the process include the following:

1. Understanding: The person must recognize his or her specific metacognitive deficits such as not planning. This was achieved by confronting various tasks in the clinic to increase awareness.
2. Practice: Efficient and specific strategies that the participant and therapist identify together (e.g., set priorities) are learned and practiced.
3. Transfer: Participants and their therapist consider when and where these strategies can be applied in real-life situations.

Computer strategy games (e.g., "Mastermind") and tabletop exercises were used during the first two phases of the training. Individualized daily activities were the focus of the generalization phase (e.g., specific work tasks). Positive results were noted on a strategy application test, tests of attention, memory tests, tests of executive function, and most important, the Occupational Therapy Functional Assessment Compilation Tool, which showed improved occupational role.

Summary

Jane's case will be revisited to serve as a summary and conclusion. Jane's initial evaluation was structured to first and foremost foster a client-centered approach to ensure that her occupational therapy sessions were tailored to her goals. Gary, Jane's husband, was also involved in this process because Jane was demonstrating poor self-awareness related to her functional limitations. Gary reported that he worked full-time and Jane would be alone for a portion of the day. He stated that he would help in any way needed but was concerned that helping with self-care would change the dynamic in their new marriage and wanted self-care to be a focus of occupational therapy. Jane was focused on (sometimes perseverating on) finishing school. It was determined that morning sessions would focus on self-care and

afternoon sessions would focus on school skills. As described earlier, the standardized FIM (required on most units) was administered. The FIM findings were supplemented by the standardized A-ONE, which documented the reasons for Jane's limited performance in areas of occupation. Since it was quickly apparent the Jane was not aware of her limitations (one of Gary's greatest concerns), the standardized Self Awareness of Deficits Interview was also administered as a priority. The OT performed nonstandardized assessments of school tasks. To assess performance, the OT requested that Gary bring in her current semester's work and supplies at the end of the second week of therapy. The OT was able to document Jane's reading comprehension, ability to attend to lectures (Jane always recorded lectures and Gary was able to locate the recordings), ability to structure note taking, and use of her laptop for e-mail functions. Deficits were noted in the areas of sustained attention, short-term memory, and being distracted by environmental stimuli.

The OT along with Jane and Gary set the following short-term goals focused on documenting improvements in areas of occupation:

Week 1:

1. Jane will complete upper body dressing with one tactile cue for initiation and no more than two verbal cues for sequencing.
2. Jane will complete grooming tasks (oral hygiene and hair care) with one tactile cue for initiation and the use of a checklist outlining the steps of the tasks.
3. Jane will persist in feeding herself for 10 minutes after one tactile cue for initiation.

Week 3:

1. All self-care tasks except for bathing will be completed with no more than one general verbal cue and external cueing devices as needed.
2. Jane will accurately write down three key points from a 10-minute lecture with one general verbal prompt to stay on task.
3. Jane will retrieve her e-mail from her laptop with no more than one verbal cue for sequencing.

In terms of interventions to meet the aforementioned goals and others, the general treatment approach chosen by Jane's OT was the multicontext approach described earlier. This model was chosen primarily because of its emphasis on awareness training so that Jane could redefine her knowledge of her strengths and weaknesses. The OT hypothesized that improving awareness would be the starting point for intervention because he felt confident that if Jane were aware of her errors, he could teach her strategies that would allow her to meet her goals. In addition, the choice of intervention activities was based on Jane's interests and goals (school tasks, reading fiction, cooking). Various processing strategies were practiced during a variety of functional activities and situations. Processing strategies were chosen to allow Jane to control the cognitive symptoms detected on her assessment. As Jane's awareness improved, the OT was vigilant in monitoring her for signs of depression and

anxiety. Jane's OT began to place emphasis on teaching specific strategies to keep Jane "on task" (sustained attention), as well as determining which external cueing devices would allow Jane to stay organized and perform the steps of various tasks in the proper sequence. The OT planned interventions to occur in multiple environments (bedside, occupational therapy clinic, hospital gift store, staff office, hospital library) to promote generalization of learning.

Review Questions

1. Name and described three levels of self-awareness.
2. What does the concept of ecologic validity refer to when discussing cognitive assessments?
3. What is the rationale for using self-report/caregiver report measures for those with cognitive impairment?
4. What are two general approaches to managing attention deficits?
5. How does the occupational therapy approach for this population differ from that by other disciplines?

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Name and locate oral structures concerned with eating and swallowing.
2. Name and describe the stages of normal eating and swallowing.
3. List the components of the swallowing assessment.
4. Name and describe normal and abnormal oral reflexes.
5. Describe the role of the occupational therapist in the clinical assessment of eating and swallowing.
6. Describe four steps in the swallowing assessment.
7. Describe the appropriate progression of foods and liquids in the assessment and intervention of deglutition and dysphagia.
8. Name two types of tracheostomy tubes, and list the advantages and disadvantages of each.
9. List symptoms of swallowing dysfunction.
10. Identify basic intervention goals for clients with eating and swallowing dysfunction.
11. Describe the roles of the dysphagia team members.
12. Describe proper positioning for safe feeding and swallowing.
13. Describe two methods of non-oral feeding.
14. List principles of oral feeding.
15. List and describe intervention techniques for management of eating and swallowing dysfunction.

Case Study | Mattias

Mattias, a 65-year-old man, experienced a right cerebrovascular accident (RCVA) 3 days ago, which resulted in left hemiplegia. During his occupational therapy (OT) evaluation of activities of daily living (ADLs), it was determined that Mattias had difficulties with self-feeding, chewing, and swallowing at meals. He had frequent episodes of coughing, pocketing food in the left cheek, and often had food on his left side of his face. His oral intake is below the normal calorie range at this time. He complains that he chokes on many foods, including water.

An occupational profile provided the following background information on Mattias. He is married and has two daughters. Until onset, he was working full time as a vice president for marketing in the computer industry. He and his wife are active socially in their golf and tennis club. They also entertain with frequent dinner parties and both are exceptional cooks. Their oldest daughter is engaged and planning to be married in 4 months.

During the OT assessment, Mattias was asked to prioritize his concerns regarding his occupational performance. Mattias wants to be able to attend and participate in his daughter's

wedding in 4 months. His goal is to be able to escort her down the aisle. He wants to be able to eat and drink without concerns about choking or coughing, particularly because he and his wife were going to prepare the dinner for the wedding rehearsal party. He also wants to be able to make and drink a toast to his daughter and her new husband without risk of choking. He had planned to work to the end of the year and then retire. Upon retirement he and his wife planned to travel to Italy to attend a 1-week cooking class.

Critical Thinking Questions

1. What evaluations would you perform to develop an intervention plan for his eating and swallowing needs based on the information described?
2. What interventions would you consider to address his goals of participating in his daughter's wedding?
3. How does context influence Mattias' need to eat safely and eat a variety of foods? How would you incorporate this knowledge into your intervention plan?
4. How would you systematically grade the challenges in the intervention program for Mattias?

Ethical Considerations

Continuing education and special training are required for competence in assessing and intervening with clients who have dysphagia.

Eating is the most basic activity of daily living, necessary for survival from birth until death. Eating occurs throughout life development in a variety of contexts and in every culture and is an essential activity of daily living that facilitates an individual's basic survival and well-being.^{3,8}

Although eating and feeding are closely related, these terms are not synonymous. The Occupational Therapy Practice Framework: Domain and Process, Second Edition (OTPF-2) defines feeding as “the process of setting up, arranging, and bringing food (fluids) from the plate or cup to the mouth; sometimes called self feeding” and eating or deglutition as “the ability to keep and manipulate food/fluid in the mouth and swallow it; eating and swallowing are often used interchangeably” (p. 631).³ Swallowing is a complicated act that involves moving food, fluid, medication, or saliva through the mouth, pharynx, and esophagus into the stomach.^{5,43} Feeding, eating, and swallowing are influenced

by contextual issues, including psychosocial, cultural, and environmental factors.⁵ Dysphagia is difficulty with swallowing or the inability to swallow.

Feeding, eating, and swallowing are within the domain and scope of practice of occupational therapy, and occupational therapists are trained to assess and provide intervention for the performance issues involved in these activities.^{3,4}

Performance skills such as motor and praxis, sensory-perceptual, emotional regulation, and cognitive skills; *client factors* such as muscle strength, endurance and motor control, muscle tone, normal and abnormal motor reflexes, respiratory system function, and digestive system function; *activity demands* such as social demands relating to the social environment and cultural contexts, sequence and timing, and required body functions and structures; and *performance patterns* including the habits, routines, and rituals that may interfere with the eating process are assessed. The *contexts* and *environments*, including those that are cultural, personal, and social, that may influence the client's successful engagement in eating are also assessed.⁵

This chapter provides the occupational therapist with a foundation for the assessment and intervention process of the adult client with eating and swallowing dysfunction. Conditions that can result in eating and swallowing problems include cerebral vascular accident (CVA), traumatic brain injury, brain tumor, anoxia, Guillain-Barré syndrome, Huntington's disease, Alzheimer's disease, multiple sclerosis, amyotrophic lateral sclerosis, Parkinson's disease, myasthenia gravis, poliomyelitis, post-polio syndrome/muscular

atrophy, and quadriplegia.²² Anatomic or developmental dysphagia is not included in this chapter.

Anatomy and Physiology of Normal Eating Swallow

Deglutition, the normal consumption of solids or liquids, is a complex sensorimotor process involving the brain stem, the cerebral cortex, six cranial nerves, the first three cervical nerve segments, and 48 pairs of muscles.^{28,43} A normal swallow requires that all these structures be intact (Figure 27-1). Therefore, occupational therapists who work with clients with eating and swallowing problems must have a thorough understanding of the anatomy and physiology of all phases of the swallow (Table 27-1). The eating and swallowing process can be divided into four stages: oral preparatory phase, oral phase, pharyngeal phase, and esophageal phase (Figure 27-2).^{5,43} An additional phase, the anticipatory phase, will also be discussed.

Anticipatory Phase

Psychological factors, social interactions, a poor dining environment, and cultural differences contribute to feeding difficulties.¹² The psychological, emotional, and social aspects surrounding mealtime can have a huge impact on an elderly individual's participation in the feeding process and oral intake. Factors to be considered that may have an effect on the anticipatory phase include the variety of foods

FIGURE 27-1 Oral structures, swallowing mechanism at rest.

TABLE 27-1 | Swallowing Process

Structure	Muscle Movement	Cranial Nerve	Sensation Oral	Preparatory Stage
Jaw	Pterygoideus medialis	Opens jaw	←Trigeminal (V) →	Face, temple, mouth, teeth, mucus
	Pterygoideus medialis and lateralis	Protrudes lower jaw; moves jaw laterally		
	Masseter	Closes jaw		
	Digastricus; mylohyoideus; geniohyoideus	Depresses lower jaw		
Mouth	Orbicularis oris	Compresses and protrudes lips	←Facial (VII)	
	Zygomaticus minor	Protrudes upper lip		
	Zygomaticus major	Raises lateral angle of mouth upward and outward (smile)		
	Levator anguli oris	Moves angle of mouth straight upward		
	Risorius	Draws angle of mouth backward (grimace)		
	Depressor labii inferioris	Draws lower lip downward and outward		
	Mentalis Depressor anguli oris	Protrudes lower lip (pouting) Draws down angles of mouth		
Tongue	Superior longitudinal	Shortens tongue; raises sides and tip of tongue	Facial (VII) →	Taste, anterior two thirds of tongue
	Transverse	Lengthens and narrows tongue	←Glossopharyngeal (IX) →	
	Vertical	Flattens and broadens tongue	←Hypoglossal (XII)	
	Inferior longitudinal	Shortens tongue; turns tip of tongue downward		
Oral Stage				
Tongue	Styloglossus	Elevates and pulls tongue posteriorly	←Accessory (XI)	
	Palatoglossus	Elevates and pulls tongue posteriorly; narrows fauces	←Hypoglossal (XII)	
	Genioglossus	Depresses, protrudes, and retracts tongue; elevates hyoid		
	Hyoglossus	Depresses and pulls tongue posteriorly		
Soft palate	Tensor veli palatini	Tenses soft palate	←Trigeminal (V) →	Mouth
	Levator veli palatini	Elevates soft palate	←Accessory (XI)	
	Uvulae	Shortens soft palate		
Pharyngeal Stage				
Fauces	Palatoglossus	Narrows fauces	←Vagus (X) →	
	Membranes of pharynx Palatopharyngeus	Elevates larynx and pharynx		
Hyoid	Suprahyoideus	Elevates hyoid anteriorly, posteriorly	←Trigeminal (V)	
	Stylohyoideus	Depresses thyroid cartilage	←Cervical segments 1,2,3	
	Sternothyroideus			
	Omohyoideus	Depresses hyoid

offered, presentation of food, seating during meals, meal-time atmosphere, respect of caregivers for food preferences (Carrier, West, & Ouellet, 2009), and mealtime habits and routines.

The anticipatory phase begins even before the client enters the dining area. The client's expectations of the eating experience will influence his or her reaction to the dining environment and to the foods presented. Appetite/hunger; the sensory qualities of the food; the sensory qualities of the utensils, cups, and plates; the client's motivation to eat; and cognitive awareness of the eating activity will all have an impact on the degree to which the client engages in the feeding process. The anticipatory phase is an important precursor to successful eating. The occupational therapist can be instrumental in identifying environmental modifications that can positively influence the client's response to the eating experience.

Oral Preparatory Phase

In the oral preparatory phase of the swallow, food is masticated by the teeth and gums (if necessary) and manipulated by the lips, cheek, and tongue to form a bolus of appropriate texture for swallowing.^{5,46} Visual and olfactory information stimulates salivary secretions from three pairs of salivary glands. Saliva is mixed with the food to prepare the bolus for the swallow.²⁹ As tactile contact is made with the food, the jaw comes forward to open. The lips close around the glass or utensil to remove the food or liquid. The labial musculature forms a seal to prevent any material from leaking out of the oral cavity. This phase reflects the close relationship between feeding and eating. As Mattias brought food to his mouth, he did not have symmetrical lip closure on utensils or a glass and often food or fluid would dribble from the left side of his mouth.

FIGURE 27-2 The normal swallow. **A**, Lateral view of bolus propulsion during the swallow, beginning with the voluntary initiation of the swallow by the oral tongue. **B**, Triggering of the pharyngeal swallow. **C**, Arrival of the bolus in the vallecula. **D**, Tongue base retraction to the anteriorly moving pharyngeal wall. **E**, Bolus in the cervical esophagus and the cricopharyngeal region.

(From Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed.)

As chewing begins, the mandible and tongue move in a strong, combined rotary and lateral direction. The upper and lower teeth shear and crush the food. The tongue moves laterally to push the food between the teeth. The buccinator muscles of the cheeks contract to act as lateral retainers, to prevent food particles from falling into the sulcus between the jaw and cheek.⁴³ The tongue sweeps through the mouth, gathering food particles and mixing them with saliva. Recall that Mattias frequently had food remaining in his cheek after swallowing. This pocketing of food in the cheek may occur from diminished motor control of the tongue to manipulate the bolus or may indicate diminished sensory appreciation for food remaining in the sulcus. Sensory receptors throughout the oral cavity carry information of taste, texture, and temperature of the food or liquid through the seventh and ninth cranial nerves to the brain stem. The chewing action of the mandible and tongue is repeated rhythmically, repositioning the food until a cohesive bolus is formed. The length of time needed to form a bolus one can safely swallow varies with the viscosity of the food. A short time is needed for soft foods, and a longer time is needed for more textured or dense foods.^{32,53} Large amounts of thick liquids or thick and dense foods require the tongue to divide the food into smaller parts to be swallowed one at a time. The posterior portion of the tongue forms a tight seal with the velum, preventing slippage of the bolus or liquid into the pharynx.⁴³ Foods that are a mixture of liquid and solids (such as soup with chunks of vegetables) require greater oral motor control and often present a difficulty for clients with oral preparatory phase swallowing problems.

In preparation for the next stage, the solid or liquid bolus, having been formed into a cohesive and swallowable mass, may be held between the anterior tongue and palate, with the tongue tip either elevated or dipped toward the floor of the mouth.⁴³ The tongue cups around the bolus to seal it against the hard palate. The larynx and the pharynx are at rest during this phase of the swallowing process, and the airway is open.

Problems at the oral preparatory phase can lead to a disruption in the normal swallow sequence. Mattias has problems with this phase of the eating process. Of additional concern to Mattias is the embarrassment of having food or fluid dribble from the left side of his mouth. His decreased sensory awareness compromises his ability to notice foods/fluids and use a napkin to wipe the remaining food from his face.

Oral Phase

The oral phase of swallowing begins when the tongue initiates posterior movement of the bolus toward the pharynx.³⁷ The tongue elevates to squeeze the bolus up against the hard palate and forms a central groove to funnel the bolus posteriorly. As the viscosity of the food increases, the amount of pressure created by the tongue against the palate increases.

Thicker foods require more pressure to propel them efficiently through the oral cavity.⁴³

The oral phase of the swallow is voluntary, requiring the person to be alert and involved in the process. A normal voluntary oral phase is necessary to elicit a strong swallow response during the pharyngeal stage that follows. This stage of the swallow requires intact labial musculature to maintain food or liquid inside of the oral cavity, intact lingual movement to propel the bolus toward the pharynx, intact buccal musculature to prevent material from falling into the lateral sulci, and the ability to comfortably breathe through the nose.¹⁹ The oral phase takes approximately 1 second to complete with thin liquids and slightly longer with thick liquids and textured foods.

Mattias is alert but has difficulties maneuvering food within his mouth during the oral phase. His ability to chew textured foods is compromised, and he requires additional time to chew foods. This contributes to the decreased oral intake.

Pharyngeal Phase

Voluntary and involuntary components are necessary for a normal swallow. Neither mechanism alone is sufficient to produce the immediate, consistent swallow necessary for normal eating.⁴³ The pharyngeal phase marks the beginning of the involuntary portion of the swallowing process.

This phase of swallowing begins when the bolus passes any point between the anterior faucial arches and where the tongue base crosses the lower rim of the mandible into the pharynx, marking the start of the involuntary component of the swallow.^{43,61} After the swallow response has been triggered, it continues with no pause in bolus movement until the total act has been completed. The pharyngeal swallow is controlled by central pattern-generating (CPG) circuitry of the brain stem and peripheral reflexes.³⁷ Within the medulla oblongata the medullary reticular formation is responsible for screening out all extraneous sensory patterns and for responding only to those patterns that indicate the need to swallow. The reticular formation also assumes control of all motor neurons and related muscles needed to complete the swallow. Higher brain functions such as speech and respiration are preempted.⁴⁸

When the swallow response is triggered, several physiologic functions occur simultaneously. The velum elevates and retracts, closing the velopharyngeal port to prevent regurgitation of material into the nasal cavity. The tongue base elevates to direct the bolus into the pharynx. The hyoid and the larynx elevate and move anteriorly. There is closure of the larynx at the vocal folds, the laryngeal entrance and the epiglottis to prevent material from entering the airway. The pharyngeal tube elevates and contracts from the top to the bottom in the pharyngeal constrictors using a squeezing motion to move the bolus through the pharynx toward the esophagus. The bolus passes through the pharynx, dividing in half at the valleculae and moving down each side through

the pyriform sinuses toward the esophagus. The upper esophageal sphincter (UES) relaxes and opens, allowing the material to enter the esophagus.^{29,43} This movement must be rapid and efficient so that respiration is interrupted only briefly. The pharyngeal phase of the swallow takes approximately 1 second to complete for thin liquids.

Mattias frequently coughs, indicating difficulties with the timing and coordination of the pharyngeal phase. His problems swallowing water may indicate diminished laryngeal elevation and decreased airway protection during the swallow.

Esophageal Phase

The esophageal phase of the swallow starts when the bolus enters the esophagus through the cricopharyngeal juncture or upper esophageal sphincter (UES). The esophagus is a straight tube, approximately 10 inches long, that connects the pharynx to the stomach. The pharynx is separated from the esophagus by the UES. The lower esophageal sphincter (LES) separates the esophagus from the stomach. During the swallow, the strong muscles of the esophagus contract and the bolus is transported through the esophagus by peristaltic wave contractions. The overall transit time needed for the bolus to reach the stomach varies from 8 to 20 seconds. As the food enters the esophagus, the epiglottis returns to the relaxed position, and the airway opens.^{29,43}

Mattias complains of frequently coughing and choking on food and fluid. This may be due to problems with the preoral, oral, pharyngeal, or esophageal phase of eating. As you read the following section, use the case presentation of Mattias and consider what assessment results you would look for to identify which phase is producing the episodes of coughing and choking.

Eating and Swallowing Assessment

When a referral is received from a physician, a thorough eating and swallowing assessment for possible dysfunction must be completed. The occupational therapist reviews the client's medical history and assesses the client's perceptual, and cognitive skills; physical control of head, trunk, and extremities; oral structures; sensation and swallowing ability.

Medical Chart Review

A review of the client's medical chart before initiating the bedside assessment reveals important information. The therapist should take note of the client's diagnosis, pertinent medical history (including prior incidents of aspiration), prescribed medications, and current hydration and nutritional status.

The medical diagnosis may indicate the etiology or cause of the client's eating or swallowing problems. For example, a diagnosis of a neurologic disorder such as a CVA should alert the therapist that eating or swallowing problems may exist.²² It is important to know whether problems developed suddenly or gradually. The therapist should seek

information regarding the duration of the client's swallowing difficulties and note any secondary diagnoses that could contribute to dysphagia such as gastrointestinal or respiratory problems or changes in medication. A diagnosis of dehydration, weight loss, or malnutrition may indicate a chronic problem with deglutition.

Particular attention should be paid to reported episodes of pneumonia or aspiration (entry of food or material into the airway below the level of the true vocal folds).²⁸ Aspiration pneumonia occurs when food or material enters into the lung and can be a serious medical complication that is identified by x-ray and treated with antibiotics. Possible predictors of pneumonia include the need for frequent suctioning, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), use of a feeding tube, weight loss, swallowing problems, multiple medications, and eating dependence.³⁸ An elevated temperature may also indicate that a client is aspirating.

An examination of the client's current hydration and nutritional status provides valuable information about the client's ability to manage oral intake. This information can be found in the dietary section of the chart or in the nursing progress notes in the intake and output (I & O) record. An altered diet texture (pureed food or thickened liquids) alerts the therapist to a potential problem with the client's ability to safely eat a regular diet. The presence of an intravenous (IV) fluid may indicate dehydration. Weight loss is frequently a result of a swallowing problem. Consideration should be given to prescribed medications that may alter the client's alertness, orientation, saliva production, appetite, and muscle control. The nursing notes may also indicate whether the client coughs or chokes when taking medications. How the client is receiving nutrition is also important—for example, the presence of a non-oral feeding device such as a nasogastric tube (NG tube) or gastrostomy tube (G tube) is often an indication of a serious dysphagia problem.

Occupational Profile

In the beginning of the evaluation process, the therapist obtains information from the client to develop the occupational profile. Information gathered for the profile is designed to help the therapist understand what is meaningful and important to the client.³ Prior eating habits and routines and the importance of eating to the client (and the client's family or significant other) are essential to know so that interventions can be established to meet the client's needs. The occupational therapist must take into consideration the cultural values, beliefs, habits, and routines of the client revolving around food and eating. The client may have strong feelings about particular foods, food temperatures, or food textures. Food and food preparation methods may be symbolically meaningful to clients and may have a strong impact on the client's oral intake. The presentation of food may have a significant influence on

the individual's desire to participate in eating. Most adults have firmly rooted routines surrounding the activity of eating. For example, an elderly person may eat a late breakfast, a larger meal at midday, and only a light meal in the evening. He or she may watch TV while eating. This routine can be severely interrupted in an institutionalized setting.

OT Practice Notes

It is important to know the previous habits and routines of the individual and to incorporate them into the intervention program. The therapist must also be sensitive to cultural issues that revolve around eating and foods.

The intervention program is developed based on information provided to the therapist in the occupational profile. Mattias clearly identified his intervention priorities and discussed his concerns about participating in his daughter's wedding. The issues related to eating and drinking are closely tied to the cultural and social expectations for the father of the bride.

Cognitive-Perceptual Status

The client's cognitive and perceptual abilities are assessed to determine if the client can actively participate in an eating and swallowing assessment and intervention program. The therapist should establish whether the client is alert, oriented, and able to follow simple directions, either verbal, with demonstration, or with manual guidance. It is important to assess the client's memory to determine if he or she will be able to recall strategies for safe eating. The therapist should also evaluate the client's visual function, visual-perceptual skills, and motor planning skills, as they are important for independent feeding. An individual who exhibits confusion, dementia, poor awareness of the eating task, poor attention span, or impaired perception or memory will require close supervision during eating for safe consumption.^{10,12,49}

Physical Status

Control of head and trunk is an important component of a safe swallow. To assess head control, the therapist asks the client to turn the head from side to side and up and down. The therapist assesses the client's range of motion and motor control. Assessment should include the quality of head movement without physical assistance or support initially and with assistance, if needed. The therapist should also gently move the client's head passively from side to side and up and down to look for stiffness or abnormal muscle

tone. Poor head control may indicate decreased strength, decreased or increased muscle tone, or decreased awareness of posture. Appropriate head control is necessary to provide a stable base for adequate jaw and tongue movement, allowing an optimal swallow response. Head control is also necessary to anatomically position the client in the safest posture to reduce the risk of aspiration.

In assessing the client's trunk control, the therapist observes whether the client is sitting in midline with equal weight bearing on both hips. The therapist assesses the client's ability to maintain the midline position independently when involved in eating or whether he or she requires the use of postural supports (such as wheelchair trunk supports or a lap board) or physical assistance. It is also important to determine if the client can return to midline if a loss of balance occurs. To participate in an eating and swallowing intervention program, the client must maintain an upright position with the head and trunk in midline to provide correct alignment of the swallowing structures and reduce the risk of aspiration caused by poor positioning.

Mattias is able to independently sit in a chair and at the side of the bed. His head control appears adequate, but he tends to sit shifted to his right side, and his head is most often facing to the right side instead of positioned in midline. This indicates poor trunk and head alignment and can impact eating.

Oral Assessment

Outer Oral Status

The face and mouth are sensitive areas to assess. Most adults are cautious about or even threatened by having another person touch their face. Therefore, each step of the assessment process should be carefully explained prior to touching the client, using terms that the individual understands. The therapist also should tell the client how long he or she will be touching the face—for example, "For a count of three." The therapist assesses the outer oral structures, including the facial musculature and mobility of the cheeks, jaw, and lips. Working within the client's visual field, the therapist moves his or her hand(s) slowly toward the client's face. This allows the individual time to process and acknowledge the approach.

Sensation

Indications of poor oral sensation include drooling, food remaining on the lips, and food falling out of the mouth without the client being aware of these events. To assess the client's awareness of touch, the therapist occludes the client's vision and uses a cotton-tipped swab to touch the client gently with a quick stroke to different areas of the face. The individual is asked to point to where he or she was touched. If pointing is difficult, the client is asked to nod or say yes or no when touched. The client with intact sensation responds accurately and quickly.

The client's ability to sense hot and cold should be assessed. The therapist may use two test tubes, one filled

with hot water and one with cold water. A laryngeal mirror that is first heated and then cooled using hot and cold water may also be used. The client's face or lips are touched in several places, and the client is asked to indicate whether the touch was hot or cold. An aphasic client or an client with cognitive impairment may have difficulty responding accurately. In this instance, the therapist must make an assessment from clinical observations.

Poor sensory awareness affects the client's ability to move facial musculature appropriately. The client's self-esteem may be affected, especially in social situations, if decreased awareness causes the client to ignore saliva, food, or liquids remaining on the face or lips.

Consider Mattias and his personal goal of eating at his daughter's wedding rehearsal dinner. The diminished sensation around Mattias' face will need to be addressed to avoid his embarrassment during this important event. Strategies that promote compensatory habit formation should be used, such as having Mattias wipe his face after every second or third bite of food to remove any food on his face. This strategy provides additional sensory input to the face in addition to decreasing the potential embarrassment of having food remain on his face.

Musculature

An assessment of the facial muscles provides the therapist with information about the movement, strength, and tone available to the client for chewing and swallowing. The

therapist first observes the client's face at rest and notes any visible asymmetry. If a facial droop is obvious, the therapist should observe whether the muscles feel slack or taut. A masked appearance, with little change in facial expression, may also be observed. The therapist should observe whether the client appears to be frowning or grimacing with the jaw clenched and the mouth pulled back. This facial posture may indicate increased or decreased muscle tone.

The therapist tests the facial musculature by asking the client to perform the movements listed in Table 27-2. The therapist should note how much assistance the client needs to perform these movements. As the client moves through each task, symmetry of movement is assessed. Asymmetry could indicate weakness or increased tone. Musculature is palpated for abnormal resistance to the movement.

If the client is able to hold the position at the end of the movement, the therapist applies gentle pressure against the muscle to determine strength. An individual with normal strength is able to hold the position throughout the applied resistance. The person who is able to hold the position briefly against pressure may have adequate strength for chewing and swallowing but may require an altered diet.

Oral Reflexes

A client who has sustained damage to brain stem or cortical structures may demonstrate primitive oral reflexes that interfere with a dysphagia-retraining program. The presence

■ TABLE 27-2 | Outer Oral Motor Assessment

Function	Instruction to Client	Testing Procedure*
Facial expression	"Lift your eyebrows as high as you can."	Place one finger above each eyebrow. Apply downward pressure.
	"Bring your eyebrows toward your nose in a frown."	Place one finger above each eyebrow. Apply pressure outward.
	"Wrinkle your nose upward."	Place one finger on tip of nose and apply downward pressure.
	"Suck in your cheeks."	Apply pressure outward against each inside cheek.
Lip control	"Smile."	Observe for symmetrical movement. Palpate over each cheek.
	"Press your lips together tightly and puff out your cheeks."	Place one finger above and one finger below lips. Apply pressure, moving fingers away from each other; check for ability to hold air.
	"Pucker your lips as in a kiss."	Apply pressure inwardly against lips (toward teeth).
Jaw control	"Open your mouth as far as you can."	Help patient maintain head control. Apply pressure from under chin upward and forward.
	"Close your mouth tightly. Don't let me open it."	Help client maintain head control. Apply pressure on chin downward.
	"Push your bottom teeth forward."	Place two fingers against chin and apply pressure backward.
	"Move your jaw from side to side."	Place one finger on left cheek and apply pressure to right.

*Apply resistance only in the absence of abnormal muscle tone.

Data from Alta Bates Hospital Rehabilitation Services: Bedside dysphagia evaluation protocol, Berkeley, CA, 1999; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 1999; Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed; Miller R: Clinical examination for dysphagia. ■ TABLE 27-3 | Oral Reflexes

Reflex	Assessment	Functional Implications
Rooting (0-4 months)	Stimulus: touch client on right or left corner of mouth Response: client moves lips and head in direction of stimulus	Limits isolated motor control of lip muscles Moves head out of midline, which alters alignment of swallowing mechanism
Bite (4-7 months)	Stimulus: touch crowns of teeth with unbreakable object Response: client involuntarily clamps teeth shut	Prevents normal forward, lateral, and rotary movements of jaw necessary for chewing
Suck-swallow (0-4 months)	Stimulus: introduction of food and liquid Response: sucking	Prevents development of normal voluntary swallow
Tongue thrust (abnormal)	Stimulus: introduction of food and liquid Response: tongue comes forward to front of teeth	Interferes with ability to keep lips and mouth closed Prevents tongue from propelling food to back of mouth in preparation for swallow; prevents formation of bolus, loss of tongue lateralization
Gag (0-adult)	Stimulus: pressure on back of tongue Response: tongue humping, pharyngeal constriction	Protects airway (not always present in normal adult); hypersensitive gag reflex can interfere with chewing, swallowing
Palatal (0-adult)	Stimulus: stroke along faucial arches Response: constriction of faucial arches; elevation of uvula	Protects airway, closes off nasal passages, triggers swallow response

Data from Avery-Smith W: Management of neurologic disorders: the first feeding session. In Groher M, editor: *Dysphagia: diagnosis and management*, ed 3, Newton, MA, 1997, Butterworth-Heinemann; Farber S: *Neurorehabilitation: a multisensory approach*, Philadelphia, 1982, WB Saunders; Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed; Schulze-Delrieu K, Miller R: Clinical assessment of dysphagia. In Perlman A, Schulze-Delrieu K, editors: *Deglutition and its disorders: anatomy, physiology, clinical diagnosis and management*, San Diego, CA, 1997, Singular.

of the rooting, bite, or suck-swallow reflex, normal from 0 to 5 months of age, will interfere with oral motor control in adults. Persistence of these primitive oral reflexes interferes with the client's isolated oral motor control, which is needed for chewing and swallowing. The gag, palatal, and cough reflexes should be present in adults and contribute to airway protection. The absence or impairment of these important reflexes may interfere with a safe swallow. Specific assessment techniques are presented in [Table 27-3](#).

Intraoral Status

An assessment of the client's intraoral status includes an examination of oral structures, including the tongue and palatal function. Each procedure is first explained to the client. The therapist works within the client's visual field and gives the person time to process the instructions found in [Table 27-4](#).

Standard precaution techniques are used throughout the assessment and include the use of examination gloves and careful hand washing. The therapist should check for allergies to latex before examining the person's mouth and use an examination glove of appropriate material for an intraoral examination. The therapist must place only a wet, gloved finger or dampened tongue blade into the client's mouth. The mouth is normally a wet environment and a dry finger or tongue blade can be uncomfortable. After a count of three, the therapist removes the finger and allows the client to swallow the secretions that may have accumulated.

Dentition

Because the adult uses teeth to shear and grind food during bolus formation, it is important for the therapist to assess the condition and quality of the client's teeth and gums.

TABLE 27-4 | Intraoral Motor Assessment

Function	Instruction to Client	Testing Procedure*
Tongue		
Protrusion	“Stick out your tongue.”	Apply slight resistance toward the back of the throat with tongue blade after client exhibits full range of motion.
Lateralization	“Move your tongue from side to side.”	Apply slight resistance in opposite direction of motion with tongue blade.
	“Touch your tongue to your inside cheek—right, then left; move your tongue up and down.”	Using finger on outside of cheek, push against tongue inwardly.
Tipping	“Touch your tongue to your upper lip.”	With tongue blade between tongue tip and lip, apply downward pressure.
	“Open your mouth. Touch your tongue behind your front teeth.”	With tongue blade between tongue and teeth, apply downward pressure on tongue.
Dipping	“Touch your tongue behind your bottom teeth.”	With tongue blade between tongue and bottom teeth, apply upward pressure.
Humping	“Say, ‘ng’; say, ‘ga.’”	Observe for humping of tongue against hard palate. Tongue should flow from front to back.
	“Run your tongue along the roof of your mouth, front or back.”	Observe for symmetry and ease of movement.
Swallow		
Hard palate	“Open your mouth and hold it open.”	Using flashlight, gently examine for sensitivity by walking finger from front to back.
Soft palate	“Say, ‘ah’ for as long as you can (5 seconds). Change pitch up an octave.”	Observe for tightening of faucial arches, elevation of uvula. Using laryngeal mirror, stroke juncture of hard and soft palate to elicit palatal reflex. Observe for upward and backward movement of soft palate.
Hyoid elevation (base of tongue)	“Can you swallow for me?”	Place finger at base of client’s tongue underneath the chin, and feel for elevation just before movement of the larynx.
Laryngeal		
Range of motion	“I am going to move your Adam’s apple side to side.”	Grasp larynx by placing fingers and thumb along sides. Move larynx gently side to side; evaluate for ease and symmetry of movement.
Elevation	“Can you swallow for me?”	Place fingers along the larynx: first finger at hyoid, second finger at top of larynx, and so on. Feel for quick and smooth elevation of larynx as the client swallows.
Cough		
Voluntary	“Can you cough?”	Observe for ease and strength of movement, loudness of cough, swallow after cough.
Reflexive	“Take a deep breath.”	As client holds breath, using palm of hand, push downward (toward stomach) on the sternum. Evaluate strength of reaction.

*Apply resistance in absence of abnormal muscle tone.

Data from Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 1999; Coombes K: *Swallowing dysfunction in hemiplegia and head injury*, course presented by International Clinical Educators, Aug 24-27, 1986, and Aug 24-28, 1987, Los Gatos, CA; Hislop H, Montgomery J, Connelly B: *Daniels & Worthington’s muscle testing: techniques of manual examination*, ed 6, Philadelphia, 1995, WB Saunders; Miller R: Clinical examination for dysphagia. In Groher M: *Dysphagia diagnosis and management*, ed 3, Newton, MA, 1997, Butterworth-Heinemann; Schulze-Delrieu K, Miller R: Clinical assessment of dysphagia. In Perlman A, Schulze-Delrieu K, editors: *Deglutition and its disorders: anatomy, physiology, clinical diagnosis and management*, San Diego, CA, 1997, Singular.

Poor dental status or inadequate denture fit can contribute to dysphagia, discomfort or pain with swallowing, dehydration, malnutrition, low dietary intake, poor nutritional status, and weight loss.^{49,54,55}

For assessment purposes, the mouth is divided into four quadrants: right upper, right lower, left upper, and left lower. Each quadrant is assessed separately, as is each side (e.g., assess the right upper side, then the right lower side). First the therapist slides a wet fifth finger under the client's upper lip and moves it back toward the cheek, rubbing the gums three times.¹⁶ The therapist notes whether the client's gums are bleeding, tender, or inflamed and whether the gums feel spongy or firm. Loose teeth and sensitive or missing teeth are also noted.

OT Practice Notes

The therapist should take caution to avoid placing his or her finger between the client's teeth until it has been determined that the client does not have a bite reflex.

After assessing the gums, the therapist turns over his or her finger, slides the pad of the finger against the inside of the client's cheek, and gently pushes the cheek outward to feel the tone of the buccal musculature. The therapist notes whether the cheek is firm with an elastic quality, too easy to stretch, or tight without any stretch. The therapist observes the condition of the inside of the client's mouth, checking for bite marks on the tongue, cheeks, and lips. Next, the therapist should remove the finger from the client's mouth, allow or assist the client to swallow saliva, and assist the client to move the lip and cheek musculature into the normal resting position. This procedure is repeated for each quadrant.

If the client has dentures, the therapist must determine whether the fit is adequate for chewing. Because dentures are held in place and controlled by normal musculature and sensation, changes in these areas, or marked weight loss, affect the client's ability to use dentures effectively for eating. Dentures should fit over the gums without slipping or sliding during eating or talking. Well-fitting dentures should be worn during all oral intake. A dental consultation may be needed to ensure appropriate fit if dentures cannot be held firmly with commercial adhesive creams or powders. Loose dentures or teeth may necessitate changes in food consistencies that the client may have otherwise managed. Clients who have gum or dental problems require appropriate follow-up and excellent oral hygiene to participate in a feeding and eating program. Poor oral hygiene can lead to the development of bacteria, which, if aspirated, contributes to the increased risk of pneumonia.^{6,21,27,47,57}

Tongue Movement

The tongue has a critical role in the normal chewing and swallowing process. Controlled lingual movement is necessary to assist in the preparation and movement of food in the mouth.¹⁹ The extrinsic muscles of the tongue control the position of the tongue in the oral cavity, and the intrinsic muscles are responsible for changing the shape of the tongue, which is necessary in propelling the bolus posteriorly.⁶⁰ Lingual discoordination is one of the most commonly reported problems affecting the oral stage of swallowing.⁶⁶ A thorough assessment of the tongue's strength, range of motion, control, and tone is an important component of the swallowing assessment.

The client is asked to open the mouth, and the therapist assesses the appearance of the tongue using a flashlight and notes whether the tongue is pink and moist, red, or heavily coated and white. A heavily coated tongue decreases the client's sensations of taste, temperature, and texture and may indicate poor tongue movement or may be a sign of infection.

When examining the shape of the tongue, the therapist notes whether it is flattened, bunched, or rounded. Normally, the tongue is slightly concave with a groove running down the middle. The therapist observes the tongue at rest in the mouth and determines whether it is in the normal position of midline, resting just behind the front teeth, retracted or pulled back away from the front teeth, or deviated to the right or left side. A retracted tongue may indicate an increase of abnormal muscle tone or a loss of range of motion as a result of soft-tissue shortening. The client exhibiting tongue deviation with protrusion may have muscle weakness on the affected side, causing the tongue to deviate toward the unaffected side because the stronger muscles dominate. The client also may have abnormal tone, which results in the tongue deviating toward the affected side.

Using a wet gauze pad to grasp the tongue gently between the forefinger and thumb, the therapist pulls the tongue slowly forward. Next, the therapist walks a wet finger along the tongue from front to back to determine whether the tongue feels hard, firm, or mushy. The tongue should feel firm. An abnormally hard tongue may be the result of increased muscle tone, and a "mushy" tongue is associated with low muscle tone. The right side of the tongue is compared with the left side for symmetry.

While continuing to grip the tongue between forefinger and thumb, the therapist assesses the client's range of motion by moving the tongue forward, side to side, and up and down. The tongue with normal range will move freely in all directions without resistance. Moving the tongue through its range, the therapist can simultaneously evaluate tone. As the therapist gently pulls the tongue forward, he or she determines whether it is easily moved or whether resistance is noted. A tongue pulling back against the movement indicates increased tone. A tongue that seems to stretch too far beyond the front teeth

indicates decreased tone. When moving the tongue side to side, the therapist notes whether it is easier to move in one direction or the other direction. Increased tone makes it difficult for the therapist to move the tongue in any direction without feeling resistance against the movement. Clients who are confused or apraxic may resist this passive motion but not have an actual increase in tone.

To assess the tongue's motor control (strength and coordination), the therapist asks the client to elevate, stick out, and move the tongue laterally (see Table 27-4). If the client has difficulty understanding verbal directions, the therapist can use a wet tongue blade to guide the client through the desired movements.

Poor muscle strength or abnormal tone decreases the ability of the tongue to sweep the mouth and gather food particles to form a cohesive bolus. If the tongue loses even partial control of the bolus, food may fall into the valleculae, the pyriform sinuses, or the airway, possibly leading to aspiration before the actual swallow.⁴³ The back of the tongue must also elevate quickly and strongly to propel the bolus past the faucial arch into the pharynx to trigger the swallow response.²⁸ The therapist must carefully assess the tongue's function. The client with poor tongue control may not be a candidate for eating or may need altered food textures. The therapist must first normalize tone and improve tongue movement before attempting to introduce food to the client. The correct selection of appropriate food textures also facilitates motor control when the client is ready for eating. Close supervision by an experienced therapist is required for this type of client to participate in eating.

Mattias had decreased tongue mobility and control. When he protruded his tongue, it was deviated toward the left, which indicates diminished motor control on the left side of his tongue. An additional indication of diminished tongue control is the pocketing of food in his mouth following a swallow.

Clinical Assessment of Swallowing

Because aspiration is a primary concern in swallowing, the occupational therapist must carefully assess the client's ability to swallow safely. Before the therapist presents the client with material to swallow, he or she should assess the client's ability to protect the airway. The client must have an intact palatal reflex, elevation of the larynx, and a productive cough. The purpose of a productive cough is to remove any food or liquid from the airway.^{29,43} Directions for assessing all the components of the swallow are described in Table 27-4. The therapist should note the speed and strength of each component. The client with intact cognitive skills may accurately report to the therapist where and when difficulty occurs with the swallow.

The occupational therapist integrates all the information from the assessment process. Clinical judgment plays an important role in the accurate assessment of dysphagia.^{5,13} The following questions should be asked:

1. Is the client alert and able to participate in a swallowing assessment?
2. Does the client maintain adequate trunk and head control, with or without assistance?
3. Does the client display adequate tongue control to form a cohesive bolus and move the bolus through the oral cavity?
4. Is the larynx mobile enough to elevate quickly and with sufficient force during the swallow?
5. Can the client handle the saliva with minimal drooling?
6. Does the client have a productive cough, strong enough to expel any material that may enter the airway?

If the answer is yes to all of these questions, the therapist may assess the client's oral and swallow control with a variety of food consistencies.

The therapist should request an assessment tray from dietary services. The following foods are merely suggestions and the therapist must consider cultural factors and medical conditions that influence the selection of foods. For example, a vegetarian or a person who is lactose intolerant will require an appropriate selection of foods. The tray should contain a sample of foods of various textures including pureed food such as pudding or applesauce, soft foods such as a banana or macaroni and cheese, and a mechanical soft-textured food such as ground tuna with mayonnaise or chopped meat with gravy. The tray should also include a thick drink such as nectar blended with half of a banana for a 7-ounce drink, a semithick drink such as fruit nectar or a yogurt drink, and a thin, flavored liquid such as juice and water.

To minimize the risk of aspiration, pureed foods are chosen for clients with decreased oral motor control and chewing difficulties or apraxia. Clients who have poor endurance or have difficulty attending to the task of eating may also require pureed foods. Soft foods are more easily formed into a bolus and require less chewing than regular or ground textures for clients who have impaired oral motor control. Soft foods are also easier for the client to keep in a cohesive bolus as they are moved through the oral cavity. Ground foods allow the therapist to assess a client's ability to chew, form a cohesive bolus, and move it in the mouth. Thick liquids move more slowly from the front of the mouth to back, giving the client with a delayed swallow or impaired oral motor skills more time to control the liquid until the swallow response is triggered. Thin liquids are the most difficult to control because they require intact oral motor strength and coordination, and an intact swallow to prevent aspiration.

For the client who appears to have some ability to chew, the therapist should start with pureed and soft textures. Solid textures may be introduced next if the client is able to safely and efficiently swallow the pureed and soft food textures. The following procedures should be completed after each swallow of food or liquid:

1. The therapist places a small amount ($\frac{1}{3}$ teaspoon) of food or liquid on the middle of the client's tongue. The client is asked to swallow. Two to three bites are presented of each texture to check for fatigue in controlling that texture.
2. The therapist palpates for the swallow by placing the index finger at the hyoid notch, the second finger at the top of the larynx, and the third finger along the midlarynx. The therapist can feel the strength and smoothness of the swallow and can note whether the client requires subsequent or additional swallows to clear the bolus.⁴³ The therapist evaluates oral transit time by noting when food entered the mouth, when tongue movement was initiated, and when the elevation of the hyoid notch was felt, which indicates the beginning of the swallow process. The therapist can time the swallow from the time that hyoid movement begins to when laryngeal elevation occurs, indicating triggering of the swallow response.⁴³ A normal swallow takes only 1 second to complete for thin liquids and slightly longer for textured foods.
3. The therapist asks the client to open the mouth to check for remaining food. Food is commonly seen in the lateral sulci, under the tongue, on the base of the tongue, and against the hard palate.⁴³ Food remaining in the mouth indicates decreased or impaired oral transit skills. The client who exhibits oral motor deficits has increasing difficulty with chewing, shaping a bolus, and moving the bolus in the oral cavity as textured foods are introduced.
4. The therapist asks the client to say "ah." By listening carefully, the therapist can assess the client's voice quality and classify the sound production as strong, clear, gurgly, or gargling.⁴³

A gurgly voice may result from a delayed swallow response, which allows material to collect in the larynx prior to the initiation of the swallow. The therapist asks the client to take a second "dry" swallow to clear any pooling of material. Asking the client to say "ah" again enables the therapist to assess whether the voice quality remains gurgly or gargling for any length of time after the dry swallow. In addition, the therapist asks the client to pant for a few seconds. This will shake loose any material that may remain in the pyriform sinuses or valleculae. If the voice is still gurgly, the therapist should be concerned with the possibility that material has come into contact with or is sitting on the vocal cords.⁴³

If the client has significant coughing episodes, particularly before the therapist feels the initiation of the swallow (elevation of hyoid notch) with all consistencies, the presentation of food should not be continued. Strategies and techniques to facilitate a safe swallow are appropriate to introduce at this point. If the client continues to have significant coughing or other signs that may suggest aspiration, a videofluoroscopy swallow study is indicated.^{35,50}

Although Mattias had frequent episodes of coughing during the bedside evaluation, no gurgly or raspy vocal quality was noted during speech. He is able to clear material from his vocal folds with a strong protective cough. He is able to swallow his secretions, but drooling was noted from the left corner of his mouth, which indicates diminished sensation.

A client with central nervous system damage and impaired sensation may have difficulty with a pureed food because it does not stay together as a bolus. The weight of soft foods, denser than a pureed food, may facilitate the triggering of the swallow response. If the client continues to cough even with soft foods, the swallow assessment should be discontinued. In this instance, a videofluoroscopy swallow study is indicated. If a client is having difficulty at this level, only a prefeeding intervention program should be considered.

Because Mattias is able to safely manage a modified diet texture using positioning strategies and does not have signs and symptoms of aspiration, a videofluoroscopy was not deemed necessary.

A client who has difficulty managing solid consistencies may or may not have difficulty with liquids. To assess the client's swallow with liquids, the therapist starts with a thickened (thick) nectar, then a pure nectar (semithick), and finally a thin liquid such as water or juice (see Table 27-8, presented later in the chapter). Small amounts of the liquid are placed on the middle of the client's tongue with a spoon. The therapist proceeds by following the four-step sequence described earlier for solid foods. The therapist assesses the client's skill at moving material from front to back, the time of oral transit and swallow, and the voice quality after each swallow. Each liquid consistency is assessed for two or three swallows to check for fatigability. If the client tolerates and swallows liquids by spoon without difficulty, the therapist assesses the client's ability to tolerate liquids from a cup or with a straw. The client's voice quality is checked following each swallow.

A client with a poor swallow may aspirate immediately or may pool liquids in the pyriform sinuses and valleculae, which, when full, overflow into the laryngeal vestibule and down into the trachea. If a client continues to have a gurgling or gargling voice after a second dry swallow or has substantial coughing with any of the liquid consistencies, the assessment should be discontinued (Figure 27-3).

The therapist must also assess the client's ability to alternate between liquids and solids, which occurs naturally during meals. The therapist presents the client with an easily managed food bolus, followed by the safest type of liquid tolerated, and then assesses the client for coughing when the consistency of the food is changed.

A client with a tracheostomy tube in place can be assessed as previously described. The same criteria must be met before the therapist assesses the client's eating and swallowing of food or liquids. The therapist must have a thorough understanding of the types of tracheostomy tubes and varied functions. The therapist must also be aware that

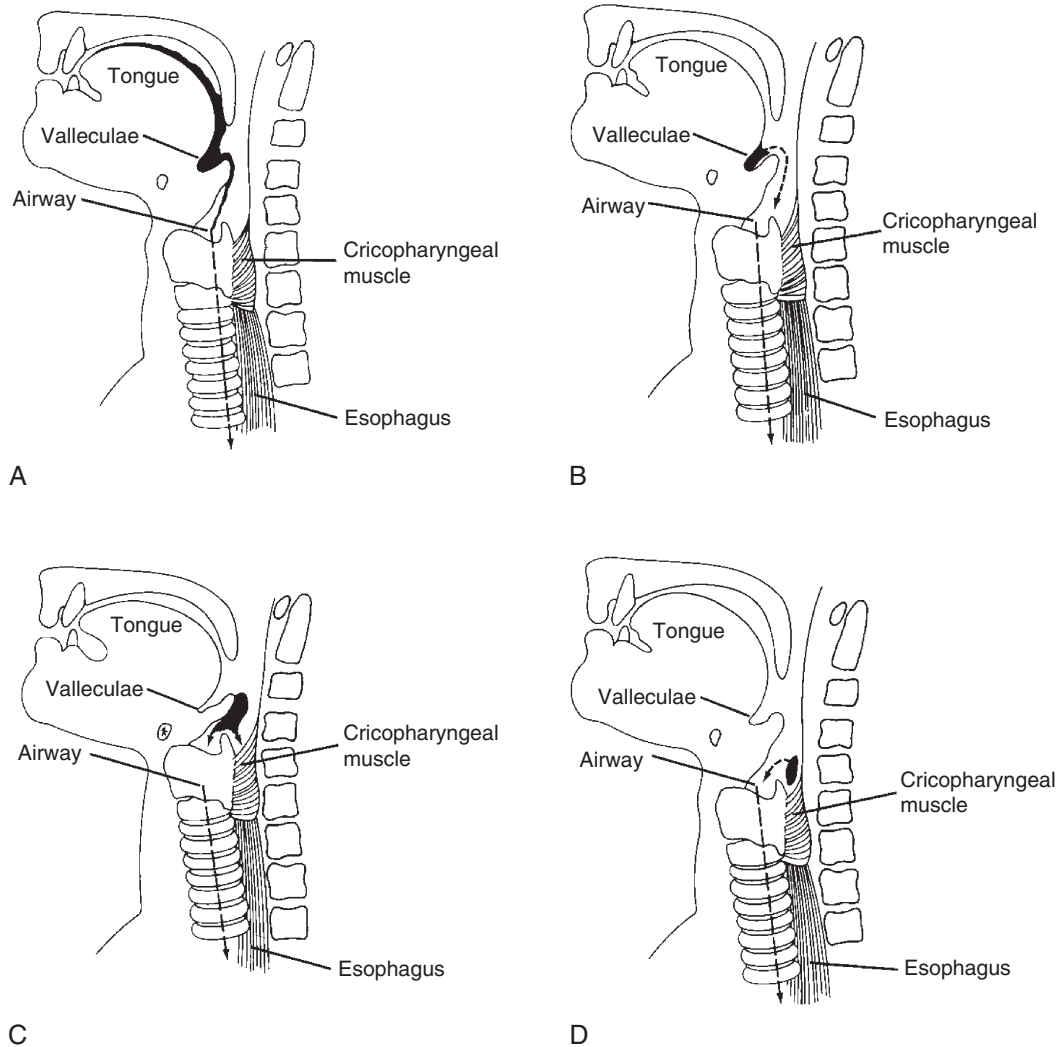

FIGURE 27-3 Types of aspiration. **A**, Aspiration before swallow caused by reduced tongue control. **B**, Aspiration before swallow caused by absent swallow response. **C**, Aspiration during swallow caused by reduced laryngeal closure. **D**, Aspiration after swallow caused by pooled material in pyriform sinuses overflowing into airway.

(From Logemann J: *Evaluation and treatment of swallowing disorders*, San Diego, 1983, College-Hill Press.)

clients who have had a tracheostomy tube, especially those on ventilation for any length of time, may experience changes in the swallowing mechanism such as muscle atrophy, decreased sensation, and laryngeal damage.¹⁵

Two main types of tracheostomy tubes exist: fenestrated and nonfenestrated (Figures 27-4 and 27-5).⁴³ A fenestrated tube is designed with an opening in the middle to allow increased air flow. This type of tube is frequently used for clients being weaned from a tube because it allows a client to breathe nasally as he or she relearns a normal breathing pattern. Placement of an inner cannula piece into the tracheostomy tube allows the fenestrated opening to be closed off. With the inner cannula removed, a trachea button may be used to allow the client to talk. A nonfenestrated tube has no opening. A fenestrated tube is preferred for treating a client with dysphagia.

A tracheostomy tube may be cuffed or uncuffed. A cuffed tube has a balloon-like cuff surrounding the bottom

of the tube.^{28,43} When inflated, the cuff comes into contact with the trachea wall, preventing the aspiration of secretions into the airway. A cuffed tube is used in cases in which aspiration has occurred. The therapist should consult with the client's attending physician to see whether the client is still at risk of aspiration or if it is safe to deflate the cuff for an eating and swallowing assessment.

The presence of a tracheostomy tube may affect a client's swallow because secretions increase, laryngeal mobility decreases, the oropharynx and larynx are desensitized, cough effectiveness is reduced, subglottal air pressure is reduced, and there is disuse atrophy of the laryngeal muscles.⁶³ However, a tracheostomy in and of itself has not been proven to increase the risk for aspiration.^{40,62}

Before the therapist presents food or liquid to the client with a tracheostomy who has a fenestrated tube, the inner cannula should be in place. If the client has a cuffed tube, the therapist should thoroughly suction orally and around

FIGURE 27-4 Tracheostomy tube components.
 (From Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed.)

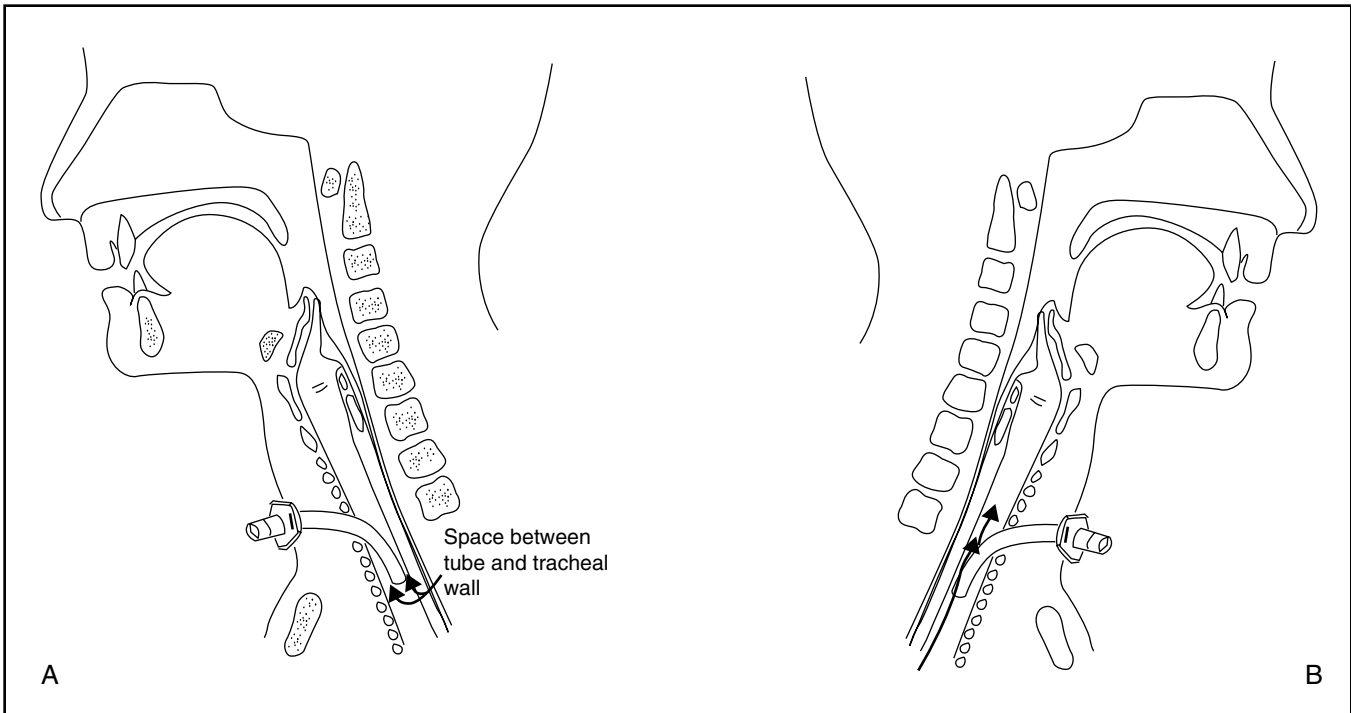

FIGURE 27-5 **A**, Midsagittal section of the head and neck showing the position of an uncuffed tracheostomy tube. **B**, Midsagittal section of the head and neck showing the passage of air between the tracheostomy tube and the tracheal wall.
 (From Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed.)

the cuff, present food, and slowly deflate the cuff while suctioning to prevent substances from penetrating the airway. The airway again needs to be suctioned orally and through the tracheostomy to ensure that all secretions have been cleared.⁴³ The nursing staff or a therapist who has been

trained and is considered competent can perform the suctioning procedure.

After presenting food or liquids, the therapist should assess oral transit skills and the pharyngeal swallow as previously described. Blue food coloring may be added to food

or liquids presented orally if the client is not allergic to dyes.²⁰ This can help the therapist identify aspirated material in the trachea. Use of blue food coloring is contraindicated for critically ill clients.^{35a,44a} The client or the therapist can use a gloved finger to cover the trachea opening and thereby achieve a more normal tracheal pressure,² which has been shown to improve the pharyngeal swallow.^{31,63} The effect of tracheostomy occlusion (which must be accompanied by cuff deflation) on reducing aspiration is inconclusive.⁶³

If the tracheostomy tube is cuffed and inflated during the assessment, the cuff is slowly deflated after the client has swallowed. The airway is suctioned through the tracheostomy tube to determine whether any material entered the airway. The swallow assessment should not be continued if material is found in the trachea.⁴³ When the assessment is complete, the airway is thoroughly suctioned. The inner cannula is removed from the fenestrated tube, or the cuff is inflated to the level prescribed by the physician.

The client's performance on the swallowing assessment determines whether the client is able to participate in a feeding program and which diet texture is the most appropriate to ensure a safe, efficient swallow. The safest consistency is that which the client is able to chew, move through the oral cavity, and swallow with the least risk of aspiration.

Indicators of Eating and Swallowing Dysfunction

Symptoms of oropharyngeal dysphagia include (but are not limited to) the following:^{21,42}

1. Difficulty with bringing food to the mouth
2. Difficulty or inability to shape food into a cohesive bolus-prolonged chewing
 - Loss of food or liquids from the mouth; drooling
 - Loss of food or liquids from the nose (nasal regurgitation)
3. Coughing or frequent throat clearing before, during, or after the swallow
4. Wet or gurgling voice quality after eating or drinking
5. Changes in mealtime behaviors
 - Food residue remaining in the mouth (cheeks, gums, teeth, tongue)
 - Loss of appetite; dehydration or weight loss
 - Discomfort or pain when swallowing
 - Difficulty breathing while eating
 - Unusual head or neck movements when swallowing
6. Delayed or absent swallow response
7. Weak cough
8. Reflux of food after meals
 - Heartburn
 - Changes in eating—for example, eating slowly or avoiding social occasions
 - Food avoidance
 - Prolonged meal times
 - Recurrent episodes of pneumonia

The presence of any swallowing dysfunction can lead to aspiration pneumonia. The following are acute symptoms of aspiration occurring immediately after the swallow:²⁸

1. Any change in the client's color, particularly if the airway is obstructed
2. Prolonged coughing
3. Gurgling voice and extreme breathiness or loss of voice

During the 24 hours immediately after the swallow, the therapist and medical staff must observe the client for additional signs of aspiration. These may be a nasal drip, an increase in profuse drooling of a clear liquid, and temperatures of 100° F or greater, which may not have been evident during the clinical examination.²⁸ If aspiration pneumonia develops, the client must be reevaluated for a change in diet levels or taken off the feeding program, if necessary. An alternative feeding method may be necessary to ensure adequate hydration and nutrition.

Instrumental Assessment

Instrumental assessments are important techniques for evaluating biomechanical and physiologic function and for determining swallow safety as well as assessing the effects of compensatory strategies (i.e., posture and bolus texture) on swallowing. They are performed in conjunction with the clinical bedside assessment to rule out or identify silent aspiration. Silent aspiration may not always be accurately identified solely through a clinical bedside assessment. Studies have shown that 2% to 25% of clients with acute stroke⁵² and up to 50% or more with neurologic impairment^{11,25} are found to be silent aspirators during instrumental assessment. Aspiration can occur before the swallow because of poor tongue control, pooled material in the valleculae, or a delayed or absent swallow response. Poor laryngeal closure can result in aspiration during the swallow. Aspiration after the swallow is the result of pooled material in the pyriform sinuses or in the valleculae overflowing into the trachea. Understanding why a client is aspirating can help the occupational therapist plan appropriate intervention. Instrumental evaluations provide valuable information about a client's swallow during a specific period of time, under specific conditions. This information must be considered as part of the complete evaluation process, which includes the bedside assessment and client performance during intervention sessions and meal activities.^{58,59}

The two most common instrumental evaluations used, videofluoroscopy (VFSS) and fiberoptic endoscopy (FEES), are described next.

Assessment with Videofluoroscopy

The videofluoroscopic swallow study (VFSS) is the most commonly used instrumental assessment tool to examine oropharyngeal swallowing disorders. This assessment uses fluoroscopy to capture the client's swallow with a variety of

Ethical Considerations

Instrumental assessment procedures require advanced knowledge and training in techniques, purpose, and indications for use. Only OTs who have these advanced skills may use instrumental evaluation procedures.⁵

foods and textures. The VFSS allows the therapist to see the client's jaw and tongue movement, measure the transit times of the oral and pharyngeal stages, observe the stages of the swallow, note any residue in the valleculae and the pyriform sinuses after the swallow, and identify aspiration. With videofluoroscopy, the therapist can determine the anatomic or physiologic cause of aspiration. Various compensatory techniques may also be assessed to determine if the airway can be protected and if swallow function can be improved, which may allow the therapist to initiate a feeding program.^{35,43,44} Videofluoroscopy, in conjunction with the clinical assessment, may be used to select appropriate intervention techniques and assist the therapist in determining the safest diet level to help the client achieve a safe swallow.

The VFSS is conducted in the hospital radiology department. Present during the evaluation is the radiologist, the radiology technician, and the swallowing therapist. Equipment necessary for the VFSS includes the fluoroscopy x-ray machine, a monitor for viewing the movement of the bolus in real time. The images are usually videotaped or digitally recorded to allow the radiologist and the therapist to review the recording in slow motion or frame by frame for more in-depth analysis. Other equipment normally available in a radiology department are lead-lined aprons, lead-lined gloves, and foam positioning wedges. Although this VFSS subjects the client to radiation, videofluoroscopy can be performed using minimal radiation doses, with the benefits of assessing oropharyngeal swallow biomechanics and intervention strategies outweighing any risk of exposure to radiation.⁶⁷

The client is positioned to allow a lateral view, with the fluoroscopy tube focused on the lips, hard palate, and posterior pharyngeal wall. The lateral view is most frequently used because it allows the therapist to evaluate all four stages of the swallow. This view clearly shows the presence of aspiration. A posterior-anterior view also may be needed to evaluate asymmetry in the vocal cords and pooling of the valleculae or pyriform sinuses.

During the VFSS, the therapist presents the client with food or liquid to which barium paste or powder has been added.^{43,44} The barium contrast allows the bolus to be visible on videofluoroscopy. The therapist mixes or spreads small amounts of paste or powder onto or into each food or liquid consistency. Premixing the consistencies with the barium paste or powder prevents time-consuming interruptions during the actual assessment procedure.

Food and liquids are presented in the same sequence used for the clinical assessment. Starting with pureed foods,

the client is given $\frac{1}{2}$ teaspoon at a time of each consistency and asked to swallow when instructed. Liquids are tested separately, beginning with the thickened substance. Material is given in small amounts to reduce the risks of aspiration. An experienced dysphagia therapist may choose to use only foods or liquids that the client had difficulty with during the clinical examination, rather than to proceed through the entire sequence. The therapist continues to present each consistency to determine if the client can swallow safely and efficiently without aspirating. If aspiration occurs, the therapist should try compensatory strategies and reassess with the same texture. If aspiration occurs while using the strategies, the assessment with this texture is discontinued.

The videofluoroscopy procedure can also be used to observe for fatigue of the oral or pharyngeal musculature or the swallow reflex. The client is asked to take repeated, or serial swallows of solids and liquids. The therapist also assesses the client's ability to control mixed consistencies of solids and liquids such as soups with broth and bits of vegetables, as well as the client's ability to alternate between solids and liquids. The solid and liquid consistency that the client manages without aspiration is selected as the starting point for eating and swallowing intervention. A client aspirating on pureed or soft foods is not suited for an oral program. The client who is aspirating thick liquids is not a candidate for liquid intake.

VFSS is a valuable tool to be used in conjunction with the clinical examination. It can provide the therapist with additional information regarding the client's difficulties. By identifying silent aspiration, the therapist can feel comfortable with the decisions made in determining a course of treatment. The therapist must keep in mind that VFSS records the client's performance in an isolated instance and is not a conclusive indicator of the client's potential ability in a feeding program.⁴⁵ If a client continues to progress without difficulty, a second study may not be necessary. A second VFSS may be needed, however, to reevaluate a client who previously was unable to safely swallow on video but now shows signs of readiness to participate in a feeding program.⁴³ Contraindications to performing VFSS include a poor level of awareness or poor cognitive status, oral stage problems only, and the physical inability of the client to undergo the test.

When the results of a VFSS test are documented, foods that were presented, problems that occurred at each stage, and the number of swallows taken to clear the food or liquid are recorded. The therapist also should document compensatory strategies or facilitation techniques that worked effectively to elicit a safe swallow or reduce aspiration risk.

Assessment with Fiberoptic Endoscopy

Fiberoptic endoscopy (FEES) is a nonradioactive alternative to the VFSS. FEES allows for direct assessment of the motor and sensory aspects of the swallow. It can be repeated as often as necessary without exposure to radiation. FEES has

been shown to be highly effective in detecting aspiration and critical features of pharyngeal dysphagia.^{17,39,41,56,64}

The equipment needed for a FEES includes a flexible fiberoptic nasopharyngolaryngoscope, a portable light source, a video camera, a video recorder, and a monitor. Placed on a rolling cart, this system can be brought directly to the client's bedside. The therapist passes a flexible fiberoptic tube through the nasal fossa, along the floor of the nose through the velopharyngeal port, ending in the hypopharynx.⁶⁵ The scope allows the therapist to observe the oral cavity, the base of the tongue, and the swallowing structures. The client is given foods and liquids. As the client swallows, the therapist is able to observe on the monitor tongue movement, pharyngeal and laryngeal function both before and after the swallow, and assess for penetration and aspiration.^{34,41} The results of a thorough assessment determine the course of intervention to increase a client's ability to safely eat. Upon completion of the entire dysphagia assessment, the therapist should clearly document the client's strengths, major problems, goals and objectives, and intervention plan. The objectives should be concise and measurable. The intervention plan should include the type of diet needed, the training and facilitation that the client requires, positioning techniques to be used during feeding, and the type of supervision that must be provided. Recommendations should be communicated to the appropriate nursing and medical staff.

Intervention

Because a client may display more than one problem at each stage of deglutition, the intervention program for eating and swallowing problems is multifaceted. Intervention for the client with dysphagia involves trunk and head positioning techniques to facilitate oral performance, improve pharyngeal swallow, and reduce the risk of aspiration. The occupational therapist uses clinical reasoning skills to evaluate the interplay of physical, cognitive, environmental, and sociocultural factors that have an impact on feeding, eating, and swallowing.⁵ Clients with severe problems can require a prolonged course of intervention before they reach optimal recovery.

Intervention falls into two broad categories: rehabilitation techniques and compensatory strategies. Rehabilitation techniques include the use of exercise to improve strength and function. Oral motor exercises are specifically designed to improve the strength and coordination of facial musculature, the tongue and jaw. An effortful swallow in which the client is instructed to swallow with maximal effort either with or without food has been shown to increase tongue base retraction and oral and pharyngeal pressure to improve the swallow.^{11a} Other swallowing maneuvers such as the Mendelsohn maneuver, the Masako maneuver, and the Shaker head lift are rehabilitative techniques used to physically change swallow function. Compensatory swallowing strategies increase swallow safety and decrease the client's

TABLE 27-5 | Postural Techniques Used in Dysphagia Management

Problem	Posture	Rationale
Impaired oral transit	Head back	Utilizes gravity to clear oral cavity
Delay in triggering of pharyngeal swallow	Chin down	Widens valleculae to prevent bolus from entering airway; narrows airway entrance; pushes epiglottis posteriorly
Residue in valleculae after the swallow	Chin down	Pushes tongue base backward
Reduced laryngeal closure	Chin down, head rotated to weak side	Narrows laryngeal entrance, increases vocal fold closure
Reduced pharyngeal contraction (residue in pharynx)	Lying down on side	Eliminates gravitational effect in pharynx
Unilateral oral and pharyngeal weakness	Head tilt to stronger side	Directs bolus down stronger side
Cricopharyngeal dysfunction (residue in pyriform sinuses)	Head rotated	Pulls cricoid cartilage away from posterior pharyngeal wall, reducing resting pressure in cricopharyngeal sphincter

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed.

symptoms, such as aspiration, but do not change the physiology of the swallow. Postural techniques such as those listed in Table 27-5 have been found to be effective in redirecting bolus flow and reducing aspiration risk.^{5,7} Rehabilitative techniques and compensatory strategies are often both used during the client's therapy program.

Goals

The overall goals of OT in the remediation of eating and swallowing dysfunction are as follows:*

1. Facilitation of appropriate positioning during eating
2. Improvement of motor control at each stage of swallow, through normalization of tone and the facilitation of quality movement

*References 3, 4, 7, 8, 16, 21, 37.

3. Maintenance of an adequate hydration and nutritional intake
4. Prevention of aspiration
5. Reestablishment of oral eating to the safest, optimum level on the least restrictive diet

Team Management

Because of the complex nature of dysphagia treatment, the client's optimal progress is facilitated by the use of a team approach.^{16,28,42} The dysphagia team should include the client's attending physician, the occupational therapist, the dietitian, the nurse, the physical therapist, the speech-language pathologist, the radiologist, and the client's family. Each professional contributes expertise to facilitate client improvement. All members of the dysphagia team should have training and knowledge for working with clients with dysphagia. Interdepartmental in-service education is frequently required so that team members have a similar frame of reference.

The occupational therapist's role is to select, administer, and interpret assessment measures; develop specific intervention plans; and provide therapeutic interventions.⁵ The American Occupational Therapy Association [AOTA] has prepared a document, *Specialized Knowledge and Skills in Feeding, Eating, and Swallowing for Occupational Therapy Practice*, that describes the knowledge and skills that occupational therapists and occupational therapy assistants should have to provide comprehensive feeding, eating, and swallowing management and services.⁵ The occupational therapist may also be responsible for coordinating the team effort, which includes obtaining physician's orders as needed, communicating with other team members and staff, providing family education to ensure proper follow-through, and selecting the appropriate diet.

The attending physician's role involves the medical management of the client's health and safety. The physician gives the orders for clinical and instrumental assessments and approves intervention and program recommendations. He or she oversees all decisions regarding treatment for diet level selection, oral and non-oral feeding procedures, and the progression of treatment as recommended by the team. The physician also reinforces the course of treatment with the client and the family.^{28,30}

The dietitian is responsible for monitoring the client's caloric intake. He or she makes recommendations to ensure that the client receives a balanced, nutritional diet in accordance with the medical condition. The dietitian is involved in suggesting types of feeding formulas for the non-oral client. Diet supplements to augment oral intake may be recommended. In conjunction with the dysphagia team, the dietitian ensures that the client receives the proper food and liquid consistencies. Additional training may be necessary for the dietary staff, because dysphagia diets vary from traditional medical diets.

The client's physical therapist is involved in muscle reeducation and tone normalization techniques. The client

receives treatment in balance, strength, and control. The physical therapist and the occupational therapist collaborate on positioning options. The physical therapist is involved in increasing the client's pulmonary status for breath support, chest expansion, and cough.

The role of the speech-language pathologist (SLP) involves reeducating the oral and laryngeal musculature used in speaking, voice production, and swallowing. The SLP is a key member of the dysphagia team.⁷

The nurse is another important member of the dysphagia team. The nursing staff is responsible for monitoring the client's medical and nutritional status. Nurses who are available on a 24 hour basis in the hospital setting and who are trained in dysphagia screening are in a key position to administer initial swallowing screenings.³³ The nurse usually is the first to notice changes in the client's condition, such as an elevated temperature; an increase in pulmonary congestion; and an increase in secretions, which indicates swallowing dysfunction.²⁸ The nurse informs the physician and the dysphagia team of these changes. The client's oral and fluid intake is recorded in the nursing notes, and the nurse notifies the dysphagia team when the client's nutritional status is adequate or inadequate. The nursing staff members administer supplemental tube feedings that have been ordered by the physician; the staff also provides oral hygiene, tracheostomy care, and supervision for appropriate clients during meals.^{28,33}

The client's family is included on the team to act as program supporters. Families frequently underestimate the danger of aspiration. Therefore, both the family and the client must be educated, beginning with the first day of assessment. The family and client should understand which food consistencies are safe to eat and which foods must be avoided.^{2,4}

The roles of the team members may vary from one treatment facility to another. Designated roles must be clearly defined to ensure a coordinated team approach. Therapists who are responsible for direct treatment should have advanced knowledge and training in dysphagia treatment procedures.

Positioning

Proper positioning is essential when working with the client who has dysphagia.²⁸ The client should be positioned symmetrically with normal alignment between the head, neck, trunk, and pelvis. The ideal position is as follows:

1. The client is seated on a firm surface, such as a chair.
2. The client's feet are flat on the floor.
3. The client's knees are at 90-degree flexion.
4. There is equal weight bearing on both ischial tuberosities of the hips.
5. The client's trunk is flexed slightly forward (100-degree hip flexion) with the back straight.

6. Both of the client's arms are placed forward on the table.
7. The head is erect, in midline, and the chin is slightly tucked.

For the client who may be restricted to bed but is able to sit in a semireclined position, the same positioning principles apply: equal weight bearing on both ischial tuberosities for the hips, the trunk flexed slightly forward (100-degree hip flexion) with the back straight, knees slightly flexed, and both arms placed forward on a bedside table. The head and neck should be aligned appropriately to reduce the risk of aspiration.

For the client who must remain completely supine in bed, oral feeding is generally contraindicated. If the client can be positioned sidelying in bed, appropriate head and neck alignment must be achieved before the assessment of feeding skills. The client's knees and hips should be slightly flexed and trunk aligned while supported in the sidelying position. The use of additional pillows, rolls, and supports may be required to maintain the appropriate alignment.

Mattias was able to sit in a chair and responded well to physical prompts to sit aligned with both arms supported on the tabletop. Although he was concerned that resting his arms on the table was impolite, his therapist suggested using a chair with armrests. He typically would slightly extend his neck when attempting to swallow foods, and using the technique of a slight chin tuck diminished the coughing and choking episodes when he ate textured foods.

Figure 27-6 shows two different supportive positions that allow the therapist to help the client maintain head control. Correct positioning allows more appropriate muscular action, which thereby facilitates quality motor control

and function of the facial musculature, jaw and tongue movement, and the swallowing process, all of which minimize the potential for aspiration.

A client who has difficulty moving into the correct position or maintaining the position presents a challenge to the occupational therapist. A careful analysis of the client is needed to determine the major problem preventing proper positioning. Poor positioning may be a result of decreased control, strength or balance secondary to hypertonicity, hypotonicity, or weakness or poor body awareness in space secondary to perceptual dysfunction (Figure 27-7).²⁶ After the cause is identified, the therapist develops intervention to address the specific problems. Treatment suggestions are described later in this chapter. To assist in maintaining trunk position, the therapist may consider the use of an adaptive lateral trunk support. Seating the client at a table provides forward trunk support.

Oral Hygiene

Oral care by nursing and therapy team members prevents gum disease, the accumulation of secretions, the development of plaque, and the aspiration of food particles that remain after eating. Poor or inadequate oral hygiene has been linked with healthcare-associated pneumonia, respiratory tract infections, and influenza in elderly people.^{27,47,57}

The client who is hypersensitive or resistant to having anything in the mouth may require intervention from the occupational therapist. Preparation steps may include firmly stroking outside the client's mouth or lips with the client's or therapist's finger. Sensitive gums can also be firmly rubbed, preparing the client for the toothbrush.

For cleaning purposes, the mouth can be divided into four quadrants. A toothbrush with a small head and soft

bristles is used to clean each quadrant, starting with the top teeth and moving from front to back. When brushing the bottom teeth, the therapist brushes from back to front. Next, holding the toothbrush at a vertical angle, the therapist brushes the inside teeth downward from gums to teeth. Finally, the cutting surfaces of the teeth are brushed. An electric toothbrush can be more effective, if the client can tolerate it.

After each procedure the client is allowed to dispose of secretions. After brushing, the client is carefully assisted in rinsing the mouth. If the client can tolerate thin liquids, small amounts of water can be given. Having the client flex the chin slightly toward the chest helps prevent the water from being swallowed. The therapist can help the client expel the water by placing one hand on each cheek and simultaneously pushing inward on the cheeks while the chin remains slightly tucked. If the client has no ability to manipulate liquids, a dampened sponge toothette can be used.

Oral hygiene for the non-oral or oral client can be used as effective sensory stimulation of touch, texture, temperature, and taste. It can be used to facilitate beginning jaw and tongue movements and to encourage an automatic swallow.^{6,89} Lack of oral stimulation over a prolonged time leads to hypersensitivity within the oral cavity. Clients who display poor tongue movement or decreased oral sensation and who are able to eat, frequently have food remaining on their teeth or dentures or between the cheek and gum. A client with decreased sensation is not aware of the remaining food. A thorough cleaning should follow each time the client eats.

Non-oral Feedings

A client who aspirates more than 10% of food or liquid consistencies or whose combined oral and pharyngeal transit time is more than 10 seconds, regardless of positioning or facilitation techniques, is an inappropriate candidate for oral eating.^{39,43} This client needs a non-oral nutritional method until eating and drinking capability is regained. Clients who lack the endurance to take in sufficient calories also may require non-oral feedings or supplements.

The two most common procedures for non-oral feedings involve the NG tube and the G tube.^{23,24} The NG tube is passed through the nostril, through the nasopharynx, and down through the pharynx and esophagus to rest in the stomach.²⁴ The NG tube is a temporary measure that should not be used for longer than 1 month.³⁹ The NG tube has several advantages:

1. The NG tube can be inserted and removed nonsurgically.
2. The NG tube allows the physician to choose between continuous or bolus feedings (a feeding that runs no more than 40 minutes).
3. The NG tube allows the therapist to begin prefeeding and feeding training while the tube is in place.
4. The NG tube provides full nutrition and hydration if necessary and keeps the digestive system active, which is important for moving to oral feedings.

The NG tube also has some disadvantages:^{24,27,39,43,59}

1. It can desensitize the cough reflex and the swallow response.

2. It can interfere with a positioning program (the client needs to be elevated to 30 degrees during feeding).
3. It can increase aspiration risk, pharyngeal secretions, and nasal reflux.
4. It can decrease the client's self-esteem.

Placement of a G tube is a minor surgical procedure. The client receives a local anesthetic, and a small skin incision is made to create an external opening in the abdominal wall for a percutaneous endoscopic gastrostomy (PEG) procedure. A tube is passed through the opening into the stomach. A G tube offers several advantages:

1. Using a G tube allows the physician to choose between continuous or bolus feedings.
2. The G tube provides full nutrition and hydration if necessary and keeps the digestive system active, which is important for moving to oral feedings.
3. It allows the therapist to begin a prefeeding or feeding program while the tube is in place.
4. It carries less risk of reflux and aspiration.
5. It does not irritate or desensitize the swallowing mechanisms.
6. It does not interfere with a positioning program.
7. It can be removed when the client no longer requires supplemental feedings or liquids.

However, use of a G tube does have some disadvantages:^{24,27,39,52}

1. The stoma site can become irritated or inflamed.
2. The family can perceive the tube as being permanent.

A G tube is the ideal choice for the client who may require tube feeding or supplemental feedings for longer than 1 month.⁴³

A commercially prepared liquid formula that provides complete nutrition usually is used for tube feedings. Many types and brands are available. The physician and dietitian determine which formula is best suited to the client. The feedings are administered by either a bolus or a continuous method. A bolus feeding takes 20 to 40 minutes to run through either the NG tube or the G tube. It can be gravity assisted or run through a feeding pump. Bolus feedings can be scheduled at numerous times throughout a 24-hour period.

Continuous feedings, which the client may better tolerate, provide smaller amounts that are administered continuously by a feeding pump. The feeding pump can be set to regulate the rate at which the formula is dripped into the tube. A disadvantage of continuous feedings is that the client must be attached to the feeding pump during tube feedings, which limits mobility. However, the feedings can be scheduled for times when the client would typically be sleeping or resting so as to have a minimal effect on the client's quality of life.

As a client begins to eat enough to require an adjustment in the intake amount of formula, bolus feedings become

the preferred method. A bolus feeding allows the therapist to work with the physician to wean the client from formula feeding. A bolus feeding can be held back before a feeding session, and the number of bolus feedings per day can be decreased as the client improves. If satisfied by the tube feedings, the client will not have an appetite and will have decreased motivation to eat.

As the client improves, oral intake can be increased, and the formula feeding can be used to supplement the client's caloric intake. An accurate calorie count, determined by recording the percentage of oral intake, assists the physician in decreasing the calories received through the tube feedings as the client begins to meet nutritional needs orally. If the client has progressed only enough to handle solids, the NG or G tube can be used to meet the client's total or partial fluid requirements.²⁹ When the client is able to meet nutrition and hydration needs through oral feedings, the NG or G tube can be removed.

Oral Feedings

For a client to be an appropriate candidate for oral feeding, several criteria must be met. The therapist can use the criteria for evaluating a client's swallow with foods or liquids. To participate in an oral feeding program, a client must (1) be alert, (2) be able to maintain adequate trunk and head positioning with assistance, (3) have beginning tongue control, (4) manage secretions with minimal drooling, and (5) have a reflexive cough. The therapist needs to identify the food or liquid consistency that is most appropriate for the client. The safest consistency with which to initiate the oral program is one that enables the client to complete the oral and pharyngeal stages combined in less than 10 seconds and to swallow with minimal aspiration (10% or less).⁴³ The ultimate goal of an oral feeding program is for the client to achieve swallowing without any aspiration.

Diet Selection

For those diagnosed with dysphagia, the texture of their food may need to be modified to help make swallowing safer and more efficient and to help prevent aspiration. A dysphagia diet must be carefully selected to reflect the needs of the client. In general, foods chosen for dysphagia diets should (1) be uniform in consistency and texture, (2) provide sufficient density and volume, (3) remain cohesive, (4) provide pleasant taste and temperature, and (5) be easily removed or suctioned when necessary.^{16,17,24}

The following foods are contraindicated for dysphagia diets: foods with multiple textures, such as vegetable soup and salads; fibrous and stringy vegetables, meats, and fruits; crumbly and flaky foods; foods that liquefy, such as gelatin and ice cream; and foods with skins and seeds.¹

The therapist should work closely with the dietitian to identify the appropriate dysphagia diet for the client. Using established dysphagia diets develops a standard for consistently describing which food textures and what foods are allowed at each level. This consistency is critical for client

safety. Because many disciplines are involved in the care of an individual with dysphagia, standardized language is needed when describing food and liquid textures to facilitate the diagnostic and nutritional management of the client.¹ The National Dysphagia Diet Task Force (NDDTF) has developed a science-based, multilevel, standardized diet for clients with dysphagia. Once the appropriate diet level has been determined by the therapist, all members of the team, including the family and the client, should be educated about which foods are acceptable in each level, and

which foods should be avoided to ensure the client's safety. Liquid diet levels should also be established. When requesting a dysphagia diet, the therapist should specify both levels desired, liquid and solid, because a client may handle each differently.

Diet Progression

Tables 27-6 through 27-8 list foods in three progressive dysphagia levels. These levels reflect the food texture levels recommended by the National Dysphagia Diet Task Force.¹

■ **TABLE 27-6** | Dysphagia, Level 1: Dysphagia Pureed

Food Groups	Recommended	Avoid
Cereals and breads	Pureed bread mixes, pregelled slurried breads, pancakes, or French toast Smooth, homogenous cooked cereals, creamed wheat or rice, Malto Meal. Cereals should have a pudding-like consistency	All other breads, rolls, crackers, muffins, etc. All dry cereals and any cereals with lumps Oatmeal
Eggs	Custard, pureed eggs	All others
Fruits	Pureed fruits or well-mashed bananas Applesauce	All others—any whole fruits (fresh, frozen, canned)
Potatoes and starches	Mashed potatoes with gravy, pureed potatoes with gravy, butter, margarine, or sour cream Pureed well-cooked noodles, pasta or rice. Must be pureed to a smooth, homogenous consistency	All others
Soups	Soups that have been pureed in a blender or strained. May need to be thickened. Thickened, strained cream	Soups that have chunks or lumps soups (to a consistency of pureed vegetables)
Vegetables	Pureed vegetables without lumps, chunks, pulp, or seeds	All vegetables that have not been pureed
Meat and meat substitutes	Pureed meat Pureed poultry with gravy Softened tofu mixed with moisture Hummus or other pureed legume spread	Whole or ground meats, fish, or poultry Cottage cheese, cheese Peanut butter, unless pureed into foods
Desserts	Smooth puddings, custards, yogurt, pureed desserts and soufflés	Ices, gelatins, frozen juice bars, bread and rice pudding, yogurt with fruit All other desserts These foods are considered thin liquids and should be avoided if thin liquids are restricted. Frozen malts, milk shakes, frozen yogurt, ice cream, sherbet, gelatin
Fats	Butter, margarine, strained gravy, sour cream, mayonnaise, cream cheese, whipped topping	All fats with chunky additives

■ **TABLE 27-7 | Dysphagia, Level 2: Dysphagia Mechanically Altered Characteristics (Mechanical Soft)**

Food Groups	Recommended	Avoid
Cereals and breads	Cooked refined cereals with little texture (e.g., oatmeal) Slightly moistened dry cereals with little texture (e.g., Corn Flakes, Rice Krispies) Soft pancakes with syrup French toast without crust Graham crackers	Very coarse cooked cereals that may contain seeds or nuts Whole-grain dry or coarse cereals All others
Eggs	Poached, scrambled or soft eggs (egg yolks should be moist and mashable with butter, not runny) Souffles—may have small chunks	Hard cooked or fried eggs
Fruits	Soft canned or cooked fruits without seeds or skin Soft, ripe bananas Baked apple (no skin)	Fruits with seeds, coarse skins, fibers; fruits with pits, raisins, grapes, all raw fruits except those listed
Potatoes and starches	Well-cooked, moistened, boiled, baked, or mashed potatoes Well-cooked noodles in sauce	Potato skins and chips, fried potatoes, rice
Soups	Soups with easy to chew or easy to swallow soft meats or vegetables (particle sizes < ½ inch) Cream soups	Soups that have large chunks of meat or vegetables Soups with rice, corn, peas
Vegetables	Soft, well-cooked vegetables; should be easily mashed with a fork	All raw vegetables Cooked corn and peas Broccoli, cabbage, brussels sprouts, asparagus, or other fibrous, non-tender cooked vegetables
Meat and meat substitutes	Moistened ground or cooked meat, poultry, or fish. May be served with gravy Casseroles without rice Soft-moist lasagna, moist macaroni and cheese Moist meatballs, meat loaf, or fish loaf Tuna or egg salad without large chunks, celery, or onion Cottage cheese, smooth quiche Tofu All meats or protein substitutes should be served with sauces or moistened to help maintain cohesiveness in the oral cavity	Dry, tough meats (such as bacon, sausage, hot dogs) Peanut butter Dry casseroles Pizza Sandwiches All other cheeses
Desserts	Pudding and custard Soft fruit pies with bottom crust only Crisps and cobblers without seeds or nuts Canned fruit (excluding pineapple) Soft, moist cakes with icing Pregelged cookies or soft moist cookies “dunked” in milk, coffee, or other liquid	Dry, coarse cakes or cookies Anything with nuts, seeds, coconut, pineapple, or dried fruit Rice or bread pudding
Fats	Butter, margarine, strained gravy, sour cream, mayonnaise, cream cheese, whipped topping	All fats with chunky additives

Data from American Dietetic Association: *National dysphagia diet: standardization for optimal care*, Chicago, 2002, American Dietetic Association; American Occupational Therapy Association: *AOTA resource guide: feeding and dysphagia*, Rockville, MD, 1997, American Occupational Therapy Association; Avery-Smith W: An occupational therapist coordinated dysphagia program, *Occup Ther Pract* 3:10, 1998; Community Hospital of Los Gatos, Rehabilitation Services: *Dysphagia protocol*, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Curran J: Nutritional considerations. ■ **TABLE 27-8 | Dysphagia, Level 3: Dysphagia Advanced**

Food Groups	Recommended	Avoid
Cereals and breads	All well-moistened cereals Any well-moistened breads, muffins, pancakes, waffles, etc. Add butter, margarine, syrup, etc., to moisten	Coarse or dry cereals such as shredded wheat Dry toast, crackers Crusty bread such as French bread, hard rolls Popcorn
Eggs	Eggs, prepared any way	
Fruits	All canned and cooked fruit Soft, peeled fresh fruit, without seeds Soft berries	Difficult to chew fresh fruits such as apples or pears Stringy, high-pulp fruits such as papaya or pineapple Uncooked dried fruit Fruit with seeds or coarse skins
Potatoes and starches	All, including rice and fried potatoes	Potato skins Tough, crisp-fried potatoes
Soups	All soups except those on the Avoid list	Soups with tough meats Corn or clam chowders Soups with large chunks (>1 inch)
Vegetables	All cooked, tender vegetables Shredded lettuce	All raw vegetables, except shredded lettuce Cooked corn Nontender, stringy, cooked vegetables
Meat and meat substitutes	Thin-sliced tender or ground meats and poultry Well-moistened fish Casseroles with small chunks of meat, ground meats, or tender meats	Tough, dry meats and poultry
Desserts	All except those on the Avoid list	Dry, coarse cakes or cookies Anything with nuts, seeds, coconut, pineapple, or dried fruit
Fats	All except those on the Avoid list	All fats with chunky additives

Data from American Dietetic Association: *National dysphagia diet: standardization for optimal care*, Chicago, 2002, American Dietetic Association; American Occupational Therapy Association: *AOTA resource guide: feeding and dysphagia*, Rockville, MD, 1997, American Occupational Therapy Association; Avery-Smith W: An occupational therapist coordinated dysphagia program, *Occup Ther Pract* 3:10, 1998; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Curran J: Nutritional considerations. After mastering Level 3 the client may progress to a regular diet. Dysphagia Diet Level I (Dysphagia Pureed) is for individuals with moderate to severe swallowing difficulty who may have a reduced ability to protect their airway. All foods are pureed. This food group is best for persons with little or no jaw or tongue control, a moderately delayed swallow, and a decreased pharyngeal transit, resulting in pooling in the valleculae and pyriform sinuses. Pureed foods move more slowly past the faucial arches and into the pharynx, which allows time for the swallow response to trigger. Pureed foods should be homogenous, pudding-like in consistency. No coarse textures, raw fruits or vegetables, or nuts are allowed. Any foods that require mastication are not allowed. Level 1 foods are best used only to increase the client's oral intake. It may be difficult to meet caloric and

nutrition needs on this diet and often high caloric, nutrient dense foods are recommended. The client should be advanced to the next level as soon as possible.

Mattias agreed to eat pureed foods to increase his caloric intake and joked with his wife that his OT gave him permission to eat ice cream. He was progressed to textured foods (Level 2) but continued to use the pureed foods as a supplement because of the effort required to eat a sufficient quantity of textured foods.

Level 2 items are soft foods that stay together as a cohesive bolus; thus, the possibility of particles spilling into the airway is decreased. Dysphagia Diet Level 2 (Dysphagia Advanced Altered) foods are best for clients with a beginning rotary chew, enough tongue control with assistance to propel food back toward the pharynx, and a minimally

delayed swallow. Mechanical soft foods reduce the risk of aspiration in individuals who have both a motor and a sensory loss. Mechanical soft foods with a density provide increased proprioceptive input throughout the mouth. Meats should be ground or minced and kept moist with gravies and sauces. These foods also stay together as a cohesive bolus rather than crumbling and falling uncontrolled into the airway. The level 2 diet is for individuals with mild to moderate swallowing difficulties.

Dysphagia Diet Level 3 (Dysphagia Advanced) requires that the client be able to chew and have adequate oral motor skills to form a cohesive bolus of textured foods and move the bolus posteriorly in the oral cavity. This food group offers a wider variety of consistencies and food choices. Level 3 is a step down from a regular diet. Level 3 foods work well for the client who has minimal problems with jaw or tongue control and a mildly delayed but intact swallow response. The client who has reached a Level 3 diet needs to be concerned with a delayed swallow only when fatigued. Dysphagia Level 4 (Regular) diet includes all foods.

After 3 weeks of intervention, Mattias progressed to a Level 3 diet, which greatly increased the variety of foods he could eat and increased his overall satisfaction with meal selections. He continued to support caloric intake using foods from both Level 1 and 2 because of motor coordination and fatigue issues. His daughter selected foods for the wedding meal that required minimal chewing including baked sole and crème brulee in addition to the wedding cake.

When a client is ready to progress to the next diet level, the therapist can adjust the meals by requesting one or two items from the higher group, which enables assessment at the new level. This technique is also appropriate for clients who become fatigued. The client is thus able to work with the therapist on the more challenging food items first and continue the meal with foods that are easier as the client begins to fatigue. The therapist also may consider arranging several small meals throughout the day for the client who fatigues, rather than three traditional meals.

A client should progress to a regular diet when oral motor control is within functional limits, allowing the client to chew and form any consistency of food into a bolus and propel it back toward the faucial arches. The client at this level should be able to swallow all food and liquid consistencies with only occasional coughing. Continuing dietary precautions for a client with a history of dysphagia include avoiding raw vegetables, stringy foods, and foods containing nuts or seeds.¹

Many individuals with dysphagia have difficulty with thin liquids, as this texture requires greater oral-motor and pharyngeal control as well as an intact swallow response. Increasing the viscosity of the liquid is often used as a strategy to decrease aspiration risk. The liquid progression is divided into four groups: “thin,” “nectar-like,” “honey-like,” and “spoon-thick.” Thin liquids include water, coffee, tea, soda or anything else that will quickly liquefy in the mouth. Thin liquids require an intact swallow. Nectar-like liquids

are thickened to a consistency that coats and drips off a spoon, similar to unset gelatin. Honey-like liquids have been thickened to a honey consistency; the liquid flows off of a spoon in a ribbon, like honey. Spoon-thick liquids are thickened to a pudding consistency and remain on the spoon in a soft mass.¹ The liquid consistency chosen depends upon the client’s swallowing problem. Examples of liquids in these levels are given in Table 27-9.

Thick liquids are the appropriate choice for clients with cognitive problems that interfere with bolus preparation, moderate to severely impaired oral motor skills, markedly delayed swallow response, or diminished ability to protect the airway.²⁴ A thick liquid moves more slowly through the oral cavity, which allows the client with impaired motor skills to have greater control of the bolus, preventing it from entering the pharynx and open airway before the swallow

TABLE 27-9 | Liquids

Liquid Level	Examples
Thin	Water, ice chips Coffee, tea Milk Hot chocolate Fruit juices Broth or consommé Gelatin dessert Ice cream Sherbet
Nectar-like	Nectars Extra thick milkshake Extra thick eggnog Strained creamed soups Yogurt and milk blended V-8 juice
Honey-like	Nectar thickened with banana Nectar thickened with pureed fruit Regular applesauce with juice Eggnog with baby cereal Creamed soup with mashed potatoes Commercial thickener
Spoon-thick	Commercial thickener

Data from American Dietetic Association: *National dysphagia diet: standardization for optimal care*, Chicago, 2002, American Dietetic Association; American Occupational Therapy Association: *AOTA resource guide: feeding and dysphagia*, Rockville, MD, 1997, American Occupational Therapy Association; Avery-Smith W: An occupational therapist coordinated dysphagia program, *Occup Ther Pract* 3:10, 1998; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Curran J: Nutritional considerations. In Groher M, editor: *Dysphagia: diagnosis and management*, ed 3, Newton, MA, 1997, Butterworth-Heinemann; Rader T, Rende B: *Swallowing disorders: what families should know*, Tucson, AZ, 1993, Communication Skill Builders.

has been triggered. Videofluoroscopic studies show higher aspiration rates for thin liquids compared to thicker liquid consistencies for individuals with dysphagia.³⁶ Care must be taken when a client is on modified liquids to ensure that adequate hydration is maintained. Many clients dislike thickened liquids and do not take them in sufficient amounts, putting them at risk for dehydration.

Thickened liquids are made by adding thickening agents such as banana, pureed fruit, yogurt, dissolved gelatin, baby cereal, cornstarch, or a commercial thickener to achieve the appropriate viscosity. The thickened drink or soup should stay blended and not separate or liquefy. It is important that everyone involved in the client's care understand what constitutes the various liquid levels so that the correct amount of thickening agent is added. Commercially prepared thickened liquids (all levels) are available for use in the hospital setting and at home. Using a commercially prepared product guarantees the proper viscosity.

Principles of Oral Feeding

The therapist should incorporate certain principles into the oral feeding program. An important aspect of the oral preparation stage is looking at, recognizing, and reaching for food. The client must actively participate in the eating process. Food should be presented within the client's visual field. If the client has a severe visual field deficit or unilateral neglect, the therapist must help the client to scan the plate or tray visually.

When physically possible, the client should feed himself or herself, even if assistance is necessary. If the client does not have a normal hand-to-mouth movement pattern, the therapist must help the client achieve one by guiding the extremity in the correct pattern. Abnormal movement of the upper extremity influences abnormal movement in the trunk, head, face, tongue, and pharynx and decreases the client's ability to safely swallow.

If the client is not capable of self-feeding, the therapist can keep the client actively involved by allowing the client to choose which food or liquid is preferred for each bite. Food is presented by moving the utensil slowly from the front, toward the mouth, so that the client can see the food the entire time. The client should be allowed as much control of the eating situation as possible.

For adults, eating is a social activity shared with friends and family. A normal dining environment facilitates normal eating. If the client has difficulty in this environment, intervention can be directed toward reducing distractions and identifying environmental modifications that will allow the client to be successful. Cultural preferences must be taken into account when selecting foods and dining settings. The client's normal eating habits and routines should be considered in the development of the eating program. Special care must be taken to obtain this information during the initial assessment.

The OT must continually assess the client's positioning, muscle tone, oral control, and swallow. If the client

displays poor oral motor skills, the therapist assesses for food pocketing after every few bites. The rate of the client's intake is monitored. The therapist should determine when too much food is in the mouth and when the client puts food into the mouth before the previous bite has been cleared. The therapist feels for the swallow with a finger at the hyoid notch if the client displays abnormal laryngeal movement or a delayed swallow.⁴³ The therapist also assesses the client's voice quality upon completion of the swallow.

The frequency with which the therapist must check each component depends on the skill level and performance of the client. The more difficulty the client exhibits, the more frequent the assessment. The therapist may find it necessary to assess after each bite or sip, after a few bites or sips, or after each food item. Use of keen observational skills allows the therapist to make the appropriate clinical decision. Specific techniques for assessment during feeding trials can be found in the swallowing assessment section of this chapter. After completing the feeding process, the client should remain in an upright position for 15 to 30 minutes to reduce the risk of refluxing food and of aspirating small food particles that may remain in the throat.

The therapist must observe the client for signs of aspiration while eating and monitor for the development of aspiration pneumonia over time. Clients vary in the amount of aspiration they can tolerate before developing aspiration pneumonia, according to age, health, and pulmonary status. The signs of acute and chronic aspiration were outlined previously.

When a client with compromised swallow function is participating in oral feedings, careful monitoring of the nutritional status is necessary. Nutrient requirements and fluid intake needs are determined by a nutrition assessment.^{10a,47a} Nutritional deficiency is a concern, especially for older individuals, and places the client at risk for adverse health outcomes such as decreased functional ability and increased use of healthcare services.^{10b} The client's caloric needs are determined by the dietitian and the physician and depend on the client's height, weight, activity level, and medical condition.^{10a} Caloric and fluid intake is monitored by having the physician order a calorie count and a liquid intake and output hydration count (I and O). Each person who works with the client with oral intake should record the percentage of each item the client eats or drinks. The dietitian converts the percentages into a daily calorie total. The client also should be monitored for physical signs of nutritional deficiency and dehydration. These symptoms include weakness, irritability, depression, decreased alertness, changes in eating habits, hunger, thirst, decreased turgor, and changes in amounts or color of urine. If a client is not able to take in the necessary calories, supplemental feedings are necessary to make up the difference. The physician and dietitian decide on the number of supplemental feedings.

TABLE 27-10 | Dysphagic Treatment: Oral Preparatory Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Trunk	Leaning to one side	Decreased trunk tone Ataxia Increased trunk tone Poor body awareness in space	Facilitate trunk strength Exercises at midline Have client clasp hands, lean down, and touch foot, middle, other foot; rotate trunk with hands clasped and shoulders flexed to decrease or normalize tone	Assist client to hold correct position; assist with head control Assist client to hold correct feeding position; provide with perceptual boundary; consider lateral trunk support
	Hips sliding forward out of chair	Increased tone in hip extensors Poor body awareness in space	See previous entry above Provide firm seating service	Adjust positioning so that client leans slightly forward at hips, arms forward on table
Head	Inability to hold head in midline	Decreased tone Weakness	Facilitate strength through neck and head exercises in flexion, extension, and lateral flexion	Assist with head control
	Inability to move head	Increased tone Poor range of motion	Tone reduction of head, shoulders, and trunk Facilitate normal movement Myofascial release techniques Soft tissue mobilization	Assist with head control
Upper extremity	Spillage of food from utensils	Decreased tone Apraxia Decreased coordination	Facilitate increased tone through weight bearing, sweeping, or tapping muscle belly of desired muscle	Guide client through correct movement pattern Provide adaptive equipment or utensils as needed
	Inability to self-feed	Increased tone Abnormal movement patterns Weakness or decreased motor control	Reduce proximal tone with scapula mobilization, weight bearing through arm Strengthening exercises Facilitation of normal movement	Guide client through correct movement pattern Provide adaptive equipment or utensils as needed
Face	Drooling, food spillage from mouth	Decreased lip control Poor lip closure secondary to decreased tone, poor sensation Apraxia	Place a wet tongue blade between client's lips; ask client to hold tongue blade while therapist tries to pull it out Vibrate lips with back of electric toothbrush down cheek and across lips Lip exercises: movements described in outer oral motor evaluation; client performs repetitions 2-3 times daily Blow bubbles into glass of liquid with straw	Using side handgrip for head control, the therapist approximates lip closure by guiding and assisting with jaw closure Have client use a straw when drinking liquids until control improves Place food to unimpaired side Use cold food or liquids
		Decreased sensation	Fan lips so that client feels drool or wetness on lips or chin to increase awareness	Teach client to pat mouth (versus wiping mouth) and chin every few bites or sips

Techniques for the Management of Dysphagia

Tables 27-10 through 27-13 provide intervention techniques for the management of dysphagia. These techniques are not intended to be used in all situations. Each client

presents a different clinical picture and may display one deficit or a combination of deficits. After careful assessment, the therapist must determine the primary cause of the client's deficits and intervene accordingly. The occupational

■ TABLE 27-10 | Dysphagic Treatment: Oral Preparatory Stage—cont'd

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Tongue	Pocketing of food in cheeks or sulci Poor bolus formation	Poor tongue control for lateralization or tipping Decreased tone Poor sensation	Tongue exercises: use movements described in inner oral motor evaluation	Avoid crumbly foods Stroke client's outside cheek where pocketing occurs with index finger back and up toward-client's ear; instruct client to check cheek for pocketing
	Retracted tongue	Increased tone Retracted jaw	Tongue range of motion: wrap tip of tongue in wet gauze; gently pull tongue forward, side to side and up and down; move slowly Pull tongue wrapped in wet gauze forward past front teeth, using index and middle fingers to vibrate tongue back and forth sideways to decrease tone and facilitate protrusion	Avoid crumbly foods Reduce tone as needed during meal Double swallow Resist head flexion to facilitate jaw closure Resist head extension to facilitate jaw opening

Data from American Occupational Therapy Association: *Am J Occup Ther*, 1996; Avery-Smith W: Management of neurologic disorders: the first feeding session. In Groher M, editor: *Dysphagia: diagnosis and management*, ed 3, Newton, MA, 1997, Butterworth-Heinemann; Bobath B: *Adult hemiplegia: evaluation and treatment*, ed 2, London, 1978, William Heinemann Medical Books; Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003, Community Hospital of Los Gatos; Coombes K: *Swallowing dysfunction in hemiplegia and head injury*, course presented by International Clinical Educators, Aug 24-27, 1986, and Aug 24-28, 1987, Los Gatos, CA; Davies P: *Steps to follow*, New York, 1985, Springer-Verlag; Farber S: *Neurorehabilitation: a multisensory approach*, Philadelphia, 1982, WB Saunders; Logemann J: *Manual for the videofluorographic study of swallowing*, ed 2, Austin, TX, 1993, Pro-Ed.

profile determines the focus of OT services and identifies the importance of dysphagia intervention within the client's priorities.

Intervention for clients with dysphagia is multifaceted and may involve rehabilitative techniques and compensatory strategies. It is essential to have an excellent understanding of the underlying problems causing the swallowing disorder so that an intervention program can be designed that directly addresses these problems. The overarching goal of dysphagia intervention is the resumption of safe oral intake. The therapist should strive toward facilitating the return of normal eating habits and routines for each client. Establishing proper positioning for safe swallowing is often the first therapeutic intervention in dysphagia management. This may involve the use of positioning equipment, therapeutic exercises to improve trunk and head control, and mechanical positioning by feeding staff.

When a client is unable to orally manage food, an *indirect swallowing intervention* program is initiated. Indirect intervention does not involve the ingestion of food or liquid. Indirect intervention techniques include facilitation of tone and movement for hypotonic muscles, desensitization for hypersensitive areas of the face and oral cavity, sensory stimulation to heighten sensation and proprioception, range of motion and gentle resistive exercises to strengthen weak oral and pharyngeal musculature,

swallowing stimulation (without food), and oral-motor exercises and tasks (Avery-Smith, 2003).⁹

Intervention for swallowing performance is called *direct intervention* because it involves the ingestion of food or liquid. These interventions are aimed at facilitating oral performance, improving the pharyngeal swallow, and reducing the risk of aspiration. Examples include compensatory swallowing techniques and strategies, thermal or tactile stimulation, gradation or alteration of the bolus size/texture/consistency, or method of food presentation and specialized positioning.⁵

Compensatory techniques are introduced to improve swallow safety by helping to control the flow of food and liquid and reduce the risk of aspiration. They do not change the physiology of the individual's swallow. Compensatory strategies used in dysphagia intervention include (1) postural techniques, (2) techniques to improve oral sensory awareness, (3) modification of bolus volume and speed of presentation, and (4) texture modifications. See [Box 27-1](#). Compensatory strategies often allow a client to safely engage in oral eating while continuing to work on remediation of the underlying problems. The client and those involved with assisting the client to eat are trained in the use of these strategies.

Rehabilitative or remediation techniques include oral motor range of motion exercises, oral motor strengthening exercises, bolus control exercises, vocal fold adduction

TABLE 27-11 | Dysphagic Treatment: Oral Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Tongue	Slow oral transit	Poor anterior to posterior movement; decreased tone, poor sensation	Practice “ng-ga” sounds	Tuck chin toward chest
	Tongue retraction	Increased tone	Grasping tongue wrapped in gauze, pull it forward past front teeth; use finger or tongue blade to vibrate base of tongue back and forth sideways Improve tongue range of motion	Position food in center, midtongue Avoid crumbly foods Use cold or hot foods instead of warm Correct positioning Place index finger at base of tongue under chin; stroke up and forward
	Slow oral transit time Inability to channel food back toward pharynx	Inability to form central groove in tongue Apraxia	Grasping tongue wrapped in gauze, pull forward to front teeth; stroke firmly down middle of tongue with edge of tongue blade	Tuck chin toward chest Position food in center, midtongue Avoid crumbly foods Use cold or hot foods instead of warm Correct positioning Place index finger at base of tongue under chin; stroke up and forward
	Repetitive movement of tongue; food is pushed out front of mouth	Tongue thrust	Facilitate tongue retraction to bring tongue back into normal resting position; vibrate on either side of the frenulum found inside the mouth, under the tongue with finger Increase jaw control; teach isolated tongue movements	Correct positioning Place food away from midline of tongue toward back of mouth Provide downward and forward pressure to back of tongue with spoon after food placement Use foods with high viscosity or density Alternate presentation of cold and hot foods during meal
	Food falls off tongue into sulci or food remains on tongue without client awareness	Poor sensation	Ice tongue with ice chips placed in gauze to prevent ice chips from slipping into pharynx Brush tongue with toothbrush to stimulate receptors	Correct positioning Place index finger at base of tongue under chin; stroke up and forward
	Slow oral transit time; food remains on hard palate; coughing before swallow	Poor tongue elevation; decreased tone	Ask client to practice “k,” “g,” “n,” “d,” and “t” sounds Lightly touch tongue blade or soft toothbrush to roof of mouth at back of tongue; instruct client to press spot with tongue; resist movement with blade or brush to increase strength Vibrate tongue at base below chin; -provide quick stretch by pushing down on base of tongue	Correct positioning With finger under chin at base of tongue, move finger upward and forward to facilitate elevation Avoid crumbly foods Double swallow
	Slow oral transit time Food remains on back of tongue because client is unable to elevate tongue to push food to hard palate Coughing before the swallow Retracted tongue	Decreased sensation Increased tone Decreased range of motion Soft tissue shortening	Tone tongue with gauze reduction; grasping wrapped tongue forward with around tip, pull finger or tongue blade Apply pressure to base of tongue right to left Grasping base of tongue under chin between two fingers, move it back and forth to decrease tone Tone reduction Range of motion exercises Place a variety of tastes on lips to facilitate tongue-licking lips	Adjust correct positioning by increasing forward flexion at hips, arms forward to decrease tone Reduce tone as needed; give client breaks because tone increases with effort With finger under chin at base of tongue, move finger upward and forward to facilitate tongue elevation

Data from Community Hospital of Los Gatos, Rehabilitation Services: Dysphagia protocol, Los Gatos, CA, 2003; Coombes K: *Swallowing dysfunction in hemiplegia and head injury*, course presented by International Clinical Educators, Aug 24-27, 1986, and Aug 24-28, 1987, Los Gatos, CA; Davies P: *Steps to follow*, New York, 1985, Springer-Verlag; Farber S: *Neurorehabilitation: a multisensory approach*, Philadelphia, 1982, WB Saunders; Logemann J: *Evaluation and treatment of swallowing disorders*, ed 2, Austin, TX, 1998, Pro-Ed; Martin BJW: Treatment of dysphagia in adults. ■ TABLE 27-12 Dysphagia Treatment: Pharyngeal Stage

Structure	Symptoms	Problem	Prefeeding Technique	Feeding Technique
Soft palate	Tight voice; nasal regurgitation Air felt through nose or mist seen on mirror when client says “ah” Decreased tone Nasal speech	Increased tone Decreased tone Rigidity	Facilitate normal head/neck positioning Have client tuck chin into therapist’s cupped hand, then push into hand as therapist applies resistance; client says, “ah” afterward; speed and height of uvula elevation should increase; follow by thermal application Thermal application: using a laryngeal mirror #00 after being placed in ice water or chips for 10 seconds, touch base of faucial arch; repeat up to 10 times; process can be repeated several times a day	Facilitate normal head and neck positioning With head and neck in midline, have client tuck chin slightly to decrease rate of food entering into pharynx Alternate presentation of food; start very cold substance, then warm; cold substance can increase sensitivity of faucial arches; tuck chin slightly forward to prevent bolus entering airway
Hyoid	Delayed elevation of hyoid bone Poor tongue elevation Tongue retraction	Delayed triggering of swallow response Abnormal tongue tone; poor range of motion	Increase tongue humping because elevation of tongue and hyoid stimulates triggering of response Tone reduction	Place index finger under chin at base of tongue and push up forward to facilitate tongue elevation
Pharynx	Coughing after swallow Coating of pharynx seen on videofluoroscopy Gurgling voice Seen on videofluoroscopy, anteroposterior view; material residue seen on one side; weak or hoarse voice	Decreased pharyngeal movement Penetration into laryngeal vestibule Pharyngeal weakness Unilateral pharyngeal movement	None Isometric or resistive head and neck exercises None	If appropriate, alternate presentation of liquid with stage II or stage III solids; liquid material moves solids through pharynx Have client take second dry swallow to clear valleculae and pyriform sinuses Tilt head to stronger side Supraglottic swallow Compensatory technique for clients with low tone: have client turn head toward affected side during swallow to prevent pooling in affected pyriform sinuses; evaluate technique against its effect on client positioning and tone in trunk, upper extremities

Larynx	Coughing, choking after swallow	Decreased laryngeal elevation Decreased tone Weakness	Quickly ice up sides of larynx; ask client to swallow; assist movement by guiding larynx upward Vibrate laryngeal musculature from under chin, downward on each side to sternal notch Range of motion—place fingers and thumb along both sides of larynx and gently move it back and forth until movement is smooth and easy tone decreased Using chipped ice, form pack in washcloth and place around larynx for 5 min	Teach client to clear throat immediately after swallow to move residual Use supraglottic swallow, Mendelsohn maneuver, effortful swallow Placing fingers and thumb along both sides of larynx, assist client with upward elevation before swallow Double swallow
Trachea	Continuous coughing before, during, after swallow Client grabs or reaches for throat Reddening in the face No voice or cough	Aspiration—before: poor tongue control; during: delayed swallow response; after: decreased pharyngeal movement Blocked airway	Teach client how to produce a voluntary cough; ask client to take a deep breath and cough while breathing out; therapist uses palm of hand to push downward (toward stomach) on the sternum None	Encourage client to keep coughing; facilitate reflexive cough; push downward on sternum as client breathes out; suction client if problem increases Push into client's sternal notch to assist with cough Perform Heimlich maneuver Seek medical assistance

Data from Community Hospital of Los Gatos, Rehabilitation Services, Dysphagia protocol, Los Gatos, CA, 1999; Coombes K: *Swallowing dysfunction in hemiplegia and head injury*, course presented by International Clinical Educators, Aug 24-27, 1986, and Aug 24-28, 1987, Los Gatos, CA; Davies P: *Steps to follow*, New York, 1985, Springer-Verlag; Groher ME, Cray MA: *Dysphagia: clinical management in adults and children*, St. Louis, 2010, Mosby; Logemann J: *Evaluation and treatment of swallowing disorders*, Austin, TX, 1998, Pro-Ed; Martin BJW: Treatment of dysphagia in adults. □ **Box 27-1**

Bolus Textures and Swallow Problems

Texture	Disorders for Which This Texture Is Most Appropriate
Thin liquid	Tongue dysfunction (ROM, strength, coordination) Reduced tongue base retraction Reduced pharyngeal wall contraction Reduced laryngeal elevation Reduced cricopharyngeal opening
Thickened liquid	Tongue dysfunction (ROM, strength, coordination) Delayed pharyngeal swallow
Pureed	Oral motor impairment Delayed pharyngeal swallow Impaired cognition Decreased endurance
Mechanical soft	Oral motor impairment (decreased chew) Decreased endurance

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders*, ed 2, Austin, TX, 1998, Pro-Ed; Groher ME, Crary MA: *Dysphagia: clinical management in adults and children*, St. Louis, 2010, Mosby.

and laryngeal elevation exercises, and exercises to improve pharyngeal pressure.⁴³ Swallow maneuvers may also be introduced to improve laryngeal closure and bolus movement through the pharynx. See [Box 27-1](#) for examples of swallow maneuvers.

□ **Box 27-2**

Techniques to Improve Oral Sensory Awareness

- Downward pressure of metal spoon on tongue during presentation of food
- Cold bolus
- Sour bolus
- Larger bolus
- Bolus that requires chewing
- Thermal-tactile stimulation*

*Tactile stimulation provided directly to the anterior faucal arch using a cold, size 00 laryngeal mirror prior to the presentation of the bolus. This technique is used to heighten oral awareness and provide an alerting sensory stimulus to the cortex and brain stem to facilitate the triggering of the swallow response.

Adapted from Logemann J: *Evaluation and treatment of swallowing disorders*, ed 2, Austin, TX, 1998, Pro-Ed.

The therapist must continually assess the client's response to intervention and make necessary modifications to the eating and swallowing program. The therapist must develop excellent clinical observation skills. For complex clients, the clinician should seek a consultation with an experienced dysphagia therapist. To develop expertise in dysphagia management, it is recommended that the therapist seek continued education in this area.

Summary

Eating is the most basic activity of daily living. Several performance components are required for the client to eat and swallow effectively. Dysphagia refers to difficulty

with swallowing or an inability to swallow. The occupational therapist is trained to assess and provide intervention for many of the problems that interfere with normal eating. An understanding of the normal anatomy and physiology of swallowing and advanced training in eating and swallowing disorders are required to effectively treat dysphagia.

Assessment of the client with dysphagia includes testing of head and trunk control, sensation, perception, cognition, intra and outer oral structures, oral reflexes, and swallowing. Instrumental assessment may also include videofluoroscopy or fiberoptic endoscopy.

Several members of the rehabilitation team are involved in the treatment of the client with dysphagia. Positioning, selection of appropriate feeding procedures, diet texture selection, diet progression, and special techniques to facilitate normal patterns of swallowing are part of the

intervention plan. The social, cultural, and psychological aspects of eating are also important considerations in the intervention program.

Review Questions

1. List the components of dysphagia.
2. List the four stages of swallowing and the characteristics of each.
3. List the physiologic functions that occur when the swallow response triggers, and explain why these functions are necessary.
4. Why is it necessary to assess a client's mental status during a dysphagia evaluation?
5. Describe what the therapist should look for when evaluating the trunk and head during the dysphagia evaluation.
6. What information can the therapist gain when assessing the client's facial motor control?
7. How does poor tongue control contribute to aspiration?
8. Name the components required to protect the airway.
9. What is the safest food sequence to follow for a swallowing evaluation?
10. Describe the finger placement that a therapist can use to feel the strength and smoothness of the swallow.
11. Why should the therapist assess voice quality after a swallow?
12. Will a client who has difficulty handling solids also have difficulty with liquids?
13. List the indicators of swallowing dysfunction.
14. List the acute symptoms of aspiration.
15. When is videofluoroscopy necessary?
16. List the types of intervention used with clients with dysphagia.
17. Describe how the client should be optimally positioned for eating and give the rationale.
18. What are the indications for placing a client on a non-oral treatment program?
19. Name five important criteria a client must meet to participate in an oral feeding program.
20. List the properties of food preferred for diets for clients with dysphagia.
21. Why is it important to involve the client in the eating process?
22. What are the symptoms of nutritional deficiency?
23. Name three treatment techniques the OT can use for poor rotary jaw movement and increased tone.
24. Describe two ways a therapist can decrease abnormally high tone in the tongue.
25. Describe thermal application as a treatment technique. For which problem is it used?
26. When is use of the dry swallow technique appropriate?

Case Study Nick

Nick is a 65-year-old man who suffered a right cerebrovascular accident (CVA) with left hemiplegia 2 weeks ago. He has a G tube in place for nutrition. He recently retired from his position as vice president of a local marketing company. Nick lives with his wife. He and his wife have two grown children living in the area. Before the onset of the CVA, Nick was independent in all ADLs and instrumental activities of daily living (IADLs). He was an active member of the community.

Results of the OT evaluation indicate that Nick needs moderate to maximum assistance in dressing, toileting, bathing, eating and swallowing, and transfers. The clinical assessment of eating indicates that the client has a mild to moderate increase in jaw and facial tone with poor rotary chew, poor isolated tongue control, and a mild increase in laryngeal tone with delayed swallow.

The videofluoroscopy confirmed that the client had a mildly delayed swallow with minimal pooling in the valleculae and pyriform sinuses. Aspiration was less than 10% on pureed foods. The OT saw the client three times a day for 6 weeks. A summary of evaluation results and a treatment plan are shown in Figure 27-8.

The client responded well to treatment. The G tube was removed after 5 weeks. The client achieved all treatment goals by the time of discharge. He went home with family supervision for correct diet, positioning, and swallowing techniques during meals. The client was referred to home health OT for 2 to 3 weeks for ADLs and home modification so that independence at home could be achieved. The client returned for follow-up outpatient visits.

Dysphagia Evaluation and Treatment Plan

Pt: 65 y. male
 Dx: Ⓡ CVA
 Onset: 2 weeks ago
 Medical hx: Elevated BP—5 years. Elevated blood lipids. Otherwise unremarkable. Independent in ADL & IADL prior to onset.
 Current nutritional status: gastrostomy tube, NPO

	WNL	Adequate—without assistance	Unable	Comments
Mental status:				
Alert/oriented		̄ assist		oriented to name, max assist for date
Direction following		̄ assist		appropriate ̄ guiding
Physical status (symmetry, control, tone):				
Head control		̄ assist		slight ↑d tone ̄ head turning
Trunk control		̄ assist		ataxic, TLR present
Endurance		̄ assist		fatigues after 30 min.
Respiratory				
Suctioning required	N/A			
Tracheostomy	N/A			
Outer oral status:				
Facial expressions		̄ assist		flat affect 2° ↑d tone to moderate degree
Jaw movement			✓	poor rotary chew, poor jaw glide, pt. uses up & down movt.
Lip movement		̄ assist		unable to purse & retract, poor lip compression
Sensation		̄ assist		delayed 2° ↓d attention
Abnormal reflexes		̄ assist		suck-swallow present, others absent
Inner oral status (symmetry, control, tone):				
Dentition	✓			good, slightly inflamed gums
Tongue				
Appearance		̄ assist		slight white coating & mid ⊕ tongue laceration
Tone		̄ assist		↑d ̄ retraction
Movement: Protrusion		̄ assist		deviated to Ⓡ
Lateralization		̄ assist		mild weakness
"ng" → "ga"			✓	poor anterior to posterior
Soft palate/gag reflex:	✓			uvula rises symmetrically
Cough (reflexive/voluntary):	✓			
Swallow:				
Spontaneous	✓			intact
Voluntary		̄ assist		delayed 2° to tone
Laryngeal movement				
Tongue		̄ assist		requires tone reduction
Elevation		̄ assist		delayed fatigue factor after serial swallows
Food management:				
Puree		̄ assist		Overall pt. shows ↓d cognitive awareness of food in mouth & requires cueing
Mechanical soft		̄ assist		pt. uses suck-swallow
Chopped/ground		̄ assist		pocketing assist
Regular diet			N/A	needed ̄ rotary chew
Liquids: Thick		̄ assist		̄ straw, 5 sec. delay, Ⓡ cough
Semithick		̄ assist		̄ straw, 5 sec. delay, coughing
Thin			N/A	

FIGURE 27-8 Case study: dysphagia evaluation and treatment plan.

Dysphagia Evaluation and Treatment Plan

Major problems:

- ① ↓d cognition for attention and awareness of food in mouth & cueing.
- ② ↑d jaw & facial tone resulting in poor rotary chew.
- ③ Poor isolated tongue movements for lateralization, humping.
- ④ ↑d laryngeal tone resulting in delayed swallow.
- ⑤ Poor sitting balance.

Recommendations/treatment plan:

(positioning, diet level, environment, techniques)

- ① Positioning - upright on solid seating surface, slight forward lean.
- ② Tone reduction techniques for jaw, tongue, & larynx before & during meal.
- ③ Diet level - pureed & mechanical soft foods, thickened liquids 2x daily @ therapist only.
- ④ Therapeutic feeding in quiet setting.
- ⑤ No food or liquid in pts. room.
- ⑥ Monitor patient for signs of aspiration.
- ⑦ Videofluoroscopy for confirmation.

Long-term goals:

- ① Independent trunk and head control for self feeding.
- ② ↑ attention and awareness of food in mouth to WFL.
- ③ ↑ isolated motor control of facial expression to WNL.
- ④ ↑ isolated motor control of jaw, tongue, & larynx to WFL.
- ⑤ ↑ oral intake for solids from pureed to regular diet for all meals with family supervision.
- ⑥ ↑ oral intake for liquids from thick to thin.
- ⑦ Calorie and hydration count, wean from gastrostomy.
- ⑧ Family @ in swallowing & diet follow through.

Relapse management

Summary

■ Key Terms

Pain

Acute pain

Chronic pain

Biopsychosocial model of pain

Nociception

Suffering

Pain behavior

Pain assessment

Pain intervention

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Differentiate acute from chronic pain.
2. Explain the biopsychosocial model of pain.
3. Describe two common acute and two common chronic pain syndromes.
4. Summarize two approaches to pain evaluation.
5. Describe occupationally based approaches to pain intervention.

Threaded Case Study | Cathy

Cathy, a 34-year-old white single woman, was injured 5 months ago when catching a heavy weight while employed as an electrician. She sustained a lumbar strain. Cathy was initially treated at an emergency room, where narcotics, muscle relaxants, heat application, and bed rest were prescribed. After persistent pain complaints, she was given pelvic traction and transcutaneous electrical nerve stimulation. Cathy has not returned to work since her injury and described her current lifestyle as sedentary. She described her pain as severe (a 9 or 10 on an 11-point numerical scale, with 0 representing “no pain” and 10 indicating “pain as bad as could be”) and almost constant. She identified prolonged sitting, standing, and ambulation as exacerbating pain factors. Cathy described occasional mild pain relief with ibuprofen use and bed rest. Her self-report on the Brief Pain Inventory revealed moderate-to-high pain interference with instrumental activities of daily living (IADLs) and recreational, social, and work activities. Cathy described using pain-contingent rest and asking for assistance as the means of coping with her pain.

During evaluation, Cathy was found to have decreased active right shoulder range of motion and strength, decreased left lower extremity strength, and muscle spasms throughout the left lumbar paraspinal muscles and into the left buttocks. She demonstrated poor body mechanics, poor posture, and mild shortness of breath. Cathy offered numerous verbal complaints of pain and expressed fear that the pain would never go away.

Physical retraining and cognitive behavioral techniques were emphasized in intervention. Cathy participated in generalized

mobility, strengthening, and cardiovascular endurance exercises as a means of increasing her occupational performance, minimizing fatigue, and increasing feelings of well-being. Functional tasks were incorporated into treatment. Cathy was instructed in how to monitor her daily routine (e.g., balance of rest, relaxation, and activity) and modify faulty thinking (e.g., catastrophizing, such as thinking there is nothing that can stop the pain). Her daily routine included progressive relaxation rehearsal.

Cathy made good progress in her 4-week treatment program. She demonstrated normal mobility, strength, and endurance. Bed rest during the day was eliminated. Cathy was taught proper posture and body mechanics and was observed to use them in her routine activities. Her verbal complaints of pain remained unchanged, but she stated that she no longer felt the pain was controlling her. Cathy was now ready to progress to a work-hardening program.

Critical Thinking Questions

1. What occupational limitations would you anticipate due to Cathy's injury and pain?
2. How would you approach an occupational therapy (OT) evaluation?
3. How would you provide an occupation-based intervention program to meet Cathy's occupational performance needs?
4. What problems in social participation do you anticipate due to the level of pain Cathy experiences on a daily basis?

Pain is a primary reason for seeking healthcare. An estimated one in four adult Americans reported experiencing a daylong pain episode within the past month, with 10% stating the pain lasted at least a year.⁵⁵ The number of Americans with chronic pain is greater than those with diabetes, heart disease, and cancer combined.³ Despite people's use of pain medications, two thirds of individuals experiencing chronic pain cannot perform routine occupations.¹ At least \$100 billion is spent each year on direct medical expenses, lost income, and lost productivity let alone the inestimable costs of human suffering.³ The obligation to manage pain and relieve a client's suffering is fundamental to healthcare.¹⁹ Pain may coexist with a medical condition (e.g., arthritis) or a rehabilitative procedure (e.g., splinting); it may be the primary complaint (e.g., low back pain) or a secondary disability (e.g., chronic pain in persons with cerebral palsy). Occupational therapy practitioners may suspect that pain is impeding the client's progress but feel unsure about how to approach evaluation and intervention. This chapter defines pain, discusses the biopsychosocial model of pain, describes common pain syndromes, outlines assessment procedures, and proposes interventions.

Definitions of Pain

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage.⁵³ This definition conveys that pain is a subjective experience and is multifaceted. Individual variables such as mood, attention, prior pain experiences, and familial and cultural factors are known to affect one's experience of pain.^{4,50}

There are many types of pain, yet most investigators agree in differentiating acute from chronic nonmalignant pain, which is critical for selecting appropriate assessment and intervention strategies. *Acute pain* and its associated physiologic, psychological, and behavioral responses are typically caused by tissue irritation or damage in relation to injury, disease, disability, or medical or rehabilitative procedures. It has a well-defined pain onset. Acute pain serves a biologic purpose, directing attention to injury, irritation, or disease and signaling the need for immobilization and protection of a body part.⁵¹ Fortunately, acute pain is predictable and usually responds to medication and treatment of the underlying cause of pain.³⁴

In contrast, chronic or persistent pain may begin as acute pain or may be more insidious and endure beyond the point at which an underlying pathologic condition can be identified. Increased sympathetic nervous system activity does not continue. Chronic pain does not appear to serve a biologic purpose. It is unpredictable and not amenable to routine interventions. Chronic pain often produces significant changes in personality, lifestyle, and functional ability.^{34,39} As pain progresses from acute to chronic, factors other than tissue damage or irritation (e.g., personality changes) become more prominent. Our client, Cathy, is now experiencing chronic pain that is negatively impacting her occupational performance.

Biopsychosocial Model of Pain

Occupational therapy has long embraced the biopsychosocial model for its emphasis on the interaction of the individual's body, mind, and environment.⁵⁴ A biopsychosocial model that conceptualizes the multilayered nature of pain is critical to accurate evaluation and effective intervention. Loeser and Fordyce⁴⁵ suggested the phenomenon of pain could essentially be divided into four distinct domains: nociception, pain, suffering, and pain behavior (Figure 28-1).

Nociception is the detection of tissue damage by transducers in the skin and deeper structures, and the central transmission of this information by A-delta and C fibers in the peripheral nerves. Nociception is the body's message to do something or avoid doing something for pain relief.

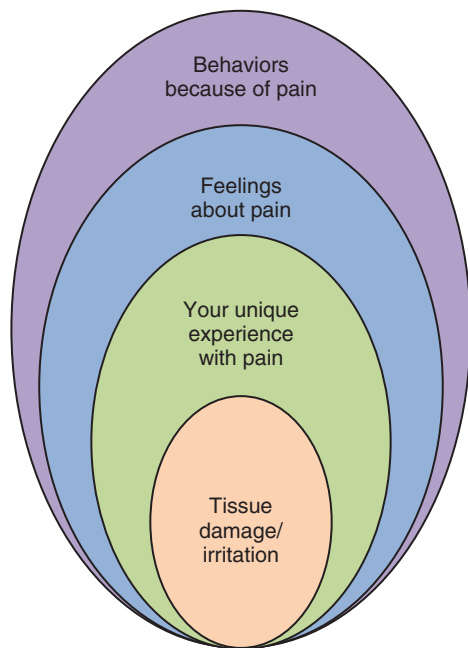

FIGURE 28-1 Loeser's model of pain.

Adapted from Loeser JD: Concepts of pain. In Stanton-Hicks M, Boas R, editors: *Chronic low back pain*, New York, 1982 Raven, p. 146.

Pain is the perceived noxious input to the nervous system. *Suffering* is the negative affective response to pain. Finally, *pain behavior* is what an individual says or does (e.g., moaning) or does not say or do (e.g., engage in occupations), which leads others to conclude that individual is experiencing noxious stimuli. Pain behaviors are observable and are influenced by familial, cultural, and environmental consequences. This model purports that one can experience or demonstrate some domains of the model in the absence of others. In chronic nonmalignant pain, pain behaviors and suffering often exist in the absence of nociception.^{23,39,45,75}

Our client Cathy stated that she continues to experience pain but also expressed fear that the pain would never go away. In that sense she is captive to her pain experience.

Pain Syndromes

The evaluation and treatment of pain resulting from trauma, disease, or unknown etiology are significant healthcare concerns. The following sections describe common pain syndromes, their etiology, and typical interventions

Headache Pain

Recurrent headaches are one of the most common pain problems. Migraines affect approximately 12% to 15% of the general population. Over half of the population of persons with headaches does not seek treatment because they perceive the problem as too trivial, have concerns about medication side effects, and believe no adequate treatment is available.⁴⁷

Migraine headaches are characterized by recurrent pain episodes varying in frequency, duration, and intensity. Migraines may occur when the individual oversleeps, when tired, when skips meals, with overexertion, when stressed, and when recovering from stress.²⁸ The pain is typically unilateral and pulsatile and may be accompanied by anorexia, nausea, vomiting, neurologic symptoms (e.g., sensitivity to light and sound), and mood changes (e.g., irritability).⁴⁷ A strong genetic predisposition exists for migraines. Experimental evidence supports the role of serotonin in migraine. Stress, attention, the environment, and mood (e.g., anxiety) affect these headaches.

Tension-type headaches (TTH) are the most common headache disorder. Approximately 73% of adult Americans experience one or more tension headaches in a year.⁹ These headaches are typically of mild-to-moderate intensity. The pain is bilateral and of a pressing character and does not have associated symptoms. Precipitating headache factors include situational stress, missed meals, sleep deprivation, and noxious stimuli (e.g., heat exposure).⁴⁷ TTH has been attributed to a disorder of central nervous system (CNS) modulation. Simple analgesics (e.g., acetaminophen) are standard treatment. Headache control is often achieved with lifestyle management and medication.

Low Back Pain

Low back pain (LBP) is the second most common pain complaint among the adult population. Approximately 3% to 7% of the population in western industrialized countries experience chronic LBP. Job absenteeism, loss of productive activity, and decreased participation are common consequences of LBP.⁷³ Fear of the etiology of pain, the interventions, and social consequences of pain can be harmful to the client. The most common causes of LBP are injury (e.g., lifting) and stress, resulting in musculoskeletal and neurologic disorders (e.g., muscle spasm and sciatica). Back pain also may result from infections, degenerative diseases (e.g., osteoarthritis), rheumatoid arthritis, spinal stenosis, tumors, and congenital disorders.⁶² LBP tends to improve spontaneously over time.⁷⁴ Numerous schools of thought govern interventions. With chronic back pain, functional restoration is key. Medication management, physical therapy (e.g., exercise, massage, traction), and self-care education are common treatment approaches. Once significant back pain has lasted for 6 months, however, the chance that the affected individual will return to work is only 50%.¹⁶ (See Chapter 41.)

Cathy's LBP has significantly compromised her ability to engage in occupations. She has not returned to work and is at risk for never being gainfully employed. Cathy is no longer able to engage in her preferred recreational activities of dancing and bowling. Her ability to care for her personal ADLs is compromised and she had difficulties stepping in and out of the tub and even bending over to turn the water faucet handles to regulate the water temperature. She must request assistance when grocery shopping since bending and reaching produce increases her pain. Cathy even reports that getting in and out of her car is difficult and requires planning and care because of her fear of increasing the pain in her back.

Arthritis

Approximately one third of all American adults experience joint pain, swelling, or limited mobility because of arthritis.⁴⁵ Osteoarthritis (OA), the most common form of arthritis, is a degenerative joint disease characterized by a progressive, dull ache and swelling, typically affecting the fingers, elbows, hips, knees, and ankles. OA may be exacerbated by movement. Degeneration of the articular cartilage leading to joint pain, reduced mobility, and swelling occur, typically affecting weight-bearing joints in persons after age 45.^{26,66}

Rheumatoid arthritis (RA) affects 1% to 2% of the American population with women more often affected.²⁶ It usually has a slow insidious onset, characterized by aches, pains, swelling, and stiffness. Any joint may be involved, but usually there is a symmetrical pattern affecting the fingers, wrists, knees, ankles, and cervical spine. This systemic disease involves remissions and exacerbations of destructive inflammation of connective tissue, especially in the synovial joints.⁶⁶ The Arthritis Foundation supports

self-management (e.g., exercise, relaxation, problem solving strategies) of the disease.⁴⁶ See Chapter 38 for more information on arthritis.

Complex Regional Pain Syndrome

The incidence of complex regional pain syndrome (CRPS) has been reported as 25.2 new cases per 100,000 annually.³³ The pain experienced with CRPS is a continuous, severe, burning pain that results from trauma, postsurgical inflammation, infection, or laceration to an extremity, causing a cycle of vasospasm and vasodilatation. Pain, edema, shiny skin, coolness of the hand, and extreme sensitivity to touch occur. An individual experiencing CRPS may also have excessive sweating or dryness. The key feature of CRPS is continuous, intense pain out of proportion to the severity of the injury (if an injury has occurred), which worsens over time. Exacerbating pain factors include movement, cutaneous stimulation, and stress.^{40,77} OT treatment strives to normalize sensation, reduce edema, and increase mobility, strength, and endurance while decreasing guarding and restoring routine activities. Simultaneously clients often receive physical therapy, psychotherapy, pharmacotherapy, recreational therapy, and vocational rehabilitation.³³

Myofascial Pain Syndrome

Muscle pain is common across all age groups, but with the elderly most often affected. Myofascial pain refers to a large group of muscle disorders defined by the presence of "trigger points" (i.e., localized areas of deep muscle tenderness). Pressure on the trigger point elicits pain to a well-defined distal area. Myofascial pain is perceived as a continual dull ache often located in the head, neck, shoulder, and low back areas. The trapezius muscle is one of the most commonly affected muscles. The pain may result from sustained muscle contraction or from an acute strain caused by a sudden overload or overstretching of the muscles in the head, neck, shoulder, or lower back regions.^{29,65} Physical therapy, needling therapies (i.e., insertion of a solid needle for relief of muscular pain), manual therapies, and modalities are common treatment approaches.¹³

Fibromyalgia

The prevalence of fibromyalgia ranges from 0.7% to 3.2% in the adult population. Fibromyalgia is widespread musculoskeletal pain in the muscles, ligaments, and tendons. Skeletal muscles have been implicated as the cause of fibromyalgia, but no specific abnormalities have been identified. Abnormalities of the neuroendocrine system, autoimmune dysfunction, immune regulation, cerebral blood flow difficulties, and sleep disturbances have been suggested.³⁵ Genetic factors, physical trauma, peripheral pain syndromes, infections, hormonal changes, and emotional distress are capable of triggering fibromyalgia. Pharmacologic therapies, cardiovascular exercise, and cognitive behavior therapy have all been proven beneficial.¹⁰

Cancer Pain

Clients with cancer often have multiple pain problems that are frequently undertreated. Cancer pain varies greatly in its frequency, duration, and intensity. In the initial and intermediate stages, 40% to 50% of clients experience moderate-to-severe pain. About 60% to 90% of clients with advanced cancer have pain. Cancer pain may result from tumor progression, interventions (e.g., surgery, chemotherapy, and radiation), infection, or muscle aches when clients decrease their activity.⁶⁸

Disability-Related Pain

Pain is a significant problem for many persons with physical disabilities,¹⁵ including cerebral palsy,¹⁷ spinal cord injury,¹² limb deficiency,³² and multiple sclerosis.³⁰ Physiologic changes resulting from the disability and psychosocial factors (e.g., negative thoughts) are known to influence the intensity and impact of pain in many persons with chronic pain as a secondary condition to their disability.³⁸ Data support the use of relaxation training, hypnosis, and medication management.

Evaluation

A referral for an occupational therapy (OT) evaluation is made when pain interferes with the client's occupational performance. As a member of an interdisciplinary or multidisciplinary team, the occupational therapist focuses the evaluation on the factors that contribute to the client's pain perception and pain interference. Before the occupational therapy program is implemented as well as throughout the interventions, objective measures of occupational performance should be obtained to determine the occupational profile of the client and the value of those occupations.³¹ Factors that may contribute to pain perception, occupational role disruption, decreased occupational performance, and diminished quality of life should be identified. In

addition to these essential measurements, pain intensity should be recognized as the "fifth vital sign" and assessed on a regular basis.²

The occupational therapist performs a pain evaluation, viewing pain as a complex phenomenon involving psychological arousal, sensations of noxious stimulation, tissue damage or irritation, behavioral changes, complaints of distress, and the social environment. Self-report measures are the most common type of pain assessment because pain is considered to be a subjective experience.⁷² The clinical interview focuses on the client's identification of pain onset, location(s), frequency, intensity, duration, exacerbating and relieving pain factors, past and current pain treatments, mood, and occupational performance. A Verbal Rating Scale (VRS), 0-10 Numeric Rating Scale (NRS), or Visual Analog Scale (VAS) (Box 28-1) may be used in assessing self-reports of pain intensity.^{57,72} These instruments have strong psychometric properties and high utility.

A VRS of pain intensity consist of a list of 4 to 15 verbal descriptors and a corresponding number (e.g., 0 = "no pain," 1 = "mild pain," 2 = "moderate pain," 3 = "severe pain"). This is an easy-to-use scale, but might have a lengthy list of verbal descriptors, and the client may not find a descriptor on the list that matches his or her experiences.³⁸

The NRS consists of a range of numbers, typically 0 ("no pain") to 10 ("worst pain possible") (Box 28-2). The client selects which one number is most representative of his or her pain intensity. Use of the 0 to 10 NRS is highly recommended. Pain ratings in the 1 to 4 range have minimal impact on functional performance and are labeled "mild" pain. Ratings of 5 or 6 ("moderate" pain) indicate that pain has a greater impact on functioning. Ratings of 7 to 10 or "severe" pain have the greatest impact on performance.¹⁴

The VAS consists of a horizontal or vertical line, typically 100 mm long, with each end of the line labeled with descriptors representing the range of pain intensity (e.g.,

Box 28-1

Examples of Pain Intensity Scales

Simple descriptive pain intensity scale*

No pain	Mild pain	Moderate pain	Severe severe pain	Very possible	Worst pain
---------	-----------	---------------	--------------------	---------------	------------

0-10 Numerical pain intensity scale*

0	1	2	3	4	5	6	7	8	9	10
No pain				Moderate pain				Worst pain possible		

Visual analog scale (VAS)†

No pain	Pain as bad as it could possibly be
---------	-------------------------------------

From US Department of Health and Human Services, Acute Pain Management Guideline Panel: *Acute pain management in adults: operative procedures. Quick reference guide for clinicians*, AHCPR Pub No. 92-0019, Rockville, MD, 1995, US Government Printing Office.

*If used as a graphic rating scale, a 10-cm baseline is recommended.

†A 10-cm baseline is recommended for VAS scales.

Box 28-2

Pain Interference Scales

A. In the past week, how much has pain interfered with your daily activities?

0-10 Numerical pain intensity scale										
0	1	2	3	4	5	6	7	8	9	10
No interference						Unable to carry out any activities				

B. In the past week, how much has pain interfered with your ability to take part in recreational, social, and family activities?

0-10 Numerical pain intensity scale										
0	1	2	3	4	5	6	7	8	9	10
No interference						Unable to carry out any activities				

C. In the past week, how much has pain interfered with your ability to work (including housework)?

0-10 Numerical pain intensity scale										
0	1	2	3	4	5	6	7	8	9	10
No interference						Unable to carry out any activities				

From National Institutes of Health, National Institute of Child Health and Human Development, National Institute of Neurological Disorders and Stroke: Ongoing research (Grant No. 1 PO1 HD/NS33988), Pain Management.

“no pain” and “pain as bad as can be”). The client draws a mark on the line that represents his or her pain intensity and the distance measured from the “no pain” anchor to the mark becomes that individual’s pain score. It should be noted some individuals have difficulties with understanding and completing the measure.³⁸

For both the NRS and VAS scales, decreases or increases between 30% and 35% appear to indicate a meaningful change in pain. Clients tend to prefer VRSs and NRSs over VASs.³⁸ It has been recommended that both clinicians and researchers use the 11-point NRS so that comparisons between studies can be made.¹⁴

When occupational therapy services were initiated for Cathy, the therapist used an NRS to determine the existence and intensity of the pain Cathy experienced on a daily basis.

Pain behaviors are often targeted in evaluation and intervention.²² Pain behaviors include guarded movement, bracing, posturing, limping, rubbing, and facial grimacing⁴¹ and are in response to pain, suffering, and distress. The University of Alabama Pain Behavior Scale is an example of a standardized rating scale that is reliable, valid, and an easy method for documenting observable behaviors.⁶⁰ Analysis of the client’s pain behaviors before, during, and after intervention with and without a significant other present can provide valuable information about the role of situational and learned factors in the individual’s pain perception, as well as responses to intervention. Healthcare utilization and medication use are additional pain behaviors that are clinically relevant.⁷⁰ Merskey cautioned practitioners not to provide treatment for reducing pain behaviors in lieu of attempts at alleviating the pain.⁵² Evaluation that focuses solely on pain behavior may lead to the inaccurate

Box 28-3

Glossary

Nociception: The detection of potentially tissue-damaging thermal or mechanical energy by specialized nerve endings.

Pain: An unpleasant sensory *and* emotional experience associated with actual or *potential* tissue damage.

Pain behavior: Observable and measurable behaviors used by the client to communicate the experience of pain to others.

Suffering: An unwanted condition and the corresponding negative emotion.

conclusion that pain behavior suggests malingering, lack of motivation, or hypochondriasis.

Occupational performance is the primary focus of the occupational therapist. The client may complete daily activity diaries as an assessment technique and outcome measure.²⁰ With this technique, the client records hourly entries of time spent in sitting, standing, reclining, and productive activities, which may be corroborated by trained staff or significant others during treatment. Activity diaries are highly reliable and valid.²²

The Brief Pain Inventory (BPI)¹¹ is a reliable and valid instrument that may also be used to measure pain interference. Pain interference is defined as the extent to which pain impacts daily functioning.³⁸ Clients rate on an ordinal scale how much their pain has interfered with general activity, mood, mobility, work, interpersonal relationships, sleep, enjoyment of life, self-care, and recreation (Box 28-3). The

responses are averaged to determine the Pain Interference score. This information may be helpful in determining baseline tolerance levels for specific occupations that may be addressed in treatment. The BPI can be used with persons with disability-related pain (e.g., spinal cord injury, cerebral palsy) as well as an outcome measure.³⁸ Similarly, the Pain Disability Index (PDI) is a brief valid and reliable self-report measure of general and domain specific pain-related disability. It uses an ordinal scale to measure how disabling pain is with family/home responsibilities, recreation, social activity, occupation, sexual behavior, self-care, and life-support activity.⁵⁹

Similarly, the Canadian Occupational Performance Measure (COPM)⁴² can also be used in valid and reliable pain assessment. The COPM detects changes over time in the individual's perceptions of his or her occupational performance in the areas of self-care, productivity, and leisure, as well as the importance of being able to perform these occupations and the level of satisfaction with performance using 10-point scales. The COPM has good evidence of concurrent criterion validity and sensitivity to change. It is especially helpful in collaborative functional goal setting.⁶¹

Finally, evaluation must acknowledge that cultural disparities in pain experiences exist. Differences in pain experiences have been found between whites and African Americans. For example, African Americans report a poorer quality of life with increasing levels of pain, disability, symptoms, and emotional distress as compared to whites. Women are known to report more pain than men. It should also be noted that persons with a lower socioeconomic status tend to be sicker and overall have more chronic health problems.⁵⁶ Lastly, pain frequently has been overlooked and therefore undertreated in children and the elderly.⁶⁹ These differences have been attributed to numerous causes such as access to healthcare and coping skills.

Cathy had indicated that her pain and the fear associated with the pain severely limited her ability to engage in several occupations. She had not returned to work and had greatly decreased social activities. Her contact with friends was limited to infrequent telephone conversations and occasionally a friend would stop by to visit. Prior to her injury she regularly went out with friends to movies, dancing, and bowling, but all those activities had been eliminated because of the pain.

Intervention

The obligation to manage pain and relieve a client's suffering is fundamental. A multiple or interdisciplinary team approach to chronic pain is common and includes the client as an active and educated participant. The occupational therapist typically works in collaboration with the client, a physician, a psychologist, a physical therapist, and a nurse. Occupational therapy interventions focus on increasing physical capacities, productive and satisfying performance of life tasks and roles, mastery of self and the environment

through activities, and education.³⁷ As the causes of pain are multifactorial, so are the approaches to treatment. Effective pain management addresses all the dimensions of pain. Typical pain interventions are described next.

Interventions may need to be introduced on a trial-and-error basis. The effectiveness of pain interventions can be measured and documented in a variety of ways. Clinical improvement can be measured in occupational performance (e.g., BPI), increased participation (e.g., diary), lower pain intensity (e.g., NRS), reduction in pain behaviors (e.g., University of Alabama Pain Behavior Scale), improved mood (e.g., Sickness Impact Profile),⁵ and decreased drug and healthcare utilization.

Medication

Medications are generally the treatment of choice for individuals experiencing acute pain. Occupational therapists need to observe clients for possible drug reactions. To reduce possible discomfort from rehabilitative procedures, practitioners should check that clients are adequately medicated in advance. The World Health Organization⁷⁶ analgesic ladder is well established in adult pain management as a stepwise approach for choosing an analgesic. Aspirin and acetaminophen are frequently used in the treatment of mild pain (e.g., backache) because of their high level of effectiveness, low level of toxicity, and limited abuse potential. Nonsteroidal anti-inflammatory agents have been used in the treatment of arthritis and inflammation of a musculoskeletal origin. Codeine is often used for moderate-intensity pain that has not responded adequately to aspirin or acetaminophen. Morphine is the standard medication used in the relief of severe pain. The use of opioid analgesics (narcotics) in chronic nonmalignant pain has been controversial because of concerns about addiction.³⁴

Activity Tolerance

Although a few days of rest may be indicated for acute pain, therapeutic activity is important for the treatment of any underlying impairment. Activity levels are increased on a gradual basis, with the client working to "tolerate" (i.e., gradual increase in task demands such as mobility, strength, and endurance), as opposed to "pain," before a scheduled rest period. The client should not initiate rest at the time of the pain onset or exacerbation because this may reinforce pain behaviors.²³ A gradual increase in activity also lessens the likelihood of an exacerbation of pain.²³ Fordyce provided guidelines for the use of quota programs for clients with chronic pain. Regular gentle exercise (e.g., walking, swimming, water aerobics) is recommended. Modalities (e.g., heat or cold) may be applied before activity as a means of enhancing functional performance. When an individual is engaged in interesting and purposeful activity, he or she may be more relaxed, less preoccupied with pain, and more fluid in movement. Task selection based on occupational roles, interests, and abilities is a unique contribution of occupational therapy in pain management.⁶⁷

The occupational therapy intervention program for Cathy considered her active lifestyle prior to the injury and began with simple activities such as accompanying a friend to a local shopping mall and walking in the complex. The occupational therapist helped Cathy plan the outing by suggesting that the walk occur during a weekday evening instead of busy weekends and that Cathy take frequent breaks during the initial walk to sit on one of the benches provided within the mall.

Body Mechanics and Posture Training

Instruction in and rehearsal of proper body mechanics and postures that will not increase the risk of low back injury or strain are essential for clients experiencing both acute and chronic LBP.⁴⁸ Practice in using the body safely and to maximum performance during routine tasks in natural (i.e., home, work, or leisure) environments is particularly important.^{64,67} The client should be taught to avoid tasks or positions that do not allow balanced posture. For detailed guidelines on proper posture and body mechanic principles, please refer to Chapter 41. For clients in wheelchairs, the information on positioning in Chapter 11 is also important.

Energy Conservation, Pacing, and Joint Protection

Instruction in energy conservation, pacing, and joint protection may be beneficial for achieving recommended amounts of rest during task completion, recommended time spent physically active, and balance between rest and physical activity. Clients, especially those with rheumatoid arthritis, are taught to use these strategies before they experience pain and fatigue so that occupational performance can continue as long as possible without pain and fatigue.²⁵ Cathy was able to use energy conservation strategies and pacing to return to many previous occupations such as doing her laundry using a portable table to place the laundry basket on the table when putting the clothes in her top loading washer. The table was also used when she removed the clothes from the washer before she moved them to the side-opening dryer. This example illustrates the use of energy conservation and pacing that was employed throughout Cathy's daily life.

Splinting

Splinting of the upper extremity may be necessary if contractures or muscle imbalances occur. In CRPS, static resting splints may provide pain relief. Splint use is alternated with tasks that require joints to be taken through range of motion, since total immobilization could lead to increased pain and dysfunction. Static resting splints maintain joint alignment, reducing inflammation and pain during flare-ups of rheumatoid arthritis. Splints that support the wrist in a functional position throughout the day and night may be necessary for 4 to 6 weeks.⁶ People should use caution because orthoses may add to the stress on proximal joints when the wrist is confined.⁸

Adaptive Equipment

Clients with acute LBP may use a back support for stabilization of the lumbar area and increased abdominal pressure to improve postural alignment. This can result in decreased muscle spasm, reduced pain, and improved ability to engage in occupations.^{6,71} Adaptive equipment is often used to increase function and comfort in persons with arthritis.⁶⁶

Relaxation

Relaxation training can be used to decrease muscle tension, which is believed to precipitate or exacerbate pain. Progressive muscle relaxation involves the systematic tensing of major musculoskeletal groups for several seconds, passive focusing of attention on how the tensed muscles feel, and release of the muscles and passive focusing on the sensations of relaxation. As the client learns to recognize muscle tension, he or she can direct attention to inducing relaxation.⁵⁸

Autogenic training is another means to inducing relaxation. This approach involves the silent repetition of self-directed formulas that describe the psychophysiologic aspects of relaxation (e.g., "My arms and legs are warm"). The client passively concentrates on these phrases while assuming a comfortable body posture, with eyes closed, in a quiet setting. Relaxation training has been used successfully to modify a variety of chronic pain complaints, including headache, LBP, myofascial pain, arthritis, and cancer pain.^{27,58}

Relaxation strategies were very helpful to Cathy and allowed her to regain a "bit of her old self." When out shopping with friends she would often pause briefly and appear to be studying the clothing item while using the relaxation strategies rehearsed during her occupational therapy sessions. This allowed her to continue with the outing.

Biofeedback

Biofeedback is the use of instrumentation to provide visual or auditory signals that indicate some change in a biologic process, such as skin temperature, as it occurs. The signals are used to increase the client's awareness of these changes so that the changes may come under voluntary control. Biofeedback is based on the assumption that a maladaptive psychophysiologic response results in pain. Despite the questionable validity of this assumption, data do exist to support the use of biofeedback for the treatment of headache disorders, LBP, arthritis, myofascial pain, and CRPS.²⁷ Biofeedback for pain control is typically done in conjunction with relaxation training.

Distraction

Distraction is often used to divert an individual's attention and concentration away from acute mild-to-moderate intensity pain and reduce distress, especially during medical and rehabilitative procedures. Distraction may have an internal focus (e.g., daydreaming, guided imagery)

or external focus (e.g., listening to music, watching television).³⁶

Therapeutic Modalities

Physical agent modalities (PAM) may be used by occupational therapists as adjuncts to or in preparation for purposeful activities. Appropriate postprofessional education is needed to ensure that the practitioner is competent in the use of these modalities.⁷ Both heat and ice are useful in reducing pain and muscle spasm of musculoskeletal and neurologic pathologies. Superficial heat includes hot packs, heating pads, paraffin wax, fluidotherapy, hydrotherapy, whirlpool, and heat lamps. The application of heat increases local metabolism and circulation. Vasoconstriction occurs initially, followed by vasodilatation resulting in muscle relaxation. The use of heat is indicated in the treatment of subacute and chronic traumatic and inflammatory conditions such as muscle spasms, arthritis of the small joints of the hands and feet, tendonitis, and bursitis.^{7,21,44}

The use of heat is contraindicated in several instances. Heat is not to be used for clients who have acute inflammatory conditions, cardiac insufficiency, malignancies, or peripheral vascular disease. Preexisting edema may be aggravated. It should not be used for clients who are insensate. Heat may cause malignancies to spread.⁴⁹

Cold can improve pain control by elevating the pain threshold (i.e., the minimal level of noxious stimulation at which the client first reports pain). Local vasoconstriction occurs in direct response to cold therapy (cryotherapy). When the area is subsequently exposed to air, vasodilatation occurs. Cold applications also result in decreased local metabolism, slowing of nerve conduction velocity, diminished muscle spasm secondary to joint or skeletal pathologic conditions and spasticity, decreased edema, and lessened tissue damage. Cold can be applied via commercial packs, sprays, ice cups, or a massage stick.^{7,44}

There are several contraindications in the use of cryotherapy. Clients who are extremely sensitive may not be able to tolerate cold. If a client has a history of frostbite in the area to be treated, another modality must be used. If a client has Raynaud's disease, severe pain may occur in the treated area. Cryotherapy is contraindicated in the very young and elderly because their thermoregulatory responses may not function sufficiently.²¹

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) is a noninvasive pain relief measure that uses cutaneous stimulation. A TENS unit consists of a battery-powered generator that sends a mild electrical current through electrodes placed on the skin at or near the pain site, stimulating A fibers. Some success has been demonstrated with using TENS to relieve acute and chronic painful conditions caused by disease or injury of nervous system structures or the skeleton, muscle pain of ischemic origin in the extremities, and angina pectoris.⁶³

Relapse Management

Clients with chronic pain frequently experience a flare-up. During the flare-up the client is typically encouraged to reduce aerobic conditioning exercises (e.g., walking, stationary biking, swimming). As pain subsides, an incremental, gradual increase in activity should be implemented.²⁴ The client should be encouraged to increase his or her use of pain-coping and self-management strategies throughout the flare-up.¹⁸

Summary

Pain is a complex phenomenon. Occupational therapists bring their understanding of anatomy, physiology, kinesiology, psychology, and function to the comprehensive evaluation and treatment of the client with pain. Interventions focus on relieving pain, improving occupational performance, and developing coping strategies. Data are needed to support the use of the OT interventions described in this chapter.

Review Questions

1. Contrast acute pain and chronic pain.
2. List and describe two different pain syndromes that may be present in persons referred for occupational therapy.
3. Identify the essential elements of a pain assessment.
4. Explain at least six interventions used in the treatment of pain.
5. Describe the role and define the scope of occupational therapy in the evaluation and treatment of pain.

---	--

Key Terms

Active occupations	Occupational genesis	Simulated or enabling activity	Isometric exercises
Egocentric realm	Physical agent modalities	Adjunctive modalities	Active exercise
Exocentric realm	Grading	Isotonic exercises	Resistive activity
Consensual realm			Passive exercise

Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Recognize the organizing concepts of occupational genesis as they relate to active occupation.
2. Discuss the role of activity analysis in the selection of therapeutic activity.
3. Understand the similarities and distinctions between the therapeutic activity and therapeutic exercise.
4. Identify the role of physical agent modalities in occupational therapy practice.
5. Describe how grading activity heightens functional performance.
6. Differentiate between the various types of therapeutic exercise.
7. Describe how and why simulated and enabling activities are used in practice.
8. Describe how and why adjunctive modalities are used in occupational therapy practice.
9. Identify the requirements established by the American Occupational Therapy Association for the use of adjunctive modalities in occupational therapy practice.
10. Perform an activity analysis appropriate for physical dysfunction.

Threaded Case Study | Fareed

Fareed is an 82-year-old retired bookkeeper whose primary diagnosis is status post (s/p) right cerebrovascular accident (CVA) with residual shoulder/hand pain of his left upper extremity (LUE). The stroke resulted in his hospitalization and subsequent admission to a subacute facility. He has a past medical history of hypertension and prostate cancer, and he has exhibited reactive depression since his recent hospitalization.

Before the recent hospitalization, Fareed lived with his wife in a private home in a suburban neighborhood. One of his children lives in a nearby town and visits weekly. His other two children and their families live in cities within a day's drive and visit several times a year.

Since his retirement, which he had looked forward to, Fareed developed or expanded several interests, including woodworking, gardening, cooking, and traveling. He also frequently communicated with his grandchildren through interactive computer sites. He and his wife have taken a yearly vacation, traveling to various locations in the United States for periods of 3 weeks since his retirement. Fareed had also been responsible for managing the family finances. In all, Fareed had an active schedule before his recent hospitalization.

Initial evaluation revealed that Fareed is dependent in dressing, independent in feeding, and exhibits a mild left visual field cut.

He has limited active and passive range of motion (ROM) of the left shoulder, with pain on passive flexion of the left shoulder at the end of the range. Active ROM is limited in the LUE, but Fareed is able to grasp, pronate his forearm, flex the elbow, and internally rotate the shoulder. His balance and mobility are impaired. Although his prospects for recovery are positive, Fareed expresses feelings of dejection about regaining his ability to resume his independence, roles, and activities.

The focus of the occupational therapy intervention was to assist Fareed in doing the following:

- Engage in meaningful occupations to reduce depression.
- Adapt and grade activities (activities of daily living [ADLs]; assistive, active, and resistive restorative activities) using unilateral, bilateral, and balance activities to enable participation in life roles.
- Reduce pain associated with movement to enable use of LUE in occupations; apply heat to left shoulder and provide analgesic 20 minutes before active occupation treatment.
- Increase ROM and strength of LUE.
- Improve balance and mobility through participation in activity.
- Join with his family to develop the skills needed for him to return home.

- Prepare to resume active and social interactions with family through the use of electronic communication devices and games.

Intervention was initiated at bedside with sitting balance activities as a preface for dressing training. The client was instructed in scanning techniques to reduce the effects of his visual field cut. Fareed learned one-handed techniques for upper extremity dressing, gradually shifting to bilateral dressing as his strength and ROM improved.

The client was further evaluated to identify an intervention activity that he would find meaningful. He decided to pursue a woodworking task, making a small bench for his youngest grandchild. Because he was not able to use his left arm actively at the initiation of occupational therapy services, the therapist set his project up by using an inclined sanding board. This permitted him first passive, then active-assistive, and then active motion to heighten performance. Before beginning the activity, to reduce pain in his LUE and heighten his tolerance for movement, heat was applied to his shoulder using hot packs. To improve his balance and standing tolerance, the sanding board was placed on a standing table. As his performance improved, Fareed was discharged to his home and he returned to the clinic as an outpatient three times per week. With encouragement from his family and his therapist, Fareed completed the bench, which resulted in feelings of self-satisfaction.

Acting on suggestions from the therapist, the family installed raised garden beds at home, enabling Fareed to participate in an occupation at home, an activity he particularly loved. These efforts resulted in his gradual recognition that he was able to engage in some of his favorite activities, albeit in adapted form. His teen-aged grandson introduced him to Wii as they engaged in simulated sports activities together. As he recovered motor performance in his arm and his balance became safer, his depression lifted, aided by some medication. He and his wife began to use the Internet to find new recipes that they could cook together, and Fareed began to write the checks again and explore potential travel opportunities.

Critical Thinking Questions

1. Identify occupations Fareed engaged in before his stroke, those in which he engaged during intervention, and those he assumed or resumed. Describe how his progress relied on evaluation of his occupational performance.
2. Explore the contextual factors that influenced Fareed in resuming preferred activities. Describe the roles he resumed as a consequence of these influences.
3. Describe how the activities in which Fareed engaged were adapted to provide an interface between activity demands and client factors.

Active Occupation

Active occupations are the foundation of occupational therapy (OT) practice. Active occupations are the activities people engage in as part of their life's roles. These include personal care; the constructional tasks that involve the use of hand and mechanical tools; technological activities that involve such tools as calculators, computers, and electronics; games of various sorts; and vocational skills. They function together in a complex process, stimulating growth and health throughout the life span.

When physical disability strikes and the ability to perform occupational roles and activities becomes impaired, the occupational therapist (OT) helps clients to regain their skills using active occupations as therapeutic tools to stimulate performance and gears intervention to enable clients to assume or resume their ability to engage in life's occupations.

Active occupation is the primary therapeutic modality of OT, designed to stimulate function and to lead to improved function, and is relevant throughout the life span. Engagement in activity enhances performance beyond the given task. Learning to perform one activity skillfully leads to skillful performance in other activities. Therefore, active occupations are the objectives and the tools of practice. Activities are the means and the end to heightened performance. Whether related to personal care, work, or leisure, active occupations constitute an effective and substantial portion of any OT program and distinguish OT as a profession.

The needs and interests of clients guide the selection of occupations used for therapy. These needs are governed by the roles clients play in their worlds. As members of society, clients represent the societies in which they perform activities, and the activities in which they engage reflect their worlds. The clients' needs and interests are tied to the societies in which they live. Therefore, active occupations reflect society's values. In a society in which independence, leisure, and work all are valued, the interests of clients are variable and include self-care, hobbies, and work-related tasks.

Clients must assume their personal and social obligations to become effective members of society. To assume these responsibilities, clients must acquire the skills needed to perform their occupational roles. The roles people assume reflect their participation in occupations. For persons with disabilities, participation may require relearning skills, learning new skills, or learning to perform activities in new ways. Therefore, the OT must be prepared with a broad knowledge of activities and techniques that may then be used as tools of therapy in a client-centered approach. OTs must understand the roles and activities in which people engage in performing their life's tasks. As a consequence, OTs must be prepared to meet the challenges that ordinarily occur as people and societies evolve and change. Currently, advances in computer technology are emerging at a rapid

rate influencing all aspects of living, and therapy. Some of the tools now available to the public are Skype, Wii, iPad, and others, with new applications and adaptations entering the market daily. The OT must keep apprised of these technological changes and be prepared to incorporate them into therapy, as they are part of patients' lives.

Just as society changes and adapts with the invention of new objects and methods, so do the activities clients use in their lives. Nowhere is this more readily observed than in an examination of the OT treatment environment. Just as the nature of activity has changed over time as societies have evolved and adapted, the scope of OT's intervention methods and modalities has changed and broadened considerably over the years.

When the field of OT became formalized in the early 1900s, the nature of human occupation was limited to the scope of activities that had been developed up to that time. Consequently, the use of handicrafts and early industrial tasks guided activity at the outset of the profession. Although commonly described as crafts, these activities can be viewed from an anthropologic perspective, representing the times in which they were developed and in which they met people's personal and social needs. For example, making baskets and clay pots was not a frivolous activity when they were first designed. Rather, they were vital containers used to gather foods and other items, and the knowledge of how to make them was an important skill. However, times changed, and along with these changes society developed new and different occupations, which require OTs to expand their skills to incorporate activities and techniques of the modern era.

OTs currently are qualified and competent in the use of a variety of therapeutic occupations and modalities, traditional and modern.¹ Their competence is derived from entry-level to advanced graduate education, specialty certification, continuing education, and work experience. The scope of practice is broad and addresses the continuum of intervention from wellness to acute care through advanced rehabilitation. Therefore, OT offers comprehensive services and challenges the OT practitioner to keep pace with new developments in society and in practice.

Philosophic Foundations

OTs organize intervention by integrating a comprehensive knowledge of the client's mind and body (the egocentric realm) with knowledge of the tangible world (the exocentric realm) and the social influences (the consensual realm) that contribute to function. Each of these elements and their components and interactions are reflected in the second edition of the Occupational Therapy Practice Framework (OTPF-2), which is committed to the use of active occupation as the basis for therapy grounded in client-centered choices.

The relationships among these three interactive forces are in constant flux in a lifelong developmental process that is

stimulated by active occupation. These forces are evident in the various theories and models of practice OTs draw up for practice.

These foundational ideas stem from the work of John Dewey¹⁹ and the other American philosophers of pragmatism whose work influenced the mental hygiene movement, which in turn influenced the founders of the profession.¹³ Dewey's use of the terms *purposive activity* and *active occupation*, along with his renowned concept of learning through doing, are found in his text *Democracy and Education*,¹⁹ published in 1916 in Chicago, a year before the establishment of the National Society for the Promotion of Occupational Therapy.

Egocentric Realm

Intensive training in the various client factors of motor, neurologic, perceptual-cognitive, and emotional skills prepares the OT with a refined knowledge of what contributes to a client's performance in all aspects of the mind and body. Mind and body are seen as interactive and together govern performance. Our client, Fareed, has experienced a loss in motor function, as a result of a neurologic insult, which contributes to a loss in occupational performance. This change in abilities has resulted in a reactive depression, which illustrates the interaction between the various egocentric factors.

Exocentric Realm

OTs have an equally refined understanding of the material world, the context in which people live, act, and react. Textures, weights, direction, location, time, and other tangible, contextual, and objective means regulate performance in the world. A person functions within a real world filled with objects and environments that must be manipulated in one manner or another. OTs are expert in adapting the tangible and durable elements of the world to enhance function, *including aspects of the electronic virtual world in that process*. Returning to our client Fareed, we need to examine the exocentric realm of *his* world. The task demands of cooking, gardening, woodworking, and traveling require the client to control and manipulate the material world. The task demands of electronic communication and the Wii introduce the virtual world, a reality-based simulation of the material world, into this process. The neurologic insult Fareed experienced compromised his ability to control and manipulate the environmental features and objects necessary to engage in preferred activities.

Consensual Realm

OTs also bring their knowledge of the effects of society and social interactions on individual and group performance. This knowledge is used to enhance clients' function by effectuation of the roles they play in their social worlds. Recognizing and valuing the sociocultural contexts of occupation and their implications for client performance contribute to the OT's knowledge base and form a fundamental

FIGURE 29-1 The egocentric (E), exocentric (X), and consensual (C) realms of the OT's knowledge base are related.

(From Breines EB: *Occupational therapy from clay to computers: theory & practice*, Philadelphia, 1995, FA Davis.)

basis for formulation of the practice environment. Our patient Fareed relies on this social realm in his interactions with his family.

Relationships among Realms

The three major aspects of OT's knowledge base, the egocentric (mind and body), exocentric (time and space), and consensual (society) realms, are thoroughly integrated in active performance, regardless of interest, purpose, environment, or era.^{12,13} OTs consider the interactions among these realms to influence or heighten the possibility of the client to engage in occupations (Figure 29-1). For example, a splint (exocentric) can be used to stabilize a wrist to reduce pain (egocentric), enabling the client to prepare a meal for the family (consensual). A walker can be adapted so that a client can carry her knitting (exocentric), allowing her to prepare gifts for her grandchild (consensual) and heighten her feelings of efficacy (egocentric).

Development and Evolution

The interaction among these three realms represents a developmental continuum. They influence one another throughout the life span in a process defined as occupational genesis.¹¹ Interactions among physical and mental capacities, the tangible world, and the roles people play in their worlds are reflected and governed by the activities in which people engage throughout their lives.

Intensive preparation in these three realms and their interactions constitute the education and preparation of the OT practitioner and guide the therapist in developing an intervention plan. With this comprehensive foundation, OTs use various modalities to integrate these three realms, which enhances client performance and enables clients to meet life needs.

Evolving Practice

Just as society and its occupations have evolved and continue to evolve, OT practice has evolved. New media and modalities (Box 29-1) have emerged to enable clients to become skilled in functional performance. In addition to

■ Box 29-1

Occupational Therapy Modalities

Modality: The employment of, or method of employment of, a therapeutic agent (*Webster's New World College Dictionary*, edition 2).¹ Traditionally, the modalities of OT were its crafts. The term has grown to be understood more broadly and defines active occupation as the primary therapeutic modality of OT. The term *modality* also includes media and methods.⁴⁴ Media are the means by which therapeutic effects are transmitted. For example, media can include a variety of objects, such as an article of clothing, a vestibular ball, or an adapted tool. Methods are the steps, sequence, or approaches used to activate the therapeutic effect of a medium, such as the movements required in the creation of a macramé plant hanger to heighten shoulder flexion or reduce edema, or the movements used with the vestibular ball to effect the desired motor responses. The modalities, media, and methods of OT are variable in their application and require considerable expertise to select, modify, adapt, and apply to elicit therapeutic effects.

therapeutic exercise and activity and the facilitation and inhibition techniques associated with various sensorimotor approaches to treatment, therapists have added adjunctive therapies to their repertoires, all designed to enhance clients' performance in purposeful occupation.

Although use of adjunctive therapies such as physical agent modalities is not considered to be an entry-level skill,^{3,5} some therapists have become increasingly skilled in the application of these therapies. These modalities traditionally were utilized by physical therapists but have long since entered the realm of OT practice. Trained OTs use them to enhance the development of the individual's ability to perform purposeful occupation, the primary objective of OT. Their use by OTs should be limited to the role of an adjunct to or preparation for purposeful active occupation.

Purposeful Occupation and Activity

One of the first principles of OT, stated by Dunton in 1918, is that some useful end to occupation must exist for it to be effective in the treatment of mental and physical disability.⁵⁰ This principle implies that occupation has a purpose, and that purposeful activity has an autonomous or inherent goal beyond the motor function required to perform the task.⁹ An individual engaged in purposeful activity focuses attention on the goal rather than on the processes required to reach the goal.^{4,6}

Conversely, nonpurposeful activity has been defined as activity that has no inherent goal other than the motor function used to perform the activity.⁵⁰ The person performing a nonpurposeful activity is likely to be focused on the activity process or movements rather than a functional or meaningful goal. Therapeutic exercise and enabling

FIGURE 29-2 Sawing wood to strengthen shoulder and elbow musculature.

activities such as moving cones and stacking blocks cannot be considered purposeful activity when they have no purpose for the client. This statement does not imply that such media have no place in the continuum of intervention. However, in accord with the OTPF-2, intervention must consider the inherent occupational objectives of the client so both tools of treatment and skills to be acquired are more readily tied to purpose, meaning, and therapeutic value and constitute the occupational nature of therapy.

Purposeful activity is the cornerstone of OT and is its primary intervention modality.^{50,52} In a position paper on purposeful activity, the American Occupational Therapy Association (AOTA) defined purposeful activity as “goal-directed behaviors or tasks that comprise occupations. An activity is purposeful if the individual is an active, voluntary participant and if the activity is directed toward a goal that the individual considers meaningful.”⁶ Although some theorists have attempted to distinguish between *purposefulness* and *meaningfulness*, others use these terms interchangeably to indicate that the investment of the performer in either purpose or meaning determines its usefulness in therapy. The uniqueness of OT lies in its emphasis on the extensive use of purposeful or meaningful activity. This emphasis gives OT the theoretic foundation for its broad application to psychosocial, physical, and developmental dysfunction, in addition to health maintenance.⁴

Purposeful activity has inherent and therapeutic goals. For example, sawing wood (Figure 29-2) may have the inherent goal of securing parts for construction of a bookshelf, whereby the therapeutic objectives may be to strengthen shoulder and elbow musculature. The conscious effort of the client is focused on the ultimate outcome of the project and not on the movement itself.⁹ The client directs and is in control of the movement; however, that control is ordinarily outside of conscious awareness as the client focuses on the goal aspects of performance. In fact,

performance outside of conscious awareness distinguishes OT's therapeutic effectiveness. To enhance skill building, performance must become automatic and decrease reliance on cognitive monitoring.¹³ Automatic performance serves as a subskill for more advanced performance. For example, Huss suggested that the child who must attend to sitting is unable to focus on the task performance that automatic sitting would ordinarily enable.²⁴ Consequently, the child cannot engage in active occupations essential to growth and the development of social roles. Ayres' emphasis on the interaction of subcortical regions of the brain as requisite to skilled performance affirms this same principle.^{8,9}

The importance of purposeful activity is readily observed in goal-directed performance. As the client becomes absorbed in the performance of any given activity, affected parts are used more naturally and with less fatigue,⁴⁹ perhaps attributable to the perception of time that derives from participation in everyday activities.³² Concentration on motion has a detrimental effect on that motion, and muscles controlled by conscious attention and focused effort fatigue rapidly. The value of goal-oriented effort in purposeful tasks is clear. It is of greater therapeutic value to focus attention on an activity of interest to the client and its inherent goal than on the muscles or motions being used to accomplish the activity,⁹ and that is what goal-directed OT effects.

A number of studies have shown the efficacy of purposeful activity.⁴⁰ Steinbeck demonstrated that clients who do purposeful activity perform for a longer period than when they are engaging in nonpurposeful activity.⁵⁰ A study of motivation for product-oriented versus non-product-oriented activity by Thibodeaux and Ludwig indicated the need to determine the client's level of interest in the process and the product and to incorporate his or her image of the activity in treatment planning.⁵² Rocker and Nelson found that not being allowed to keep an activity product can elicit hostile feelings in normal subjects,⁴⁶ which demonstrates the importance of tangible productivity for sustaining people's interest. Yoder, Nelson, and Smith studied the effects of added-purpose versus rote exercise in female nursing home residents.⁵⁶ The added-purpose exercise resulted in significantly more movement repetitions than did rote exercise.⁵⁶ These studies suggest that goal-directed, purposeful activity increases motivation for participation in sustained activity and can therefore be assumed to heighten the willingness of clients to engage in therapeutic activity.

When an intervention plan is being developed, the inherent goals of the activity, the client's level of interest in the activity, and the meaning of the activity and its product are important considerations in the ultimate effectiveness of the media and methods selected for intervention. Purposeful activities are used, or adapted for use, to meet one or more of the following therapeutic objectives: (1) to develop or maintain strength, endurance, work tolerance, range of motion (ROM), and coordination; (2) to practice and use voluntary, automatic movement in goal-directed tasks; (3) to provide for purposeful use of and general exercise to

affected parts; (4) to explore vocational potential or train in work skills; (5) to improve sensation, perception, and cognition; (6) to improve socialization skills and enhance emotional growth and development; and (7) to increase independence in occupational role performance. Some of these objectives alone may not be considered purposeful unless they relate to function. Arts, crafts, games, sports, leisure, self-care, home management, purposive mobility, and work-related activities are considered purposeful activities and may hold occupational significance for the client.

Occupation and Health

OT was founded on the concept that human beings have an occupational nature. That is, it is natural for humans to be engaged in activity, and the process of being occupied contributes to the health and well-being of the organism.^{9,12,17,25} Activity is valuable for the maintenance of health in the healthy person and for the restoration of health after illness and disability. When the client engages in relevant, meaningful, and purposeful activity, change is possible and dysfunction is reversible.¹⁷ The OT acts as facilitator of the change process.¹⁶ Therefore, physical dysfunction can be ameliorated when the client participates in goal-directed (purposeful) and thus therapeutic activity.⁹

The value of purposeful activity lies in the client's simultaneous mental and physical involvement. Activity provides the exercise needed to help develop the use of affected parts and also provides an opportunity to meet emotional, social, and personal gratification needs.^{9,49} Cynkin and Robinson pointed out that, for the attainment of optimal function and health, the human being must be consciously involved in problem-solving and creative activity, processes that are linked with the use of the hands.¹⁷

Most occupational performance involves the hands or requires the substitution of methods that simulate the use of hands. The use of a computer-driven environmental control unit operated by a sip-and-puff mechanism is an example of an activity ordinarily performed by the hands but, in this case, a substitution for hand control is made using the sip-and-puff mechanism.

The activities that form the pattern of a person's life, which are performed routinely and automatically, are taken for granted until some dysfunction disrupts their performance. The OT's role is to adapt activity so that clients can resume their ability to perform life's tasks. OT is founded on the notion that dysfunction can be modified, altered, or reversed toward function through engagement in the activities of real life. Cynkin and Robinson make several assumptions about activities,¹⁷ which are summarized as follows:

- A wide variety of activities are important to the individual. Activities fulfill many of a person's needs and wants, and they are essential to physical and psychosocial growth and development and the attainment of mastery and competence.

- Activities are socioculturally regulated by the values and beliefs of the culture that defines acceptable behavior for groups of people in the culture. Whether a society is rigid or flexible in its interpretation of acceptable behaviors for various groups, at some point deviations in behavior or activity patterns are deemed unacceptable.
- Activity-related behavior can change from dysfunctional toward more functional. Persons can change and desire change.
- Changes in activity-related behavior take place through motor, cognitive, and social learning.¹⁷

Assessment of Occupational Role Performance

The therapist should establish the client's occupational goals and needs. A top-down, client-centered approach is recommended. Identifying appropriate and meaningful therapeutic activities should begin with obtaining and analyzing the client's occupational history and interests.⁵²

The Canadian Occupational Performance Measure³⁰ and the Activity Configuration¹⁶ are two examples of occupational performance assessments. See Chapter 3 for more information about assessment of occupational performance.

Activity Analysis

Careful activity analysis is essential to the selection of appropriate treatment activities. It should yield information about various activities as intervention strategies for physical dysfunction and health maintenance. Activities should be analyzed from three perspectives: the contributions of the person or actor, the effects of the physical environment on performance, and the implications of the social environment. The therapist should recognize that these three elements are inextricable and form the context for intervention. The importance of context in intervention is widely recognized throughout the profession.^{2,7}

A number of theorists have developed comprehensive guides to activity analysis that can serve as useful resources.^{12,30,53} A guide to activity analysis specifically relevant to practice in physical dysfunction can be found in Appendix 29-1 at the end of this chapter.

Principles of Activity Analysis

Activities selected for therapeutic purposes should be goal directed; have some meaning to the client to meet individual needs in relation to social roles; require the mental or physical participation of the client at the "just right" level of challenge; be designed to prevent or reverse dysfunction; develop skills to enhance performance in life roles; relate to the client's interests; be adaptable, gradable, and age appropriate; and be selected through the knowledge and professional judgment of the OT in concert with the interests and investment of the client.²² A comprehensive activity analysis includes all aspects of performance

that are potentially elicited by specific activities and reveals their potential for therapeutic application. Fareed had expressed an interest in returning to woodworking and selected a project that he could make for his youngest grandchild. This reflects client-centered activity selection. It is not merely activity for no or limited purpose, but the client has selected the activity because it has meaning for him or her.

Therapeutic Approaches

A variety of therapeutic approaches are available to OTs. Although these approaches differ in their emphasis, all are consistent with an occupational approach to intervention. Aspects of activity analysis relevant to various therapeutic approaches are listed next.

Biomechanical Approach

The biomechanical approach to intervention is likely to be used in the treatment of lower motor neuron and orthopedic dysfunctions. Improvements in strength, ROM, and muscle endurance are the goals of OT for such dysfunctions. Thus, the emphasis of activity analysis is on muscles, joints, and motor patterns required to perform the activity. The outcome of OT service is focused on the engagement in the specified activity, but the approach is focused on the biomechanical client factors required to complete the task. Steps of the activity must be identified and broken down into the motions required to perform each step. ROM, degree of muscle strength, and type of muscle contraction to perform each step should be identified. The activity analysis format at the end of this chapter is based on the biomechanical approach.

Sensorimotor Approach

Sensorimotor approaches to intervention are likely to be used for upper motor neuron disorders such as cerebral palsy, stroke, and head injury. Activity analysis for these dysfunctions should focus on the sensory perception of the client and the movement patterns required in the particular treatment approach. The therapist must also consider the effect of the activity on balance, posture, muscle tone, and the facilitation or inhibition of abnormal reflexes and movements. For example, if the therapist is using the proprioceptive neuromuscular facilitation (PNF) approach, it is important to incorporate PNF patterns in the activity or to select activities that use these patterns naturally. For the neurodevelopmental (Bobath) approach, postures and movements that inhibit abnormal reflexes, reactions, and tone are important. These and other sensorimotor approaches and their applications to activity are discussed in Chapter 31.

Analysis of the perceptual and cognitive requirements of the activity is particularly important for clients with upper motor neuron disorders because these functions are often disturbed. The therapist must select activities that meet the

requirements for motor performance and can be performed with some success.

Regardless of diagnosis or therapeutic approach, activity analysis should include the contextual aspects of performance. The tangible environment and the social environment dictate occupational performance to the same extent that physical and mental capacities do, and they must be considered in developing an intervention plan.

Adapting and Grading Activity

Adaptation of Activity

It may be necessary to adapt activities to suit the special needs of the client or the environment. An activity may have to be performed in a special way to accommodate the client's residual abilities—for example, eating using a special splint with a utensil holder fitted to the hand (Figure 29-3). An activity may have to be adapted to the positioning of the client or to the environment—for instance, by setting up a special reading stand and providing prism glasses to enable a client to read while supine in bed. The problem-solving ability, creativity, and ingenuity of OTs in making adaptations are some of their unique skills.

The therapist should remember that for adaptations to be effective, the client must be able to use them in a comfortable position. The client must understand the need and purpose of the activity and the adaptations and be willing to perform the activity with the simple modifications. Peculiar and complicated adaptations that require frequent adjustment and modification should be avoided.^{43,49}

Grading of Activity

Grading an activity means to pace it appropriately and modify it for the client's maximal performance. If movement patterns or degree of resistance cannot be attained when the activity is performed in the usual manner, simple

FIGURE 29-3 Eating using a special splint with a utensil holder fitted to the hand.

modifications may be made. The client usually accepts changes if they are not complex and do not require strained and unnatural motions. The novice is cautioned that the value of the activity may be diminished if it is designed to be performed with artificial movements or excessive resistance. Such methods discourage participation and interfere with the development of coordination.^{27,49} They also require that the client focus on movements rather than on the goal of the activity, which reduces satisfaction and defeats the primary purpose of purposeful activity as described earlier. The skilled OT adapts and grades activities so that the client easily accepts them and they provide the “just right” demand on performance.

Activities may be graded in many ways to suit the client's needs and meet the intervention objectives. Activities can be graded for increasing strength, ROM, endurance and tolerance, coordination, and perceptual, cognitive, and social skills. Activities may also be graded according to diminishing capacities of clients, as are expected to occur with such progressive diseases such as Parkinson's disease, multiple sclerosis, and amyotrophic lateral sclerosis.

Strength

Strength may be graded by an increase or decrease in resistance. Methods include changing the plane of movement from gravity-eliminated to against-gravity, by adding weights to the equipment or to the client, using tools of increasing weights, grading the texture of the materials from soft to hard or fine to rough, or changing to another more or less resistive activity.

For example, a weight attached to the wrist by a strap increases resistance to arm movements during needle or leatherwork (Figure 29-4). A pulley-and-weight system can

FIGURE 29-4 Weight attached to the wrist increases resistance during needlework or leatherwork.

be attached to an inclined plane sanding board to increase resistance to the biceps when the sanding block is pulled downward, as the client sands a cutting board for use in one-handed cutting. Springs may be used to increase resistance on a block printing press. When grasp strength is inadequate, grasp mitts may be used to fasten the hand to a tool or equipment handle to assist grip strength and allow arm motion.

Range of Motion

Activities for increasing or maintaining joint ROM may be graded by positioning materials and equipment to demand greater reach or excursion of joints or by adapting equipment with lengthened handles to facilitate active stretching.

An example of a simple adaptation is positioning a weaving project in a vertical position to achieve the desired range of shoulder flexion while working. As the work progresses, the activity itself establishes increased demands on active range. Positioning objects, such as tiles used in a mosaic tile project, at increasing or decreasing distances from the client changes the range needed to reach the materials (Figure 29-5). Tool handles such as those used in wood-working may be increased in size by using a larger dowel or by padding the handle with foam rubber to accommodate limited ROM or to facilitate grasp (Figure 29-6). Reducing the amount of padding as range or grasp improves can facilitate grading.

Endurance and Tolerance

Endurance may be graded by moving from light to heavy work and increasing the duration of the work period. For example, an initial household task of folding paper napkins can be graded to sorting heavier and heavier objects, such as the task of sitting to sort kitchen utensils, and then graded to a standing position to organize tools on a peg-board or to place household items onto shelves. Standing

FIGURE 29-5 Placing objects at alternate distances changes the range needed to reach materials.

and walking tolerance may be graded by an increase in the time spent standing to work, perhaps at first at a standup table (Figure 29-7), and an increase in the time and distance spent in activities requiring walking, perhaps including home management and workshop activities.

When conditions that are progressively degenerative, such as muscular dystrophy, multiple sclerosis, or

FIGURE 29-6 The size of tool handles may be increased by padding the handle with foam rubber.

FIGURE 29-7 Standup table with sliding door, padded knee supports, and backrest.

Parkinson's disease, require grading endurance in a negative direction to accommodate a diminishing physical condition, it is advisable to change the activity to one that requires less effort rather than reducing the demands of an existing project. The latter can have a negative psychological effect if the client readily recognizes the reduction in performance capacity.

Coordination

Coordination and muscle control may be graded by decreasing the gross resistive movements and increasing the fine controlled movements required. An example is progressing from sawing wood with a crosscut saw to using a coping saw to using a jeweler's saw. Dexterity and speed of movement may be graded by practicing at increasing speeds once movement patterns have been mastered through coordination training and neuromuscular education.

Perceptual, Cognitive, and Social Skills

In grading cognitive skills, the therapist can begin the treatment program with simple one- or two-step activities that require little judgment, decision making, or problem solving, and progress to activities with several steps that require some judgment or problem-solving processes. A client in a lunch preparation group may butter bread that has already been lined up on the work surface. This task could be graded to lining up the bread, then buttering it and placing a slice of lunchmeat on it, and, ultimately, to making sandwiches.

For grading social interaction, the intervention plan may begin with an activity that demands interaction only with the therapist. The client can progress to activities that require dyadic interaction with another client and, ultimately, to small group activities. The therapist can facilitate the client's progression from the role of observer to that of participant and then to leader. Concomitantly, the therapist decreases his or her supervision, guidance, and assistance to facilitate more independent functioning in the client.

Selection of Activity

In the treatment of physical dysfunction, activities are usually selected for their potential to improve sensorimotor and psychosocial components to ensure that clients' motivation to engage in activity is sustained. Activities selected for the improvement of physical performance should provide desired exercise or purposeful use of affected parts. They should enable the client to transfer the motion, strength, and coordination gained in adjunctive and enabling modalities to useful, normal daily activities. If activities are to be used for physical restoration, they should have certain characteristics:

- Activities should provide action rather than merely the position of involved joints and muscles—that is, they should allow alternate contraction and relaxation of the

muscles being exercised and allow clients to course through their available ROM.

- Activities should provide repetition of motion—that is, activities should allow for a considerable number of repetitions of movement patterns sufficient to benefit the client.
- Activities should allow for one or more kinds of grading, such as for resistance, range, coordination, endurance, or complexity.^{22,49}

The type of exercise needed must be considered when choosing an activity. Active and resistive exercises are most often used in the performance of purposeful activity.⁴⁹ Requirements for passive and active-assisted exercise are harder (although not impossible) to apply to purposeful activities—for example, bilateral sanding or using a sponge with both hands to wipe a surface. Other important considerations in the selection of activity are the objects and environment required to perform the activity; safety factors; preparation and completion time; complexity, type of instruction, and supervision required; structure and controls in the activity; learning requirements; independence, decision making, and problem solving required; social interaction potential and communication skills required; and potential gratification to the person.

If an activity is selected in which the client has an interest, the client is more likely to experience sufficient satisfaction to sustain performance. The therapist's job is to guide the client to suitable therapeutic activities at just the right level of challenge so that the client will achieve satisfaction by engaging in the activity. This satisfaction is an important characteristic of intrinsic motivation. Thus, purposeful activities meet the requirements for motor performance and can be performed with success, which provides positive personal and social feedback. When the OT evaluated Fared, preferred activities and hobbies were explored. This allowed the OT to select from an array of activities that Fared had identified and that could be incorporated into the intervention plan.

Simulated or Enabling Activity

The clinical environment may not be fully equipped to meet the exact occupational needs of all clients. When this is the case, it may be necessary to simulate appropriate active occupation by adaptation of the environment or activity to meet the client's needs and retain his or her interest, called simulated or enabling activity.

OTs have developed a variety of methods to simulate active occupation. A number of these activities were devised initially from equipment and materials used in other activities. A devised activity is the simulated inclined sanding board (Figure 29-8). The sanding board was designed to incline wood while the wood was being sanded.

Therapists began using the board, without the wood, to exercise muscles of the elbow and shoulder. Without the

FIGURE 29-8 Inclined sanding board used to sand wood.

wood, no end product results and thus no inherent purposefulness. However, incorporating wood for a project can turn this from a simulated to a meaningful activity. Our client, Fareed, had indicated that he wanted to pursue a woodworking task. Instead of having Fareed engage in rote exercise using an empty sanding board, his OT placed wood on the sanding board, which Fareed would later use to construct a bench for his grandchild.

Puzzles and other perceptual and cognitive training media are used to train clients in visual perceptual functions, motor planning skills, memory, sequencing, and problem solving, among other skills (Figure 29-9). Clothing fastener boards and household hardware boards may provide practice in the manipulation of everyday objects before the client is confronted with the real task (Figure 29-10). At a higher level of technological sophistication, commercial work simulators (see Chapter 14) and computer programs are used to improve physical and cognitive client factors.

Although many of these items are readily available in clinics, the nature and purpose of OT are best encompassed in an activity in which the client finds purpose and meaning. The therapist should take into consideration the needs and interests of the client in selecting activities, rather than relying on available objects that meet only physical needs.

Enabling activities are considered nonpurposeful and generally do not have an inherent goal, but they may engage the mental and physical participation of the client. The purposes of engaging in enabling activities are to practice specific motor patterns, to train in perceptual and cognitive skills, and to practice sensorimotor skills necessary for function in the home and community. Indeed, many enabling modalities used in OT practice facilitate perceptual, cognitive, and motor learning. Such activities may be appropriate for the skill acquisition stage of learning, when the client is getting the idea of the movement and practicing problem solving. Practice should be daily or frequent and feedback given often so that errors are decreased and skills refined to

FIGURE 29-9 Puzzles and other perceptual and cognitive training media are used on the tabletop.

prepare for performance of real-life purposeful activity. These activities should be used judiciously, and their place in the sequence of the intervention program should be well planned. They may be used along with adjunctive modalities and purposeful activities as part of a comprehensive intervention program.

Adjunctive Modalities

Adjunctive modalities may be used as a preliminary to purposeful activity. When used by the OT, they are meant to prepare the client for occupational performance. Examples of adjunctive modalities are exercise, orthotics, sensory stimulation, and physical agent modalities.⁴¹ Therapeutic exercise and physical agent modalities are described next. Many of the principles of therapeutic exercise are readily and customarily incorporated into therapeutic activity and consequently are inherent aspects of OT practice.

Therapeutic Exercise and Activity

The field of OT always has recognized that the mind and body are inextricably united in performance. The psychological and physical effects of purposeful activity were recognized in the treatment of individuals with mental conditions, in addition to in the treatment of persons with physical dysfunction.^{10,13,20,25} Because it was recognized that physical benefits accrued from the performance of activity, kinesiological considerations were applied in the selection of appropriate therapeutic activities. To apply kinesiological considerations to purposeful activity, it was necessary to understand the principles of therapeutic exercise.

As intervention methods evolved, OTs began to use therapeutic exercise alone to prepare clients for purposeful activity and to expedite treatment in a healthcare system constrained by budget and time. The treatment of clients in acute stages of illness and disability imposed new demands and role responsibilities on OTs. Short therapy sessions in acute care settings, the extent of the client's physical incapacities, and shortened lengths of stay in hospital and rehabilitation facilities caused OTs to expand the range of modalities used in intervention.

The use of therapeutic exercise as an isolated modality raised considerable controversy.²¹ It was feared that if OTs used exercise or other preparatory modalities, purpose would be forgotten. Exercise and activity tended to be seen by some as mutually exclusive; however, the principles of exercise had been applied to purposeful activity from early in the history of OT. Exercise and activity are complementary in the intervention continuum, and both may be used in a single intervention plan. However, if only pure exercise is used, the client has not received OT.²¹

When used by OTs, therapeutic exercise should be used to remediate sensory and motor dysfunction, augment purposeful activity, and prepare the client for performing a desired occupation.

A comprehensive understanding of the principles of exercise is basic to the application of therapeutic activity. Therapeutic exercise is defined as any body movement or muscle contraction to prevent or correct a physical impairment, improve musculoskeletal function, and maintain a state of well-being.^{15,28} A wide variety of exercise options are available; each should be tailored to meet the goals of the intervention plan and the specific

capacities and precautions relative to the client's physical condition.

Exercise can be used to increase ROM and flexibility, strength, coordination, endurance, and cardiovascular fitness.²⁸ Specific exercise protocols may be used to achieve specific goals. However, exercise without activity is apt to place the exercise in the realm of deliberate rather than automatic performance, which therefore violates essential principles of OT discussed earlier. Although judicious application of therapeutic exercise may have a limited place in the therapeutic program, the OT should structure treatment so that the client is engaged in activity primarily to take advantage of the automaticity generated by purposeful goal-directed therapeutic activity.

Purposes

The general purposes of therapeutic exercise, as with therapeutic activity, are as follows:

- To develop awareness of normal movement patterns and improve voluntary, automatic movement responses
- To develop strength and endurance in patterns of movement that are acceptable and necessary and do not produce deformity
- To improve coordination, regardless of strength
- To increase the power of specific isolated muscles or muscle groups
- To aid in overcoming ROM deficits
- To increase the strength of muscles that will power hand splints, mobile arm supports, and other devices
- To increase work tolerance and physical endurance through increased strength
- To prevent or eliminate contractures developing as a result of imbalanced muscle power by strengthening the antagonistic muscles⁴³

Indications for Use

Therapeutic exercise is most effective when providing intervention for orthopedic disorders (such as contractures and arthritis) and lower motor neuron disorders that produce weakness and flaccidity. Examples of the latter are peripheral nerve injuries and diseases, poliomyelitis, Guillain-Barré syndrome, infectious neuritis, and spinal cord injuries and diseases.

The candidate for therapeutic exercise must be medically able to participate in the exercise regimen, able to understand the directions and purposes, and interested and motivated to perform. The client must have available motor pathways and the potential for recovery or improvement of strength, ROM, coordination, or movement patterns, as applicable. Some sensory feedback must be available to the client—that is, sensation must be at least partially intact so that the client can perceive motion and the position of the exercised part and sense superficial and deep pain. Muscles and tendons must be intact, stable, and free to move. Joints must be able to move through an effective ROM for those

types of exercise that use joint motion. The client should be relatively free of pain during motion and should be able to perform isolated, coordinated movement. If the client has any dyskinetic movement, he or she should be able to control it so that the procedure can be performed as prescribed.⁴² The type of exercise selected depends on muscle grade, muscle endurance, joint mobility, diagnosis and physical condition, treatment goals, position of the client, and desirable plane of movement. Each of these requirements is also applicable to the use of exercise-focused therapeutic activity and should underlie its selection as a therapeutic tool.

Contraindications

Therapeutic exercise and exercise-focused therapeutic activity are contraindicated for clients who have poor general health or inflamed joints or who have had recent surgery.⁴² They may not be useful where joint ROM is severely limited as the result of well-established, permanent contractures. As defined and described here, they cannot be used effectively for those who have spasticity and lack voluntary control of isolated motion or those who cannot control dyskinetic movement. The latter conditions are likely to occur in upper motor neuron disorders.

Exercise Programs

Muscle Strengthening

Active-assisted, active, and resistive isotonic exercises and isometric exercises are used to increase strength. After partial or complete denervation of muscle tissue and during inactivity or disuse, muscle strength decreases. When strength is inadequate, substitution patterns or “trick” movements are likely to develop.⁵⁵ A substitution is the attempt to achieve a functional goal by using muscle groups and patterns of motion not ordinarily used. Substitution is used when muscles normally used to perform the movements or restrictions in ROM are lost or weakened because of structural dysfunction. An example is using shoulder abduction to achieve a hand-to-mouth movement if elbow flexors cannot perform against gravity (Figure 29-11). When muscle loss is permanent, some substitution patterns may be desirable as a compensatory measure to improve performance of functional activities, such as the use of tenodesis to permit grasp that will enable self-feeding. Many substitute movements are not desirable, however, and it is often the aim of therapeutic exercise to prevent or correct substitution patterns.⁵⁵

A muscle must contract at or near its maximal capacity and for enough repetitions and time to increase strength. Strengthening programs generally are based on having the muscle contract against a large resistance for a few repetitions. Strengthening exercises are not effective if the contraction is insufficient.^{15,29} Excessive repetitions of strengthening exercises, however, may result in muscle fatigue, pain, and temporary reduction of strength. If a muscle is overworked, it becomes fatigued and is unable to

FIGURE 29-11 Using shoulder abduction as compensation to achieve hand-to-mouth movement.

contract. The type of exercise must suit the muscle grade and the client’s fatigue tolerance level. Fatigue level varies from individual to individual, and the threshold for muscle fatigue decreases in pathologic states.²⁹ Many clients may not be sensitive to fatigue or may push themselves beyond tolerance in the belief that this approach hastens recovery. Therefore, the therapist must carefully assess the client’s muscle power and capacity for performance. The therapist must also supervise the client closely and observe for signs of fatigue. These signs may be slowed performance, distraction, perspiration, increase in rate of respiration, performance of exercise pattern through a decreased ROM, and inability to complete the prescribed number of repetitions.

Increasing Muscle Endurance

Endurance is the ability of the muscle to work for prolonged periods and resist fatigue. Although a high-load, low-repetition regimen is effective for muscle strengthening, a low-load and high-repetition exercise program is more effective for building endurance.^{15,18} Having determined the client’s maximum capacity for a strengthening program, the therapist can reduce the maximum resistance load and increase the number of repetitions to build endurance in specific muscles or muscle groups. The strength versus endurance training may be seen as a continuum. Resistance and the number of repetitions can be modulated so that gains in strength and endurance accrue.¹⁵

Physical Conditioning and Cardiovascular Fitness

Improving general physical endurance and cardiovascular fitness requires the use of large muscle groups in sustained, rhythmic aerobic exercise, or activity. Examples are swimming, walking, bicycling, jogging, and some games and sports. This type of activity is often used in cardiac rehabilitation programs in which the parameters of the client’s physical capacities and tolerance for exercise should be well defined and medically supervised. To improve

cardiovascular fitness, exercise should be done 3 to 5 days per week at 60% to 90% of maximum heart rate or 50% to 85% of maximum oxygen uptake. Between 15 and 60 minutes of exercise or rhythmic activities using large muscle groups is desirable.¹⁵

Range of Motion and Joint Flexibility

Active and passive ROM activities are used to maintain joint motion and flexibility. Active exercise is performed solely by the individual. An outside force such as the therapist or a device can be used for performing passive ROM exercise. The continuous passive motion machine, a device that can be preset to provide continuous passive motion throughout the joint range, is an example. Application of any mechanical device requires caution and careful monitoring to prevent mishaps and possible deleterious effects.¹⁵

Stretching or forced exercise may be necessary to increase ROM. Some type of force is applied to the body part when soft tissue (muscles, tendons, and ligaments) is at or near its available length. The use of a low-resistance stretch of sustained duration is preferred to high resistance and repetitive, quick, bouncing movements. The former method is less likely to produce tissue tearing, trauma, and activation of stretch reflexes in hypertonic muscles. The use of thermal agents or neuromuscular facilitation techniques may enhance static stretching.¹⁵

Coordination and Neuromuscular Control

Coordination is the combined activity of many muscles into smooth patterns and sequences of motion. Coordination is an automatic response monitored primarily through proprioceptive sensory feedback. Kottke defined control as “the conscious activation of an individual muscle or the conscious initiation of a pre-programmed engram.”²⁷ Control involves conscious attention to and guidance of an activity.

A preprogrammed pattern of muscular activity represented in the central nervous system (CNS) has been described as an engram. An engram is formed only if many repetitions of a specific motion or activity occur. With repetition, conscious effort of the client is decreased and the motion becomes more and more automatic. Ultimately the motion can be carried out with little conscious attention. It has been hypothesized that when an engram is excited, the same pattern of movement is produced automatically. Neuromuscular education or control training involves teaching the client to control individual muscles or motions through conscious attention. Coordination training is used to develop preprogrammed multimuscular patterns or engrams.²⁷

Types of Muscle Contraction

Isometric or Static Contraction

During an isometric contraction, no joint motion occurs and the muscle length remains the same. The limb is set or held taut as agonist and antagonist muscles are contracted

at a point in the ROM to stabilize a joint. This action may be without resistance or against some outside resistance, such as the therapist’s hand or a fixed object. An example of isometric exercise of the triceps against resistance is pressing down against a tabletop with the ulnar border of the forearm while the elbow remains at 90-degree flexion. An example of an activity that requires isometric contraction is stabilizing the arm in a locked position when carrying a shopping bag slung over the forearm.^{23,29}

Isotonic or Concentric Contraction

During an isotonic contraction, the joint moves and the muscle shortens. This contraction may be done with or without resistance. Isotonic contractions may be performed in positions with gravity decreased or against gravity, according to the client’s muscle grade and the goal of the exercise or activity. An isotonic contraction of the biceps is used to lift a fork to the mouth for eating.^{23,29}

Eccentric Contraction

When muscles contract eccentrically, the tension in the muscle increases or remains constant, while the muscle lengthens. This contraction may be performed with or without resistance. An example of an eccentric contraction performed without resistance is the lowering of the arm to the table when placing a napkin next to a plate. The biceps contracts eccentrically in this instance. An example of eccentric contraction against resistance is the controlled return of a pail of sand-lifted from the ground. In this example the biceps is contracting eccentrically to control the rate and coordination of the elbow extension in setting the pail on the ground.^{23,29}

Exercise and Activity Classifications

Isotonic Resistive Exercise

Resistive exercise uses isotonic muscle contraction against a specific amount of weight to move the load through a certain ROM.^{15,23,29} It is also possible to use eccentric contraction against resistance. Resistive exercise is used primarily for an increase in the strength of fair plus to normal muscles but may also be helpful for producing relaxation of the antagonists to the contracting muscles. This latter purpose can be useful if increased range is desired for stretching or relaxing hypertonic antagonists.

The client performs muscle contraction against resistance and moves the part through the available ROM. The resistance applied should be the maximum against which the muscle is capable of contracting. Resistance may be applied manually or by weights, springs, elastic bands, sandbags, or special devices. The source of resistance depends on the activity, and resistance is graded progressively with an increasing amount of resistance.^{15,23,29} The number of possible repetitions depends on the client’s general physical endurance and the endurance of the specific muscle.

Many types of strength training programs exist; most are based on the principle that to increase strength, the muscle must contract against its maximal resistance. The number of repetitions, rest intervals, frequency of training, and speed of movement vary with the particular approach and with the client's ability to accommodate to the exercise or activity regimen.¹⁰ One specialized type of resistive exercise is the DeLorme method of progressive resistive exercise (PRE).^{18,48} PRE is based on the overload principle: muscles perform more efficiently if given a warm-up period and must be taxed beyond usual daily activity to improve in performance and strength.¹⁸ During the exercise procedure, small loads are used initially and increased gradually after each set of 10 repetitions. The muscle is thus warmed up to prepare to exert its maximal power for the final 10 repetitions. The exercise procedure consists of three sets of 10 repetitions each, with resistance applied as follows: first set, 10 repetitions at 50% of maximal resistance; second set, 10 repetitions at 75% of maximal resistance; third set, 10 repetitions at maximal resistance.^{15,18,48} The load must be sufficient so that the client can perform 10 repetitions. As strength improves, resistance is increased so that 10 repetitions can always be performed.¹⁰ The client is instructed to inhale during the shortening contraction and exhale during the relaxation or eccentric contraction.^{18,48}

An example of a PRE is a triceps, capable of 12 pounds maximal resistance, extending the elbow, first against 6 pounds for 10 repetitions, then against 9 pounds for 10 repetitions, and the final 10 repetitions against 12 pounds. Maximal resistance, the amount of resistance the muscle can lift through the ROM 10 times, is determined by contracting the muscle and moving the part through the full ROM against progressively increasing loads for sets of 10 repetitions, until the maximal load that can be lifted 10 times is reached.

At the beginning of the treatment program it is often difficult for the therapist to determine the client's maximal resistance. Reasons may be that the client may not know how to exert maximal effort, may be reluctant to exercise strenuously for fear of pain or reinjury, may be unwilling or unable to endure discomfort, and may have difficulty with the timing of exercises.

The experience of the therapist and trial and error aid in the determination of maximal resistance. The therapist should estimate the amount of resistance the client can take based on the muscle test results and add or subtract resistance (weight or tension) until the client can perform the sets of repetitions adequately.

The exercises should be performed once daily, four or five times a week, and rest periods of 2 to 4 minutes should be allowed between each set of 10 repetitions. The exercise procedure may be modified to suit individual needs. Some possibilities are 10 repetitions at 25% of maximal resistance, 10 repetitions at 50%, 10 repetitions at 75%, and 10 repetitions at maximal resistance. Another possibility is five

repetitions at 50% and 10 repetitions at maximal resistance. Still another possibility is to omit the second set of exercises. Adjustments in the first two sets of exercises may be made to suit the capacity of the individual.¹⁸

Another approach is the Oxford technique, essentially a reverse of the DeLorme method. The exercise sequence begins with 100% resistance and decreases to 75%, and then to 50% on subsequent sets of 10 repetitions each.^{18,48} The greatest gains may be made in the early weeks of the intervention program, with smaller increases occurring at a slower pace in the subsequent weeks or months. During performance of the exercise, the therapist should be aware of joint alignment of the exercise device; proper fit and adjustment of the device; ruling out of substitute movements; and clear instruction on speed, ROM, and proper breathing.^{18,43}

OT Practice Notes

Application to Activity

Many purposeful activities lend themselves well to resistive exercise. For instance, leather lacing can offer slight resistance to the anterior deltoid if the lace is pushed in an upward direction. Sanding wood with a weighted sand block can offer substantial resistance to the anterior deltoid and triceps if done on an inclined plane. Activities such as sawing and hammering offer resistance to upper extremity musculature. Kneading dough and forming clay objects offer resistance to muscles of the hands and arms.

Isotonic Active Exercise

Isotonic muscle contraction is used in active exercise. Eccentric contraction may also be used. Active exercise is performed when the client moves the joint through its available ROM against no outside resistance. Active motion through the complete ROM with gravity decreased or against gravity may be used for poor to fair muscles to improve strength, with the added benefit of maintaining ROM. It may be used with higher muscle grades for the maintenance of strength and ROM when resistance is contraindicated. Active exercise is not used to increase ROM because this purpose requires added force not present in active exercise.

In active exercise, the client moves the part through the complete ROM independently. If the exercise is performed in a gravity-reduced or gravity-decreased plane, a powdered surface, skateboard may be used to reduce the resistance produced by friction on a supporting surface. A deltoid aid, or free-moving suspension sling may be used to support the extremity when moving in a gravity-decreased plane of motion. The exercise is graded by a change to resistive exercise as strength improves.^{23,29}

FIGURE 29-12 Latch hooking to provide active resistive exercise to the wrist extensors.

OT Practice Notes

Application to Activity

Activities that offer little or no resistance can be used as active exercises. A needlework activity performed in the gravity-decreased plane provides active exercise to the wrist extensors. When a grade of fair, or 3, is reached, the activity can be repositioned to move against gravity, or an alternate activity may be selected, such as latch hooking (Figure 29-12).

Active-Assisted Exercise

Isotonic muscle contraction is used in active-assisted exercise. The client moves the joint through partial ROM, and the therapist or a mechanical device completes the range. Slings, pulleys, weights, springs, or elastic bands may be used to provide mechanical assistance.⁴⁸ The goal of active-assisted exercise is to increase strength of trace, poor minus, and fair minus muscles while maintaining ROM. In the case of trace muscles, the client may contract the muscle, and the therapist completes the entire ROM. This exercise is graded by decreasing the amount of assistance until the client can perform active exercises.^{23,29}

OT Practice Notes

Application to Activity

It is often possible to include a passive limb in a bilateral activity if the contralateral limb is unaffected. Several of the activities described previously for active-assisted exercise can also be used for passive exercise.

FIGURE 29-13 Passive exercise of the wrist with stabilization of the joint proximal to the one being exercised.

Passive Exercise

In passive exercise, no muscle contraction occurs. Therefore, passive exercise is not used to increase strength because no force is applied. The purpose of passive exercise is to maintain ROM, thereby preventing contractures, adhesions, and deformity. To achieve this goal, the person should perform exercise for at least three repetitions, twice daily.²⁸ It is used when absent or minimal muscle strength (grades 0 to 1) precludes the active motion or when active exercise is contraindicated because of the client's physical condition. During the exercise procedure, the joint or joints to be exercised are moved through their normal ranges manually by the therapist or client, or mechanically by an external device such as a pulley or counterbalance sling. The joint proximal to the joint being exercised should be stabilized during the exercise procedure (Figure 29-13).²³

OT Practice Notes

Application to Activity

If assistance is required to complete the movement, an activity must be structured so that the client can get assistance from the therapist, the client's other arm or leg, or a mechanical device. Various bilateral activities lend themselves well to active-assisted exercise. Bilateral sanding, bilateral sponge wiping, using a sweeper, and sawing are some examples. In bilateral activities the unaffected arm or leg can perform a major share of the work, and the affected arm or leg can assist to the extent possible.

Passive Stretch

For passive stretching, the therapist moves the joint through the available ROM and holds momentarily, applying a gentle but firm force or stretch at the end of the ROM.

No residual pain should occur when the stretching is discontinued. Passive stretch or forced exercise is meant to increase ROM. It is used when a loss of joint ROM occurs and stretching is not contraindicated. If muscle grades are adequate, the client can move the part actively through the available ROM and the therapist can take it a little farther, thus forcing or stretching the soft-tissue structures around the joint.

Passive stretching requires a good understanding of joint anatomy and muscle function. It should be carried out cautiously under good medical supervision and with medical approval. Muscles to be stretched should be in a relaxed state.²⁹ The therapist should never force muscles when pain is present, unless ordered by the physician to work through pain. Gentle, firm stretching held for a few seconds is more effective and less hazardous than quick, short stretching. The body parts around the area being stretched should be stabilized, and compensatory movements should be prevented. Incorrect stretching procedures can produce muscle tearing, joint fracture, and inflammatory edema.²⁸

OT Practice Notes
Application to Activity

Passive stretching may be incorporated into an activity if an unaffected part guides the movement of the affected part and forces it slightly beyond the available ROM. One example is the passive stretch of wrist flexors during a block printing activity if the block is pressed down to stabilize it with an open hand while the client is standing.

Active Stretch

The purpose of active stretch is the same as for passive stretch: to increase joint ROM. In active stretching, the client uses the force of the agonist muscle to increase the length of the antagonist. This requires good to normal strength of the antagonist, good coordination, and motivation of the client. For example, forceful contraction of the triceps to stretch the biceps muscle can be performed. Because the exercise may produce discomfort, a natural tendency exists for the client to avoid the stretching component of the movement. Therefore, supervision and frequent evaluation of its effectiveness are necessary.

OT Practice Notes
Application to Activity

Many activities can be used to incorporate active stretching. For example, slowly sawing wood requires a forceful contraction of the triceps with a concomitant stretch of the biceps.

Isometric Exercise without Resistance

Isometric exercise uses isometric contractions of a specific muscle or muscle group. In isometric exercises, a muscle or group of muscles is actively contracted and relaxed without producing motion of the joint that it ordinarily moves. The purpose of isometric exercise without resistance is to maintain muscle strength when active motion is not possible or is contraindicated. It may be used with any muscle grade above trace. It is especially useful for clients in casts, after surgery, and with arthritis or burns.¹⁵

The client is taught to set or contract the muscles voluntarily and to hold the contraction for 5 or 6 seconds. Without offering resistance, the therapist's fingers provide a kinesthetic image of resistance and help the client learn to set the muscle. If needed, the therapist's fingers may be placed distal to the joint on which the muscles act. If passive motion is allowed, the therapist may move the joint to the desired point in the ROM and ask the client to hold the position.

Isometric exercise affects the cardiovascular system, which may be a contraindication for some clients. It may cause a rapid and sudden increase in blood pressure, depending on the client's age, the intensity of contraction, and the muscle mass being contracted. Therefore, it should be used with caution.¹⁵

Isometric Exercise with Resistance

Isometric exercise with applied resistance uses isometric muscle contraction performed against some outside resistance. Its purpose is to increase muscle strength in muscles graded fair, or 3, to normal, or 5. The client sets the muscle or muscle group while resistance is applied and holds the contraction for 5 or 6 seconds. Isometric exercises should be performed for one exercise session per day, 5 days a week. In addition to manual resistance, the client may hold a weight or resist against a solid surface, depending on the muscle group being exercised. A small weight held in the hand while the wrist is stabilized at neutral requires isometric contractions of the wrist flexors and extensors.

Exercise is graded by increasing the amount of resistance or the degree of force the client holds against. A tension gauge should be used to accurately monitor the amount of resistance applied. Isometric exercises are effective for increasing strength, but isotonic exercise is the method of choice. Isometric exercise has several specific applications, as in arthritis, when joint motion may be contraindicated but muscle strength must be increased or maintained.^{23,43} The cardiovascular precautions stated previously are particularly important with isometric resistive exercise.

Neuromuscular Control and Coordination

Procedures for the development of neuromuscular control and neuromuscular coordination are briefly outlined in the following paragraphs. The reader is referred to original sources for a full discussion of the neurophysiologic mechanisms underlying these exercises. Neuromuscular education

OT Practice Notes Application to Activity

Any activity that requires holding or static posture incorporates isometric exercise. Holding tool handles and holding the arm in elevation while painting are examples. This type of exercise, if contraction is sustained, can be very fatiguing.

or control training involves teaching the client to control individual muscles or motions through conscious attention. Coordination training is used to develop preprogrammed multimuscular patterns or engrams.²⁷

Neuromuscular Control

It may be desirable to teach control of individual muscles when they are so weak that they cannot be used normally. The purpose is to improve muscle strength and muscle coordination to new patterns. To achieve these ends, the person must learn precise control of the muscle, an essential step in the development of optimal coordination for persons with neuromuscular disease.

To participate successfully, the client must be able to learn and follow instructions, cooperate, and concentrate on the muscular retraining. Before beginning, the client should be comfortable and securely supported. The exercises should be carried out in a nondistracting environment. The client must be alert, calm, and rested. He or she should have an adequate pain-free arc of motion of the joint on which the muscle acts, in addition to good proprioception. Visual and tactile sensory feedback may be used to compensate or substitute for limited proprioception, but the coordination achieved will never be as efficient as when proprioception is intact.²⁷

The client is first made aware of the desired motion and the muscles that produce it when the therapist uses passive motion to stimulate the proprioceptive stretch reflex. This passive movement may be repeated several times. The client's awareness may be enhanced if the therapist also demonstrates the desired movement and if the movement is performed by the analogous unaffected part. The skin over the muscle belly and tendon insertion may be stimulated to enhance the effect of the stretch reflex. Stroking and tapping over the muscle belly may be used to facilitate muscle action.²⁷

The therapist should explain the location and function of the muscle, its origin and insertion, line of pull, and action on the joint. The therapist should then demonstrate the motion and instruct the client to think of the pull of the muscle from insertion to origin. The skin over muscle insertion can be stroked in the direction of pull while the client concentrates on the sensation of the motion during the passive movement performed by the therapist.

The exercise sequence begins with instructions to the client to think about the motion, while the therapist carries

it out passively and strokes the skin over the insertion in the direction of the motion. The client is then instructed to assist by contracting the muscle while the therapist performs passive motion and stimulates the skin as before. Next the client moves the part through ROM with assistance and cutaneous stimulation, while the therapist emphasizes contraction of the prime mover only. Finally the client carries out the movement independently, using the prime mover.

The exercises must be initiated against minimal resistance if activity is to be isolated to prime movers. If the muscle is very weak (trace to poor), the procedure may be carried out entirely in an active-assisted manner so that the muscle contracts against no resistance and can function without activating synergists. Progression from one step to the next depends on successful performance of the steps without substitutions. Each step is carried out three to five times per session for each muscle, depending on the client's tolerance.

Coordination Training

The goal of coordination training is to develop the ability to perform multimuscular motor patterns that are faster, more precise, and stronger than those performed when control of individual muscles is used. The development of coordination depends on repetition. Initially in training, the movement must be simple and slow so that the client can be consciously aware of the activity and its components. Good coordination does not develop until repeated practice results in a well-developed activity pattern that no longer requires conscious effort and attention.

Training should take place in an environment in which the client can concentrate. The exercise is divided into components that the client can perform correctly. Kottke calls this approach *desynthesis*.²⁷ The level of effort required should be kept low, by reducing speed and resistance, to prevent the spread of excitation to muscles that are not part of the desired movement pattern. Other theorists offer contrary advice, which emphasizes the integration of movements that customarily occurs during activity. The therapist's experience and judgment are important in determining which method to use.

When the motor pattern is divided into units that the client can perform successfully, each unit is trained by practice under voluntary control, as described previously for training of control. The therapist instructs the client in the desired movement and uses sensory stimulation and passive movement. The client must observe and voluntarily modify the motion. Slow practice is imperative to make this monitoring possible. The therapist offers enough assistance to ensure precise movement while allowing the client to concentrate on the sensations produced by the movements. When the client concentrates on movement, fatigue occurs rapidly and the client should be given frequent, short rests. As the client masters the components of the pattern and performs them precisely and independently, the sequence

is graded to subtasks or several components that are practiced repetitively. As the subtasks are perfected, they are linked progressively until the movement pattern can be performed.

The protocol can be graded for speed, force, or complexity, but the therapist must be aware that the increased effort put forth by the client may result in incoordinated movement. Therefore, the grading must remain within the client's capacity to perform the precise movement pattern. The motor pattern must be performed correctly to prevent the development of faulty patterns.

If CNS impulses are generated to muscles that should not be involved in the movement pattern, incoordinated motion results. Constant repetition of an incoordinated pattern reinforces the pattern, resulting in a persistent incoordination. Factors that increase incoordination are fear, poor balance, too much resistance, pain, fatigue, strong emotions, prolonged inactivity,²⁷ and excessively prolonged activity.

OT Practice Notes Application to Activity

OT can be used to develop coordination, strength, and endurance. Active occupations have the advantage of engaging the client's attention and interest. Activities should be structured to enable the client to use the precise movement pattern and to work at speeds consistent with the maintenance of precision.

Therapists may initiate coordination training with neuromuscular education and progress to repetitious activities requiring desired coordinated movement patterns. Placing small blocks, marbles, cones, paper cups, or pegs is an enabling activity that demands repetitious patterns of nonresistive movement. Purposeful activities such as leather lacing, mosaic tile work, needlecrafts, and household tasks such as wiping, sweeping, and dusting also provide such repetitious movements.

Physical Agent Modalities

The introduction of physical agent modalities (PAMs) into OT practice generated considerable controversy.^{51,54} The use of such modalities was initiated by OTs who specialize in hand rehabilitation, in which inclusion of physical agents in a comprehensive treatment program became expedient.^{45,47} After much study and discussion, the AOTA published a position paper on physical agent modalities.^{3,5} In this official document, physical agents were defined and their use as adjuncts to or preparation for purposeful activity was specified. "The exclusive use of physical agent modalities as a treatment method during a treatment session without application to a functional outcome is not considered occupational therapy."⁵ Further, the use of PAMs is not considered entry-level practice: rather, appropriate

postprofessional education is required to ensure competence of the OT practitioners using these modalities.⁵ The AOTA stipulated that the practitioner must have documented evidence of the theoretic background and technical skills to apply the modality and integrate it into an OT intervention plan.^{3,5} Generated from these notions, a number of states have required in their licensure laws that OTs have advanced training to use PAMs in treatment.

PAMs are used before or during functional activities to enhance the effects of the OT intervention program. This section introduces the reader to basic techniques and when and why they may be applied. Because OTs most commonly use modalities for treatment of hand injuries and diseases, the examples provided are focused on intervention to improve upper extremity function. The use of the techniques described is not limited to the treatment of hands, however.

Thermal Modalities

In a clinical setting, heat is used to increase motion, decrease joint stiffness, relieve muscle spasms, increase blood flow, decrease pain, and aid in the reabsorption of exudates and edema in a chronic condition.³³ Collagen fibers have an elastic component and when stretched will return to their original length. Applying heat before a prolonged stretch, as in dynamic splinting, allows the permanent elongation of these fibers. The blood flow maintains a person's core temperature at 98.6° F. To obtain maximum benefits from heat, tissue temperature must be raised to 105° to 113° F. Precautions must be taken with temperatures above this range to prevent tissue destruction.

Contraindications to the use of heat include acute inflammatory conditions of the joints or skin, sensory losses, impaired vascular structures, malignancies, and application to the very young or very old. The use of heat may substantially enhance the effects of splinting and therapeutic activities that attempt to increase range of motion and functional abilities.

Conduction

Conduction is the transfer of heat from one object to another through direct contact. Paraffin and hot packs provide heat by conduction. Paraffin is stored in a tub that maintains a temperature between 125° and 130° F. The client repeatedly dips his or her hand into the tub until a thick, insulating layer of paraffin is applied to the extremity. The hand is then wrapped in a plastic bag and towel for 10 to 20 minutes.³³ This technique provides an excellent conforming characteristic, so it is ideal for use in hands and digits. Partial hand coverage is possible. The paraffin transfers its heat to the hand, and the bag and towel act as an insulator against dissipation of heat to the air.

Care must be taken to protect insensate parts from burns. To prevent excessive vasodilation, paraffin should not be applied when moderate to severe edema is present. It cannot be used if open wounds are present. Paraffin can be used in the clinic or incorporated into a home program.

The tubs are small, and the technique is safe and easy to use in the home. It is an excellent adjunct to home programs that include dynamic splinting, exercises, or general ADLs. It may be used in the clinic before therapeutic exercises and functional activities.

Hot packs contain either a silicate gel or a bentonite clay wrapped in a cotton bag and submerged in a Hydrocollator, a water tank that maintains the temperature of the packs at 160° to 175° F.³³ Because tissue damage may occur at these temperatures, the packs are separated from the skin by layers of towels. As with paraffin, precautions should be taken in application of hot packs to insensate tissue that has sustained vascular damage. Hot packs are commonly used for myofascial pain, before soft-tissue mobilization, and before any activities aimed at elongating contracted tissue.¹⁴ For a client with a hand injury, the packs may be applied to the extrinsic musculature to decrease muscle tone caused by guarding, without also heating the hand. Unless contraindicated, hot packs can be used (with precautions) when open wounds are present.

Convection

Convection supplies heat to the tissues by fluid motion around the tissues. Examples of convection are whirlpool and fluidotherapy. Whirlpool is used more commonly for wound management than for heat application. Fluidotherapy involves a machine that agitates finely ground cornhusk particles by blowing warm air through them. This device is similar to the whirlpool, but corn particles are used instead of water. The temperature is thermostatically maintained, with the therapeutic range extending to 125° F. Studies have shown this technique to be excellent for raising tissue temperature in the hands and feet.¹⁴ An additional benefit is its effect on desensitization. The agitator can be adjusted to decrease or increase the flow of the corn particles, thus controlling the amount of stimulation to the skin. Because an extremity can be heated gradually, this technique is effective as a warm-up before exercises, dexterity tasks, functional activities, and work simulation tasks.

Conversion

Conversion occurs when heat is generated internally by friction—for example, by means of ultrasound. The sound waves penetrate the tissues, causing vibration of the molecules, and the resulting friction generates heat. The energy of sound waves is thus converted to heat energy. The sound waves are applied with a transducer, which glides across the skin in slow, continuous motions. Gel is used to improve the transmission of the sound to the tissues. Ultrasound is considered a deep heating agent. At 1 MHz (1 million cycles per second), it can heat tissues to a depth of 5 cm. The previous methods produce heating to 1 cm.³⁷ Many therapeutic ultrasound machines provide a 3-MHz option for treatment of more superficial structures, with the corresponding heating depth reduced to 3 cm. Ultrasound at frequencies higher than recommended standards can destroy

tissue. In addition, precautions must be taken to avoid growth plates in the bones of children, an unprotected spinal cord, and freshly repaired structures such as tendons and nerves. Because of its ability to heat deeper tissues, ultrasound is excellent for treating problems associated with joint contractures, scarring with its associated adhesions, and muscle spasms. When applying the ultrasound, the therapist should apply a stretch to the tissues while they are being heated, followed by activities, exercises, and splints to maintain the stretch.

Ultrasound may also be used in a nonthermal application, in which the ultrasound waves are used to drive anti-inflammatory medications into tissues. This process is called phonophoresis. Ultrasound is thought to increase membrane permeability for greater symptom relief and may also be used after corticosteroid injections.

Cryotherapy, the use of cold in therapy, is often used in the treatment of edema, pain, and inflammation. The cold produces a vasoconstriction, which decreases the amount of blood flow into the injured tissue. Cold decreases muscle spasms by decreasing the amount of firing from the afferent muscle spindles. Cryotherapy is contraindicated for clients with cold intolerance or vascular repairs. The use of cryotherapy may be incorporated into intervention programs provided in the clinical setting; however, it is particularly useful in a home program.

Cold packs can be applied in a number of ways. Many commercial packs exist, which range in size and cost. An alternative to purchasing a cold pack is to use a bag of frozen vegetables or to combine crushed ice and alcohol in a plastic bag to make a reusable slush bag. Ice packs should be covered with a moist towel to prevent tissue injury. The benefit of commercial packs is that they are easy to use, especially if the client must use them frequently during the day. When clients are working, it is recommended that they keep cold packs at home and at work to increase the ease of use. The optimum temperature for storing a cold pack is 45° F.

Other forms of cryotherapy include ice massage and cooling machines. Ice massage is used when the area to be cooled is small and very specific—for example, inflammation of a tendon specifically at its insertion or origin. The procedure entails using a large piece of ice (water frozen in a paper cup) and massaging the area with circular motions until the skin is numb, usually for 4 to 5 minutes. Cooling devices, which circulate cold water through tubes in a pack, are available through vendors. These devices maintain their cold temperatures for a long time, but they are expensive to rent or purchase. They are effective in reducing edema immediately after surgery or injury, during the inflammatory phase of wound healing.

Contrast baths combine the use of heat and cold. The physical response is alternating vasoconstriction and vasodilation of the blood vessels. The client is asked to submerge the arm—for example, alternating between two tubs of water. One contains cold water (59° to 68° F), and the other

contains warm water (96° to 105° F). The purpose is to increase collateral circulation, which effectively reduces pain and edema. As with the use of cold packs, contrast baths are a beneficial addition to a home therapy program. This technique is contraindicated for clients with vascular disorders or injuries.

Electrical Modalities

Electrical modalities are used to decrease pain, decrease edema, increase motion, and reeducate muscles. As with all PAMs, OTs use these modalities to increase a client's functional abilities. Many techniques are available; those most commonly used are presented here. Electrical modalities should not be used with clients with pacemakers or cardiac conditions.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) employs electrical current to decrease pain. Pain is classified in three categories: physical, physiologic, and psychological. When trauma occurs, an individual responds to the initial pain by guarding the painful body part, often by restricting motion of the body part or assuming a posture that limits use of the painful body part. This guarding may result in muscle spasms and fatigue of the muscle fibers, especially after prolonged guarding. The supply of blood and oxygen to the affected area decreases, and resultant soft-tissue and joint dysfunction occurs.³⁶ These reactions magnify and compound the problems associated with the initial pain response. The therapist's goal after an acute injury is to prevent this cycle. In the case of chronic pain, the goal is to stop the cycle that has been established. TENS is an effective technique for control of pain without the side effects of medications. Pain medications are frequently used in conjunction with TENS, which often reduces the duration of their use. TENS is safe to use, and clients can be educated in independent home use.

TENS provides constant electrical stimulation with a modulated current and is directed to the peripheral nerves through electrode placement. The therapist can control several attributes of the modulation waveform such as the frequency, amplitude, and pulse width. When TENS is applied at a low-fire setting, endogenous opiates are released. Endorphins, naturally occurring substances, reduce the sensation of pain. The effects of high-frequency TENS are based on the gate control theory originally proposed by Melzack and Wall in 1965. This theory describes how the electrical current from TENS, applied to the peripheral nerves, blocks the perception of pain in the brain. Nociceptors (pain receptors) transmit information to the CNS through the A-delta, and C fibers. A-delta fibers transmit information about pressure and touch. It is thought that TENS stimulates the A fibers, effectively saturating the gate to pain perception, and the transmission of pain signals via the A-delta and C fibers is blocked at the level of the spinal cord.³⁵ TENS can be applied for acute or chronic pain.

TENS is frequently used postsurgically, when it is mandatory that motion be initiated within 72 hours such as in tenolysis and capsulotomy surgeries or when it is important to maintain tendon gliding through the injured area after fractures.

TENS can be especially helpful with clients who have a low threshold to pain because it makes exercising easier. TENS is also useful when working with clients with reflex sympathetic dystrophy because continued active motion is crucial.

TENS can be used to decrease pain from an inflammatory condition such as tendonitis or a nerve impingement; however, the client must be educated in tendon and nerve protection and rest, with a proper home program of symptom management, positioning, and ADL and work modification. Without the sensation of pain, the client may overdo and stress the tissues. Other techniques should be tried first to decrease pain for these clients. TENS is also used for treatment of trigger points, with direct electrode application to the trigger point to decrease its irritability.³⁸

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) provides a continuous interrupted current. It is applied through an electrode to the motor point of innervated muscles to provide a muscle contraction. The current is interrupted to enable the muscle to relax between contractions, and the therapist can adjust the durations of the on and off times. Adjustments can also be made to control the rate of the increase in current (ramp) and intensity of the contraction.

NMES is used to increase ROM, facilitate muscle contractions, and strengthen muscles.³⁹ It may be used postsurgically to provide a stronger contraction for released tendon gliding—for example, after a tenolysis. It also may be used later in the tendon repair protocol, once the tendon has healed sufficiently to tolerate stress, usually at a minimum of 6 weeks. NMES may be used to lengthen a muscle that has become weakened because of disuse. During the reinnervation phase after a nerve injury, this technique may be used to help stimulate and strengthen a newly innervated muscle. Care must be taken not to overfatigue the muscle. NMES can be applied during a dexterity or functional activity, which allows the muscle to be retrained in the purpose of its contraction. As with TENS, NMES may be incorporated into a home program with proper client education and follow-through.

Other techniques that use an electrical current include high-voltage galvanic stimulation (HVGS) and inferential electrical stimulation. These techniques are applied to treat pain and edema.³⁹ Electrical stimulation may be applied in conjunction with ultrasound through a single transducer to provide heat simultaneously with current. This approach is beneficial in treatment of trigger points and myofascial pain. Iontophoresis uses a current to drive ionized medication into inflamed tissue and scar tissue. The technique uses an electrode filled with the medication of choice. The

medicine is transferred by applying an electric field that repels the ions into the tissues.

Selection of Appropriate Modalities in the Continuum of Care

Many years ago professional roles and responsibilities were more specifically delineated. OTs initiated therapy with clients only after the clients were capable, at least to some degree, of performing purposeful activity.¹⁹ Evolution of intervention methods, trends in healthcare, and medical technology have significantly altered the role of therapists and expanded the repertoire of treatment modalities that they are competent to practice.

Clients are now referred to OT long before they are capable of performing purposeful activity. Therapists are treating clients in the very acute stages of illness and disability. Intervention is directed toward preparing the client for the time when purposeful activity is possible. This approach may mean that the OT applies a positioning splint to a client immediately after hand surgery, considering how the hand will be used in a later phase of the intervention program and in real life. It means the therapist may use sensory stimulation for the client who is comatose because arousal and interacting with persons and objects in the environment will make performance of purposeful activity possible in the future. It means the therapist may apply paraffin to decrease joint stiffness and increase mobility of finger joints before engaging in a macramé project. It also may mean preparing the client and family to plan for the future, when life skills may need to be performed in new ways, such as modified sexual positioning for clients with arthritis. The unique perspective of the OT is seeing the potential for performance and using modalities that lead incrementally to performance relevant to the lives clients wish to lead.

Summary

Engagement in occupation is the primary tool and objective of OT practice. OTs use purposeful activity, activity analysis, adaptation, grading of activities, therapeutic exercise, simulated or enabling activities, and adjunctive modalities in the continuum of intervention, and they may use these methods simultaneously toward these ends. Through this breadth of practice skills, based on the client's personal and social needs, the OT helps the client apply newly gained strength, ROM, and coordination during the performance of purposeful activity, which prepares the client to assume or reassume life roles. Appropriate therapeutic activity is individualized and designed to be meaningful and interesting to the client while meeting therapeutic objectives.

Therapeutic activity may be adapted to meet special needs of the client or the environment. It may be graded for physical, perceptual, cognitive, and social purposes to keep the client functioning at maximal potential at any

point in the treatment program. The uniqueness of OT lies in its extensive use of goal-directed purposeful activities as treatment modalities, making use of the mind-body continuum within the tangible and social context. Purposeful activity is the core of OT practice.

In practice, therapists' roles may not be sharply defined because they are subject to variations in expectations that stem from regional differences, healthcare developments, legislation, institutional philosophy, and the roles and responsibilities assigned by the treatment facility. In all instances, OTs must be well trained and well qualified to deliver all aspects of practice. They should not hesitate to refer clients to experts for treatment whenever appropriate.

Review Questions

1. Identify the three realms of occupational genesis and their relation to the concept of development.
2. Define modality.
3. What is required for an activity to be considered purposeful?
4. Name two reasons why activity is valuable.
5. Name a client-centered tool used to identify clients' goals, objectives, and lifestyles.
6. Name three perspectives of activity analysis.
7. What term best describes how activities and environments are modified to meet the individualized needs of clients?
8. What is used to create the "just right" challenge in performance?
9. What term refers to activities that are contrived to elicit movements but are considered nonpurposeful?
10. When are adjunctive modalities appropriately used by OTs?
11. For which types of disabilities would therapeutic exercise (as defined in this chapter) be inappropriate?
12. List and define three types of muscle contraction.
13. Identify an activity that can be used to provide resistive exercise, and describe how it could be done.
14. List four general categories of physical agent modalities.
15. What kinds of symptoms are treated with cryotherapy?

■ Appendix 29-1

Activity Analysis

The activity analysis offers the reader one systematic approach for looking at the therapeutic potential of activities.³¹ This model includes some factors that must be considered about the performer, the environmental context, and the activity in the selection of purposeful, therapeutic activity. In the model, just two steps of a multistep activity are analyzed for the sake of space and simplicity. The reader is encouraged to complete the motor analysis by considering movements of the shoulder, forearm, and wrist that accompany the pinch and release pattern analyzed.

I. Preliminary Information.

- A. Name of activity: Pinch pottery.
- B. Components of the task.
 1. Roll some clay into a ball, 3 to 4 inches in diameter.
 2. Place the ball centered on the worktable in front of the performer.
 3. Make a hole in the center of the ball with the right or left thumb (Figure 29-14).
 4. With the thumb and first two fingers of both hands, pinch around and around the hole from the base to the top of the ball.
 - a. Pinch by pressing the thumb against the index and middle fingers.
 - b. Release pinch by extending the thumb and the index and middle fingers slightly.
 5. Continue pinching in this way, gradually spreading the walls of the clay until a small bowl of the desired size is formed.
- C. Steps of activity being analyzed.
 1. Pinch.
 2. Release.
- D. Equipment and supplies necessary.
 1. Ball of soft ceramic clay.

FIGURE 29-14 Opening a pinch pot with the thumb.

(From Breines EB: *Occupational therapy from clay to computers: theory & practice*, Philadelphia, 1995, FA Davis.)

2. Wooden table 30 to 32 inches high or a wooden work surface fastened to a table with C clamps.
3. Chair at the worktable.
4. Sponge and bowl of water.
5. Ceramic smoothing tool.
- E. Environmental context^{16,17}: OT workshop or craft activity room. A sink and damp storage area should be available in the work area. There should be ample room around the worktable so that the performer is not crowded and can move freely between the table and the sink and damp storage closet. Lighting should be adequate for clear visualization of the clay object and work area.
- F. Position of the performer in relation to the work surface and equipment: The performer is seated in the chair at the table, at a comfortable distance for reaching and manipulating the clay and tools. The clay is centered in front of the performer, and the tool, sponge, and water bowl are to the right and near the top of the work area.

- G. Starting position of the performer: Sitting erect with feet flat on the floor; shoulders are slightly abducted and in slight internal rotation, bringing both hands to the center work surface; elbows are flexed to about 90 degrees; forearms are pronated about 45 degrees; wrists are slightly extended and in ulnar deviation, thumbs are opposed to index and middle fingers, ready to pinch the posterior surface of the opened clay ball.
 - H. Movement pattern used to perform the steps under analysis: Flexion of the MP and IP joints of index and middle fingers; opposition and flexion of the thumb (pinch) followed by extension of the MP and IP joints index and middle fingers and extension and palmar abduction of the thumb (release). Repeat the pattern around the ball of clay until a small bowl of desired size and thickness is formed.
- II. Motor Analysis.²⁶
- A. Joint and muscle activity: List the joint motions for all movements used during performance of the activity. For each, indicate amount of ROM used (minimal, moderate, or full), muscle group used to perform the motion, strength required (minimal [P to F], moderate [F to G], and full [G to N]), and type of muscle contraction (isotonic, isometric, eccentric) (Table 29-1).
 - B. Grading: Grade this activity for one or more of the following factors:
 1. ROM: Cannot be graded for ROM.
 2. Strength: Grade for strength by increasing the consistency of the clay.
 3. Endurance: Grade for sitting tolerance by increasing the length of activity sessions.
 4. Grade for sitting balance by decreasing sitting support.
 5. Coordination: Requires fine coordination as performed; grade coordination by adding scored or painted designs to surface; grade to sculpture of small clay figures.
 - C. Criteria for activity as exercise.
 1. Action of joints: Movement localized to flexion and extension of MP and IP joints of index and middle fingers; CMC, MP, and IP joint of thumb.
 2. Repetition of motion: The pinch and release sequence is repeated until the bowl has reached the desired height and thickness.

■ TABLE 29-1 | Motions for Pinch

Joint Motion	Range of Motion	Muscle Group	Strength	Type of Muscle Contraction
Index and Middle Fingers				
MP flexion	Minimal	FDP, FDS lumbricales	Moderate	Isotonic
PIP flexion	Minimal	FDP, FDS	Moderate	Isotonic
DIP flexion	Minimal	FDP	Moderate	Isotonic
Finger adduction	Maximal	Palmar interossei	Moderate	Isometric
Thumb				
Opposition	Full	Opponens pollicis, FPI, FPB	Moderate	Isotonic
Motions for Release Index and Middle Fingers				
MP extension	Minimal	EDC, EIP	Minimal	Isotonic
PIP and DIP extension	Minimal	EDC, EIP	Minimal	Isotonic
Finger adduction	Maximal	Palmar interossei	Moderate	Isometric
Thumb				
Radial abduction	Moderate	APL, APB	Minimal	Isotonic
MP, IP extension	Full	EPL, EPB	Minimal	Isotonic

Adapted from Killingsworth A: *OT120 activity module*, San Jose, CA, 1989, San Jose State University.
 APB, Abductor pollicis brevis; APL, abductor pollicis longus; DIP, distal interphalangeal; EDC, extensor digitorum communis; EIP, extensor indicis proprius; EPB, extensor pollicis brevis; EPL, extensor pollicis longus; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FPB, flexor pollicis brevis; FPL, flexor pollicis longus; IP, interphalangeal; MP, metacarpophalangeal; PIP, proximal interphalangeal.

■ **TABLE 29-2 | Sensory Analysis**

Sensory Modality		How Received
Tactile	X	Touching clay and tools
Proprioceptive (joint motion and position sense)	X	Being aware of joint position and motion during pinch/release
Vestibular (balance, sense of body, head motion)	X	Maintaining posture in chair while performing activity
Visual	X	Seeing clay object, environment
Olfactory (smell)	X	Smelling a slight odor of damp clay
Pain	O	
Thermal (temperature)	X	Hands sensing coldness of clay
Pressure	X	Fingertips and thumb tips pressing against walls of clay bowl
Auditory (hearing)	O	
Other		

O, Sensory stimuli not received; X, sensory stimuli received.

3. Gradable: The activity is gradable for strength and endurance.
- III. Sensory Analysis:^{34,35} Check the sensory stimuli received by the person performing the activity. Include any sensory experience obtained from position, motion, materials, or equipment. Describe how sensation is received (Table 29-2).
- IV. Cognitive Analysis:³⁴ Check all that apply and justify your answer (Table 29-3).
- V. Safety Factors: What are the potential hazards of this activity? Describe safety precautions necessary for this activity. There are few hazards in this activity. Ingesting clay or using the smoothing tool inappropriately is possible. Also, sitting balance must be adequate to maintain the upright posture required to perform the activity. Precautions must be taken: adequate supervision should be provided to ensure the appropriate use of clay and tool, and the task should be performed from a wheelchair with supports if sitting balance is impaired.
- VI. Interpersonal Aspects of Activity.
 - A. Solitary activity: May be done alone.
 - B. Potential for dyadic interaction: May be done in parallel with one other person but does not require interaction.

■ **TABLE 29-3 | Cognitive Analysis**

Cognitive Skill		Justification
Memory	X	Remembers instruction
Sequencing (steps in order)	X	Performs steps in order
Problem-solving skills	X	Knows what to do if clay is too wet or too dry, if walls of bowl are too thin or too thick
Following Instructions		
Spoken	X	Is able to comprehend and follow spoken instructions
Demonstrated	X	Is able to comprehend and follow demonstrated instructions
Written	O	
Concentration and attention required	X	Moderate: focuses on bowl and knows when its walls are thin enough and high enough

O, Cognitive skill not used; X, cognitive skill required in activity.

- C. Potential for group interaction: May be done in a group but does not require interaction.
- VII. Psychological and Psychosocial Factors.
 - A. Symbolism in performer's culture:¹⁶ May be seen as more feminine than masculine in mainstream American culture; may be associated with the artistic, liberal, naturalist groups of people in American society.
 - B. Symbolic meaning of activity to performer: May be seen as a leisure skill rather than work; may be regarded as child's play by some persons.
 - C. Feelings or reactions evoked in performer during performance of activity:³⁴ The soft, moist, pliable, and plastic properties of the clay may evoke soothing feelings in many persons; others may regard it as messy or dirty. The potential for personal gratification is good because an attractive end product is easy to achieve; the activity is creative, individualistic, and useful.
- VIII. Therapeutic Use of Activity.
 - A. List the autonomous goal of the activity: To make a small clay bowl.
 - B. List possible therapeutic objective(s) for the activity.
 1. To increase pinch strength.
 2. To improve coordination of opposition.
 3. To increase sitting tolerance.

Orthotics

■ Chapter Outline

Section 1: Hand Splinting: Principles, Practice, and Decision Making

Role of the occupational therapist

Anatomic structures of the hand

Wrist

Metacarpal joints

Metacarpophalangeal joints

Thumb

Interphalangeal joints

Forearm rotation

Ligaments of wrist and hand

Muscles and tendons of forearm, wrist, and hand

Nerve supply

Blood supply

Skin

Superficial anatomy and landmarks

Prehension and grasp patterns

Lateral prehension

Palmar prehension

Tip prehension

Cylindrical grasp

Spherical grasp

Hook grasp

Intrinsic plus grasp

Mechanics of the hand and principles of splinting

Axis of motion

Force

Splint classifications

Splints classified by type

Splints classified by purpose

Splints classified by design

When to splint and when not to splint

Compliance issues

Ability to don and doff a splint

Skin tolerance and hypersensitivity

Wearing schedule

Splint fabrication process

Step one: creating a pattern

Step two: choosing appropriate material

Step three: choosing the type of traction

Step four: choosing a splint design for a given purpose

Step five: fabrication

Section 2: Suspension Arm Devices and Mobile Arm Supports

Suspension arm devices

Purposes

Variations in suspension arm devices

Adjustment of suspension arm devices

Training in the use of suspension arm devices

Mobile arm supports

How mobile arm supports work

Criteria for use

Adjustment of mobile arm supports

Training

Special parts of the mobile arm support

Current development and future research

Summary

■ Key Terms

Orthosis

Tenodesis

Axis of motion

Force

Friction

Torque

Translational forces

Dynamic splints

Static splint

Serial static splint

Static progressive splints

Restriction splints

Immobilization splints

Mobilization splints

Suspension arm devices

Mobile arm supports

■ **Learning Objectives** After studying this chapter, the student or practitioner will be able to do the following:

1. Identify basic hand anatomy.
2. Describe the difference between single-axis and multi-axis joints and explain how they relate to splinting.
3. Define torque and describe how a splint produces torque.
4. Discuss the relationship of angle of approach to dynamic splinting.
5. Describe the three major purposes and goals of splints and when they should be employed.
6. Demonstrate an understanding of the principles of making a splint pattern.
7. Identify three characteristics of low-temperature thermoplastic material.
8. Discuss two ways in which splints may apply force.
9. Demonstrate how to determine the proper length of a forearm-based splint.
10. List the purposes of suspension arm devices.
11. Describe the limitations of the suspension arm support.
12. List the elements of adjustment for suspension arm devices.
13. Briefly describe the evolution of the traditional mobile arm support (MAS) and name its parts.
14. List the benefits of the MAS for persons with severe upper extremity weakness.
15. List the criteria for use of the MAS and describe how it works.
16. List two special parts of the MAS.
17. Describe the advantages of the JAECO-Rancho Multilink Mobile Arm Support.

According to *Mosby's Medical, Nursing, & Allied Health Dictionary*, orthotics is “the design and use of external appliances to support a paralyzed muscle, promote a specific motion, or correct musculoskeletal deformities”; an **orthosis** is “a force system designed to control, correct, or compensate for a bone deformity, deforming forces, or forces absent from the body ... [and] often involves the use of special braces”; and a splint is “an orthopedic device for immobilization, restraint, or support of any part of the body.”² Splints and suspension arm devices can be considered orthoses. Occupational therapists (OTs) often design and construct splints. An orthotist usually designs and constructs suspension arm devices, and OTs adjust them and train clients to use them. In practice, the term *orthosis* is used more frequently to refer to suspension arm devices than splints. Hand splinting is the topic of [Section 1](#) of this chapter, and suspension arm devices are described in [Section 2](#).

■ **SECTION 1 | Hand Splinting: Principles, Practice, and Decision Making**

DONNA LASHGARI

The human hand is the brain's most important instrument for exploring and mastering the world. We read with our hands if we suffer loss of vision; we communicate with our hands in the absence of speech or hearing. Our hands give us expression and console us. We first explore our hands and explore with our hands as infants. The wonder of the human hand is the precision with which it functions and the extremes of abuse it tolerates. We can and do take our hands for granted as they complete a multitude of

functional tasks such as dressing, cooking, or typing, because they seem to function effortlessly—that is, until we experience some level of impairment or dysfunction.

The hand does not function independently of the whole human organism. It is connected to the brain via a complex tangle of nerves and is dependent on precise synaptic connections. The hand does not function independently of the upper extremity (UE); stability and control of the shoulder, elbow, and wrist are needed to position the hand in space. Dysfunction anywhere from the brain to the fingertips may cause impaired function of the hand.

Humans achieve mastery and independence over their environment because of the superiority of the human brain and the dexterity of the hand. Tying a knot, opening a necklace clasp, wielding a hammer, and throwing a ball are abilities unique to the human hand. That we can close a necklace with our vision occluded is testament to the sensibility of the hand. That we can wield a hammer to drive a nail is testament to the integrity of the skin and the strength of the muscles that power the hand. That we can speak volumes with a sweep of our hands or a caressing touch is testament to the aesthetics of the hand. It is a remarkable instrument indeed. As Mary Reilly, one of the profession's most recognized leaders, stated in her 1961 Slagle lecture, “Man through the use of his hands as they are energized by mind and will, can influence the state of his own health.”

OTs deal with the human being as a whole, not just as a hand, a toe, or a shoulder. With the human hand, even the smallest impairment may affect function. Loss of placement of the hand may mean an inability to achieve a hand-to-mouth pattern, which makes independent feeding impossible. Pain and fear can and do accompany injury, and when independence or livelihood is threatened by hand

Threaded Case Study | Alexei, Part 1

Alexei is a delightful, witty gentleman of 78 years who resides in a nice retirement complex in the area since the passing of his wife 5 years ago. The complex offers three levels of care: independent apartment living, assisted living, and nursing care. At the time of his injury, Alexei was living in the independent area, had his own self-furnished apartment, took the van transportation provided by the complex once a week for grocery shopping, and took public transportation to his weekly computer class at a nearby senior center. The complex offers some extra services for a fee, and Alexei paid for monthly housekeeping. He does his own laundry, cooking, and light cleaning. He has diabetes and takes care of his own testing and insulin injections. His beloved parakeet recently died, and he was shopping for another. He had trained the parakeet to do several tricks, and it was his pride and joy.

It was outside a pet store that he fell and suffered a comminuted distal radius and ulna fracture of his right dominant wrist. After open reduction and internal fixation (ORIF), he was discharged to the nursing care level of his complex for 2 days, then to the assisted living level. Unless he could quickly become independent with managing his activities of daily living (ADLs) and medical needs, in his case diabetic testing and injections, he would lose his apartment and be transferred to the assisted living level permanently. This level would not allow him a pet.

Alexei was 5 weeks post ORIF when he was referred to hand therapy for beginning active range of motion (ROM) and edema reduction. He was wearing a protective removable splint. Because of maximal edema in his hand, he had only 20% total active motion of his fingers and thumb and was assisted with most self-care and ADLs, was eating with his left, nondominant hand, and was dependent on nursing for his diabetic needs. Alexei's goal was to regain enough range of motion and dexterity in his right dominant hand to be independent with all ADLs and medical needs so he could return to his apartment, which would allow him to keep his own furniture, get another bird, and set his own schedule.

Although Alexei's insurance would cover any needed therapy, he was able to attend only once a week because of transportation issues. Because his therapy time would be limited, our focus in OT was to work toward his goals by using dynamic splinting to regain ROM for functional grip and pinch, and to collaborate with the nursing staff at his assisted living residence to help him meet his goal of managing his medical

needs. Alexei attended therapy six times over the following 5 weeks. We worked closely by telephone with the nurse in assisted living, who carried out our recommended contrast baths and nightly isotoner glove application to reduce edema. We fabricated a volar-based dynamic flexion splint for metacarpophalangeal (MP) and proximal interphalangeal (PIP) flexion and a dorsal-based finger extension splint, each of which he alternated during the day for approximately 2 to 3 hours. We adjusted his splints each visit for greater ROM and proper 90-degree angle of pull on each finger; he was quick to learn his exercise regimen and followed it religiously. By his third visit, Alexei was independent in all self-care and hygiene tasks using built-up utensil handles and a zipper pull. At this time, we were able to discontinue his extension splint and focus on flexion and dexterity.

At this point, Alexei became assertive with his wish to return to his own apartment and was allowed to move back, with his assurance that soon he would once again be independent in all areas. He partnered with the nurse to work toward independence with medical needs—a difficult task because insulin needles are small and smooth. As his ROM and dexterity improved through dynamic splinting, he was able to test his sugar levels and walk to assisted living to receive insulin as needed. At 14 weeks postop, he was once again independent with his own injections using coban or rubber finger cots for traction on the needle, and was once again shopping for a parakeet.

Critical Thinking Questions

1. What would have happened to Alexei if therapy had consisted of just the 45-minute ROM and edema reduction sessions once a week, without the addition of the dynamic splint for home use?
2. How critical was the team approach of the client, the therapist, and the nurse in achieving this client's ultimate goals?
3. What part did ascertaining the client's main goal during the initial interview play in using limited time and resources to achieve that goal?
4. What would have happened if weekly therapy were conducted without that goal as the primary focus?

A client-centered focus is vital for any type of therapy. The case of Alexei illustrates how splinting was used to achieve a good outcome in a difficult case.

dysfunction, the outcomes are often dramatic, affecting that person and the family members who rely on him or her. The hand is perhaps most valued only when it ceases to function and we must give it attention.

A splint is one of the most important tools therapists use to minimize or correct impairment and to restore or augment function. Little else so readily calls attention to the hand as a splint. An individual may not receive comments on a new ring or a recent manicure, but put a splint on the

hand and all will take notice. The decision to provide or fabricate a splint requires an in-depth understanding of the pathologic condition to be affected and of the many splinting choices available.

Section 1 of this chapter serves as an introduction to the anatomic and biomechanical principles necessary for an understanding of the basic concepts and models of splinting. This section briefly reviews the anatomy of the hand and its relationship to principles of splinting, introduces the

biomechanical principles involved in splint design and fabrication, and introduces a splint fabrication process involving pattern making, material choices, types of traction, and techniques of fabrication.

Role of the Occupational Therapist

The education an OT receives in analysis of activity and assessment of human occupation and function leads naturally to the use of splinting as one therapeutic tool in the intervention regimen. OTs most commonly fabricate splints for the hand and UE, but they may be called upon to design and fabricate splints for the lower extremity (LE) and even for the back or spine. The basic principles of splinting apply, regardless of which body part is being splinted.

Involvement of the OT in all phases of splint fabrication is recommended from the initial assessment of need, through the design phase, the fabrication, and the training and follow-up necessary to ensure proper use and fit of the splint. This involvement requires an understanding of the anatomy and biomechanics of the normal, unimpaired hand and of the pathology of the impaired hand. Many excellent texts describe both hand anatomy and biomechanics in extensive detail and should be included in the library of any OT treating the hand. This chapter briefly reviews the anatomy and biomechanics of the hand most pertinent to splinting. The lists of references and suggested readings at the end of this chapter provide several excellent selections for further study.

One reference of note that should be included in every therapist's library is *Clinical Mechanics of the Hand*,⁸ 3rd edition, by Paul W. Brand and Anne Hollister. This text is an excellent source for a straightforward explanation of the mechanics of muscles, joints, and skeletal structures and how they contribute to the remarkable dexterity and strength of the hand. Brand and Hollister discuss clinical approaches and how they affect the natural biomechanics of the hand.

Anatomic Structures of the Hand

Wrist

The hand and wrist are a complex of 27 bones that contribute to the mobility and adaptability of the upper extremity; the 54 bones that make up both hands and wrists account for approximately one fourth of the total bones of the human body. The wrist is a complex that consists of the distal ulna and radius and the eight carpal bones arranged in two rows. The carpal bones form the concave transverse arch and, with the configuration of the distal radius, contribute substantially to the conformability of the hand.²⁸ The distal ulna does not articulate with any carpal bone, and its contribution to wrist stability is made through the attachments of the ulnar collateral ligament, which places a check on radial deviation (Figure 30-1).

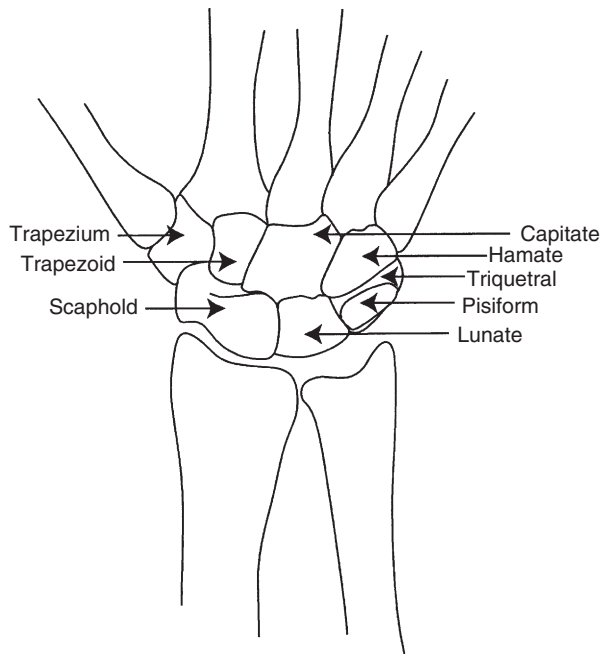

FIGURE 30-1 Skeletal structures of the wrist, dorsal view.

The wrist complex allows a greater arc of motion than any other joint complex except the ankle. This mobility is the result of a unique skeletal configuration and an involved ligamentous system. All motion at the wrist is component motion that occurs in more than one anatomic plane; no pure or isolated motions occur. This concept is key in any treatment directed at the wrist. Extension occurs with a degree of radial deviation and supination. Wrist flexion includes ulnar deviation and pronation. The wrist is contiguous and continuous with the hand. The distal carpal row (the trapezium, trapezoid, capitate, and hamate) articulates firmly with the metacarpals. Motion is produced across these articulations by muscles that cross the carpals and attach to the metacarpals. The proximal carpal row (the scaphoid, lunate, and triquetrum) articulates distally with the distal carpal row, and proximally with the radius and the triangular cartilage. Gliding motions occur between the carpal rows during flexion, extension, and deviation, and excessive motion is checked by the carpal ligaments.

Placement of the hand for functional tasks is reliant on the stability, mobility, and precision of placement permitted by the wrist complex. Any mechanism of injury or disease that alters this complex system, such as rheumatoid arthritis, translates into some level of dysfunction. Even the simplest splint that crosses the wrist will alter in some way the functional abilities of the hand.

Wrist Tenodesis

Tenodesis is the reciprocal motion of the wrist and fingers that occurs during active or passive wrist flexion and extension. Tenodesis is the action of wrist extension producing finger flexion, and wrist flexion producing finger extension.

FIGURE 30-2 Tenodesis. **A**, Active wrist extension results in passive finger flexion. **B**, Active wrist flexion results in passive finger extension.

OT Practice Note

Splint designs that attempt to augment or substitute for wrist motion are likely to limit component motions or are too complex to fabricate or wear.

It is caused by lack of change in length of the long finger muscles during wrist flexion or extension (Figure 30-2). The extrinsic finger muscle tendon units have a fixed resting length; because they cross multiple joints before inserting onto the phalanges, they can affect the position of several joints with no contraction or length change required of the muscles. This concept is crucial for understanding how passive positioning of the wrist affects the resting position of the digits. In the nerve-injured hand, tenodesis is often harnessed by splints to provide function. The client with spinal cord injury with sparing of a wrist extensor (C6 or C7 functional level) gains considerable function from a tenodesis, or wrist-driven flexor hinge hand splint. In a dynamic splint, such as a tenodesis splint, the effect that tenodesis has on tendon length will dictate in part the wrist position that will optimize forces directed at the digits.

Metacarpal Joints

The metacarpals articulate with the carpal bones proximally and with the phalanges distally. The first metacarpal, the thumb, articulates with the saddle-shaped trapezium and is

considered separately. The second metacarpal fits into the central ridge of the trapezoid, and the third articulates firmly with the facets of the capitate. These articulations form the immobile central segment of the hand around which the other metacarpals rotate. The fourth and fifth metacarpals articulate with the concave distal surface of the hamate. The shorter length of the ulnar two metacarpals and their greater mobility form the flexible arches of the hand; this allows it to conform and fold around objects of various shapes.

The distal transverse arch of the hand lies obliquely across the metacarpal heads. This obliquity is critical to the ability of the hand to adapt its shape to objects. The hand does not form a cylinder as it closes but instead assumes the position of a cone. In making a fist, the ulnar two digits of the hand contact the palm first, and the radial two digits follow. This cascade of the fingers is a direct result of the oblique angle formed at the metacarpal heads (sloping angle, not parallel to the wrist). This concept is most important in splinting in determining the distal trim lines for a wrist support when full metacarpophalangeal (MP) flexion is desired. The splint in Figure 30-3, A, is improperly trimmed distal to the MP creases. Distal trim lines should be established proximal to the MP creases, as in Figure 30-3, B.

Metacarpophalangeal Joints

The distal heads of the metacarpals articulate with the proximal phalanges to form the MP joints. Active motion is possible along an axis of flexion and extension, and along an axis of abduction and adduction. In addition, a small degree of rotation is present at the MP joints. These axes of motion allow for expansion or spreading of the hand and contribute to the ability of the hand to conform to different shapes and sizes of objects. An attempt to hold a softball without abduction of the fingers shows the importance of this motion. A splint with trim lines along the ulnar border of the hand that extend too far distally limits flexion and abduction of the fourth and fifth digits. As a result, the hand will have a limited ability to grasp large objects, and function will be restricted (Figure 30-4, A). Distal trim lines that fall proximal to the MP creases will allow for full MP flexion (Figure 30-4, B).

Thumb

The base of the first metacarpal articulates with the trapezium to form a highly mobile joint that often is compared with the shape of a saddle. The base of the first metacarpal is concave in the anteroposterior plane and convex in the lateral plane. This surface is met by reciprocal surfaces on the trapezium. This configuration allows for a wide arc of motion, with the thumb able to rotate not only for pad-to-pad opposition, but also for full extension and abduction to move away from the palm.²⁸ Both motions are important to function, that is, a thumb posted in permanent opposition may make grasp possible but release of objects

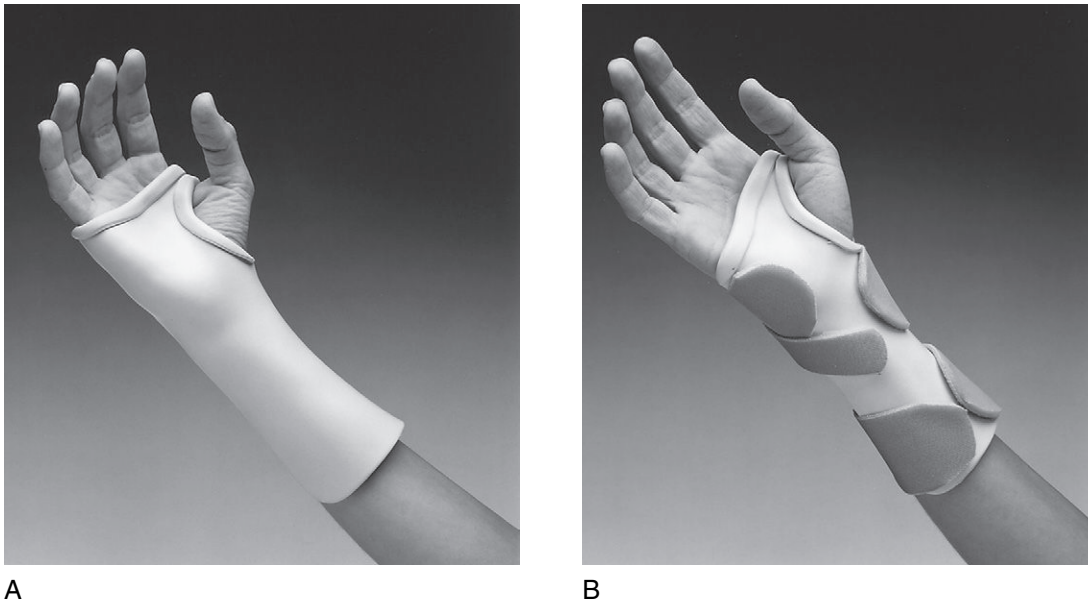

FIGURE 30-3 A, Trim lines of splint extend distal to metacarpophalangeal creases and limit finger flexion. B, Splint's distal trim lines fall proximal to metacarpophalangeal creases (following the oblique angle of the metacarpal heads) and permit full finger flexion.

FIGURE 30-4 A, Fourth and fifth digits are prevented from full flexion. B, Full finger flexion is possible with proper trim lines.

impossible. This concept is crucial to an understanding of splints that augment the tenodesis action of the hand by posting the thumb in opposition to the index and long fingers. With such splints, the therapist must carefully consider the degree of abduction and opposition in which the thumb is posted, to maximize both grasp and release.

Interphalangeal Joints

The proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints are true hinge joints, with motion in only one plane. This limitation of motion ensures greater

stability in these joints, which contributes to their ability to resist palmar and lateral stresses, and so imparts strength and precision to functional tasks.

Forearm Rotation

Close consideration of forearm rotation (i.e., supination and pronation) is necessary because of the importance of these motions to function and to the fitting of splints. Forearm rotation occurs at the elbow and at the distal forearm, with axes of rotation through the center of the radial head and capitulum and along a line extending

FIGURE 30-5 The axis of motion for supination and pronation extends the length of the forearm and is centered through the radial head and capitulum and the distal ulnar styloid.

(From Colello-Abraham K: *Rehabilitation of the hand*, ed 3, St Louis, 1990, Mosby.)

through the base of the ulnar styloid (Figure 30-5). During pronation, the ulnar styloid moves laterally, as the radial styloid travels medially. During supination, the opposite occurs, with the ulnar styloid moving medially. This movement results in displacement of the styloids, which in turn alters the architecture of the forearm in supination as compared with pronation.

The way in which this change in dimensions affects splint trim lines is shown in Figure 30-6. Lines drawn at midline along the supinated forearm shift dramatically upon pronation. Splints are generally used for function with the forearm in pronation, but they are easier to fabricate with the forearm in supination. Important to note is that if the forearm is not pronated before the splint material is set, the trim lines will be high on the radial border and low on the ulnar border.

One final active demonstration highlights the importance of forearm position for hand function. Place a coin of any size on a tabletop, and while holding the forearm in neutral (thumb straight up), attempt to pick up the coin. It becomes rapidly apparent that the ability to position the hand for function relies in great part on the more proximal joints of the forearm.

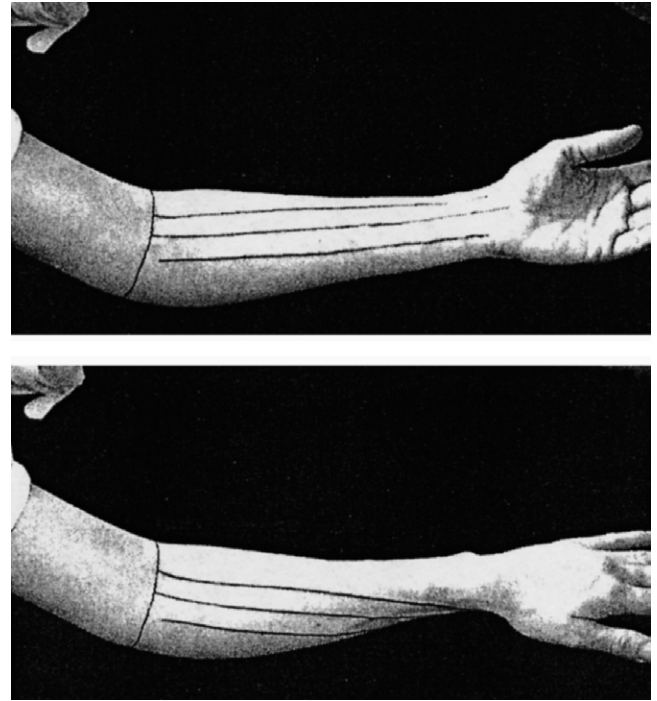

FIGURE 30-6 The shape of the forearm is altered as it moves from supination to pronation. Forearm-based splints must be repositioned to accommodate this if the forearm is rotated during the fabrication process.

(From Wilton JC: *Hand splinting, principles of design and fabrication*, Philadelphia, Pa, 1997, WB Saunders.)

Ligaments of Wrist and Hand

The ligamentous structures of the hand act as checkreins for the hand and wrist; this limits extremes of motion and provides stability. The complex motions of the wrist depend in large part on the ligaments that restrain them, rather than on the contact surfaces between the carpals and metacarpals. Three groups of ligaments are discussed briefly to highlight their contribution to wrist stability and mobility.

The palmar ligaments include the radioscaphocapitate ligament, which contributes support to the scaphoid; the radiolunate ligament, which supports the lunate; and the radioscapholunate ligament, which connects the scapholunate articulation with the palmar surface of the distal radius. The stability and mobility of the thumb and radial carpus depend on the integrity of these ligaments. Disruption of the ligaments results in instability and pain at the wrist and in significant dysfunction of the thumb. Splinting is frequently the treatment of choice to supply stability for pain reduction.

The radial and ulnar collateral ligaments provide dorsal stability. These capsular ligaments, along with the radiocarpal and dorsal carpal ligaments, provide carpal stability and permit ROM. Disruption of any of these ligaments may result in pain, loss of strength, and functional impairment.

The triangular fibrocartilage complex (TFCC) includes the ligaments and the cartilaginous structures that suspend

the distal radius from the distal ulna and the proximal carpus. Tears or strains in this complex are evidenced by pain and weakness with resultant loss of function in resistive tasks. The advent of new imaging techniques has made the diagnosis of TFCC tears more common; splinting is often ordered for support and pain relief.

Metacarpophalangeal Joints

Soft tissue structures that surround the MP joints include the joint capsule, the collateral ligaments, and an anterior fibrocartilage or volar plate. The capsule covers the head of the metacarpal and is reinforced by the collateral ligaments. The collateral ligaments are configured to allow side-to-side motion when the MP is in extension, and to tighten as the MP is flexed. The volar plate is attached to the base of the proximal phalanx and is loosely attached to the base of the neck of the metacarpal through the joint capsule. This configuration allows for sliding of the plate proximally during MP flexion. The plate returns to its lengthened state with the MP in extension and acts as a checkrein for volar displacement of the MP joint when it is extended.

When MPs are immobilized in extension, a strong tendency exists for secondary shortening of the lax collateral ligaments, in addition to contraction and adherence of the volar plate, which results in limited MP flexion and loss of functional grasp patterns. The commonly accepted resting position splint, which places the wrist in 25 degrees to 35 degrees of extension, the MP joints at 60 degrees to 70 degrees of flexion, and the PIP and DIP at 10 degrees to 35 degrees of flexion, is designed to prevent shortening and to maintain the joints in midrange for optimal function. An important consideration is to ensure that the mobile fourth and fifth digits are positioned in the splint to accommodate their additional degree of mobility by allowing somewhat greater flexion at their MP joints (Figure 30-7).

FIGURE 30-7 Oblique angle of transverse arch at metacarpophalangeal joints must be accommodated to ensure maintenance of more mobile fourth and fifth digits.

Proximal Interphalangeal Joints

The PIP joint capsule and ligaments provide stability and allow mobility in one plane only. Collateral ligaments on each side of the joint run in a dorsal-to-palmar direction, inserting into the fibrocartilage plate of the PIP. These ligaments and the plate are lax with the PIP joint in flexion and taut with it in extension. The seemingly simple joint is made more complex by inclusion of the extensor mechanism passing through the capsule dorsally and contributing slips to the system of ligaments affecting this joint. The potential for disruption of the extensor mechanism is high. Many of the most commonly fabricated finger splints are used to correct PIP boutonniere (Figure 30-8, A) and swan-neck (Figure 30-8, B) deformities.

Distal Interphalangeal Joints

The DIP joint capsule and ligaments are similar to the PIP joint but have less structural strength to the terminal insertions of the palmar plate and collateral ligaments. As the structures become smaller, they lose integrity and strength. One of the most frequent injuries to the digits is disruption of the terminal end of the extensor tendon, which results in a mallet or “baseball” finger (Figure 30-8, C).

Muscles and Tendons of Forearm, Wrist, and Hand

Balance in the hand must be considered when the hand is assessed for a splint. Two groups of muscles act on the wrist and hand: (1) the extrinsic muscles that arise from the elbow

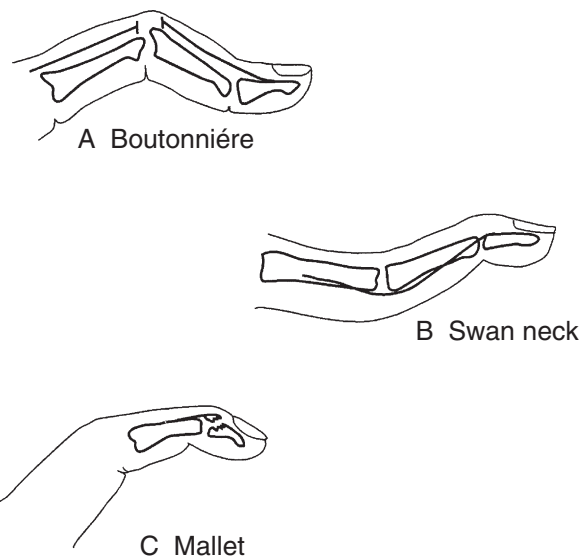

FIGURE 30-8 A, Boutonniere deformity, or joint change, characterized by proximal interphalangeal joint flexion and distal interphalangeal joint hyperextension. B, Swan-neck deformity, or joint change, with proximal interphalangeal joint hyperextension and distal interphalangeal joint flexion. C, Mallet finger with distal interphalangeal joint flexion and loss of active extension.

and the proximal half of the midforearm, and (2) the intrinsic muscles with origins and insertions entirely in the hand. The extrinsic muscles include both a flexor and an extensor group acting on the wrist and on the digits. The intrinsics include the lumbricals, the dorsal and palmar interossei, and the thenar and hypothenar groups. Smooth, coordinated motions of the hand in functional activities depend on a well-integrated balance between and within these two muscle groups. Many of the contractures that OTs attempt to correct with splinting are caused by neurologic dysfunction (central or peripheral), which results in imbalance of muscle tone or innervation.

Nerve Supply

A discussion of the nerve supply to the hand should include mention of the continuity of the brachial plexus from its origins in the spinal cord to its terminal innervations in the hand. Injuries or compressions that occur anywhere along this continuum may result in motor or sensory dysfunction. When splinting the UE, the therapist must give attention to the pathways of the nerves that supply the UE and to potential sites for nerve entrapment. In the fabrication of splints, care must be taken to avoid applying pressure over sites where the nerves are superficial and prone to compression. These sites include the ulnar nerve at the elbow in the cubital tunnel and in Guyon's canal at the ulnar border of the wrist, the radial nerve at the elbow and in the thenar snuffbox, and the digital nerves along the medial and lateral borders of the digits (Figure 30-9).

Three peripheral nerves supply motor and sensory function to the hand (Figure 30-10). The radial nerve is the primary motor supplier to the extensor and supinator muscles. The sensory fibers of the radial nerve supply the dorsum and the radial border of the hand. The median nerve provides motor supply to the flexor-pronator group, which includes most of the long flexors and the muscles of the thenar eminence. The sensory distribution of the median nerve is functionally the most important because it includes the palmar surface of the thumb, index, and long fingers and the radial half of the ring finger. The ulnar nerve supplies most of the intrinsic muscles, the hypothenar muscles, the ulnarmost profundi, and the adductor pollicis brevis. The sensory supply of the ulnar nerve includes the palmar surface of the ulnar half of the ring finger, the little finger, and the ulnar half of the palm.

Nerve dysfunction presents a challenge to the splint maker. Muscle imbalance leads to dysfunctional posturing of the hand and muscle atrophy that reduces the natural padding of the hand. Abrasions or ulcerations may occur in persons who do not remove their splints, because they do not feel pain caused by shearing forces or pressure areas inside the splint. Finally, skin with marked sensory impairment lacks natural oils and perspiration; this leads to dry skin that abrades easily. These factors must be assessed and considered carefully when splints are being fitted on persons with sensory impairment.

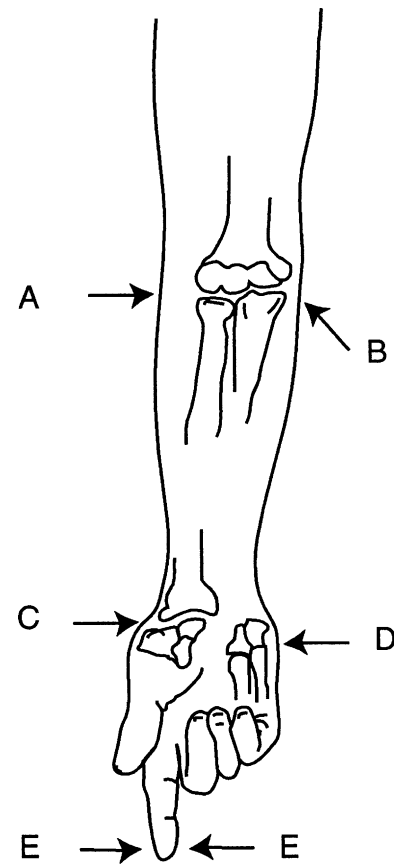

FIGURE 30-9 Potential sites for nerve compression from improperly fitted splints. A, Radial nerve. B, Ulnar nerve. C, Radial digital nerve in anatomic snuffbox. D, Ulnar nerve in Guyon's canal. E, Digital nerves.

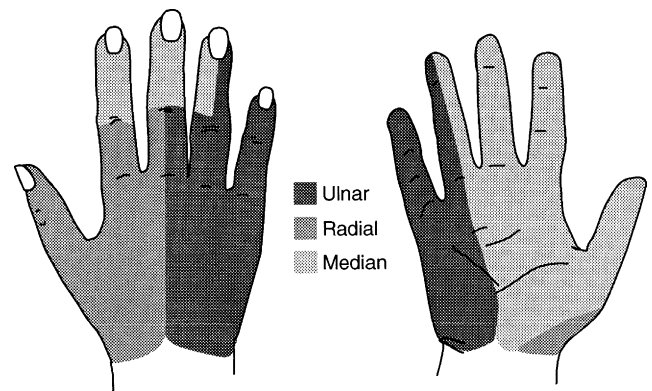

FIGURE 30-10 Sensory distribution in hand. Median nerve distribution includes most of the prehensile surface of the palm.

Splinting the neurologically impaired hand is directed at preventing joint and soft tissue contractures and restoring functional positioning. Splinting cannot restore sensibility, and care must be taken to prevent damage to sensory-impaired skin and to limit further reduction of sensory feedback by covering sensate surfaces (those surfaces that have sensation) and consequently reducing functional use of the hand in ADLs.

Little consensus has been reached on whether or not splinting the neurologically impaired hand is best practice and should or should not be done, and for what long-term goals. An excellent summary of this debate is provided by Lohman and Aragon in “Introduction to Splinting: A Clinical Reasoning and Problem-Solving Approach” (Chapter 14).¹⁰

Blood Supply

Blood supply to the hand is contributed by the radial and ulnar arteries. The ulnar artery lies just lateral to the flexor carpi ulnaris tendon, where it divides into a large branch that forms the superficial arterial arch and a small branch that forms the lesser part of the deep palmar arch. The ulnar artery is vulnerable to trauma where it passes between the pisiform and the hamate (Guyon’s canal). The radial artery divides at the proximal wrist crease into a small, superficial branch and a larger, deep radial branch. The superficial arterial arch further divides into common digital branches and then into proper digital branches.

Venous drainage of the hand is accomplished by two sets of veins: a superficial and a deep group. Therapists are more likely to be concerned with the superficial venous system because it lies superficially in the dorsum of the hand. Disruption of this superficial system may result in extensive fluid edema in the dorsum of the hand, which requires the therapist’s intervention. Care must be taken not to strap splints too tightly over the dorsum of the hand; this traps fluids from draining.

Skin

The mobility of the hand is directly related to the type and condition of the skin. Anyone who has put on a ring that is slightly too small, only to be unable to remove it, has experienced the redundancy of the skin on the dorsum of the hand. The skin on the dorsum of the hand is loosely anchored to underlying structures and moves easily to allow flexion and extension of the digits. The ring “problem” occurs because of a greater degree of elasticity in the dorsal skin when it is pulled distally, as opposed to when it is pulled proximally. This fact should be considered when the use of finger splints is contemplated.

The palmar skin, by contrast, is thicker and relatively inelastic. It is firmly connected to the underlying palmar aponeurosis for stability and protection during prehension activities. Furthermore, the underlying fascia of the palmar skin is thicker and protects the nerve endings, while it acts to supply adequate moisture and oils to the skin surface.

Superficial Anatomy and Landmarks

When fabricating a splint, therapists must consider where to apply force without causing further trauma. Despite its deftness and power, the hand’s lack of protective fascia means that it tolerates external pressures poorly and shearing stresses not at all. The prominent ulnar styloid, the distal radial styloid, and the thumb carpometacarpal joint

FIGURE 30-11 Relief “bubbled” over the ulnar styloid, accomplished by molding plastic over a pad placed on the styloid.

are common sites for pressure. A truism that will always hold in splinting is that padding adds pressure. The softest padding added to a too-tight splint will only add more pressure. Pressure is relieved by the creation of a relief in the splint or by application of padding and material molded over the pad to make it an integral part of the splint (Figure 30-11). Added padding to relieve pressure after the splint is formed should be avoided.

Prehension and Grasp Patterns

The ability of the human hand to assume myriad functional positions and to apply only the precise amount of pressure necessary to hold an object is a result of the mobility and stability supplied by the skeleton, the power of the muscles, and the remarkable degree of sensory feedback received from the nerves. This sensory feedback is used to assess the size, shape, texture, and weight of an object. The brain then determines which type of prehension to use to complete a functional task while using this object. The feedback used in grasping and lifting an object is dependent both on the brain’s interpreting correctly what is seen and on the hand’s responding appropriately. Once an object is in the hand, further adaptation in prehension will occur if the initial visual assessment was faulty.

Splints can maximize functional prehension. In achieving this goal, the therapist must be aware of what a splint can and cannot do: a splint can stabilize an unstable part, position a thumb in opposition, and even assist or substitute for lost motion. A splint with added dynamic components can even gradually revise tissue along its lines of pull by applying slow gentle stretch to gain increased functional range of motion. However, the splint maker must be aware that a splint may negatively limit mobility at uninvolved joints, reduce sensory feedback, add bulk to the hand, and transfer stresses to unsplinted joints proximal or distal to the part being splinted.

The prehension patterns the hand is able to achieve are as exhaustive as the objects that are available to grasp or

pinch. Several authors have contributed to classifications of normal prehension, and the presentation by Flatt¹² is recommended for further study of the subject. It is possible to reduce the many patterns to two basic classifications—prehension and grasp—from which other patterns may be derived. *Prehension* is defined as “a position of the hand that allows finger and thumb contact and facilitates manipulation of objects.” *Grasp* is defined as “a position of the hand that facilitates contact of an object against the palm and the palmar surface of partially flexed digits.”

The thumb is involved in all but one type of grip, that of hook grasp. Carpometacarpal and MP rotation is crucial to prehension and cannot be overstressed in terms of its importance in splinting to achieve function. This rotation allows for full contact of the thumb in pad-to-pad prehension; this motion is used in a normally active person hundreds of times daily in performance of all areas of occupation, including ADLs, instrumental activities of daily living (IADLs), work, leisure, and social participation.

Lateral Prehension

In lateral prehension, the pad of the thumb is positioned to contact the radial side of the middle or distal phalanx of the index finger (Figure 30-12, A). Most commonly, this pattern

of prehension is used in holding a pen or eating utensil, and in holding and turning a key. The short or long opponens splint is used to stabilize the thumb to achieve this prehension pattern.

Palmar Prehension

Palmar prehension is also called “three-jaw chuck pinch.” The thumb is positioned in opposition to the index and long fingers (Figure 30-12, B). The important component of motion in this pattern is thumb rotation, which allows for pad-to-pad opposition. This prehension pattern is used in lifting objects from a flat surface, in holding small objects, and in tying a shoe or bow. The short and long opponens splints may be fabricated to position the thumb in palmar prehension.

Tip Prehension

In tip prehension, the IP joint of the thumb and the DIP and PIP joints of the finger are flexed to facilitate tip-to-tip prehension (Figure 30-12, C). These motions are necessary for picking up a pin or a coin. It is difficult to substitute for tip prehension because it is rarely a static holding posture. Once a pin is in the hand, tip prehension will convert to palmar prehension to provide more skin surface

FIGURE 30-12 A, Lateral prehension or key pinch in short opponens splint that positions thumb in lateral opposition to index finger. B, Palmar prehension or three-jaw chuck pinch in short opponens that positions thumb in opposition to index and long fingers. C, Tip prehension with thumb and index finger in interphalangeal blocker that secures interphalangeal joint in slight flexion to assist tip prehension.

area to retain a small object. A thumb IP hyperextension block is useful in limiting IP hyperextension and in facilitating the IP flexion required for tip prehension. In the case of Alexei, maximal edema and stiffness prevented him from achieving the tip or palmar prehension needed for his diabetes management, which included manipulation of small objects.

Cylindrical Grasp

Cylindrical grasp, the most common static grasp pattern, is used to stabilize objects against the palm and the fingers, with the thumb acting as an opposing force (Figure 30-13, A). This pattern is assumed for grasping a hammer, a pot handle, a drinking glass, or the handhold on a walker or crutch. Static splinting offers little to restore this grasp directly, although positioning the wrist in extension offers greater stability to the hand as it assumes this grasp pattern. However, a dynamic outrigger component

can be added to a volar splint to gently gain increased MP and PIP flexion to enhance cylindrical grasping ability, as was found to be successful for Alexei. A dorsal wrist stabilizer alone offers stability while minimizing palm coverage.

Spherical Grasp

Also called *ball grasp*, this pattern is assumed for holding a round object, such as a ball or an apple. It differs from cylindrical grasp primarily in positioning of the fourth and fifth digits. In cylindrical grasp, the two ulnar metacarpals are held in greater flexion. In spherical grasp, the two ulnar digits are supported in greater extension to allow a more open hand posture (Figure 30-13, B). In splinting, to facilitate or support this pattern of grasp, the wrist-stabilizing splint must be trimmed proximal to the distal palmar crease and contoured to allow for obliquity at the fourth and fifth metacarpal heads.

FIGURE 30-13 A, Cylindrical grasp in dorsal splint that stabilizes wrist to increase grip force and minimizes palm covering. B, Spherical grasp in dorsal splint. Splint stabilizes wrist to increase grip force and permits metacarpal mobility required for spherical grasp. C, Hook grasp does not involve thumb. Grasp pattern is seen in median and ulnar neuropathy; splinting is aimed at correcting rather than augmenting grasp. D, Figure-eight splint substitutes for loss of intrinsic function with median and ulnar neuropathy.

Hook Grasp

Hook grasp is the only prehension pattern that does not include the thumb to supply opposition. The MPs are held in extension, and the DIP and PIP joints are held in flexion (Figure 30-13, C). This is the attitude the hand assumes when holding the handle of a shopping bag, a pail, or a briefcase. In the nerve-injured hand, splinting is directed more commonly at correcting this posture by flexing the MPs than at facilitating it.

Intrinsic Plus Grasp

Intrinsic plus grasp is characterized by positioning of all MPs of the fingers in flexion, the DIP and PIP joints in full extension, and the thumb in opposition to the third and fourth fingers (Figure 30-13, D). This pattern is used in grasping and holding large, flat objects such as books or plates. Intrinsic plus grasp is often lost in the presence of median or ulnar nerve dysfunction, and a figure-eight or dynamic MP flexion splint is used for substitution.

Mechanics of the Hand and Principles of Splinting

McCullough and Sarrafian stated that the three basic motor functions of the upper limb are “prehension and release, transfer of objects in space, and manipulation of objects within the grasp.”²⁰ These functions depend on the structural integrity of the skeleton, the muscles that provide power, and the feedback to which the brain responds when enabling the limb to meet functional demands. The task of restoring any one of these basic functions through the application of a splint is complex and relies on an understanding of the biomechanics of the hand and the mechanics involved in splinting. It is beyond the scope of this chapter to present this topic in depth. Presented here is an introduction to those tenets of clinical mechanics deemed necessary for the beginning splint maker.

Mechanics deals with the application of force, and biomechanics may be viewed as the body’s response to those forces. In the hand, the force required to produce motion is supplied by muscles. The force then is transmitted by the tendons to the bones and joints, with control supplied by the skin and pulp of the fingers and palm.¹¹ How the application of a splint affects the transmission of force to produce motion depends on the relationship between the axis of rotation of joints and anatomic planes and the forces imposed on the hand.

Axis of Motion

Hollister and Giurintano¹⁴ define *axis of motion* as “a stable line that does not move when the bones of a joint move in relation to each other” (Figure 30-14). This stable line is illustrated by Figure 30-14, B, which shows a tire perfectly balanced around its axis of motion. When a tire is perfectly

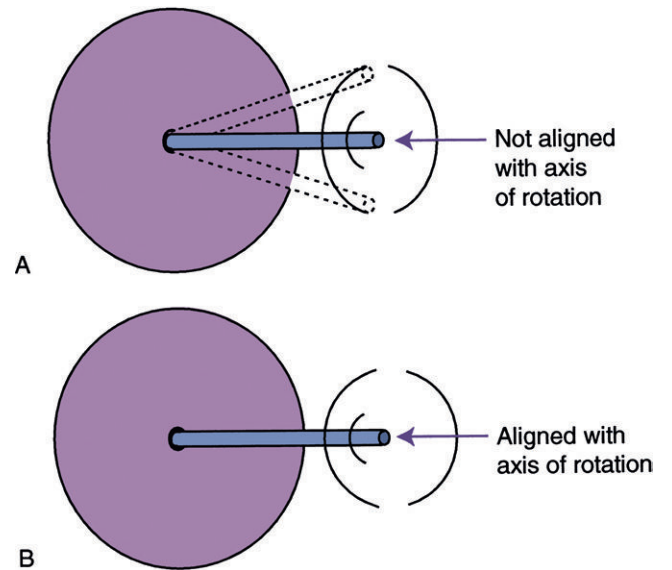

FIGURE 30-14 A, If a tire is not balanced around its axis, it wobbles. If a splint hinge is not aligned with the joint axis, wobble is seen as binding of the joint. B, Proper alignment of a tire or of a hinge with an anatomic joint results in smooth, unimpeded motion.

balanced, it does not wobble; it has pure motion around a single point.

In a single-axis joint, motion occurs in only one plane. The PIP joint is an example of a single-axis joint in alignment with an anatomic plane. It moves only in the plane of flexion and extension.

Joints that have more than one axis of motion may move in more than one plane at a time. For example, the wrist complex has two axes of motion: flexion-extension and radial-ulnar deviation. A joint with multiple axes has conjoint motions that occur in addition to the primary motions described by the joint. Wrist flexion occurs with a moment of ulnar deviation and with a small degree of pronation. Wrist extension occurs with radial deviation and slight supination. These conjoint motions are what make circumduction of the wrist possible. They are also what make splinting the wrist with hinged joints a challenge.

A splint with a movable hinge or coil has a single axis. When used to splint a single-axis joint such as a PIP joint, a hinge can and should be properly aligned to avoid binding that will limit motion. If a single-axis hinge or coil is used to reproduce motion in a multiaxis joint, some binding or friction will always occur, no matter how well aligned, because the hinge or coil does not allow for, or reproduce, the conjoint motions available in the unsplinted joint.

Force

It is crucial to understand basic principles of **force** and apply them correctly in splinting. An understanding of the forces applied by levers and the stresses that occur between opposing surfaces can help to explain what happens as forces are applied within the body by muscles and externally by splints.

Definitions

Use of the term *force*, as it relates to splinting, describes the effects that materials and dynamic components have on bone and tissue. *Force* is a measure of stress, friction, or torque. *Stress* is resistance to any force that strains or deforms tissue. Shear stress occurs when force is applied to tissues at an angle or in opposing directions. Pinching skin between the surface of a splint and the underlying bony structures causes shear stress.

Friction occurs when one surface impedes or prevents gliding of a surface on another. Friction is produced in the stiff or contracted joint when soft tissue restriction prevents gliding of the bones. Splints may contribute to friction if they are misaligned in relation to a joint axis. For example, a hinged splint that is not properly aligned with the axis of rotation will limit motion by producing friction as the joint attempts to move.

Torque is a measure of the force that results in rotation of a lever around an axis. The torque created when a lever rotates depends on the force used and the length of the lever employed. In the body, muscles are the levers that create torque when they act to move a joint. Externally, splints may act as levers to apply the force necessary to move a bone around its axis. The measure of torque is given by the following formula:

$$\text{Torque} = (\text{amount of}) \text{ Force} \times (\text{length of}) \text{ Lever arm}$$

Internally, the length of the lever arm is measured as the perpendicular distance from the axis of the joint to the tendon. Externally, the length of the lever arm is measured as the estimated distance from the joint axis to the attachment of force. In splinting, the attachment point of the force is usually a soft or molded cuff. If the splint includes an outrigger with a finger cuff, as shown in Figure 30-15, the lever arm is the distance from the axis of the joint to the finger cuff, as indicated in line M.

FIGURE 30-15 Tension F on the phalanx has a moment arm of M acting on the joint. Tension F1 has a smaller moment arm, M1 (with less resulting torque), when the angle of approach is not 90 degrees.

(From Brand PW, Hollister A: *Clinical mechanics of the hand*, ed 2, St Louis, 1993, Mosby.)

Figure 30-15 demonstrates that the angle of approach of the force to the finger also affects the length of the lever arm and ultimately the torque applied. The angle of approach is the angle that the line of traction makes as it meets the part being splinted. When the angle of approach is at a right angle (90 degrees) to the long axis of the phalanx, the lever arm is M. When the cuff is at less than 90 degrees to the long axis of the phalanx, the lever arm is shortened to M1. This shorter lever arm will produce less torque and therefore less rotation unless greater force is applied.

Given an equal amount of resistance or load, a 2-foot lever will require half as much force to create motion around an axis as will a 1-foot lever. The important principle for splint makers is that as the distance between the attachment of the cuff or strap and the joint axis increases, less force is required to achieve motion.

Translational Forces

In addition to the angle of approach affecting the length of the lever arm, an approach of less than or greater than 90 degrees results in **translational forces**. The outrigger splint in Figure 30-16, A, shows a 90-degree angle of approach between the nylon line and the phalanx, demonstrating the correct angle of pull.

When force is applied at any angle other than 90 degrees, translational forces are created. This alteration of the angle of approach translates some of the rotational force away from producing joint extension and directs the force into joint compression or joint distraction (Figure 30-16, B and C). The greater the deviation from 90 degrees, the greater is the translational force. Depending on the type of splint and the condition of the joint, joint compression or distraction may lead to mere discomfort or to actual joint damage. Translational force is also undesirable because it undermines the effectiveness of the splint by shortening the lever arm.⁸

The challenge in splinting with an outrigger is to position the splint so that a 90-degree angle of approach exists.

FIGURE 30-16 A, Angle of approach is 90 degrees to middle phalanx, ensuring that force pulling the proximal interphalangeal joint into extension is not causing distraction or compression. B, Angle of approach less than 90 degrees to middle phalanx causes joint compression. C, Angle of approach greater than 90 degrees distracts joint.

FIGURE 30-17 As dynamic traction acts on range of motion at the proximal interphalangeal joint, splint must be adjusted to maintain 90-degree angle of approach.

In the outrigger in [Figure 30-17](#), as long as the finger does not move, the 90-degree angle will remain. As soon as the finger moves, however, the 90-degree angle changes. Because few outriggers allow for this automatic readjustment in position, the outrigger must be adjusted as the contracture lessens to maintain the 90-degree angle of approach.

Alexei required weekly adjustments of his flexion outrigger to maintain the 90-degree angle of approach as his MP and PIP flexion increased. As his finger flexibility and functional hand motion improved, he was able to lessen time spent in the splint.

Splint Classifications

Splints may be described in various ways. Terminology varies, and it is useful to understand some of the ways that splints may be described. For purposes of clarity, splint classifications are described here according to type, purpose, and design.

One reference to be considered when classification is discussed is the Splint Classification System (SCS),¹ as published by The American Society of Hand Therapists (ASHT). The SCS describes splint nomenclature based on the functional requirement of a splint, as well as on the anatomy affected. This nomenclature is quite inclusive of the broad variety of UE splints fabricated by occupational therapists and is suggested for study. However, the widely used terms *static*, *serial static*, *dynamic*, and *static progressive* are not included in the SCS. These splint choices are noted under “Common Names.” An excellent summary of the

FIGURE 30-18 Forearm-based four-digit outrigger with dynamic extension assist supplied by springs.

Splint Classification System can be found in Jacobs and Austin’s “Splinting the Hand and Upper Extremity, Principles and Process” ([Chapter 1](#)).¹⁵

Splints Classified by Type

Dynamic splints include one or more resilient components (elastics, rubber bands, or springs) that produce motion. The force applied from the resilient component is constant even when tissues have reached end range. Dynamic splints are designed to increase passive motion, to augment active motion by assisting a joint through its range, or to substitute for lost motion. Dynamic splints generally include a static base on which movable, resilient components can be attached ([Figure 30-18](#)). A common use of dynamic splinting is to gain greater finger range of motion by adding dynamic MP extension and/or MP flexion components to a splint. [Figure 30-18](#) shows the type of dynamic splint fabricated for Alexei to gain finger extension. [Figure 30-19](#) shows the type of dynamic splint fabricated for Alexei to gain finger flexion.

A **static splint** has no movable components and immobilizes a joint or part. Static splints are fabricated to rest or protect, to reduce pain, or to prevent muscle shortening or contracture. An example of a static splint is a resting pan splint that maintains the hand in a functional or resting position ([Figure 30-20](#)).

A **serial static splint** achieves a slow, progressive increase in ROM by repeated remolding of the splint or cast. The serial static splint has no movable or resilient components, but rather is a static splint whose design and material allow repeated remoldings. Each adjustment repositions the part at the end of the available range to progressively gain passive motion. A cylindrical cast designed to reduce a PIP joint flexion contracture through frequent removal and recasting is a classic example of a serial static splint ([Figure 30-21](#)).

Static progressive splints include a static mechanism that adjusts the amount or angle of traction acting on a part. This mechanism may be a turnbuckle, a cloth strap, nylon line, or a buckle. The static progressive splint is distinguished from the dynamic splint by its lack of a resilient

FIGURE 30-19 Dynamic splint for finger flexion.

FIGURE 30-20 Single-surface static resting splint positions hand in 20-degree to 30-degree wrist extension, 45-degree to 60-degree metacarpophalangeal flexion, and 15-degree to 30-degree proximal interphalangeal and distal interphalangeal flexion.

FIGURE 30-21 A series of cylindrical plaster casts is made to reduce flexion contracture at proximal interphalangeal joint.

FIGURE 30-22 Static progressive web strap adjusts with hook closure. Client is taught to adjust strap as tolerance permits.

force. It is distinguished from a serial static splint in having a built-in adjustment mechanism, so that the part can be repositioned at end range without the need to remold the splint. Generally, the static progressive mechanism can be adjusted by the client as prescribed or as tolerated (Figure 30-22).

Splints Classified by Purpose

Although nomenclatures may vary, the categories presented in the splint classification system (SCS) describe splints in functional rather than design terms.¹ Splints are broadly described first as articular or nonarticular, and then by location and direction. The SCS then is divided into three overriding purposes of splints: restriction, immobilization, and mobilization. The publication also lists many functions of splints, each of which is placed in one of three categories. Splints may fulfill more than one function or purpose, depending upon the method of fabrication and the problems they address.

Restriction Splints

Restriction splints limit joint ROM but do not completely stop joint motion. One example is the splint in Figure 30-23, which blocks PIP joint hyperextension while allowing unlimited PIP joint flexion. Semiflexible splints are available that limit motion at the extremes of range but allow motion in the middle of the range. Although the splint may be restrictive, the goal or function of the splint may vary.

Immobilization Splints

Immobilization splints may be fit for protection to prevent injury, for rest to reduce inflammation or pain, or for positioning to facilitate proper healing after surgery. The classic example is the resting pan splint (see Figure 30-20), which serves two of the three functions. A resting splint fit for a client after a cerebrovascular accident (CVA) positions the

A

B

FIGURE 30-24 Spring coil splint substitutes for absent wrist extension in radial nerve injury.

wrist and digits to maintain soft tissue length and can protect the desensate hand against damage.

Mobilization Splints

Mobilization splints are designed to increase limited ROM or to restore or augment function. A mobilizing splint may assist a weak muscle or substitute for motion lost because of nerve injury or muscle dysfunction (Figure 30-24). The splint may attempt to balance the pull of unopposed spastic muscles to prevent deformity or joint changes and to assist function. A splint may provide resistance against which a weak muscle can exercise to improve its strength or to facilitate tendon gliding after tendon surgery. Frequently, mobilizing splints are used to increase the ROM of contracted joints, as in the case of Alexei, who experienced severe finger stiffness as a result of edema, which pooled in his hand after his forearm fracture.

Splints Classified by Design

After the purpose of the splint has been determined, the next decision relates to its design. Each of the types of splints described earlier (static, dynamic, serial static, and static progressive) may be fabricated as a single-surface design, a circumferential design, or a three-point design. A final category, the loop design, is generally limited to acting on finger IP joints by providing a loop of material that

wraps around the joints to restore the final degrees of joint flexion.

All splints are designed to provide some degree of force. This force may be distributed as a continuous loop, with equal and opposing forces wrapping around two or more joints (Figure 30-25, A). More commonly, the force is applied through three points of pressure (Figure 30-25, B). Although the loop design generally is used only on finger IP joints, some variation of the three-point pressure design is used in all other splints.

Three-point finger splints that incorporate springs, spring wire, or elastics are often used to correct DIP and PIP joint flexion contractures. A flexion contracture exists when a joint will not move passively out of a closed position into extension. These designs include two points of pressure—one proximal to the joint and one distal—and the third or central opposing force, acting directly over or close to the joint, as in Figure 30-25, B. In a three-point finger splint, the force of the central point is equal to the sum of the two forces of the correcting points. This fact is clinically important because tissue tolerance under this central point may be insufficient and may react with pain and inflammation. This problem is seen frequently at the PIP joint, where limited surface area exists over which to distribute pressure. Pressure must be distributed with contoured surfaces that are as broad as possible, and the spring or elastic force and the wearing time must be adjusted to the client's tolerance. Proper padding incorporated into the splint can aid in distributing pressure.

The dynamic finger-based three-point splint just described is a unique design that does not adhere to the 90-degree rule, that is, when the splint is applied to a joint with a flexion contracture, the angle of approach of the line of traction is never 90 degrees. The more severe the contracture, the greater the translational force that is present; therefore, it is less effective than a properly contoured outrigger splint that adheres to the 90-degree rule. This design should be fitted only in the presence of IP joint flexion contractures of 35 degrees or less. For finger contractures in

FIGURE 30-25 A, Final flexion strap designed to restore full interphalangeal joint flexion provides equal force on all surfaces of the digit. B, Three-point pressure splint with spring wire reduces proximal interphalangeal joint flexion contractures of 35 degrees or less.

excess of 35 degrees, a hand- or forearm-based outrigger splint is recommended because it can be positioned to apply force at a 90-degree angle of attack. Alternatively, a conforming, serial static splint can be used, as described in the section on traction.

Single-Surface or Circumferential Design

If a molded splint is to be fabricated, the next decision is whether to use a circumferential or single-surface design. Single-surface splints are fabricated to cover only one surface—the volar or dorsal surface of a limb, or the ulnar or radial half of the hand or forearm. Straps are added to create the three points of pressure necessary to secure the splint (Figure 30-26, A).

Circumferential splints wrap around a part, covering all surfaces with equal amounts of pressure (Figure 30-26, B). Straps are used solely to close the splint or to create an overlap. Thinner materials can be used in molding a circumferential splint, because increased contours in the material add to the rigidity of the splint. An example of added strength from contours is corrugated paper. Consequently, circumferential splints can be made lighter and out of highly perforated materials for air circulation without sacrifice of control.

Indications for Single-Surface Splinting

Single-surface splinting is effective for supporting joints surrounded by weak or flaccid muscles, for instance, following a CVA or peripheral nerve injury. Because little or no

FIGURE 30-26 A, Single-surface splint requires properly placed straps to create three-point pressure systems to secure splint and ensure distribution of pressure. B, Circumferential splints create multiple three-point pressure systems to secure splint for immobilization.

active motion is available, the extra control given by circumferential splinting is not needed, and donning and doffing the splint will be easier. A single-surface splint is also effective as the base for attaching outriggers in dynamic splinting, and for postoperative splints in which fabrication of a circumferential splint may damage repaired structures.

Indications for Circumferential Splinting

Circumferential splinting is effective for immobilizing painful joints or for protecting soft tissue (see Figure 30-25, B). Because the circumferential design gives comfortable, complete control, it is particularly helpful when the client will be wearing the splint during activity, when shear forces can be a problem. This comfortable, complete control also makes a circumferential design useful for serial static splints used to reduce contractures. The control that a circumferential design supplies makes it a good design for stabilizing proximal joints when outriggers are applied to act on more distal joints.

When to Splint and When Not to Splint

A first step in deciding which splint style and design to choose is to determine whether the client is a good candidate for wearing a splint. Several issues should be examined in this regard.

Compliance Issues

First, the therapist must consider whether or not the client is likely to comply with the splinting program. The splint may have a negative effect on the client's ability to be independent in self-care or to function at work. Some clients are sensitive about their appearance and may refuse to wear a splint if it offends their aesthetic sense or negatively affects their body image. Compliance with a splinting program may be poor if the client's general level of motivation to get better is low. On the other hand, some clients are so highly motivated that they will overdo the splinting program and cause themselves damage. Finally, the client's cognitive and perceptual ability to follow a splinting program should be considered, especially if no responsible care provider is available to supervise the splint-wearing precautions.

Ability to Don and Doff a Splint

Even if compliance is not an issue, the client may have problems donning and doffing (putting on and removing) the splint. For example, the client may have no one at home to assist in donning and doffing a difficult splint. The hospitalized client may not have adequate staff help to follow the wearing schedule or to apply the splint correctly.

Skin Tolerance and Hypersensitivity

The therapist must assess the skin condition of the client before deciding to fit a splint. Clients who experience diaphoresis and produce excessive perspiration that may lead to skin maceration need to be evaluated more carefully for splint consideration and type, such as ventilated plastics and absorbent padding. Some clients are intolerant of any pressure because of extremely fragile skin or sensory dysfunction. If these issues arise and cannot be ameliorated, safe

alternative therapeutic interventions must be substituted for the splint.

Wearing Schedule

If none of the preceding issues prevents the client from being a candidate for splinting, the therapist must decide on the optimum wearing schedule for the splint. Nighttime may be the best time for a client to wear a static splint designed to change ROM. It is also the time when clients need resting splints to prevent them from sleeping in positions that may damage the hand or allow nerve compression. During the daytime, the client may wear a dynamic splint or a splint designed to assist function. It is often best to minimize splinting during the day if possible, so that the client can use his or her hand as normally as possible. For some who must wear positioning hand splints at night, it may be advisable to alternate wearing splints on one hand at a time so that the individual is not left without the sensory input and function of a splint-free hand. Such a splint-wearing schedule, although not ideal for meeting therapeutic goals, may at least offer a compromise for better compliance.

Splint Fabrication Process

Step One: Creating a Pattern

Once the decision has been reached to fabricate a splint, arguably the most important step in the fabrication process is deciding on and creating a pattern. Although it may seem elementary even to the novice splint maker, this step can determine the success of the splint in terms of fit and function. Allowing the time to make a well thought-out and properly fitted pattern gives the splint maker the chance to deal with such issues as what he or she is trying to accomplish with the splint and how the splint is going to fit. Ultimately a properly fitted pattern will make the entire fabrication process easier and faster and will increase the chance of success.

OT Practice Note

The process of making a pattern involves an understanding of the anatomy and biomechanics of the hand and the materials to be used, in addition to a bit of old-fashioned dressmaking. Understanding how positional changes alter length and how depth and width relate to the pattern is paramount to success.

The common technique of making a pattern starts with a tracing or outline of the hand. This generally is taken with the hand lying flat when possible, or by tracing the uninjured hand if necessary. An amount is added to this outline to approximate the width and length needed for the splint. A common error in this technique is not taking into account

FIGURE 30-27 A, Tracing with pencil perpendicular to the arm creates a true size pattern. B, Pattern is full length with hand flat. C, Pattern is too long when fit on the volar surface with hand in resting position. D, Pattern is too short when fit on dorsum of hand with wrist and fingers in flexion.

the position in which the hand (or other body part) will ultimately be held in the splint.

Figure 30-27, *A* and *B*, shows a pattern taken with the hand lying flat, with no length added to the pattern. In Figure 30-27, *C*, when the pattern is fit on the volar surface of the hand with the hand in functional position (the wrist in 35 degrees of extension, the MP joints at 70 degrees of flexion, and the IP joints in 10 to 20 degrees of flexion), the pattern extends beyond the fingertips and in fact is too long. The same pattern on the dorsum of the hand (Figure 30-27, *D*) with the wrist now in flexion illustrates that the pattern is now too short. Going from the volar surface of the hand to the dorsal surface is akin to driving around the inside of a curve as opposed to the outside of a curve. As any race car driver knows, the inside of a curve is the shorter distance. Altering the position of the hand and the surface to which the splint will be fit alters the length of the pattern. The splint maker must accommodate for this by checking the splint pattern on the hand in the position in which the hand will be splinted.

Depth is the second dimension that must be considered when a pattern is made. The ideal trim lines of a

single-surface splint fall at midline along the arm, hand, leg, or foot. A splint trimmed at midline provides optimal support and allows for proper strapping to help secure the splint in place (Figure 30-28).

To determine how much to add to the outline to achieve midline trim lines, the maker must observe the width and depth of the arm or hand. The forearm is cone-shaped, not a straight cylinder, and it graduates in depth over the forearm muscle. Even the thinnest forearm graduates in width and depth proximally. Persons with significant muscle bulk may have graduation at quite an acute angle from the wrist to the proximal forearm. Determination of how much to add to a forearm trough must consider how much the splint must come out, around, and up the forearm to reach midline. The depth of the hand, particularly the depth of the hypothenar eminence, must be known to create the proper trim lines for a hand platform.

In the fit of any forearm-based splint, the proximal trim lines must take advantage of the soft muscle bellies that protect the radius and the ulna. The proximal borders of the splint should be flared so that the trim line

FIGURE 30-28 Forearm trim lines. **A**, Trim lines are too high, extending above forearm. Straps will bridge arm and will be ineffective. **B**, Trim lines are too low. Straps cannot substitute for too-low trim lines without applying excessive pressure. **C**, Midline trim lines ensure that straps properly secure splint on arm and hand.

FIGURE 30-29 **A**, Narrowing the proximal pattern will cause trim lines to drop below midline. **B**, Flaring the proximal border of the splint maintains trim lines at midline.

remains at midline to help secure the splint in place on the arm (Figure 30-29).

A forearm-based splint should extend approximately two thirds of the length of the forearm, as measured from the wrist proximally. A good rule to remember is to bend the client's elbow fully and mark where the forearm and the biceps muscle meet. The splint should be trimmed one-quarter inch below this point to avoid limiting elbow flexion, and to prevent the splint from being pushed distally when the elbow is flexed (Figure 30-30).

Most low-temperature thermoplastics used to make splints will stretch to conform around angles and contours. When a pattern is created that will go around an acute angle, such as a 90-degree angle around a flexed elbow or wrist, the pattern should include a dart, where the material can be overlapped without causing undue bulk (Figure 30-31). The pattern may be angled where necessary to accommodate acute angles. A well-fit and well-thought-out pattern translates to less material wasted, less expense, and shorter fabrication time.

FIGURE 30-30 Length of forearm-based splint is checked by flexing elbow and noting where biceps meets forearm. Splint is trimmed $\frac{1}{4}$ to $\frac{1}{2}$ inch distal to point of contact.

FIGURE 30-31 Drawing darts in elbow pattern allows material to be overlapped and contoured without excess material.

Step Two: Choosing Appropriate Material

The materials commonly used for custom-fabricated splints are those in a family of plastic polymers that become pliable at a temperature low enough for the material to be molded directly onto the skin. The low-temperature thermoplastics (LTs) currently available have certain characteristics that

can be defined according to how a material reacts or handles when warm, and how it reacts once molded.

Choosing the optimal material for a given splint application can make the difference between a quick and easy splint-making process and one that requires extensive adjustments and reheating. It behooves every splint maker, novice to advanced, to sample a variety of materials and test the handling characteristics, so that no surprises occur when a material is heated and is ready to be cut and fitted to a client.

Characteristics of Splint Materials

Each LTT has some handling characteristics that apply when the materials are warm and pliable, and others that apply when they are cold or molded. Following is a list of the most common characteristics and a description of how each contributes to the choice of a material for a specific application.

Resistance to Stretch

Resistance to stretch describes the extent to which a material resists pulling or stretching. The greater the resistance, the greater is the degree of control that the splint maker will have over the material. Materials that resist stretch tend to hold their shape and thickness while warm and can be handled more aggressively without thinning. More resistant materials are recommended for large splints and for splints made for persons who are unable to cooperate in the fabrication process. In contrast, the less resistance to stretch a material has, the more the material is likely to thin during the fabrication process, and the more delicately it must be handled. The advantage of stretch is seen in the greater degree of conformability attained with less effort on the part of the splint maker.

Conformability or Drape

Resistance to stretch and conformability or drape describe nearly the same characteristic, that is, if a material stretches easily, it will have better drape and conformability. The great advantage of materials with a high degree of drape or conformability is that with a light, controlled touch or simply the pull of gravity, they readily conform around a part for a precise fit. The disadvantage of materials with a high degree of drape (and generally also low resistance to stretch) is that they tolerate only minimal handling, and care must be taken to prevent overstretching and fingerprints in the material. Materials with a high degree of drape are not recommended for large splints or for uncooperative clients. They are ideal, however, for splinting postoperative clients when minimal pressure is desired, and for dynamic splint bases, in which conformability secures the splint against migration (movement distally) when components are attached. Materials with a low degree of drape must be handled continuously until the materials are fully cooled to achieve a contoured fit; often they will not conform intimately around small parts such as the fingers.

Memory

Memory is the ability of a material, when reheated, to return to its original, flat shape after it has been stretched and molded. The advantage of high memory in a material is that the splint can be remolded repeatedly without thinning and weakening of the material. Materials with memory require handling throughout the splint-making process because until they are fully cooled and molded, they tend to return to a flat shape. This and the slightly longer cooling time of materials with high memory can be used to advantage with clients who require more aggressive handling to achieve the desired position. Disadvantages of materials with excellent memory are their tendency to return to a flat sheet state when an area is spot heated for adjustment, and their need for longer handling to ensure that they maintain their molded shape until fully cooled.

Rigidity vs. Flexibility

Rigidity and *flexibility* in cold splint material are terms that describe the amount of resistance a material gives when force is applied to it. A highly rigid material is very resistive to applied force and may, with enough force, break. A highly flexible material bends easily when even small force is applied to it, and it is not apt to break under high stress. Materials are available that fall all along this continuum.

Generally, the thicker a thermoplastic and the more plastic its formula contains, the more rigid the material will be. Thermoplastics come in thicknesses ranging from $\frac{1}{8}$ inch (3.2 mm) to as thin as $\frac{1}{16}$ inch (1.6 mm). Thinner materials and thermoplastics that contain rubber-like polymers in their formula tend to have greater flexibility in their molded state. Flexibility in a material allows for easier donning and doffing of splints and may be desirable for clients unable to tolerate the more unforgiving rigid materials. Rigidity is also a factor of the number and depth of contours included in the design. The same material may yield a semiflexible splint when used to make a single-surface splint with shallow contours, or a rigid splint when used to make a tightly filled circumferential splint.

Bonding

Bonding is the ability of a material to adhere to itself when warmed and pressed together. Many materials are coated to resist accidental bonding and require solvents or surface scraping to remove the coating to bond. Uncoated materials, which require no solvents or scraping, have very strong bonding properties when two warm pieces are pressed together. Self-bonding is helpful when outriggers or overlapping corners are applied to form acute angles, but can be a problem if two pieces adhere accidentally.

Self-sealing Edges

Self-sealing edges are edges that round and seal themselves when heated material is cut. This characteristic produces smooth edges that require no additional finishing, which adds time to the fabrication process. Materials with little or

no memory and high conformability generally produce smooth, sealed edges when cut while warm. Materials with memory and those with high resistance to stretch resist sealing, requiring additional finishing.

Soft Splint Materials

Soft, flexible materials such as cotton duck, neoprene, knit elastics, and plastic-impregnated materials may be used alone or in combination with metal or plastic stays to fabricate semiflexible splints. These materials allow fabrication of splints that permit partial motion around a joint, yet still limit or protect the part. Semiflexible splints sometimes are used during sporting activities and to assist clients with chronic pain in returning to functional activity. Semiflexible splints are also used for geriatric clients and for clients with arthritis, who often cannot tolerate rigid splints.

Neoprene splints can be fabricated with the use of sealing glue or iron-on tapes. Careful attention must be given to the patterns for soft splints, because the support they offer relies primarily on achieving a secure fit without gapping or excess material. Most other soft materials require sewing, and the fully equipped OT department should include a sewing machine. A sewing machine is useful for adapting and adjusting prefabricated soft splints to ensure that each splint that leaves the clinic is indeed custom-fit, if not custom-fabricated.

Choosing the Best Category of Material for the Splint

Although an experienced splint maker can make many types of splints from the same material, it is better to choose a material with appropriate handling characteristics for the type of splint being made. The following list can be used as a guide from which to start choosing materials for different applications. The availability of materials and the experience level of the therapist assist in determining the most appropriate material.

Forearm-Based and Hand-Based Splints

Splints need close conformability around a part when they serve as a base for a dynamic splint, stabilize a part of the body, reduce contractures, remodel scar tissue, or immobilize to facilitate healing of an acute condition. Such splints should be made from a material with a high degree of conformability to achieve a conforming fit. When conformability is not crucial, the splint can be made from a material with high resistance to stretch and low to moderate drape. Splints fabricated for burns and other acute trauma do not require as conforming a fit and can be made from low-drape materials. Materials that resist stretch and tolerate aggressive handling are recommended for positioning of a spastic body part, because such materials will not stretch and thin during the splint-making process. Experienced OTs who work without a formal pattern choose a material with a higher degree of drape and conformability and allow gravity to assist in the splinting process.

Large Upper and Lower Extremity Splints

Long splints fabricated for the elbow, shoulder, knee, or ankle generally should be made of materials that have high resistance to stretch, to provide the control necessary for dealing with large pieces of material. Such splints generally do not need to be highly conforming because they are molded over broad expanses of soft tissue. Care must be taken to provide relief for bony prominences, or to provide padding to distribute pressure.

Circumferential Splints

A splint designed to wrap all the way around the part should be fabricated from materials that have a high degree of memory and that tolerate stretching without forming thin spots. The materials should be highly perforated, thin, and able to be stretched evenly. After being stretched, these materials will cinch in around the body part while still allowing sufficient flexibility for easy donning and doffing. These materials work very well for fracture bracing and for circumferential splints that are used for contracture reduction and for stabilizing or immobilizing joints. Another choice for making less restrictive circumferential splints is the use of semiflexible materials, which facilitate easy donning and doffing and allow limited motion within the available arc of motion.

Serial Splints

Serial splints that require frequent remolding to accommodate increases in joint range of motion should be made from a material that has considerable memory or is highly resistant to stretch, to avoid thinning with repeated remolding. The chosen material should have moderate to high rigidity when molded to resist forces from contracted joints or from spastic muscle tone.

Step Three: Choosing the Type of Traction

All splints provide some form of traction to move or stabilize a joint or joints. The traction mechanism may be dynamic, using a spring, hinge, or elastic. Traction may also be static, employing straps or turnbuckles or involving remolding of the splint base itself. If the mechanism moves or is resilient, the splint is called a *dynamic splint*, and if it does not move, the splint is called a *static splint*. The following section describes the various options for applying traction and discusses appropriate uses of each option.

Dynamic Traction

The purpose of dynamic splints is mobilization of a joint through the use of a resilient force attached to an outrigger, or through the use of a spring coil. Each mechanism of force has advantages and disadvantages that make it suited for some uses and ill-suited for others. Construction techniques differ substantially when spring coils are used versus outriggers with elastic components. Thus, the indications for each style of splint vary.

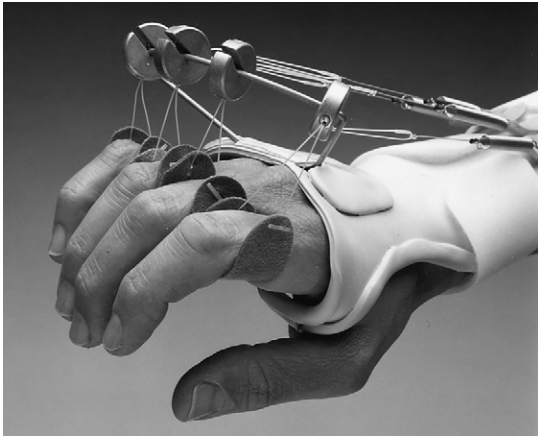

FIGURE 30-32 Easily adjustable Phoenix outrigger with slotted pulleys allows frequent changes in angle of approach.

Spring coils are best suited to assist weak muscles or to substitute for paralyzed muscles (see [Figure 30-24](#)). Clients with weak or paralyzed muscles will likely require the splint for a long time and will wear it while working or performing their ADLs. The low-profile, lightweight construction of a coil splint is recommended because it is less likely to interfere with hand function. Spring coils retain their force and alignment over time, rarely require adjustment, and are ideal for long-term conditions.

Splints with outriggers are the optimal choice for splinting postoperative clients ([Figure 30-32](#)). These splints allow frequent adjustments to maintain correct positioning and to accommodate changes in bandage thickness and edema as healing and rehabilitation progress. The postoperative client will likely use the splint for only a short time, generally 4 to 6 weeks. Such a client will not be returning to normal functional activities with the affected hand during that time. Thus, the bulkiness and limited function associated with an outrigger splint are relatively unimportant, but it is vital that the splint be able to be self-donned, because it is usual for the client to remove it for periods of time or to alternate it with other splints. Alexei's dynamic extension outrigger (see [Figure 30-18](#)) is an example of this. He alternated it with his dynamic flexion outrigger and discontinued it after 3 weeks, when his extension goal was met.

Splints with outriggers are also used for contracture reduction. For this purpose, they are generally most effective when used during the early stages of healing, when the contracture feels soft and is easy to reduce.⁹ Frequently, clients at this stage still have pain and inflammation. They cannot tolerate a rigid, static splint, but they will tolerate a light force provided by an outrigger.

Static Traction

The overall purpose of static traction splints is to apply traction to immobilize or restrict motion. When static splints immobilize, they are protecting, resting, or positioning. When they restrict, they are blocking motion, aligning

joints, or limiting motion. When static splints are used to mobilize, they are used in a serial static or static progressive fashion to reduce contractures and remodel scars.

Serial Static Traction

A serial static splint is fabricated by repeated adjustments that position a joint at its end range of motion each time to achieve slow, progressive increases in ROM. For example, a cylindrical cast made for gaining PIP extension must be remade after a time (usually 1 to 3 days) to reposition the joint at the end of its range of motion (see [Figure 30-21](#)).

Static Progressive Traction

A static progressive splint requires a built-in mechanism for adjusting the traction. Choosing which mechanism to use, be it a turnbuckle, a Velcro strap, or a buckle (see [Figures 30-22 and 30-25, A](#)), depends on availability, the therapist's experience, and the client's ability to manage the mechanism. A good rule to follow is to choose the simplest component that will achieve the desired goal.

Serial static splints and static progressive splints each have certain advantages and disadvantages. Serial static splints are useful for difficult clients who have high muscle tone, or who are cognitively impaired and would have problems with the adjustment mechanisms. This splint choice also gives the therapist the control necessary for clients who are noncompliant, or who would be overly zealous and would apply too much force. Disadvantages are that the splint requires more therapist time because it must be remolded many times, and if the client does not remove it for several days, some ROM may be lost in the direction opposite to that in which the splint is applying force.

Advantages of a static progressive splint are that the therapist has to make only one splint, and that reliable clients with normal muscle tone may make more rapid progress because they can tailor the adjustment to their own pace and tolerance. The disadvantage of a static progressive splint is that it cannot be used on the client who has abnormal tone, or who is unreliable.

Implications of Application of Force

All splints, whether static or dynamic, apply force and to some degree stress on the structures they contact. The unimpaired hand tolerates a wide range of stresses by adaptation when possible and by avoidance when not. The client with sensory or cognitive impairment may lack the protective responses necessary to reposition the hand away from stresses applied by splints.

Pressure causes ischemia (localized anemia caused by obstruction of blood supply to tissues), and pressure is increased when splints are contoured too sharply, when they do not conform uniformly, or when they do not cover a broad enough area of soft tissue. Splints that migrate or move on the hand because of insufficient strapping or contouring may actually apply pressure in areas that the splint was designed to relieve.

Amount of Force to Apply

How much force can be applied safely? No absolute rules exist regarding the amount of force that can be applied for immobilization, or to a restricted joint to produce motion. The splint maker must apply sufficient force to create motion, but not so much as to cause ischemia. Much depends on the degree of the contracture, how long the restriction has existed, the age of the client, and the location of the restriction. This leaves the therapist with several options when choosing which force and how much force to apply.

For example, external force in dynamic splints generally is applied through the addition of rubber bands, elastic, or springs. No option is ideal, and all require careful selection, frequent adjustment, and client education on frequent skin checks. The amount of force supplied by rubber bands and springs depends on their thickness and their length. The thickness of the band or spring determines its potential force, whereas the length of the band or spring (or the number of coils in the spring) determines the ROM through which the force can be applied. When bands or springs are used, it is desirable to use the optimal force (i.e., the greatest tolerable force over the longest wearing time) that does not produce ischemia. To accomplish this, the midrange of the bands or springs should be used, rather than their end ranges, which may be too slack or too strong. A gauge is available for measuring the applied force of elastic, which generally should be between 100 and 300 g.

Techniques are available for avoiding pressure areas and shear forces in a dynamic splint, particularly when traction is applied to mobilize a finger joint. First, the joint(s) proximal to the finger joint being splinted must be stabilized. For instance, to mobilize a PIP joint with an outrigger and cuff, the MP joint must be held securely, so that no movement occurs to cause the splint to produce pressure points elsewhere on the hand or digits. Care must be taken in contouring the splint around the proximal phalanx, to distribute pressure and prevent motion that could cause shearing over the dorsum of the finger. In this case, padding may be necessary to help distribute pressure over the small and thinly padded phalanx (Figure 30-33).

Duration of Traction

Basic to answering the question, “How long should traction be applied?” is an understanding of theories of tissue stretching versus tissue growth. Three key concepts aid in the understanding of these two different tissue responses. First, all materials, including human tissue, respond to applied stress. If stress is applied over time and then is relaxed, the tissue will no longer return to its original shape but will adapt to the new shape. This stretching phenomenon in skin is a result of its plastic behavior and is known as *creep*. The lengthening that occurs with creep is found to be the result of “a slippage of short collagen fibers on one another within the tissue. Some fibers may rupture, while others just slide on each other.”⁸

FIGURE 30-33 Felt padding distributes pressure over bony proximal phalanx.

The second concept is that of the elastic limit of tissue. Think of pulling on a rubber band. As the band is pulled, tension increases until the elastic limit is reached. If pulled beyond its elastic limit, the rubber band will break. In clinical terms, the end of the elastic limit is the point of tissue elongation at which pain will be felt and tissue damage may occur. Stretching tissue beyond its elastic limit does not lead to permanent lengthening, but it does cause unwanted tearing and probable further tissue contracture.⁸ For creep to occur in living tissue, traction must hold the skin with sufficient force to exceed the elastic limit of the skin. This may cause tearing of small fibers, which leads to inflammation and additional scarring caused by fibrogen deposits.

The third concept is tissue growth. True growth occurs when “living cells will sense strain and collagen fibers will be actively and progressively absorbed and laid down again with modified bonding patterns with no creep and no inflammation.”⁸ This is the aim of splinting when the goal is contracture reduction or lengthening of restricted soft tissue.

Two approaches may be used to apply traction to lengthen soft tissue and reduce contractures. One approach is to position the tissue at the end range of its elastic limits and hold it statically for short periods, and then to relax and reposition it frequently. This approach is termed *stress relaxation*.⁷ The second approach is to apply force within the elastic limits of the tissue, hold it for a long period, and then reposition it. Differences between these two approaches include time and ability to judge the elastic limits of tissue. The first approach relies on principles of stress relaxation, which theorize that tissues reach their elastic limit over a shorter period with frequent repositioning and will retain this newly set limit over time.⁷ The second and more commonly used approach relies on the application of a low load over a long time to allow tissue growth to occur. Both approaches have merit, and it is up to the therapist, who develops this skill with experience over time, and the prescribing physician to determine the appropriate approach in each instance.

Step Four: Choosing a Splint Design for a Given Purpose

Mobilizing Splints to Remodel Scar Tissue and Reduce Contractures

Scar tissue is one of the major contributors to deformity or joint changes. Any time an insult to tissue occurs, as after an open injury or after surgery, scar tissue is produced by the body to heal the wound. The scar may be subcutaneous, superficial, or both. When it is subcutaneous, it often results in loss of motion, because scar tissue acts like glue, keeping tissue planes from gliding. Scar also contracts; when this contracture occurs over a joint, loss of joint motion results. To restore motion, scar tissue must be remodeled, that is, it must be softened and lengthened. If the contracture is caused by shortened soft tissue that is not scar, that soft tissue must also be lengthened. The process is the same for scar or soft tissue.

The effectiveness of splinting for remodeling scar and reducing contractures can be increased greatly by application of a deep heat modality, such as paraffin or moist heat, before application of the splint. When tissue is unheated, it is less elastic, meaning that it has a great deal of tension and is difficult to elongate. With the application of heat, tissue becomes temporarily more elastic, meaning that tension in the tissue is reduced and the tissue is much easier to elongate.

Many approaches are available for splinting for remodeling scar and reducing contractures. Three-point splints can be used for flexion contractures (extension ROM is decreased), loop splints for IP joint extension contractures (flexion ROM is decreased), and outriggers for MCP extension contractures (lack full flexion ROM at the MCPs). Dynamic outriggers can be used to reduce early, soft tissue contractures, particularly when the client cannot tolerate a static splint. Static progressive splints or static splints can be used in a serial fashion.

Immobilizing and Restrictive Splints for Pain Reduction

Of the many uses of splints, perhaps the most common is to limit or reduce pain by providing rest and support. The most common splint prescriptions are written for splints to reduce the pain caused by the inflammatory processes of tendinitis or after sprain or strain injuries.

Several questions help determine which splint will best serve the client's needs. First, if the injury is caused by an acute sprain, the choice may be an immobilizing splint until pain and edema have subsided. If the pain is chronic in nature and is caused by the performance of a particular activity, a semiflexible splint may serve best. A semiflexible restrictive splint may sufficiently reduce pain by limiting ROM, yet still allow function without increasing stress on unaffected joints or tissue (Figure 30-34).

A second question concerns the need for full-time splinting versus intermittent wear. In the presence of an acute injury with orthopedic involvement or tissue damage, the

FIGURE 30-34 Flexible thumb splint provides support yet allows midrange movement.

splint may need to immobilize and to protect the part from further damage. Here, client tolerance and compliance will in part determine material and design choice. The therapist may also need to consider the integrity of the tissue and the need to accommodate bandages and bandage changes. If the splint is indicated only for intermittent wear, the design choice may depend more on the client's ability to readily don and doff the splint. The choice of materials may be dictated by the functional needs of the client. For intermittent splints used for vocational activities, lightweight, well-aerated materials may be indicated. For intermittent splints used for positioning, such as a resting splint designed to maintain functional position between exercise sessions, stronger materials may be indicated, and perforations may not be necessary.

A third important question in deciding on a splint design is, "What structures need to be immobilized or supported, and which should be left free?" When protective or pain-reducing splints are provided, care must be taken to splint only the involved structures without impeding motion elsewhere. If the purpose of the splint is to rest the tendons at the wrist to reduce inflammation, the splint must not limit carpometacarpal (CMC) or MP joint motion if these structures are not symptomatic. If used during the performance of ADLs, splints that fully immobilize a joint may transfer stress to joints proximal or distal to the immobilized joint. For this reason, semiflexible splints that restrict only end ranges of motion may be indicated during activity, whereas an immobilizing splint may be indicated for total rest at night.

Immobilizing Splints for Positioning

One of the splints most frequently fabricated by OTs is the resting pan (also known as the resting hand or functional position splint), which is used to maintain the hand in a functional position (see Figure 30-20). The purpose of this positioning splint is to keep the soft tissues of the hand in midrange to maintain optimal mobility and to prevent shortening of the soft tissue structures around the joints. Occasionally, positioning splints are prescribed to position joints at end range to prevent contractures in the presence

of severe tissue damage, as with burns. The important decision involves determining the optimal position for the most functional outcome.

Positioning splints may be fabricated for temporary use after surgery and may require frequent adjustment to accommodate changes in edema and bandages. The materials chosen for these splints should have memory to allow for remolding while keeping their thickness and strength. The choices of a dorsal versus a volar-based splint and a single-surface versus a circumferential splint depend on surgical and wound sites, the need for ease of donning and doffing, the client's available sensation, and the therapist's and physician's preferences and experience.

Step Five: Fabrication

The fabrication processes for single-surface and circumferential splints differ significantly. They do have a starting point in common: the pattern from which the splint will be made. Starting with a paper pattern is recommended, particularly for the novice splint maker. One very basic rule of splinting is to get the pattern right before beginning to work with plastic. It is far less expensive to discard a few pieces of paper than even a small piece of LTT. Also, if one saves the paper splint pattern in the client's chart, it is easy to use to fabricate another should the splint be lost, or to enlarge it as a pediatric client grows. Pattern making, design principles, and principles of fit are important components of knowledge for splint fabrication; these concepts can be learned by the novice splint maker by going online to the Evolve Website associated with this publication, or by referring to a book such as *Hand and Upper Extremity Splinting: Principles and Methods*.¹¹

Fabrication Techniques for Single-Surface Splinting

Single-surface splints cover the volar surface, the dorsal surface, the ulnar half, or the radial half of the arm and hand. Generally, single-surface splints have gentle contours and cover as broad an area of tissue as is feasible to distribute pressure. The following steps should be used as a guide in the process of creating a single-surface splint. For the sake of demonstration, the single-surface and circumferential splints described and pictured are wrist extension (cock-up) splints (Figure 30-35, A):

1. Except for the fingers, $\frac{1}{8}$ -inch-thick material is recommended to obtain sufficient rigidity to hold the joint firmly in position. The broad contours of single-surface splints require thicker materials to provide sufficient support.
2. Etch the pattern onto the cold thermoplastic material with a scratch awl or wax pencil before placing the material in a hot water bath. The water temperature required for most materials to soften properly is approximately 160° F. Temperature and time will vary, depending on the material and its thickness; this information is typically provided by the material's

manufacturer in the accompanying literature. Most materials heat to the pliable stage in 1 to 2 minutes.

3. Carefully remove the material from the hot water bath and lay it flat on the table for cutting. To prevent stretching, avoid holding material unsupported while cutting (Figure 30-35, B).
4. Starting at the neck of the scissors, cut with long, even strokes to prevent jagged edges.
5. Reheat the material if it has cooled too much to be formed. Place the material on the forearm and hand with the forearm in supination so that gravity can assist the initial molding. Some therapists prefer the elbow propped on a table with the hand in the air if the client is compliant. Check that the trim lines fall at the midline. If they do not, mark where excess material needs to be removed. Trim the material before it cools. Note areas that will need to be folded for clearance and for creation of smooth edges. Fold and secure the edges firmly in place (Figure 30-35, C).
6. Reposition the splint on the forearm. Maintaining control on the wrist and forearm sections, carefully pronate the forearm. Maintain the wrist in extension at all times. The tendency for the wrist to drop into flexion when the forearm is pronated is universal. Controlling the wrist will ensure that the desired wrist position is maintained at all times (Figure 30-35, D). If necessary, rotate the forearm section to ensure that the trim lines are at midline. Refer to Figure 30-6 to review the importance of the changing shape of the forearm from a supinated to a pronated position.
7. Allow the splint to cool until it holds its shape. It does not have to be held in place until completely cold. Remove the splint. Heat and smooth any rough edges as needed, and apply the straps.
8. Strapping is critical to secure the splinted part in the splint and to diminish shear forces and the possibility that pressure areas may develop. The splint may require several straps; wide or crossed straps are suggested to obtain the necessary control. Because the forearm is cone shaped, straps placed straight across the forearm will contact the skin effectively only on their proximal surface (Figure 30-36). To have the forearm straps apply effective and well-distributed pressure, you may consider placing them at an angle.
9. Single-surface splints rely on strapping to hold them in place and to create one or more three-point pressure systems to securely hold the joint or joints being splinted (see Figure 30-25, B). For straps to function properly, trim lines must fall midline along the arm and hand. If the trim lines are left too high, making the trough too deep for the part, the straps will bridge the part and sit up on the edge of the splint, where they are ineffective. The most effective way to secure a splint in place on the forearm is to apply pressure through the splint onto the soft tissue

FIGURE 30-35 **A**, Pattern for single-surface cock-up splint on left requires precision for a proper fit. Pattern on right for circumferential splint does not need precise fit because material stretches and overlaps to achieve proper size. **B**, Support material on table to prevent stretching, and cut with long strokes of scissors. **C**, Fold edges of material and gently press flat to create thin, smooth edges that distribute pressure better. **D**, Gently support the wrist at all times to achieve proper fit.

FIGURE 30-36 Forearm is cone shaped, gradually widening from wrist to elbow. **A**, Strap laced straight across broader proximal forearm contacts skin only at point A and does not secure splint. **B**, Strap placed at angle applies even pressure along line BC to secure splint.

of the forearm muscle bellies. If the forearm trim lines angle below the muscle bellies, the splint will no longer be secured on the muscle bellies.

- Instruct the wearer regarding the wearing schedule and proper care of the splint. To prevent ischemia and shear forces, check the fit of the splint regularly.

Fabrication Techniques for Circumferential Splints

- Use a thin or highly perforated elastic material or a flexible rubber material that has some memory. For hand- and forearm-based splints, thin elastic materials ($\frac{1}{16}$ -, $\frac{1}{12}$ -, or $\frac{3}{32}$ -inch) provide sufficient strength because of the rigidity provided by the curves of the splint. For splints covering larger areas, a highly perforated $\frac{1}{8}$ -inch material is recommended. Materials for circumferential splints should be coated to prevent permanent adherence when warm or should be able to be pulled apart once cooled.
- Etch the pattern onto the material. Because the materials for circumferential splints are generally stretched to contour around the arm, the pattern does not need to be as precise as for a single-surface splint. It is important to know how much the material will be pulled and if it will be overlapped or finished edge to edge, so that a piece of sufficient size is cut (Figure 30-37).
- Wrap the material all the way around the part being splinted. Two techniques can be used to create closure for a circumferential splint. The first is to pull the

FIGURE 30-37 Circumferential splint trimmed to close edge to edge.

material around the part and pinch the remaining material together to create a seam. Gently tug on the seam to conform the material. When the material is cool, open the seam and trim the splint. The second technique is to overlap the two ends to form a flap (Figure 30-38). To prevent the flap from adhering (this may happen when the coating is thinned as the material is stretched), wait until it has cooled slightly before overlapping.

4. Smooth edges as necessary. The circumferential splint creates multiple three-point pressure systems by virtue of its design, and strapping is used only to hold the splint firmly closed.

Fabrication and Fitting of Semiflexible Splints and Prefabricated Splints

Materials used in the fabrication of semiflexible splints include neoprene, cotton duck, woven elastics, and thermoplastic-impregnated materials. Neoprene splints are generally fabricated with use of a special glue that adheres pieces together at the edges. The patterns for neoprene splints must be precise to achieve a conforming fit. Cotton duck and other woven materials require sewing and considerable skill in pattern creation and the addition of darts to ensure a good fit. Very thin thermoplastic materials can be used to create semiflexible splints, and certain patterns can be adapted to allow for partial range of motion within a splint.

Many commercially prefabricated splints are made from woven materials, because these materials present the broadest range of size adjustability and are less likely to require custom fabrication. It is highly recommended that even a prefabricated splint should be custom fit by a therapist to ensure proper fit and adherence to an appropriate wearing schedule. A well-supplied splint department should include a sewing machine for use in custom fitting all splints.

FIGURE 30-38 Circumferential splint made from flexible material with overlap for easy donning and doffing.

Remember that it is the therapist's responsibility to take the time to develop the skills needed to ensure that even prefabricated splints fit the client as if they were custom made.

SECTION 2 | Suspension Arm Devices and Mobile Arm Supports

Y. LYNN YASUDA

Suspension arm devices and mobile arm supports are commonly used and can fulfill several treatment objectives for the person with severe physical disability. These devices can support the shoulder and forearm, encourage motion of weakened proximal musculature, prevent disuse atrophy, prevent loss of ROM, provide pain relief, provide proximal support for distal function, and enable occupational performance.

Suspension Arm Devices

Suspension arm devices are suspended from above the head, generally on an overhead suspension rod that most often is attached to a wheelchair. They also can be attached to regular chairs, a child's highchair, a body jacket, or even an overhead track used for walking clients.⁶ Without the

Threaded Case Study | Alexei, Part 2

Using the Occupational Therapy Practice Framework, the evaluation of Alexei began with an occupational profile to establish his needs, priorities, and goals, which included the ability to administer his own medications and to be independent in his ADLs so he could return to his independent living apartment. Analysis of Alexei's occupational performance identified his inability to grasp small objects such as insulin syringes and a glucose level tester, and to perform ADLs such as grasping a normal eating utensil or toothbrush, zipping his pants, or taking money from his wallet. Alexei demonstrated problems within the performance skills category, including poor coordination of motion and difficulty manipulating objects. Under the category of client factors, problems with his right dominant hand included lack of ROM and the mobility required for successful task performance. The personal (or internal) contexts supporting Alexei that were identified during the evaluation revealed his flexibility and intelligence, his engaging and assertive communication style, his ability to learn an exercise regimen and how to use complex splints, his history of successfully managing health-related problems such as diabetes, his strong motivation to remain independent in his own apartment, and his psychological need to live in a place that would allow him to have a companion pet. His external contexts, including physical and social contexts, both supported and interfered with Alexei's achieving his goals. Positive aspects included his living in a full-service senior housing complex, a supportive nursing staff at his complex willing to help him regain independence, and an administrator

at the complex who was willing to modify the rules slightly to support Alexei's goal of returning to his apartment in the independent living section of the complex. Negative aspects of these contexts included lack of adequate transportation to therapy and the living site's strict procedural rules that residents must stay in the least restrictive setting.

What would have happened to Alexei if OT intervention had consisted of just therapy sessions with no dynamic splinting? ROM gains achieved during therapy probably would not have been maintained. The intervention plan of dynamic splinting was established on the basis of Alexei's limited ability to get to therapy appointments, coupled with his ability to carry out much of his rehabilitation on his own or with the assistance of nursing staff at the assisted living complex.

How critical was the team approach, and how important was ascertaining the client's main goal during the initial evaluation? The outcome was ultimately successful because (1) a collaborative relationship was formed between the very motivated client, the OT, and the nursing staff, with all participants focusing on and working toward the goal of retraining Alexei in independent medical management, and (2) the complex administrator agreed to bend the rules for a month until Alexei's goal of complete independence could be achieved. Without a focused goal, much therapy time could have been lost working toward gains less important to the client, which may have ultimately robbed him of his independence.

Threaded Case Study | Manny, Part 1

Manny is 31 years old. He has been married for 5 years and has a 3-year-old daughter. He had been working for 5 years in a law firm with 20 attorneys. He incurred a complete C5 level spinal injury in an auto accident 1 month ago. He is currently in a rehabilitation center in the city, where he lives and worked. Upon arrival at the rehabilitation center, his early expectation was that he would recover from his spinal cord injury. However, as the medical staff described to him evidence of a complete fracture dislocation in the cervical spine, Manny began to think that he would need the ability to perform selective occupations in an adaptive manner to resume life in the community where he resided before his injury occurred.

In an OT assessment in which the Canadian Occupational Performance Measure was used, the client was asked to identify the most important occupations in which he would like to participate upon his return home. The occupation of greatest importance to Manny was to resume his law practice. This occupation was of primary importance so that he could financially support his family and regain his sense of integration back into the community. This meant that he would have to be able to manage the occupations of written communication, phone use, computer use, and essential activities and basic ADLs (i.e., self-feeding, pressure relief, and independent mobility) in the office. He also felt that he needed

to resume the role of father by being able to play with his child, and he wanted to be able to participate in social activities with his wife, such as attending dinners in restaurants. Upon admission, Manny was unable to participate in any of the occupations just listed. In terms of his performance skills, his upper extremity strength was 2 (poor) in the proximal muscles, 2 (poor) in elbow flexion, 0 in elbow extension, and 0 in skeletal muscles distal to the forearm. Manny's sensation was partially absent in the upper arm and completely absent in the elbow distally. Because of appropriate intervention during his admission to an acute care facility, his passive range of motion throughout his stay was within the functional range.

Critical Thinking Questions

1. Given Manny's performance skills, would any equipment enable him to resume his most important occupation of practicing law? What is this equipment?
2. How would you approach discussion with this client regarding equipment needs for his return to work?
3. What series of interventions will you provide to enable Manny to return to his law firm, where the partners are concerned about his ability to manage the many aspects of the job of an attorney?

suspension rod, they are attached to over-bed frames to allow the client to use the device while in bed. These suspension arm devices were found in OT clinics as early as the 1940s. Ease of management, low cost, and ability to support proximal weakness of the upper limb contributed to their early popularity,¹⁹ and they continue to be used for selected purposes.

Purposes

Suspension arm devices may be used to meet some of the following objectives:

- To position the shoulder girdle musculature to allow distal muscles to engage in occupational performance
- To assist and support below fair-grade (F or 3) shoulder girdle musculature
- To allow gravity-eliminated exercise for weak shoulder girdle musculature
- To encourage increased ROM through repetitive activities¹⁹
- To prepare clients to use **mobile arm support (MAS)** by encouraging weak proximal musculature to move
- To support a painful shoulder
- To position an edematous hand away from a dependent position
- To prevent loss of shoulder ROM

Suspension arm devices generally are more effective for positioning and exercise than for occupational performance because of the mechanical principles on which they operate. The upper limb swings as a pendulum from straps or springs attached to the suspension rod; this makes it difficult to make fine adjustments in movement.¹⁹

Variations in Suspension Arm Devices

Several variations of suspension arm devices are available. The overhead rod may be the same, but the attachments to the rod reflect variation. The variations discussed here are commercially available and are in current use.

Suspension Sling

The suspension sling (Figure 30-39) has a single strap (A) suspended from the suspension rod (B). A horizontal bar (adjustable balance bar, JAECO Orthopedic Inc., Hot Springs, Ark.¹⁶) with holes for adjustment of the fulcrum (C) supports the two leather suspension slings (D). These slings provide support for the wrist and elbow separately. The adjustable suspension mount (E) is attached to the wheelchair and holds the suspension rod.

Suspension Arm Support

The suspension arm support (JAECO¹⁶) (Figure 30-40) has a forearm support that is the same as that used in the mobile arm support. It is suspended from a single point on the suspension rod. This device can be used as an initial step for the client who can benefit from an MAS and is easily applied to the wheelchair. It can be easily attached and adjusted to over-bed frames to allow clients who are

FIGURE 30-39 Suspension sling. A, Strap. B, Suspension rod. C, Horizontal bar (adjustable balance bar). D, Wrist and elbow suspension slings. E, Adjustable suspension mount.

(Adapted with permission from Occupational Therapy Department, Rancho Los Amigos Hospital, Downey, Calif.)

confined to bed to perform tabletop activities, in addition to hand-to-face occupations, with this device (Figure 30-41). However, it does not have the fine adjustment capabilities of the MAS, which extremely weak clients need. With a special mount (Figure 30-42), the suspension arm support is easily adaptable to the reclining wheelchair. This feature makes it useful during the rehabilitation of clients who cannot yet sit fully upright.

Adjustment of Suspension Arm Devices

Straps

The strap that connects the suspension rod to the limb directly or by the horizontal bar (adjustable balance bar) or forearm support attachment may be adjusted for length. This provides elevation control for the entire limb or for the wrist and elbow separately when separate supports are provided. Adjustments for height relative to the work surface or to the face are similar to adjustments discussed in the later section on MAS.

Height

The suspension rod can be adjusted on the wheelchair suspension mount. The higher the suspension rod, the flatter is the arc of pendulum swing when the arm is in

FIGURE 30-40 Suspension arm support. A, Adjustable suspension mount. B, Forearm support. C, Springs. D, Suspension rod. E, Suspension bar. F, Rocker arm (offset swivel).

motion. Usually the rod is kept as high as possible while allowing the wheelchair to pass through doorways. Lowering the rod shortens the pendulum arc and causes the upper limb to move uphill at each extreme of the arc. Lowering the suspension rod can add undesirable resistance to a group of muscles during occupational performance.

Rotation

The shoulder can be placed in horizontal abduction and external rotation as the suspension rod is rotated outward, or in horizontal adduction and internal rotation if the suspension rod is rotated inward. This gives a mechanical advantage to those muscles held in shortened range and offers resistance to opposing muscles.^{4,19}

Springs

Springs of various tensions may be inserted into the straps supporting the upper limb. In early muscle re-education, these springs allow the very weak client to produce and visualize some slight bouncing movement while upright by contracting available muscles—a motion that is not as easily possible with straps alone.

Horizontal Bar

Moving the strap on the holes on the horizontal bar (also called an adjustable balance bar, made by JAECO¹⁶) will position the elbow in greater or lesser degrees of flexion.

The bar is often positioned for the comfort of the client; if edema is present, the hand is held higher than the elbow.

Forearm Support

Forearm support (manufactured by JAECO¹⁶) is the same that is used in the MAS. However, this forearm support has a vertical metal suspension rod attached to the rocker arm (also called *offset swivel*). The rocker arm can be moved on the forearm support, which permits greater directional assistance for vertical motion, up or down, depending on the client's specific weakness in shoulder rotator or elbow musculature.

Reclining Suspension Mount

For all suspension devices, the suspension rod may be supported by a reclining suspension mount that permits the suspension to be perpendicular to the floor when the client is reclined in the wheelchair (see Figure 30-42).

Training in the Use of Suspension Arm Devices

Suspension arm supports can be used as training for or as an interim device before the MAS is used. Training can include exercises for the shoulder and elbow, including scapular protraction and adduction, shoulder flexion and extension, elbow flexion and extension, and shoulder internal and external rotation (especially with use of the forearm support and the rocker arm). Because the forearm support is easily attached to over-bed frames, occupational performance can be practiced using a table surface and any distal orthoses and adapted equipment that are needed⁷ before the client is able to be upright in a wheelchair.

OT Practice Note

Clients should recognize early in rehabilitation that they can manage an occupation of choice so that feelings of helplessness and hopelessness are not overwhelming.

Mobile Arm Supports

Mobile arm supports are mechanical devices that support the weight of the arm and provide assistance to shoulder and elbow motions through a linkage of ball-bearing joints. They are used for persons with weakness of the shoulder and elbow that affects their ability to position the hand. Mobile arm supports are or have been known by other names. Among these are *MAS*, *ball-bearing feeder*, *ball-bearing arm support*, *balanced forearm orthosis (BFO)*, and *arm positioner*.

The MAS typically used (Figure 30-43) has not changed significantly in design since 1952.⁵ Earlier prototypes were reported as long ago as 1936, when a client at the Georgia

FIGURE 30-41 Suspension arm support attached to bed.
 (From ARHP Arthritis Teaching Slide Collection, American College of Rheumatology.)

Threaded Case Study | Manny, Part 2

When Manny first was admitted to rehabilitation, he was hopeful that he would recover from his spinal cord injury with no physical loss. It could be difficult, at this time, to introduce the idea of arm supports, which may appear to him as taking away his hope for recovery. Manny was educated by the OT to understand that use of this equipment would facilitate any recovery that may be possible. He was confined to bed for the first few days in rehabilitation, but he was medically cleared to use his upper extremities and to partially sit in bed. Use of the suspension arm support in bed would allow him to participate in some occupation that he wishes to do and that is not overly challenging. Manny decided that turning pages would be a

good initial occupation because he likes to read, and because it would be a first step toward doing what he would need to do in his law practice. A suspension arm support was attached to overhead bars attached to his bed. An over-bed tray with a book rack held his book. A universal cuff with the eraser end of a pencil attached and a wrist support enabled Manny to turn pages with his suspension arm support and with his bed raised for partial sitting. This allowed Manny to start thinking early in his rehabilitation about occupations he could manage with arm supports, in addition to working on the performance skill of strengthening upper extremity musculature, which otherwise would be underused while Manny was lying in bed.

Warm Springs Foundation was given a Barker feeder, a device that was bolted to the lapboard of a wheelchair that required shoulder depression to bring the hands toward the head. Several other models were subsequently reported in the literature, until the 1952 segmented arm feeder was designed; this had close similarities to devices used today.^{5,27}

MASs have increased upper extremity function for persons with severe arm paralysis caused by conditions such as cervical spinal cord injury, muscular dystrophy, Guillain-Barré syndrome, amyotrophic lateral sclerosis, poliomyelitis, and polymyositis.^{13,30} The MAS has also been used for pain relief in the upper arm during occupational

performance for clients with arthritis and other painful conditions.

How Mobile Arm Supports Work

MASs compensate for proximal weakness in the upper extremities in three ways: (1) they provide arm motion, which allows for active ROM in the shoulder and elbow; (2) they allow weak muscles that cannot perform movement to allow for occupational performance; and (3) they enable hand placement in a variety of positions for occupational performance.

Mobile arm supports can be used for occupational performance (i.e., allowing the weak arm to perform tabletop and hand-to-face occupations, which otherwise are impossible or difficult) and for therapeutic exercises (i.e., improving ROM, strength, and endurance). These devices may be temporary or permanent.²⁴

The mechanical principles of mobile arm supports are threefold: the MAS (1) uses gravity to assist weak muscles, (2) supports a weak arm to reduce the load on weak muscles, and (3) reduces friction by using ball-bearing joints.²⁴

Criteria for Use^{24,32}

Occupational Performance Need

The person must have a need to perform specific occupations that cannot otherwise be accomplished because of weak shoulder and elbow musculature.

Adequate Source of Power

The source of power can be the muscles of the neck, trunk, shoulder, shoulder girdle, and elbow.

Adequate Motor Control

The person must be able to contract and relax functioning muscles. People with such conditions as cerebral palsy or significant elbow flexor tone usually are not good candidates for use of mobile arm supports.

Sufficient Range of Motion

The preferred ROM for joints to use the MAS well consists of shoulder flexion and abduction of 90 degrees, shoulder external rotation of 30 degrees, normal shoulder internal rotation and elbow flexion, forearm pronation of 80 degrees, and hip flexion of 100 degrees.

Stable Trunk Positioning

An upright sitting posture is ideal. Good head and neck positioning is important.

Client Motivation

The client must want to use the device and must have sufficient motivation for training to use it proficiently.

Supportive Environment

Generally, individuals who use this device cannot put it on themselves and will need help.

Manny meets all of the criteria listed here. He has occupations of interest that can be accomplished through the use of a mobile arm support. He has adequate performance skills (strength, ROM, stable sitting posture, and motor control) that will allow him to use the MAS. He is highly motivated to return to his law practice and has a very supportive wife. The support of the law firm is somewhat questionable, because staff members wonder how Manny will be able to manage all aspects of the work of an attorney in their offices.

Adjustment of Mobile Arm Supports

Adjustment of MASs generally requires postgraduate hands-on training. However, acquiring some knowledge of adjustment will give the reader a greater appreciation for the need to obtain additional training to learn how to make fine adjustments. One study has shown that even when the MAS is not adjusted correctly, a person with sufficient muscle power can overcome the lack of fine adjustment.³¹ This does not negate the need for therapists to be trained to ensure the best possible

FIGURE 30-44 Parts of traditional mobile arm support. **A**, Distal arms, right and left. **B**, Proximal arms. **C**, Semireclining mounts, right and left. **D**, Forearm supports.

adjustment and mechanical advantage for clients using the MAS.

Even with hands-on training, additional parts beyond the basic pieces can enhance the effectiveness of the device. The training needed to use these additional parts comes with practice, experience, and consultation with therapists familiar with the use of special parts.

Adjustment of Basic Parts

See Figure 30-44.

Forearm Support

Forearm support is initially attained by bending the dial to accommodate the left or right elbow (Figure 30-44, D).

Rocker Arm

The rocker arm is attached to the support. The standard rocker arm is attached to the first and third holes closest to the elbow.

Semireclining Mount, Proximal Arm, Distal Arm, and Forearm Support

The mount (Figure 30-44, C) is attached to the left or right wheelchair upright, the proximal arm (Figure 30-44, B) is placed in the mount, the distal arm (Figure 30-44, A) is placed in the proximal arm, and the forearm support is placed in the distal arm.

Balancing the Mobile Arm Support at Neutral

The mount is adjusted so that the ball bearings are parallel to the floor.

Checking Mount Height

The client is placed in the MAS, and the therapist passively moves the hand to the mouth. If the shoulder is elevated or depressed, the height of the mount should be adjusted.

Assessing Forearm Support for Fit and Adaptations

The support is observed for forearm comfort and allowance of wrist flexion (if the client has active motion). Measurements are taken to have the support cut if necessary to prevent discomfort and nonconformity with the size and shape of the forearm.

Adjusting for Horizontal Motion

The mount is rolled to assist horizontal abduction or adduction. The pitch of the mount or the distal bearing is adjusted to achieve maximum horizontal motion in front of the client.

Adjusting for Vertical Motion

The rocker arm is moved on the mount if up or down motion is difficult.

Readjusting for Fine Balance

The therapist reviews all adjustments to ensure maximum motion.

Checking Fit During Occupational Performance

Further adjustments may be needed with the weight of objects in the hand.²⁴

Training

Training includes practice in all occupations that interest the client and that need to be performed. Any of these occupations may require various adjustments until the final settings are achieved. If strength or ROM increases during the training period, further adjustments may be needed. Adapted equipment can be used in conjunction with the MAS. A wrist-hand orthosis may be required or adjusted for use with the MAS.²⁴

Follow-up with clients is indicated, especially for a growing child. MASs can result from adjustments over time. The questions in Box 30-1 are modified from an MAS appraisal form that was developed during the polio era at Rancho Los Amigos National Rehabilitation Center.²³ It can serve as a useful tool for checking the adequacy of fit of the MAS when the client returns to the clinic for follow-up visits.

Special Parts of the Mobile Arm Support

Commonly used special parts include the outside rocker arm assembly (also known as an *offset swivel*) (Figure 30-45, A) and the elevating proximal arm (Figure 30-45, B).¹⁶ The outside rocker assembly has a ball-bearing joint that allows greater freedom in vertical motion. The elevating proximal arm is useful for the person who has deltoid muscles that are between fair (F or 3) and poor (P or 2). The client initiates the elevating motion, and rubber band assists allow the client to flex and abduct the humerus to a higher level.

Threaded Case Study | Manny, Part 3

After 2 weeks in rehabilitation, Manny was able to sit in a wheelchair 2 to 3 hours daily. He was given a motorized wheelchair, which he operated with a chin switch for mobility and for reclining the wheelchair to obtain pressure relief every hour while he was awake. He was still unable to participate in any of the most important occupations needed to return to his law practice.

He was given a traditional MAS and a lapboard on his wheelchair. He continued to turn pages, now with an MAS and his wrist-hand orthosis. With the MAS, his wrist-hand orthosis, and a computer, he began to compose written communications, sending e-mails to his wife, his child, coworkers, and friends. Occupational performance activities that require hand-to-mouth skills are more complex than tabletop activities, so these occupations were introduced more slowly by working on reaching higher and higher in vertical motions. Games, such as building pyramids with blocks, were used until Manny could reach his mouth with his hand; then eating activities were introduced, using a wrist-hand orthosis that could hold an adapted spoon and fork.

Although with Manny's available upper extremity strength, it was questionable whether he could use his MAS for driving his

motorized wheelchair, Manny wanted to do so. He did not like the image of a chin switch to drive his wheelchair. He practiced using the MAS to drive his wheelchair until this task was accomplished. With practice, he also could efficiently operate his computer, turn pages, manage a speakerphone, and feed himself simple meals. He needed assistance in removing his MAS when he reclined, so that pressure on his ischium was relieved.

When he was discharged, Manny returned to the outpatient OT clinic, where a plan was made to have the OT and Manny visit the law office to determine how he could perform occupations needed in the law office. In addition to equipment obtained as an inpatient, it was recommended that Manny could benefit from a large round desk that acted as a turntable operated electrically. With this turntable, he could access his special phone, computer, and reading matter. Also, Manny learned that through his oratory skills, he could project a positive image that would be perceived by members of the public arriving to his office. This visit and the implementation of equipment recommendations resulted in Manny's return to his law practice 2 months after discharge.

Box 30-1

Mobile Arm Support Appraisal

1. Are the client's hips set back in the chair?
2. Is the spine in good vertical alignment?
3. Is there good lateral trunk stability?
4. Are the chair seat and back adequate for comfort and stability?
5. Is the client able to sit upright?
6. If the client wears wrist-hand orthoses, are they on?
7. Does the client have adequate passive ROM?
8. Is the mount tight on the wheelchair and positioned perpendicular to the floor?
9. Is the mount at the proper height so that the shoulders are not forced into elevation?
10. Is the proximal arm all the way down in the mount?
11. Does the elbow dial clear the lap surface when the trough is in the "up" position?
12. When the forearm support is in the "up" position, is the client's hand as close to the mouth as possible?
13. Can the client obtain maximal active reach?
14. Is the forearm support the correct length? Does the distal end of the forearm support stop at the wrist joint?
15. Are the forearm support edges rolled so that they do not contact the forearm?
16. Is the elbow secure and comfortable in the elbow support?
17. Is the forearm support balanced correctly?
18. In vertical motion, is the dial free of the distal arm?
19. Can the client control motion of the proximal arm from either extreme?
20. Can the client control motion of the distal arm from either extreme?
21. Can the client control vertical motion of the trough from either extreme?
22. Have stops been applied to limit range, if necessary?
23. Can the client lift a sufficient amount of weight to perform desired occupational performance?

Many other useful, but not commonly used, special parts are commercially available for clients with special problems. Understanding the use and adjustment of these special parts generally requires training.²⁴ With the advent of new designs for wheelchairs, it sometimes becomes necessary to adapt the MAS bracket for attachment to these newer chairs. Wheelchair manufacturers can assist by providing solutions to problems; some centers have developed common solutions.²⁴

Current Development and Future Research

The traditional MAS has been used effectively for longer than 50 years. However, until recently, little evidence could be found in the literature to show advancements in the design of commercially available MASs that would expand their use to those who have upper extremity weakness.

A

B

FIGURE 30-45 A, Offset swivel with up and down stops and humeral rotation assist (outside rocker arm with rubber band assist). B, Elevating proximal arm.

(Courtesy JAECO Orthopedic, Inc., Hot Springs, Ark.)

An example of development during this period was an attempt by engineers approximately 40 years ago to provide a powered arm for persons who have minimal strength in the upper extremities. The Rancho Electric Arm was developed to meet the needs of those who are too weak to use a conventional MAS.²⁹ It requires that clients use their tongue to operate seven tiny toggle switches in complex patterns to achieve motions at the joints of the arm and hand.¹⁸

In 1995 the Rehabilitation Engineering Program at Rancho Los Amigos National Medical Center received a National Institute on Disability and Rehabilitation Research (NIDRR) grant to design, develop, and test a new MAS.²¹ During 12 years of grants related to this new design (NIDRR#H133E003001, #H133E020732), the project developed an entirely new MAS system. It incorporated a multilink arm that has a low profile and a high-tech appearance (Figures 30-46 and 30-47, A). The new mount fits many current wheelchairs, has simple, intuitive adjustability without tools, and locks in position to retain adjustments (Figure 30-47, B). The forearm support includes a slide-lock to adjust its pivot point (Figure 30-47, C). The new JAECO/Rancho Multilink Arm (MAS) was transferred to a manufacturer (JAECO) that made it available commercially in 2003.²¹ In addition, mount adapters (an example is shown in Figure 30-47, D) provided by this manufacturer enable the new JAECO/Rancho MAS mount or the traditional MAS bracket to attach to the expanding variety of wheelchairs that have exploded onto the market.²¹ Also, a manual height adjuster has been made available, if needed, to allow for mount height changes from desk to mouth level occupational performance.²⁶ An elevation assist for the Multilink has been made available by JAECO for the Multilink Arm. This part functions similarly to the elevating proximal arm of the traditional MAS.¹⁷

FIGURE 30-46 New multilink mobile arm support.

(From Rancho Los Amigos National Rehabilitation Center, Rehabilitation Engineering Center, Downey, Calif.)

To further identify some of the issues related to use of the traditional MAS during the grant periods, a survey was conducted of 17 OTs, each with an average of 15 years' experience working with clients with spinal cord injury in various parts of the United States and Canada.^{3,31} One of the questions asked of respondents was to identify problems with the traditional MAS. The following is a partial list of some of the more highly ranked limitations of the MAS as determined by these therapists:

1. It is difficult to adjust the MAS, especially for weak clients.
2. Parts extend too far out from the wheelchair, which limits the client's ability to go through doorways.

FIGURE 30-47 A, JAECO/Rancho Multilink Mobile Arm Support. (1) MAS mount. (2) Proximal shaft with bubble level. (3) Multilink. (4) Forearm support with elbow dial. (5) Offset swivel with adjustable slide. B, JAECO/Rancho Multilink Mobile Arm Support mount. Two knobs control adjustment without use of tools. C, JAECO/Rancho Multilink Mobile Arm Support offset swivel with adjustable slide. (1) Offset swivel with (2) adjustable slide. (3) Spring-loaded pull-out knob to adjust position on the forearm support (4). D, JAECO Mount Adapter MR-10 enables the JAECO/Rancho mount to attach to wheelchairs with tubular back posts.

(Courtesy JAECO Orthopedic, Inc., Hot Springs, Ark.)

3. The MAS sometimes hits the table, wheelchair armrest, or joystick control when the client is moving the arm.
4. The MAS cannot be mounted or easily mounted on all wheelchairs.
5. Adjustments have to be made with changing activities such as driving and eating.
6. The MAS does not easily accommodate the client who needs to recline routinely.

The first three problems listed here have been addressed with the now commercially available JAECO/Rancho Multilink Mobile Arm Support: (1) adjustment is easier, (2) the device is narrower to allow entrance through doorways, and (3) it is easier to use the device when moving horizontally to bypass armrest, joystick, or table edge.²⁵ For problems (4) and (5) in the list, the new mount adapters and the manual height adjuster provide solutions. Problem (6) has not yet been solved.

Besides the JAECO/Rancho Multilink MAS, another MAS, the Wilmington Robotic Exoskeleton (WREX), has recently been developed in the United States, especially for people with proximal arm weakness who have hand function, primarily those with neuromuscular diseases such as spinal muscular atrophy.^{10,22} This device is now commercially available.

Threaded Case Study Manny, Part 4

With Manny's performance skills, he was at first able to benefit from using suspension arm supports in bed, wearing a wrist-hand orthosis, and using adapted equipment to read and turn pages. When he was sitting up in a motorized wheelchair, he was given an MAS, with which he continued to use his wrist-hand orthosis along with other adapted equipment to perform the occupations he needed to perform to return to work in his law firm. Because of his early expectation that he would recover from his spinal cord injury, it was important for the OT to acknowledge Manny's hopes, while discussing with him what was available for him to do to work on returning to work soon, using the equipment he would need to do so.

The series of interventions that the OT used included the following: (1) worked on occupations that Manny could perform while in bed, (2) applied MASs to his motorized wheelchair and found adaptive equipment that he could hold with his wrist-hand orthosis, (3) provided games and other activities that would strengthen his upper extremity musculature to perform vertical motions in his MAS so that he could eventually feed himself, (4) practiced all occupations needed in his job—helped to find a phone that he could use with his MAS and wrist-hand orthosis, found a joystick to drive his wheelchair that was comfortable to use with an MAS and wrist-hand orthosis, and found other adaptive equipment that was reliable for him to use on the job, (5) located and provided information on community resources to help Manny manage in his home community, including sources for adaptive equipment and adaptations that would allow a vehicle to carry a motorized wheelchair, and (6) made a worksite visit with Manny when he was ready to return to work, to ensure that his equipment works in the office and to talk with staff about assistance that he may need.

Summary

Section 1 of this chapter introduced the basic concepts of splint design and problem solving that must precede fabrication of a splint. Anatomy and biomechanics of the hand and types of grasp and prehension were reviewed. Splint classification and the purposes of splinting were described. Section 2 presented a variety of splinting materials and

explained their appropriate uses for different types of splints. Principles of safe and effective splinting and basic fabrication techniques were also described. The OT must bring to the splinting process knowledge of anatomy and biomechanics, skills in assessing function, and the ability to determine the optimal intervention for each client.

Clients of all ages with a variety of diagnoses and various patterns of weakness have been known to have the same MAS for at least 10 years. When fitted correctly, the MAS enhances occupational performance and can facilitate remediation of performance skills. For some clients, the device is useful for life. For other clients, the mobile support is a temporary device that allows function and enables exercise until the musculature is strong enough that they can engage in occupations without the device.

Over the few years since the JAECO/Rancho Multilink MAS first became available, fitting and adjustments have been streamlined, the device has become less conspicuous and more aesthetically appealing to clients, and adjustments have been simplified for therapists working with patients without complex or profound weakness. It remains unknown whether these new devices will supplant the traditional MAS, which has been adjusted for profoundly weak patients by those with expert knowledge and skill. The JAECO manufacturer has found that more customers are purchasing supports with newer designs (e.g., Multilink, WREX) than the traditional mobile arm support.¹⁰ With current advancements in design, it is hoped that more clients who can benefit will be fitted with an MAS to engage in occupations and to fully participate in the home and community to which they belong.

Review Questions

1. Describe the role of the OT in the splint-making process.
2. What is wrist tenodesis and how can it be used functionally?
3. Describe the axis of motion of forearm rotation, and discuss how it affects the fit of a splint.
4. Name the three major nerves that supply the hand and describe their sensory innervation patterns.
5. Why is tip prehension considered to be a dynamic rather than static prehension pattern?
6. What is the one grasp pattern that does not include the thumb?
7. Define the terms friction, torque, and stress.
8. How is shear stress created and how can it best be avoided?
9. Why do translational forces minimize the effectiveness of a splint?
10. Describe the difference between a dynamic and a static splint.
11. How may a splint pattern vary if it is to be fitted on the dorsum of the hand, as compared with the volar surface?

12. How does the amount of drape in a low-temperature thermoplastic material affect the making of a splint?
13. What is the recommended type of material for small finger splints? Why?
14. What is the recommended type of material for large elbow and lower extremity splints? Why?
15. What is the importance of straps on a single-surface splint?
16. What are the purposes of suspension arm devices and MASSs?
17. Where are suspension arm devices attached?
18. What are the limitations of suspension arm devices?
19. What is the difference between a suspension arm sling and a suspension arm support?
20. Who are good candidates for suspension arm devices?
21. How are suspension arm devices adjusted?
22. Approximately how long have traditional mobile arm supports been used?
23. Name the parts of the MAS.
24. What are the benefits of the MAS?
25. How does the MAS work?
26. What are the criteria necessary to use the MAS?
27. How is the MAS adjusted for each client?
28. What is the advantage of the JAECO/Rancho Multilink Mobile Arm Support?

The philosophy of neurodevelopmental treatment

Key principles of neurodevelopmental treatment

Using neurodevelopmental treatment to restore participation in occupation

Evaluation

Intervention

Neurodevelopmental treatment and evidence-based practice

Review questions

■ Key Terms

Lower motor neurons	Generalizability	Verbal commands	Traction
Upper motor neurons	Reciprocal inhibition	Verbal mediation	Approximation
Motivational urge	Cocontraction	Manual contacts	Maximal resistance
Conation	Proprioceptive stimulation	Part-task practice	Repeated contractions
Movement strategy	Vestibular stimulation	Whole-task practice	Rhythmic initiation
Motor program	Inhibitory techniques	Stepwise procedures	Slow reversal
Sensorimotor system	Proprioceptive neuromuscular facilitation	Unilateral patterns	Stabilizing reversals
Reflex and hierarchic models	Diagonal patterns	Bilateral patterns	Rhythmic stabilization
Sensory stimulation	Stretch	Symmetric patterns	Contract-relax
Mass movement patterns		Asymmetric patterns	Hold-relax
		Reciprocal patterns	Slow reversal–hold-relax
		Combined movements	Rhythmic rotation

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the four general processes of information flow related to control of movement.
2. Define motivational urge, and name the locus of this function in the brain.
3. Trace the flow of information in the central and peripheral nervous systems that leads to purposeful movement.
4. Define the sensorimotor system, its locus in the brain, and its function during motor performance.
5. List the structures that constitute the higher, middle, and lower levels of the central nervous system components for movement.
6. Name the four traditional sensorimotor approaches to intervention and the theorist responsible for each.
7. Name the two models of motor control that form the basis for the sensorimotor approaches to treatment.
8. Briefly describe each of the four traditional sensorimotor approaches to intervention; compare and contrast their similarities and their differences.
9. Understand and apply proprioceptive neuromuscular facilitation as a preparatory method to facilitate client participation in desired occupations.
10. Define proprioceptive neuromuscular facilitation and how this approach facilitates adaptive responses that are performed in daily occupations.
11. Understand the principles of proprioceptive neuromuscular facilitation and how to apply them to enhance client performance.
12. Describe the influence of sensory input on motor learning.
13. Use the proprioceptive neuromuscular facilitation evaluation to determine factors limiting clients' participation in their occupation.
14. Recognize upper and lower extremity diagonal patterns in daily performance skills.
15. Name the theorists who developed the proprioceptive neuromuscular facilitation approach.
16. Discuss the historical background and current use of neurodevelopmental treatment within occupational therapy.
17. Identify theoretic foundations of neurodevelopmental treatment, as well as current principles of evaluation and intervention.
18. Identify management strategies associated with neurodevelopmental treatment intervention and treatment techniques.
19. Integrate neurodevelopmental treatment within an occupation-centered and client-centered approach to evaluation and intervention.
20. Discuss the relationship between evidence-based practice and neurodevelopmental treatment, and discuss types of evidence available to support the use of neurodevelopmental treatment in occupational therapy.

Overview

WINIFRED SCHULTZ-KROHN

Case Study Carlos

Carlos, a 59-year-old construction foreman, suffered a right cerebrovascular accident 3 days earlier and currently requires maximum assistance for most self-care tasks. He is able to speak, recognizes his wife and two adult children, but appears easily confused when expected to participate in self-care activities. He has no functional motor control of his left arm or hand, and sensation is markedly impaired on his left extremities. He exhibits a decorticate posture in both left extremities, with flexion tone dominating his arm and extensor tone dominating his leg. He is able to partially roll to the right side of the hospital bed and push up on his right arm to a sitting position, but at home he sleeps on the opposite side of the bed. He is able to stand by using a quad cane in his right hand but is unable to safely walk from the bed to the bathroom in his hospital room.

As Carlos's occupational therapist, you are expected to design and implement an intervention plan based on the best evidence available. Occupational therapists working with clients who have sustained damage to the central nervous system are often concerned with enhancing functional movement as a means of promoting independence in occupational performance.¹⁶ To achieve this objective, a variety of intervention approaches are available from which the therapist may choose. This chapter reviews the traditional sensorimotor approaches and presents a brief description of each.

Critical Thinking Questions

The following questions should be considered as you read this overview of the traditional sensorimotor approaches to intervention.

1. How can a traditional intervention approach improve Carlos's occupational performance?
2. What potential difficulties should be anticipated when using a traditional intervention approach?
3. What current knowledge of central nervous system function could be used to support the selection and implementation of traditional sensorimotor intervention methods?

Neurologic Considerations for Traditional Sensorimotor Approaches to Intervention

Occupation performance frequently requires precise voluntary movement, which is controlled and monitored by the nervous system. Various structures within the nervous system are coordinated to selectively activate specific muscles

to initiate, perform, and complete a desired task or activity. If a movement is performed poorly and thereby compromises performance of a task, feedback occurs through knowledge of the results of the action, and the neurologic commands to the muscles are modified so that accuracy of movement is achieved. Knowledge of the intricate working of the nervous system is of special importance to occupational therapists (OTs) concerned with refinement and improvement of the motor performance of clients with neurologic conditions.³ A brief overview of the flow of information associated with the control of movement is described in the following sections.

Central Nervous System Control of Movement

Firing of motor neurons located in the anterior horn of the spinal cord produces all movements.⁶⁵ These neurons directly innervate the skeletal muscles. The activity of the spinal or lower motor neurons can be modulated by the segmental spinal circuitry and by the descending influence of the motor neurons located in the motor cortex and brainstem.^{39,40} These neurons are referred to as upper motor neurons. Two other structures, the basal ganglia and the cerebellum, as well as their associated pathways, are also intimately involved in motor control. Lesions in these structures are associated with characteristic movement disorders.

Production of movement does not begin and end with the upper or lower motor neurons. Many central nervous system (CNS) structures contribute to development of the signals that activate muscles. Although much about control of movement is still unknown, animal and human research suggests that four general processes are related to the flow of information needed to control movement. The four general processes of information flow are motivation, ideation, programming, and execution.^{8,13} A schematic diagram that indicates the main direction of information flow connecting the various motor centers appears in Figure 31-1.

The motivation or emotive component of movement is a function of the limbic system.^{8,59} The motivational urge or impulse to act associated with the limbic system is transformed to ideas by the cortical association areas. This connection of knowledge and affective behavior is also referred to as *conation*.²⁸ Conation represents the intentional, deliberate, and goal-directed aspect of behavior and is related to the individual's reason for the motor performance. The association areas of the frontal, parietal, temporal, and occipital lobes are concerned with ideation, or the goal of the movement, and with the programming or movement strategy (plan) that best achieves the goal. Programming of a movement strategy also involves the premotor areas, the basal ganglia, and the cerebellum. The motor program is the procedure or the spatiotemporal order of muscle activation that is needed for smooth and accurate motor performance. The execution level, represented by the motor cortex, the cerebellum, and the spinal cord, is concerned with activation of the spinal motor neurons and

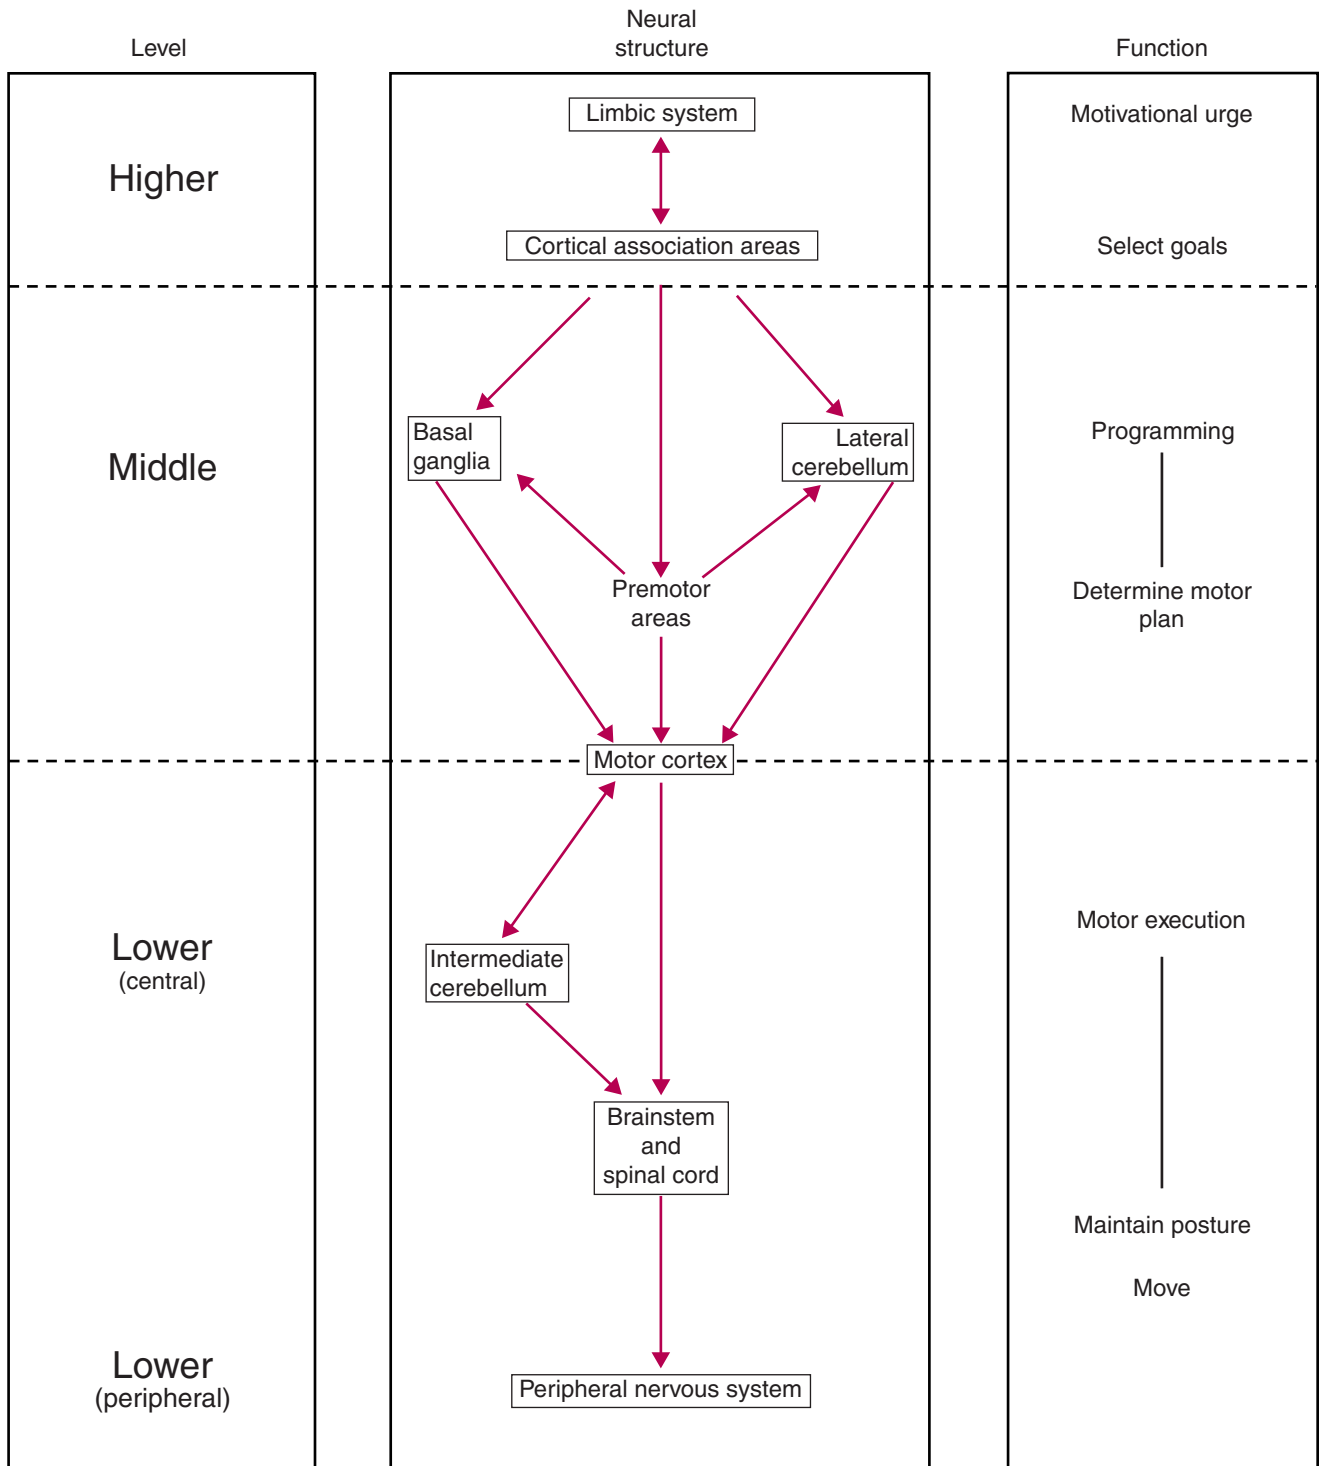

FIGURE 31-1 Schematic representation of the hierarchy of the neural structures involved in motor control. The *left column* indicates the hierarchic level and the *right column* the major function of the neural structures shown in the center column during motor performance.

(Adapted from Cheney PD: Role of cerebral cortex in voluntary movements: a review, *Phys Ther* 65[5]:624, 1985.)

interneurons that generate the goal-directed movement and the necessary postural adjustments.

To appreciate the flow of information leading to purposeful movement, consider the actions of your client Carlos, who sustained a right cerebrovascular accident

(CVA) with resultant left hemiplegia, is thirsty, and is reaching for a glass of water while seated at a table for support (Figure 31-2). The limbic system, which connects with the areas of the midbrain and brainstem that control vital functions such as hunger and thirst, has registered the need for

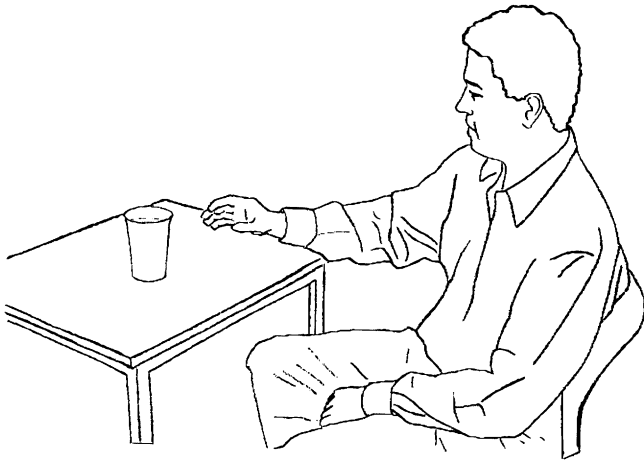

FIGURE 31-2 A person reaching for a glass of water.

water.²⁶ This need for drinking water has been conveyed to the cortical association areas, which also received visual, auditory, somatosensory, and proprioceptive information about precisely where the body is in space and where the glass of water is relative to the body.³⁰ This sensory information is needed before the movement is initiated. Strategies or motor plans are formulated to move the arm and hand from their immediate location in space to one in which the glass of water is picked up and moved to the mouth. Motor programs are generated by the association cortex in conjunction with the basal ganglia, lateral cerebellum, and premotor cortex. Once a strategy is selected, the motor cortex is activated. The motor cortex, in turn, conveys the action plan to the brainstem and spinal cord. Activation of the cervical spinal neurons generates a coordinated and precise movement of the shoulder, elbow, wrist, and fingers. Input from the brainstem and cerebellum ensures that the necessary postural adjustments are made by the axial musculature. Sensory information during the movement is necessary to ensure smooth performance of the ongoing movement and to improve subsequent similar movements. Because the motor areas rely heavily on sensory feedback provided by exteroceptors and proprioceptors regarding the accuracy of movement, the structures of the brain that control movement are often referred to as the sensorimotor system. Carlos is able to use his right hand to pick up the glass of water but has compromised postural control. When he is supported, sitting at the table, he is able to complete this task, but when standing and holding his cane in his right hand, he is unable to use his left arm and hand to reach and pick up the glass of water. The resultant motor problems from the right CVA further compromise his ability to perform a bimanual task such as pouring liquid into a glass even when he has the necessary motivational urge or intention for movement.

Given the motivation-ideation-programming-execution scheme of how information is organized through the nervous system, it is obvious that control of voluntary movement

FIGURE 31-3 Areas of the neocortex intimately involved in planning of and instruction for voluntary movement. Areas 4 and 6 constitute the motor cortex.

(From Bear MF, Connors BW, Paradiso MA: *Neuroscience: exploring the brain*, Baltimore, Md, 1996, Williams & Wilkins.)

involves almost all of the neocortex. Voluntary movement depends on knowledge of where the body is in space, where the body intends to go with respect to this external space, the internal and external loads that must be overcome, and formulation of a strategy or plan to perform the movement. Once a strategy or plan has been formulated, it must be held in memory until execution, at which point appropriate instructions are sent to the spinal motor neurons. The primary functional aspects of the sensorimotor areas involved in motor control are examined in the next section.^{8,35,59}

Sensorimotor Cortex

The sensorimotor cortex is the major integrating center of sensory input and motor output. It is composed of cortical areas located immediately anterior and posterior to the central sulcus (Figure 31-3). The three principal motor regions located in the frontal lobe are the primary motor area, the supplementary motor area, and the premotor area. The two principal sensory regions located in the parietal lobe are the primary somatosensory cortex and the posterior parietal cortex. Each area of the sensorimotor cortex (primary motor cortex, primary somatosensory cortex, posterior parietal cortex, supplementary motor area, and premotor cortex) is arranged in a manner that provides a topographic representation of the contralateral body segments.^{35,52} Each of these areas is responsible for certain aspects of generating movement. In the previous example of reaching for a glass of water, Carlos had a mental image of his body and its relation to the surrounding space by integrating the information supplied through somatosensory, proprioceptive, and visual input to the

posterior parietal cortex. Clients with a lesion in this area demonstrate impairment of body image and its relation to extrapersonal space and, in the extreme situation, neglect of the contralateral body segments.

The posterior parietal cortex integrates and translates sensory information so that the ensuing movements are directed appropriately in extrapersonal space. It is extensively interconnected with the association areas of the frontal lobe that are thought to be involved in determination of the consequences of movement strategies such as moving the arm forward, curling the fingers around the glass, and lifting the glass to the mouth. The fingers begin to curl appropriately before any contact occurs with the glass; therefore, the size and shape of the glass must be recognized before grasping. The prefrontal association areas and the posterior parietal cortex project to the premotor area, which is thought to be concerned with orientation of body segments before initiation of movement. The input of the posterior parietal cortex to the premotor area may be important in the somatosensory guidance of movement.¹³ Lesions of the premotor area or posterior parietal cortex have been demonstrated to result in the generation of an inappropriate movement strategy.³²

Planning of movement is considered to be the function of the supplementary motor area. In animal studies, electrophysiologic recordings of cells in this area indicate that the cells typically increase discharge rates about a second before the observable execution of movement of either hand.⁶⁹ The same findings have been corroborated in humans with the use of imaging techniques to study patterns of cortical activation. Imaging studies using positron emission tomography monitor changes in local blood flow because an increase in local cerebral blood flow is associated with increased neuronal activity. Under these conditions, when subjects were asked to imagine a movement without actually moving the finger, blood flow to the supplementary motor cortex increased and no comparable increase in blood flow was seen in the primary motor area.⁵⁵ When subjects were asked to perform a series of finger movements from memory, blood flow to the supplementary motor cortex increased in advance of the movement but not during performance of the movement. Unilateral lesions of the supplementary motor area result in apraxia (loss of the ability to perform movement in the absence of motor or sensory impairments). Another effect of such lesions is an inability to produce the correct sequence of muscle activation for complex motor activities such as speaking, writing, buttoning, typing, sewing, and playing the piano.

The primary somatosensory cortex projection to the primary motor cortex and association areas provides the sensory input needed for motor planning, initiation of movement, and regulation of ongoing movement.²⁰ The primary motor cortex integrates the information that it receives from other areas of the brain and generates the descending command for the execution of movement. Not only is this descending command sent to the brainstem and

spinal cord, but a copy of it is also sent to the basal ganglia and cerebellum. The descending command specifies the muscles to be activated and the direction, speed, and required force.¹³ Lesions of the primary somatosensory cortex typically result in contralateral sensory loss. Movements are uncoordinated because the ability to register sensory feedback during and after the movement is compromised. Damage to the primary motor area results in deficits in motor execution. The client presents the classic picture of contralateral muscle weakness, spasticity, and poor isolation of movement with corresponding loss of function.

Relation to Sensorimotor Intervention Approaches

The CNS structures involved in movement can be grouped functionally into higher, middle, and lower levels. The higher level consists of the limbic system and association areas, where the motivation for action is generated. The sensorimotor areas, along with the basal ganglia and cerebellum, form the middle level, and the lower level consists of the nuclei in the brainstem and spinal cord. Under normal circumstances, an individual's repertoire of motor activity is varied and complex to meet the unique task and environmental demands. After damage to the CNS regions involved in movement, the coordinated effort between the various levels of motor control is disrupted, and the motor response may be limited or stereotyped. Traditional sensorimotor approaches to intervention can be viewed as targeting the middle sensorimotor level, the motor planning–strategy formulation process, and the lower-level execution process, with the aim of reintegrating, as far as possible, a complete motor control hierarchy. It can easily be seen that a motor-relearning program (discussed in Chapter 32) should also be cognitively oriented and targeted toward achieving a goal or “occupational” task and include all three levels of CNS function related to motor control. This represents the inherent limitation of the traditional sensorimotor approaches. These approaches do not actively engage the client's volitional intent or motivation to perform a motor act. The limitations of traditional sensorimotor approaches must be considered carefully before selecting this form of intervention for the client.

The foundational premise of these traditional sensorimotor approaches posits that clients need to be taught motor strategies or compensatory mechanisms to adapt to the deficits produced by a lesion. Compensatory mechanisms and the shaping of motor programs are brought about by the use of sensory input. The sensorimotor approaches use sensory stimulation to elicit specific movement patterns. Early in the intervention phase, emphasis is placed on the use of external sensory stimuli. Once a movement response is obtained, to reinforce and strengthen the response, the focus shifts to the use of intrinsic sensory information, which thereby encourages voluntary motor control.

The four traditional sensorimotor intervention approaches used historically by occupational therapy practitioners are

the Rood approach, the Brunnstrom (movement therapy) approach, the proprioceptive neuromuscular facilitation (PNF) approach, and the neurodevelopmental treatment (Bobath or NDT) approach. These approaches, developed in the 1950s and 1960s, all have their theoretic basis in the reflex and hierarchic models of motor control. Although more contemporary models are currently being used to guide intervention in clients who demonstrate CNS dysfunction, an understanding of these traditional approaches is warranted to appreciate their contributions to clinical practice and to recognize appropriate application of these approaches in selected populations.

Reflex and Hierarchic Models of Motor Control

The reflex and hierarchic models of motor control view movement strategies along a developmental continuum. Two major fundamental assumptions underlie the reflex and hierarchic models.

The basic units of motor control are reflexes. Reflexes are motor responses that occur in response to specific sensory stimuli. Reflexes are automatic, predictable, and stereotypic; they are normal responses seen from early infancy. As the CNS matures, reflexes become integrated and are believed to form the foundation for volitional motor control. Volitional (purposeful) movement is the summation and integration of reflexive movement. When damage to the CNS occurs, a resurgence of reflexive motor activity takes place in addition to an inability to modulate these reflexive movements.

Motor control is hierarchically arranged. In a hierarchic model of motor control, the CNS is believed to have a specific organizational structure, and motor development and function depend on that structure. This hierarchic organization refers to a system in which the higher centers of the brain regulate and exert control over the lower centers of the CNS. The higher centers, specifically the cortical and subcortical areas, are responsible for regulation and control of volitional, conscious movement. The lower levels regulate and control reflexive, automatic, and responsive movement. Based on this conceptualization, when damage to the CNS occurs, it is believed that the damaged area can no longer regulate and exert control over the underlying areas. Motor control, according to this belief, becomes a function of the next lower functioning level of the CNS. Typically, this means a return to more reflexive and primitive movement patterns.

The four traditional sensorimotor intervention strategies rely heavily on these basic assumptions about motor development and motor control. Consequently, the intervention strategies used in these approaches frequently involve the application of sensory stimulation to muscles and joints to evoke specific motor responses, handling and positioning techniques to effect changes in muscle tone, and the use of developmental postures to enhance the ability to initiate and carry out movements. [Table 31-1](#) presents a comparison and summary of the key treatment strategies used in each of the four traditional sensorimotor approaches.

SECTION 1 | The Traditional Sensorimotor Intervention Approaches

WINIFRED SCHULTZ-KROHN

The Rood Approach

Margaret Rood drew heavily from both the reflex and the hierarchic models in designing her intervention approach.⁵⁶⁻⁵⁸ Key components of the Rood approach are the use of sensory stimulation to evoke a motor response and the use of developmental postures to promote changes in muscle tone. Sensory stimulation is applied to muscles and joints to elicit a specific motor response. Stimulation has the potential to have either an inhibitory or a facilitatory effect on muscle tone. Types of sensory stimulation described by Rood include the use of slow rolling, neutral warmth, deep pressure, tapping, and prolonged stretch. Examples of how this stimulation may be applied include tapping over a muscle belly to facilitate (increase) muscle tone and applying deep pressure to a muscle's tendinous insertion to elicit an inhibitory (decreased) effect. Rood also described the use of specific developmental sequences believed to promote motor responses.⁵⁷ These sequences were proximal to distal and cephalocaudal. Treatment strategies move clients through these developmental sequences.

In current clinical practice, practitioners may use selected principles from Rood's work as adjunctive or preliminary interventions to prepare an individual to engage in a purposeful activity—for example, application of quick stretch over the triceps before instructing a client to reach for a cup or glass to improve elbow extension.⁶⁷ A client may be instructed in ways to apply his or her own sensory stimulation to enhance performance of activities of daily living (ADLs). For example, during upper extremity dressing, the OT may ask Carlos to perform a prolonged stretch of the left biceps; this results in a reduction in muscle tone, which may, in turn, increase the ease with which the arm is moved through the sleeve of his shirt.

Limitations in the use of Rood's approach are numerous and include the passive nature of the sensory stimulation (it is applied "to" an individual) and the short-lasting and unpredictable effect of some of the sensory stimulation. Please refer to the discussion later in this chapter for additional details regarding the Rood approach to intervention.

The Brunnstrom (Movement Therapy) Approach

Signe Brunnstrom, a physical therapist (PT), developed an intervention approach specifically for individuals who had sustained a CVA.^{9,10} The approach that she designed draws strongly from both the reflex and hierarchic models of

■ **TABLE 31-1** | Comparison of Key Treatment Strategies Used in the Traditional Sensorimotor Approaches

Key Treatment Strategies	Rood Approach	Brunnstrom Approach (Movement Therapy)	Proprioceptive Neuromuscular Approach	Neurodevelopmental Treatment
Sensory stimulation used to evoke a motor response	YES (uses direct application of sensory stimuli to muscles and joints)	YES (movement occurs in response to sensory stimuli)	YES (tactile, auditory, and visual sensory stimuli promote motor responses)	YES (abnormal muscle tone occurs, in part because of abnormal sensory experiences)
Reflexive movement used as a precursor for volitional movement	YES (reflexive movement achieved initially through the application of sensory stimuli)	YES (move the patient along a continuum of reflexive to volitional movement patterns)	YES (volitional movements can be assisted by reflexive supported postures)	NO
Treatment directed toward influencing muscle tone	YES (sensory stimuli used to inhibit or facilitate tone)	YES (postures, sensory stimuli used to inhibit or facilitate tone)	YES (movement patterns used to normalize tone)	YES (handling techniques and postures can inhibit or facilitate muscle tone)
Developmental patterns/ sequences used for the development of motor skills	YES (ontogenic motor patterns used to develop motor skills)	YES (flexion and extension synergies; proximal to distal return)	YES (patterns used to facilitate proximal to distal motor control)	YES
Conscious attention is directed toward movement	NO	YES	YES	YES
Treatment directly emphasizes the development of skilled movements for task performance	NO	NO	NO	YES

motor control. Brunnstrom conceptualized clients who had sustained a CVA as going through an “evolution in reverse.” Spastic or flaccid muscle tone and the presence of reflexive movements that may be evident after a client sustains a CVA are considered part of the normal process of recovery and are viewed as necessary intermediate steps in regaining volitional movement.⁶² Brunnstrom clearly detailed stages of motor recovery after a CVA (Table 31-2). These stages include the description of flexor synergy patterns and extensor synergy patterns for the upper and lower limbs and are used as descriptors of change following a CVA.²³ Carlos currently displays flexor tone dominating his left arm and extensor tone dominating his left leg. This dominating tone interferes with isolated control of his left extremities.

In the Brunnstrom approach, emphasis is placed on facilitating the progress of the individual by promotion of movement, from reflexive to volitional. In the early stages of recovery this may include the incorporation of reflexes and associated reactions to change tone and achieve movement. For example, to generate reflexive movement in the

arm, resistance may be applied to one side of the body to increase muscle tone on the opposite side. This technique is applied until the client demonstrates volitional control over the movement pattern.

Proprioceptive Neuromuscular Facilitation Approach

The PNF approach is grounded in the reflex and hierarchic models of motor control. Developed through the collaborative efforts of a physician, Dr. Herman Kabat, and two PTs, Margaret Knott and Dorothy Voss, in the 1950s, this intervention approach continues to be used but has not been revised since its origins. The major emphasis in this approach is on the developmental sequencing of movement and the balanced interplay between agonist and antagonist in producing volitional movement.⁷⁴ PNF describes mass movement patterns, which are diagonal in nature, for the limbs and trunk. Intervention strategies use these patterns to

■ **TABLE 31-2 | Motor Recovery After a Cerebrovascular Accident***

Stage	CHARACTERISTICS		
	Leg	Arm	Hand
1	Flaccidity	Flaccidity, inability to perform any movements	No hand function
2	Spasticity develops, minimal voluntary movements	Beginning development of spasticity; limb synergies or some of their components begin to appear as associated reactions	Gross grasp beginning, minimal finger flexion possible
3	Spasticity peaks, flexion and extension synergy present, hip-knee-ankle flexion in sitting and standing	Spasticity increasing; synergy patterns or some of their components can be performed voluntarily	Gross grasp, hook grasp possible, no release
4	Knee flexion past 90 degrees in sitting, with the foot sliding backward on the floor; dorsiflexion with the heel on the floor and the knee flexed to 90 degrees	Spasticity declining; movement combinations deviating from synergies are now possible	Gross grasp present, lateral prehension developing, small amount of finger extension and some thumb movement possible
5	Knee flexion with the hip extended in standing, ankle dorsiflexion with the hip and knee extended	Synergies no longer dominant, more movement combinations deviating from synergies performed with greater ease	Palmar prehension, spherical and cylindrical grasp and release possible
6	Hip abduction in sitting or standing, reciprocal internal and external rotation of the hip combined with inversion and eversion of the ankle in sitting	Spasticity absent except when performing rapid movements, isolated joint movements performed with ease	All types of prehension, individual finger motion, and full range of voluntary extension possible

*Recovery of hand function is variable and may not parallel the six recovery stages of the arm. From Brunnstrom S: *Movement therapy in hemiplegia*, New York, NY, 1970, Harper & Row.

promote movement. The use of sensory stimulation, including tactile, auditory, and visual input, is also actively incorporated into treatment to promote a motor response.

In clinical occupational therapy practice, the inclusion of PNF patterns can often be seen in the way that functional activities are designed, especially in the placement of objects during purposeful activities. For example, a client is asked to reach into a shopping bag placed on his left side to retrieve objects that will then be placed in a cabinet on his right side. Specific information regarding the application of PNF is discussed later in [Section 2](#) of this chapter. This approach has been used successfully to increase range of motion (ROM) and for stretching of tightened muscles.⁶⁴

Neurodevelopmental Treatment Approach

The NDT approach, also known as the Bobath treatment approach, is based on normal development and movement. Berta Bobath, a PT, and her husband Karel Bobath, a physician, provided the initial theoretic foundations of NDT in the 1950s.²⁷ At that time they drew from the hierarchic model of motor control. The primary objectives of NDT are to normalize muscle tone, inhibit primitive reflexes, and

facilitate normal postural reactions.⁵ Improving the quality of movement and helping clients relearn normal movement patterns are key objectives of this approach. To achieve these objectives, therapists use numerous techniques, including handling techniques, weight bearing over the affected limb, use of positions that encourage the use of both sides of the body, and avoidance of any sensory input that may adversely affect muscle tone.¹⁶ In clinical practice today, many of these techniques and strategies are used within the context of purposeful activities.

NDT has continued to revise its theoretic framework in response to new evidence on the function of the CNS.²⁷ Discussions on the rationale for NDT include the current understanding of motor systems and motor learning. See [Section 3](#) of this chapter for further descriptions.

Summary

Movement takes place within an occupational context. Emotional needs influence motor strategies. The spinal cord or brainstem can mediate reflexive responses, but interpretation and transformation of sensory signals by all areas of the sensorimotor system are essential for voluntary movement to occur with precision. The primary somatosensory cortex and posterior parietal cortex are primarily responsible for

processing sensory information. The premotor area uses sensory information for planning movements, the supplementary motor area is important for bimanual coordination, and the motor cortex is important for execution.

The traditional sensorimotor intervention approaches have their theoretic basis in the reflex and hierarchic models of motor control. These approaches offer a valuable link between neurophysiologic principles and the rehabilitative treatment of clients with CNS dysfunction. In contemporary practice, many of the techniques described in these approaches are used as adjunctive or preliminary techniques or are incorporated into more task-directed treatment activities.

■ SECTION 2 | Proprioceptive Neuromuscular Facilitation Approach

SARA A. POPE-DAVIS
JUDY M. JOURDAN

Threaded Case Study Leticia, Part 1

Leticia, a 34-year-old married mother of two, was involved in an automobile accident in which she sustained a brain injury and fractures of her left wrist and several ribs. Leticia's injuries left her with diplopia, a rigid posture, and lack of motor control as a result of the ataxia. As a mother, Leticia had always been involved with her children and was a teacher's aide at their grade school. It is important to Leticia that she resume her parenting role, including caring for their home, driving a car, and resuming her work in the classroom. Unfortunately, she fatigues quickly and struggles to engage in the routine daily activities that she used to enjoy with her family. She specifically references her desire to be able to play games with her children, prepare family meals, and tutor children in the third grade class in which she assisted before her accident.

Critical Thinking Questions

1. How do you know which movement patterns to select to help Leticia regain the ability to perform these family- and work-related occupations or tasks?
2. Which PNF techniques will most effectively address Leticia's impairments, and how do you select a PNF technique to facilitate the desired performance of a task?
3. How do you determine the progression of intervention from a PNF perspective?

Based on normal movement and motor development, PNF is more than a technique—it is a philosophy of intervention. Through the case study of Leticia we will discuss the application of PNF in the evaluation and intervention of

occupational therapy. Basic principles, diagonal patterns, and more commonly used techniques will be introduced, and their application and presence in routine daily life skills will be demonstrated. PNF addresses the client factors of posture, mobility, strength, effort, and coordination. To use PNF effectively, it is necessary to understand normal development, learn the motor skills to use the techniques, and apply the concepts and techniques to occupational therapy activities.⁴ This section should form the basis for further reading and training under the supervision of a therapist experienced in PNF.

PNF is based on normal movement and motor development. In normal motor activity the brain registers total movement and not individual muscle action.³¹ Encompassed in the PNF approach are mass movement patterns that are spiral and diagonal in nature and that resemble the movement seen in functional activities. In this multisensory approach, facilitation techniques are superimposed on movement patterns and postures through manual contact, verbal commands, and visual cues by the therapist. These facilitation techniques and movement patterns can be preparatory methods that prepare the client to participate more effectively in daily occupations or be applied within the performance of a task.

PNF is used as an intervention technique for numerous conditions, including Parkinson's disease, spinal cord injuries, arthritis, stroke, head injuries, and hand injuries. It has been effectively combined with neuromobilization techniques to reduce sensory deficits in individuals who have sustained a CVA.⁷⁶

History

PNF originated with Dr. Herman Kabat, physician and neurophysiologist, in the 1940s. He applied neurophysiologic principles, based on the work of Sherrington, to interventions for paralysis secondary to poliomyelitis and multiple sclerosis. In 1948, Kabat and Henry Kaiser founded the Kabat-Keiser Institute in Vallejo, California. Here, Kabat worked with PT Margaret Knott to develop the PNF method of intervention. By 1951 the diagonal patterns and core techniques were established. PNF is now used to treat numerous neurologic, musculoskeletal, and general medical conditions.

In 1952 Dorothy Voss, a PT, joined the staff at the Kaiser-Kabat Institute. She and Knott undertook the teaching and supervision of staff therapists. In 1954 Knott and Voss presented the first 2-week course in Vallejo. Two years later, the first edition of *Proprioceptive Neuromuscular Facilitation* by Margaret Knott and Dorothy Voss was published by Harper & Row.

During this same period several reports in the *American Journal of Occupational Therapy* described PNF and its application to occupational therapy intervention.^{4,12,14,34,71,75} It was not until 1974 that the first PNF course for OTs, taught by Dorothy Voss, was offered. Since then, Beverly

Myers, an OT, and others have offered courses for OTs throughout the United States. In 1984, PNF was first taught concurrently to both PTs and OTs at the Rehabilitation Institute in Chicago.^{49,74} Today, courses are offered throughout the United States, as well as Europe, Asia, and South America.

Principles of Intervention

Voss presented 11 principles of intervention at the Northwestern University Special Therapeutic Exercise Project in 1966. These principles were developed from concepts in the fields of neurophysiology, motor learning, and motor behavior and are still essential to the practice of PNF today.⁷²

All human beings have potentials that have not been fully developed. This philosophy is the underlying basis of PNF. Therefore, during evaluation and intervention planning, the client's abilities and potentials are emphasized. For example, a client who has weakness on one side of the body can use the intact side to assist the weaker part. Likewise, a client who has hemiplegia with a flaccid arm can use the intact head, neck, and trunk musculature to begin reinforcement of the weak arm in weight-bearing activities.

Normal motor development proceeds in a cervicocaudal and proximodistal direction. The cervicocaudal and proximodistal direction is followed in evaluation and intervention. When severe disability is present, attention is first directed to the head and neck region, with its visual, auditory, and vestibular receptors, and then to the upper part of the trunk and extremities. If the superior region is intact, an effective source of reinforcement for the inferior region is available.⁷⁴ The proximodistal direction is followed by developing adequate function in the head, neck, and trunk before developing function in the extremities. This approach is of particular importance in interventions that facilitate fine motor coordination in the upper extremities. Unless adequate control exists in the head, neck, and trunk region, fine motor skills cannot be developed effectively. For example, Leticia needs to strengthen her head, neck, and trunk muscles to regain adequate postural control before she can adequately perform the fine motor tasks required in her job, such as cutting with scissors. This illustrates how addressing a specific client factor of postural control can influence occupational performance.

Early motor behavior is dominated by reflex activity. Mature motor behavior is supported or reinforced by postural reflexes. As humans mature, primitive reflexes are integrated and available for reinforcement to allow progressive development, such as rolling, crawling, and sitting. Reflexes have also been noted to have an effect on changes in tone in the extremities. Hellebrandt, Schade, and Carns studied the effect of the tonic neck reflex and the asymmetric tonic neck reflex on changes in tone and movement in the extremities of normal adults.²⁵ They found that head and neck movement significantly affected arm and leg movement. In applying this finding to intervention, for example,

weak elbow extensors can be reinforced with the asymmetric tonic neck reflex by having the client look toward the side of weakness. Likewise, the client can be assisted in assuming postures with the influence of reflex support. For example, Leticia can use the body-on-body righting reflex to support her ability to assume sitting upright on the edge of the bed from a side-lying position when she gets up in the morning.

Early motor behavior is characterized by spontaneous movement, which oscillates between extremes of flexion and extension. These movements are rhythmic and reversing in character. During intervention it is important to attend to both directions of movement. When the occupational therapy practitioner is working with a client on getting up from a chair, attention must also be given to sitting back down. Often with an injury, the eccentric contraction (e.g., sitting down) is lost and becomes very difficult for the client to regain. If not properly treated, the client may be left with inadequate motor control to sit down smoothly and thus may “drop” into a chair. This eccentric control would be particularly important for Leticia because she is required to sit in low chairs at her children's school. Similarly, in training for ADLs the client must learn how to get undressed and dressed.

Developing motor behavior is expressed in an orderly sequence of total patterns of movement and posture. In a normal infant the sequence of total patterns is demonstrated through the progression of locomotion. The infant learns to roll, to crawl, to creep, and finally to stand and walk. Throughout these stages of locomotion the infant also learns to use the extremities in different patterns and within different postures. Initially, the hands are used for reaching and grasping within the most supported postures, such as supine and prone. As postural control develops, the infant begins to use the hands in side-lying, sitting, and standing positions. During intervention, to maximize motor performance, clients should be given opportunities to work in a variety of developmental postures. Use of the extremities in total patterns requires interaction with component patterns of the head, neck, and trunk. For example, when swinging a tennis racquet in a forehand stroke, the arm and the head, neck, and trunk move in the direction of the swing. Without the interaction of the distal and proximal components, movement becomes less powerful and less coordinated.

The growth of motor behavior has cyclic trends, as evidenced by shifts between flexor and extensor dominance. The shifts between antagonists help develop muscle balance and control. One of the main goals of the PNF intervention approach is to establish a balance between antagonists. Developmentally, the infant establishes this balance before creeping (i.e., when rocking forward [extensor dominant] and backward [flexor dominant] on hands and knees). Postural control and balance must be achieved before movement can begin in this position. During intervention it is important to establish a balance between antagonistic muscles by first observing where imbalance exists and then facilitating the weaker component. For example, if a client

who has sustained a stroke demonstrates flexor synergy (flexor dominant), extension should be facilitated.

Normal motor development has an orderly sequence but lacks a step-by-step quality. Overlapping of skills occurs. A child does not perfect performance of one activity before beginning another, more advanced activity. When trying to ascertain in which total pattern to position the client, normal motor development should be heeded. If one technique or developmental posture is not effective in obtaining the desired result, it may be necessary to try the activity in another developmental posture. For example, if a client who has ataxia, such as Leticia, is unable to perform a fine motor task while sitting, it may be necessary to practice skills in a more supported posture, such as prone on the elbows or with her elbows supported on a surface such as a table. Just as the infant reverts to a more secure posture when attempting a complex fine motor task, so must the client. On the other hand, if the client has not perfected a motor activity such as walking on level surfaces, he or she may benefit from attempting a higher-level activity such as walking up or down stairs, which in turn can improve ambulation on level surfaces. It is natural for the client to move up and down the developmental sequence, and this allows multiple and varied opportunities for practicing motor activities. The cognitive demands of the task in relation to the developmental posture must also be considered. When the client's position is varied, either by changing the base of support or by shifting weight on different extremities, the quality of visual and cognitive processing is influenced.¹

Locomotion depends on the reciprocal contraction of flexors and extensors, and maintenance of posture requires continual adjustment for nuances of imbalance. Antagonistic pairs of movements, reflexes, and muscles and joint motion interact as necessary with the movement or posture. This principle restates one of the main objectives of PNF—to achieve a balance between antagonists. An example of imbalance is a client with a head injury who is unable to maintain adequate sitting balance for a tabletop cognitive activity because of a dominance of trunk extensor tone. Another example is a client who has hemiplegia with tight finger flexors secondary to a flexor-dominant tone in the hand. During intervention, emphasis is placed on correcting the imbalances. In a client with spasticity, first the spasticity is inhibited and then the antagonistic muscles, reflexes, and postures are facilitated.

Improvement in motor ability is dependent on motor learning. Multisensory input from the therapist facilitates motor learning in the client and is an integral part of the PNF approach. For example, the therapist may work with a client on a shoulder flexion activity such as reaching into a cabinet for a cup. The therapist may say, “Reach for the cup,” to add verbal input. This approach also encourages the client to look in the direction of the movement to allow vision to enhance the motor response. Thus, tactile, auditory, and visual input is used. Motor learning has occurred when these external cues are no longer needed for adequate performance.

Frequent stimulation and repetitive activity are used to promote and retain motor learning and to develop strength and endurance. Just as a therapist who is learning PNF needs the opportunity to practice the techniques, a client needs the opportunity to practice new motor skills. With practice, habits will be formed that support motor performance in occupation. In the process of development an infant constantly repeats a motor skill in many settings and developmental postures until it is mastered, as becomes apparent to anyone who watches a child learning to walk. Numerous attempts fail, but efforts are repeated until the skill is mastered. After the activity is learned, it becomes part of the child. He or she is able to use the activity automatically and deliberately as the occasion demands.⁷⁴ The same is true for a person learning to play the piano or to play tennis. Without the opportunity to practice, motor learning cannot occur successfully. Just as Leticia's students may be given homework to help them practice the material that they learn in school, Leticia will also need to be given a home program that encourages her to practice the postures and movements facilitated in therapy.

Goal-directed activities coupled with techniques of facilitation are used to hasten learning of total patterns of walking and self-care activities. When facilitation techniques are applied to self-care, the objective is improved functional ability, but improvement is achieved by more than instruction and practice. Correction of deficiencies is accomplished by direct application of manual contact and techniques to facilitate a desired response.²⁹ During an intervention session, this approach may mean applying stretch to the finger extensors to facilitate release of an object or providing joint approximation through the shoulders and pelvis of a client who has ataxia to provide stability while the client is standing to wash dishes. With repetition of appropriate facilitation techniques, Leticia will have the opportunity to feel more normal movement and need to rely less on the therapist's external input.

Motor Learning

Motor learning requires a multisensory approach. The auditory, visual, and tactile systems are all used to achieve the desired response. The correct combination of sensory input in each client should be ascertained, implemented, and altered as the client progresses. The developmental level of the client and the ability to cooperate should also be taken into consideration.⁷⁴ The approach used with a client who has aphasia differs from that used with a client who has a hand injury. For example, verbal instructions would be better understood by the client with a hand injury than the client with aphasia. Less verbal and more tactile and gestural cues would be appropriate with the client who has aphasia. Similarly, the approach used with a child varies greatly from that used with an adult. Interventions with Leticia must take into consideration her visual deficits in addition to any cognitive impairment that remains as a result of her head injury.

Auditory System

Verbal commands should be brief and clear. It is important to time the command so that it does not come too early or too late in relation to the motor act. Tone of voice may influence the quality of the client's response. Buchwald states that tones of moderate intensity evoke gamma motor neuron activity and that louder tones can alter alpha motor neuron activity.¹¹ Strong, sharp commands simulate a stress situation and are used when maximal stimulation of motor response is desired. A soft tone of voice is used to offer reassurance and to encourage a smooth movement, as in the presence of pain (e.g., when techniques are used to increase mobility in Leticia's left wrist). When a client is giving the best effort, a moderate tone can be used.⁷⁴

Another effect of auditory feedback on motor performance was studied by Loomis and Boersma.⁴⁰ They used a "verbal mediation strategy" to teach wheelchair safety before clients with right CVA transferred out of the chair. Loomis and Boersma taught clients to say aloud the steps required to leave the wheelchair safely and independently. They found that only clients who used verbal mediation learned the wheelchair drill sufficiently to perform safe and independent transfers. These clients also had better retention of the sequence of steps, which suggests that verbal mediation is beneficial in reaching independence with better sequencing and fewer errors.

When Leticia first arrived in therapy, she suffered considerable pain at the site of her wrist fracture. Early PNF intervention should use soft verbal commands when activities that involve wrist mobility are performed. In contrast, when facilitating Leticia's ability to perform assumption of postures (i.e., moving from side lying to tall kneeling), more forceful, sharp commands may be needed.

Visual System

Visual stimuli assist in initiation and coordination of movement. Visual input should be monitored to ensure that the client is tracking in the direction of movement. For example, the therapist's position is important because the client often uses the therapist's movement or position as a visual cue. If the therapist desires Leticia to move in a forward direction, the therapist should be positioned diagonally in front of the client. In addition to the therapist's position, placement of the occupational therapy activity should also be considered. Using one of her children's favorite board games, the therapist could place it in front and to the left of Leticia to achieve the goal of increased head, neck, and trunk rotation. Because occupational therapy is activity oriented, an abundance of visual stimuli is offered to the client.

Special consideration will need to be given to the use of vision when working with Leticia. Her stronger head and neck musculature can be used to reinforce oculomotor control. Total body and extremity diagonal patterns can be used to reinforce eye teaming.

Tactile System

Developmentally the tactile system matures before the auditory and visual systems.¹⁷ Furthermore, the tactile system is more efficient because it has temporal and spatial discrimination abilities, as opposed to the visual system, which can make only spatial discriminations, and the auditory system, which can make only temporal discriminations.²² Affolter stated that during development, processing of tactile-kinesthetic information can be considered fundamental for building cognitive and emotional experience.² Looking at and listening to the world do not result in change; however, the world cannot be touched without some change taking place. A Chinese proverb often cited in PNF courses reinforces this viewpoint: "I listen and I forget, I see and I remember, I do and I understand."

It is important for the client to feel movement patterns that are coordinated and balanced. This is particularly important for clients with ataxia, such as Leticia. With the PNF approach, tactile input is supplied through manual contact with the therapist to guide and reinforce the desired response. This approach may involve gently touching the client to guide movement, using stretch to initiate movement, and providing resistance to strengthen movement. The type and extent of manual contact depend on the client's clinical status, which is determined through evaluation and re-evaluation. For example, the use of stretch or resistance in an individual with musculoskeletal instability may be contraindicated, as in the early healing phases of Leticia's fractures. Likewise, stretch or resistance should not be used if they cause increased pain or an imbalance in tone.

To increase speed and accuracy in motor performance, the client needs the opportunity to practice. Through repetition, habit patterns that occur automatically without voluntary effort are established. The PNF approach uses the concepts of *part-task practice* and *whole-task practice*. In other words, to learn the whole task, emphasis is placed on the parts of the task that the client is unable to perform independently. The term *stepwise procedures* is descriptive of the emphasis on a part of the task during performance of the whole.⁷⁴ Performance of each part of the task is improved by combining practice with appropriate sensory cues and techniques of facilitation. For example, a client learning to transfer from a wheelchair to a tub bench may have difficulty lifting the leg over the tub rim. This part of the task should be practiced, with repetition and facilitation techniques involving the hip flexors, during performance of the transfer. When the transfer becomes smooth and coordinated, it is no longer necessary to practice each part individually. It is also unnecessary for the therapist to provide continued facilitation.

Leticia has difficulty getting down on the floor to play games with her children. During intervention she should be provided with facilitation and practice in moving from sitting on a chair to tall kneeling to side sitting on the floor. She will initially require considerable manual facilitation by

the therapist to move through and achieve these various movement patterns. As she develops more skill, the therapist will reduce and adjust the intensity of the tactile input.

In summation, several components are necessary for motor learning to occur. In the PNF intervention approach, these components include multisensory input from the therapist's verbal commands, visual cues, and manual contact. Touch is the most efficient form of stimulation and provides the opportunity for the client to feel normal movement. Current motor-learning theory argues that for motor learning to occur, the client cannot be a passive recipient of intervention. Therefore, the client needs opportunities to practice motor skills in the context of functional life situations. Initially, the therapist's manual contact and sensory input are needed. These should be decreased, however, as the client demonstrates and learns skilled movement. The amount of feedback from the therapist should also be decreased as the client learns to rely on his or her own internal feedback system for error detection and correction.

Assessment

Assessment of the client requires astute observational skills and knowledge of normal movement. An initial assessment is performed to determine the client's abilities, deficiencies, and potential. After the intervention plan is established, ongoing assessment of the client is necessary to ascertain the effectiveness of intervention and to make modifications as the client changes.

The PNF assessment follows a sequence from proximal to distal. First, vital and related functions are considered, such as breathing, swallowing, voice production, facial and oral musculature, and visual-ocular control. Any impairment or weakness in these functions is noted. Because Leticia fatigues quickly, breathing patterns and efficiency need to be closely evaluated as she engages in her daily activities.

The head and neck region is observed after vital functions. Deficiencies in this area directly affect the upper part of the trunk and extremities. Head and neck positions are observed in varying postures and total patterns during functional activities. It is important to note (1) dominance of tone (flexor or extensor), (2) alignment (midline or shift to one side), and (3) stability and mobility (more or less needed).⁴⁹

After observation of the head and neck region, the assessment proceeds to the following parts of the body: upper part of the trunk, upper extremities (UEs), lower part of the trunk, and lower extremities (LEs). Each segment is assessed individually in specific movement patterns, in addition to during developmental activities in which the body segments interact. For example, shoulder flexion can be observed in an individual UE movement pattern, in addition to during a total developmental pattern such as rolling.

During assessment of developmental activities and postures, the following issues should be addressed:

- Is more stability or mobility needed?
- Is there a balance between the flexors and extensors, or is one more dominant?
- Is the client able to move in all directions?
- What are the client's major limitations (e.g., weakness, incoordination, spasticity, and contractures)?
- Is the client able to assume a posture and maintain it? If not, which total pattern or postures are inadequate?
- Are the inadequacies more proximal or distal?
- Which sensory input does the client respond to most effectively—auditory, visual, or tactile?
- Which techniques of facilitation does the client respond to best?

When applying these questions to Leticia's evaluation, the following observations can be made. First, Leticia will need to work on developing stability to diminish the effects of her ataxia. She is not dominated by either flexor or extensor tone but, when fatigued, has more difficulty maintaining an upright posture. She will therefore need to have facilitation of the head, neck, and trunk extensors when fatigued. She can move in all directions but has less stability when walking backward. Her major limitations are poor motor control and rigidity, but prevention of a wrist contracture is also a concern. Leticia is having difficulty assuming kneeling, sitting, and standing postures because of her instability. Once in an upright posture, she can maintain it for a few minutes, but fatigue then sets in. She will therefore need to build endurance in more supported lower developmental postures. When moving into more upright postures, she will need PNF techniques to build strength and endurance. Her inadequate proximal control and trunk rigidity affect her ability to effectively use her extremities, especially in higher developmental positions. Visual sensory input may not be the best to start with because of her diplopia; however, facilitation of oculomotor control using PNF techniques will be of benefit as she progresses. The facilitation techniques that Leticia responds to best are rhythmic stabilization, stabilizing reversals, and approximation.

Finally, the client is observed during self-care and other ADLs to determine whether performance of individual and total patterns is adequate within the context of a functional activity. The client's performance may vary from one setting to another. After the client leaves the structured setting of the occupational or physical therapy clinic for the less structured home or community environment, deterioration of motor performance is not unusual. Thus, the intervention plan must accommodate the practice of motor performance in a variety of settings in locations appropriate to the specific activity.

Intervention Implementation

After assessment, an intervention plan is developed that includes goals that the client hopes to accomplish. The techniques and procedures that have the most favorable

influence on movement and posture are used. Similarly, appropriate total patterns (developmental postures) and patterns of facilitation are selected to enhance performance.

Diagonal Patterns

The diagonal patterns used in the PNF approach are the mass movement patterns observed in most functional activities. Part of the challenge in occupational therapy assessment and intervention is recognition of the diagonal patterns in ADLs. Knowledge of the diagonals is necessary for identifying areas of deficiency. Two diagonal motions are present for each major part of the body: head and neck, upper and lower parts of the trunk, and extremities. Each diagonal pattern has a flexion and extension component, together with rotation and movement away from or toward the midline.

The head, neck, and trunk patterns are referred to as (1) flexion with rotation to the right or left and (2) extension with rotation to the right or left. These proximal patterns combine with the extremity diagonals. The UE and LE diagonals are described according to the three movement components at the shoulder and hip: (1) flexion and extension, (2) abduction and adduction, and (3) external and internal rotation. Voss introduced shorter descriptions for the extremity patterns in 1967 and referred to them as diagonal 1 (D_1) flexion/extension and diagonal 2 (D_2) flexion/extension.⁷² The reference points for flexion and

extension are the shoulder and hip joints of the UEs and LEs, respectively.

The movements associated with each diagonal and examples of these patterns seen in self-care and other ADLs are presented in the following sections. Note that during functional activities, not all components of the pattern or full ROM are necessarily seen. Furthermore, the diagonals interact during functional movement, changing from one pattern or combination to another, when they cross the transverse and sagittal planes of the body.⁴⁸

Unilateral Patterns

1. UE D_1 flexion (shoulder flexion–adduction–external rotation): Scapula elevation, abduction, and rotation; shoulder flexion, adduction, and external rotation; elbow in flexion or extension; forearm supination; wrist flexion to the radial side; finger flexion and adduction; and thumb adduction (Figure 31-4, A). Examples in functional activity: hand-to-mouth motion in feeding, tennis forehand, combing the hair on the left side of the head with the right hand (Figure 31-5, A), and rolling from supine to prone.
2. UE D_1 extension (shoulder extension–abduction–internal rotation): Scapula depression, adduction, and rotation; shoulder extension, abduction, and internal rotation; elbow in flexion or extension; forearm pronation; wrist extension to the ulnar side; finger

extension and abduction; and thumb in palmar abduction (Figure 31-4, B). Examples in functional activity: pushing a car door open from the inside (Figure 31-5, B), tennis backhand stroke, and rolling from prone to supine.

3. UE D₂ flexion (shoulder flexion-abduction-external rotation): Scapula elevation, adduction, and rotation; shoulder flexion, abduction, and external rotation;

elbow in flexion or extension; forearm supination; wrist extension to the radial side; finger extension and abduction; and thumb extension (Figure 31-6, A). Examples in functional activity: combing the hair on the right side of the head with the right hand (Figure 31-7, A), lifting a racquet in a tennis serve, and back stroke in swimming. The D₂ flexion pattern would be emphasized in Leticia's left UE to facilitate supination

and wrist extension, which are weak secondary to her wrist fracture.

4. UE D₂ extension (shoulder extension-adduction-internal rotation): Scapula depression, abduction, and rotation; shoulder extension, adduction, and internal rotation; elbow in flexion or extension; forearm pronation; wrist flexion to the ulnar side; finger flexion and adduction; and thumb opposition (see Figure 31-6, B). Examples in functional activity: pitching a baseball, hitting a ball during a tennis serve, and buttoning pants on the left side with the right hand (see Figure 31-7, B). The rotational component in LE D₁ flexion and extension parallels the UE patterns.
5. LE D₁ flexion (hip flexion-adduction-external rotation): Hip flexion, adduction, and external rotation; knee in flexion or extension; and ankle and foot dorsiflexion with inversion and toe extension. Examples in functional activity: kicking a soccer ball, rolling from supine to prone, and putting on a shoe with the legs crossed (Figure 31-8, A).
6. LE D₁ extension (hip extension-abduction-internal rotation): Hip extension, abduction, and internal rotation; knee in flexion or extension; and ankle and foot plantar flexion with eversion and toe flexion. Examples in functional activity: putting a leg into pants (Figure 31-8, B) and rolling from prone to supine. The rotational component of LE D₂ flexion and extension is opposite that in the UE patterns.

7. LE D₂ flexion (hip flexion-abduction-internal rotation): Hip flexion, abduction, and internal rotation; knee in flexion or extension; and ankle and foot dorsiflexion with eversion and toe extension. Examples in functional activity: karate kick (Figure 31-9, A) and drawing the heels up during the breaststroke in swimming.
8. LE D₂ extension (hip extension-adduction-external rotation): Hip extension, adduction, and external rotation; knee in flexion or extension; and ankle and foot plantar flexion with inversion and toe flexion. Examples of functional activity: push-off in gait, the kick during the breaststroke in swimming, and long sitting with the legs crossed (Figure 31-9, B).

Bilateral Patterns

Movements in the extremities may be reinforced by combining diagonals in bilateral patterns as follows:

1. Symmetric patterns: Paired extremities perform similar movements at the same time (Figure 31-10, A). Examples: bilateral symmetric D₁ extension, such as pushing off a chair to stand (Figure 31-11, A); bilateral symmetric D₂ extension, such as starting to take off a pullover sweater (Figure 31-11, B); and bilateral symmetric D₂ flexion, such as reaching to lift a large item off a high shelf (Figure 31-11, C). Bilateral symmetric UE patterns facilitate trunk flexion and extension.

(From Myers BJ: *Unit 1: PNF diagonal patterns and their application to functional activities, videotape study guide*, Chicago, Ill, 1982, Rehabilitation Institute of Chicago.)

2. Asymmetric patterns: Paired extremities perform movements toward one side of the body at the same time, which facilitates trunk rotation (see [Figure 31-10, B](#)). The asymmetric patterns can be performed with the arms in contact, such as in the chopping and lifting patterns in which greater trunk rotation is seen ([Figures 31-12 and 31-13](#)). Furthermore, with the arms in contact, self-touching occurs. This is frequently observed in those with pain or in reinforcement of a motion when greater control or power is needed.⁷⁴ This phenomenon is observed in a baseball player at bat and in a tennis player who uses

a two-handed backhand to increase control and power. Asymmetric patterns with the arms in contact would be beneficial for Leticia to control ataxia. Examples of asymmetric patterns are bilateral asymmetric flexion to the left with the left arm in D₂ flexion and the right arm in D₁ flexion, such as when putting on a left earring ([Figure 31-14](#)), and bilateral asymmetric extension to the left with the right arm in D₂ extension and the left arm in D₁ extension, such as when zipping a left-sided zipper.

3. Reciprocal patterns: Paired extremities move in opposite directions simultaneously, either in the

FIGURE 31-14 Putting on earring requires use of the upper extremity bilateral asymmetric flexion pattern.

same diagonal or in combined diagonals. If paired extremities perform movements in combined diagonals (see Figure 31-10, C), a stabilizing effect occurs on the head, neck, and trunk because movement of the extremities is in the opposite direction while the head and neck remain in the midline. During activities requiring high-level balance, reciprocal patterns with combined diagonals come into play, with one extremity in D₁ extension and the other extremity in D₂ flexion. Examples are pitching in baseball, sidestroke in swimming, and walking a balance beam with one extremity in a diagonal flexion pattern and the other in a diagonal extension pattern (Figure 31-15). In contrast, reciprocal patterns in the same diagonal, such as D₁ in arm swing during walking, facilitate trunk rotation. Leticia needs to work with reciprocals of D₁ to improve her rhythm of arm swing and trunk rotation during walking.

Combined Movements of the Upper and Lower Extremities

Interaction of the UEs and LEs results in (1) ipsilateral patterns, with extremities on the same side moving in the same direction at the same time; (2) contralateral patterns, with extremities on opposite sides moving in the same direction at the same time; and (3) diagonal reciprocal patterns, with contralateral extremities moving in the same

FIGURE 31-15 A bilateral reciprocal pattern of the upper extremities is used to walk a balance beam.

direction at the same time while the opposite contralateral extremities move in the opposite direction (see Figure 31-10, *D*, *E*, and *F*).

Combined movements of the UEs and LEs are observed in such activities as crawling and walking. Awareness of these patterns is important in the assessment of a client's motor skills. The ipsilateral patterns are more primitive developmentally and indicate a lack of bilateral integration. Less rotation is also observed in ipsilateral patterns. Therefore, the goal in intervention is to progress from ipsilateral to contralateral to diagonal reciprocal patterns.

The use of diagonal patterns has several advantages in intervention. First, crossing of the midline occurs. This movement is of particular importance in the remediation of perceptual motor deficits such as unilateral neglect, in which integration of both sides of the body and awareness of the neglected side are intervention goals. Second, each muscle has an optimal pattern in which it functions. For example, a client who has weak thumb opposition benefits from active movement in D_2 extension. Similarly, D_1 extension is the optimal pattern for ulnar wrist extension. Leticia should work on D_2 flexion after her Colles wrist fracture is stable. This pattern will increase ROM and strengthen supination and radial wrist extension. Third, the diagonal patterns use groups of muscles, which is typical of the movement

seen in functional activities. For example, when eating, the hand-to-mouth action is accomplished in one mass movement pattern (D_1 flexion) that uses several muscles simultaneously. Therefore, movement in the diagonals is more efficient than movement performed at each joint separately. Finally, rotation is always a component in the diagonals (e.g., trunk rotation to the left or right and forearm pronation and supination). With an injury or with the aging process, rotation is frequently impaired and can be facilitated by movement in the diagonals. During intervention, attention should be given to the placement of activities so that movement occurs in the diagonal. For example, if a client is working on a wood-sanding project, trunk rotation with extension can be facilitated by placing the project on an inclined plane in a diagonal. Leticia can incorporate rotational movements into homemaking activities such as unloading the dishwasher.

Total Patterns

In PNF, developmental postures are also called total patterns of movement and posture.⁴⁷ Total patterns require interaction between the proximal (head, neck, and trunk) and distal (extremity) components. The assumption of postures is important, as is the maintenance of postures. When posture cannot be sustained, emphasis should be placed on the assumption of posture.⁷³ For example, before a client can be expected to sustain a sitting posture, he or she must have ability in the lower developmental total patterns of movement, such as rolling and moving from side lying to side sitting.

Active assumption of postures can be included in occupational therapy activities. For example, a reaching and placing activity could be set up so that the client must reach for the object in the supine posture and place the object in the side-lying posture. The use of total patterns can also reinforce individual extremity movements. For example, in an activity such as wiping a tabletop, wrist extension is reinforced when the client leans forward over the supporting arm. This would be a way to make homemaking activities part of Leticia's home exercise program for her wrist in the later stages of recovery.

Several facts support the use of total patterns in the PNF intervention approach.⁴⁷ First, total patterns of movement and posture are experienced as part of the normal developmental process in all human beings. Therefore, recapitulation of these postures is meaningful to the client and acquired with less difficulty. Second, movement in and out of total patterns and the ability to sustain postures enhance components of normal development, such as reflex integration and support, balance between antagonists, and development of motor control in a cephalocaudal, proximodistal direction. Third, the use of total patterns improves the ability to assume and maintain postures, which is important in all areas of occupation.

The sequence and procedures for assisting clients in the developmental postures were developed by Voss. In 1981

Myers developed a videotape that shows use of the sequence and procedures in occupational therapy.⁴⁷ This video demonstrates more information on application of the total patterns and postures in occupational therapy.

Procedures

PNF techniques are superimposed on movement and posture. Among these techniques are basic procedures considered essential to the PNF approach. Two procedures, verbal commands and visual cues, were discussed previously. Other procedures are described in the following sections.

Manual contact refers to placement of the therapist's hands on the client. Such contact is most effective when applied directly to the skin. Pressure from the therapist's touch is used as a facilitating mechanism and serves as a sensory cue to help the client understand the direction of the anticipated movement.⁷⁴ The amount of pressure applied depends on the specific technique being used and on the desired response. The location of manual contact is chosen according to the groups of muscles, tendons, and joints responsible for the desired movement patterns. If a client is having difficulty reaching back to comb her hair because of scapular weakness, the desired movement pattern is D₂ flexion. Manual contact should be on the posterior surface of the scapula to reinforce the muscles that elevate, adduct, and rotate the scapula.

Stretch is used to initiate voluntary movement and enhance speed of response and strength in weak muscles. This procedure is based on Sherrington's neurophysiologic principle of reciprocal innervation.⁶⁵ When a muscle is stretched, the Ia and II fibers in the muscle spindle send excitatory messages to the alpha motor neurons that innervate the stretched muscle. Inhibitory messages are sent to the antagonistic muscle simultaneously.¹⁷

When stretch is used in the PNF approach, the part to be facilitated is placed in the extreme lengthened range of the desired pattern (or where tension is felt on all muscle components of a given pattern). This range is the completely shortened range of the antagonistic pattern. Special attention is directed to the rotatory component of the pattern because it is responsible for elongation of the fibers of the muscles in a given pattern. After the correct position for the stretch stimulus has been achieved, stretch is superimposed on the pattern. The client should attempt the movement at the exact time that the stretch reflex is elicited. The use of verbal commands also should coincide with the application of stretch to reinforce the movement. Discrimination should be exercised with use of stretch to prevent an increase in pain or muscle imbalance.

Traction facilitates the joint receptors by creating a separation of the joint surfaces. It is thought that traction promotes movement and is used for pulling motion.⁷⁴ In activities such as carrying a heavy suitcase or pulling open a jammed door, traction can be felt on the joint surfaces. Although traction may be contraindicated in clients with acute symptoms, such as after surgery or a fracture, it can

sometimes provide relief of pain and promote greater ROM in painful joints.

Approximation facilitates joint receptors by creating compression of the joint surfaces. It promotes stability and postural control and is used for pushing motion.⁷⁴ Approximation is usually superimposed on a weight-bearing posture. For example, to enhance postural control in the prone-on-elbows posture, approximation may be given through the shoulders in a downward direction. As part of a home program to enhance proximal stability, Leticia could play board games on the floor with her children in weight-bearing positions such as prone on elbows or side sitting. A weighted vest could be used in place of the therapist's manual contact to provide approximation.

Maximal resistance is a procedure that involves Sherrington's principle of irradiation—namely, that stronger muscles and patterns reinforce weaker components.⁶⁵ This procedure is frequently misunderstood and applied incorrectly. The procedure is defined as the greatest amount of resistance that can be applied to an active contraction while allowing full ROM to take place or that can be applied to an isometric contraction without defeating or breaking the client's hold.⁷⁴ Maximal resistance is not the greatest amount of resistance that the therapist can apply. The objective is to obtain maximal effort on the part of the client because strength is increased by movement against resistance that requires maximal effort.²⁴

If the resistance applied by the therapist results in uncoordinated or jerky movement or if it breaks the client's hold, too much resistance has been given. Movement against maximal resistance should be slow and smooth. To use this technique effectively, the therapist must sense the appropriate amount of resistance. For clients with neurologic impairment or pain, the resistance may be very light, and light resistance is probably maximal for the client's needs. The therapist's manual contact may offer light resistance that actually assists by providing the client with a way to track the desired movement. In the presence of spasticity, resistance may increase existing muscle imbalance and thus needs to be monitored. For example, if an increase in finger flexor spasticity is noted with resisted rocking in the hands-knees position, resistance should be decreased or eliminated or an alternative position used.

Techniques

Specific techniques are used in conjunction with these basic procedures. A few have been selected for discussion. These techniques are divided into three categories: those directed to the agonists, those that are a reversal of the antagonists, and those that promote relaxation.⁷⁴

Techniques Directed to the Agonists

The use of repeated contractions is a technique based on the assumption that repetition of an activity is necessary for motor learning and helps develop strength, ROM, and endurance. The client's voluntary movement is facilitated

with stretch and resistance by performing isometric and isotonic contractions. Repeated contractions could be used to increase trunk flexion with rotation in a client who has difficulty reaching to put on a pair of shoes from the sitting position. The client bends forward as far as possible. At the point where active motion weakens, the client is asked to “hold” with an isometric contraction. This action is followed by isotonic contractions, facilitated by stretch, as the client is asked to “reach toward your feet.” This sequence is repeated until either fatigue is evident or the client is able to reach the feet. The pattern can be reinforced further by asking the client to hold with another isometric contraction at the end of the sequence.

Rhythmic initiation is used to improve the ability to initiate movement, which may be a problem in clients with Parkinson’s disease or apraxia. This technique involves voluntary relaxation, passive movement, and repeated isotonic contractions of the agonistic pattern. The verbal command is, “Relax and let me move you.” As relaxation is felt, the command is, “Now you do it with me.” After several repetitions of active movement, resistance may be provided to reinforce the movement. Rhythmic initiation allows the client to feel the pattern before beginning active movement. Thus, the proprioceptive and kinesthetic senses are enhanced.

Techniques Involving Reversal of Antagonists

Reversal-of-antagonist techniques use a characteristic of normal development—namely, that movement is reversing and changes direction. These techniques are based on Sherrington’s principle of successive induction, according to which the stronger antagonist facilitates the weaker agonist.⁶⁵ The agonist is facilitated through resistance to the antagonist. The contraction of the antagonist can be isotonic, isometric, or a combination of the two. These techniques may be contraindicated in clients in whom resistance of antagonists increases symptoms such as pain and spasticity. For example, facilitation of finger extension (agonist) would not be achieved effectively through resistance applied to spastic finger flexors (antagonist). In this situation, finger extension may be better facilitated through the use of repeated contractions, in which the emphasis is only on the extensor surface.

Slow reversal is an isotonic contraction (against resistance) of the antagonist followed by an isotonic contraction (against resistance) of the agonist. Slow reversal–hold is the same sequence, but with an isometric contraction at the end of the range. For a client who has difficulty reaching his or her mouth for oral hygiene because of weakness in the D₁ flexion pattern, the slow-reversal procedure is as follows: an isotonic contraction against resistance in D₁ extension with the verbal command, “Push down and out,” followed by an isotonic contraction of D₁ flexion against resistance with the verbal command, “Pull up and across.” An increase or buildup of power in the agonist should be felt with each successive isotonic contraction.

Slow reversal used in conjunction with repeated contractions could be applied to trunk movement patterns to help Leticia overcome her rigidity and improve the balance of antagonists. This sequence of techniques could also be used to increase Leticia’s wrist ROM and strength once her fracture is stable.

Stabilizing reversals are characterized by alternating isotonic contractions opposed by enough resistance to prevent motion. In practice, the therapist provides resistance to the client in one direction while asking the client to oppose the force, with no motion allowed. Once the client is fully resisting the force, the therapist gradually moves the resistance in another direction. Each time that the client is able to respond to the new resistance, the therapist moves the hand to resist a new direction, with directions reversed as often as needed to achieve stability. This technique is used to increase stability, balance, and muscle strength.

Rhythmic stabilization is used to increase stability by eliciting simultaneous isometric contractions of antagonistic muscle groups. Cocontraction results if the client is not allowed to relax. This technique requires repeated isometric contractions, which leads to increased circulation or the tendency for the client to hold his or her breath, or both. Therefore, rhythmic stabilization may be contraindicated in clients with cardiac involvement, and no more than three or four repetitions should be done at a time with any clients.

In rhythmic stabilization, manual contact is applied to both agonist and antagonist muscles, with resistance given simultaneously. The client is asked to hold the contraction against graded resistance. Without allowing the client to relax, manual contact is switched to the opposite surfaces. Rhythmic stabilization is useful in clients lacking postural control because of ataxia or proximal weakness. Used intermittently during an activity requiring postural stability, such as meal preparation in a standing posture, this technique enhances muscle balance, endurance, and control of movement. Rhythmic stabilization techniques were found to be effective in improving postural control and reducing pain in individuals who had chronic low back pain.³⁶

Because these two stabilizing techniques can be superimposed on activity-based movements, they could be used to facilitate Leticia’s ability to perform numerous daily activities. For example, rhythmic stabilization could be used to improve trunk endurance and stability when Leticia experiences fatigue while standing at the sink to wash dishes.

Relaxation Techniques

Relaxation techniques are an effective means of increasing ROM, particularly in clients with pain or spasticity, which may be increased by passive stretch.

Contract-relax involves passive motion to the point of limitation in movement patterns. This is followed by an isotonic contraction of the antagonist pattern against maximal resistance, with only the rotational component of the diagonal movement allowed. This action is followed by

relaxation and then by further passive movement into the agonistic pattern (e.g., contract-relax could involve passive motion to the point of limitation of D₂ flexion, which would be followed by an isotonic contraction of D₂ extension and then by further passive movement into D₂ flexion). This procedure is repeated at each point in the ROM in which limitation is felt to occur.⁷⁴ Contract-relax is used when no active range in the agonistic pattern is present. However, the ultimate goal is active movement through the full range. Therefore, once relaxation and increased ROM occur, active movement should be facilitated. The contract-relax technique has been demonstrated to be an effective means to gain ROM when compared with passive stretch, but the mechanism underlying this technique is not clear.⁴⁶

Hold-relax is performed in the same sequence as contract-relax but involves an isometric contraction (no movement allowed) of the antagonist, followed by relaxation and then active movement into the agonistic pattern. It has been recommended that the static contraction be held for 3 seconds to achieve the greatest improvement in ROM.⁶⁴ Because this technique involves an isometric contraction against resistance, it is particularly beneficial in a client with pain or acute orthopedic conditions. For a client with reflex sympathetic dystrophy (RSD) who has pain during shoulder flexion, abduction, and external rotation, the therapist asks the client to hold against resistance in the D₂ extension pattern and then to initiate active movement into the D₂ flexion pattern. This technique is beneficial for a client with RSD during self-care activities such as shampooing the hair and zipping a shirt in back.

Slow reversal–hold–relax begins with an isotonic contraction, followed by an isometric contraction, relaxation of the antagonistic pattern, and then active movement of the agonistic pattern. When the client has the ability to move the agonist actively, the technique is preferred. For example, to increase active elbow extension in a client with tight elbow flexors, the therapist asks the client to perform D₁ flexion with elbow flexion as resistance is applied. When the ROM is complete, the client is asked to hold with an isometric contraction, followed immediately by relaxation. When relaxation is felt, the client moves actively into D₁ extension with elbow extension. This technique helps increase elbow extension for such activities as reaching to lock the wheelchair brakes or picking up an object off the floor.

Rhythmic rotation is effective in decreasing spasticity and increasing ROM. The therapist passively moves the body part in the desired pattern. When tightness or restriction of movement is felt, the therapist rotates the body part slowly and rhythmically in both directions. After relaxation is felt, the therapist continues to move the body part into the newly available range. This technique is effective in preparing a paraplegic client with LE spasticity or clonus to don a pair of pants. The technique is also effective in preparing for splint fabrication on a spastic extremity.

Threaded Case Study Leticia, Part 2

To respond to the initial three questions at the beginning of this section, we need to review our assessment of Leticia.

To determine the most effective movement patterns, we need to observe Leticia in her daily tasks, in addition to her performance of specific diagonal patterns and total patterns of movement. Techniques and procedures that best address Leticia's key deficits in motor control and rigidity should be selected. In addition to a focus on these key areas, special attention should be given to whether more mobility or stability is needed. Trunk ataxia would respond best to stabilizing techniques such as rhythmic stabilization, stabilizing reversals, and approximation. Rigidity would need mobilizing techniques such as slow reversal, slow reversal–hold, and repeated contractions. These techniques can be applied to clients during occupation-based activity.

The progression of intervention begins at the time of evaluation and considers the client's abilities, as well as deficiencies. In Leticia's case, intervention will need to follow the PNF principles. Intervention should initially address proximal control and start in lower developmental positions where she has ability to perform coordinated movement. Once more proximal stability is achieved, intervention can progress to work in higher developmental postures such as standing. Integrated into this progression of movement patterns and techniques are selected procedures that facilitate the desired motor response or activity performance.

Summary

The PNF approach emphasizes the client's abilities and potential so that strengths assist weaker components. Strengths and deficiencies are assessed and addressed during intervention within total patterns of movement and posture. Carefully selected techniques are superimposed on these total patterns to enhance motor response and facilitate motor learning.

PNF uses multisensory input. Coordination and timing of sensory input are important in eliciting the desired response from the client. The client's performance should be monitored, and sensory input should be adjusted accordingly.

To use PNF effectively, the therapist must understand the developmental sequence and the components of normal movement. The therapist must learn the diagonal patterns and how they are used for ADLs, must know when and how to use the techniques of facilitation and relaxation, and must be able to apply patterns and techniques of facilitation to occupational therapy evaluation and intervention. Attaining these skills requires observation and practice under the supervision of a therapist experienced in the PNF approach.

Case Study | Sophia

Sophia, a 50-year-old woman, was referred for occupational therapy services after a right CVA resulting in left hemiplegia. Before the CVA she had a history of hypertension but otherwise good health. Referral to occupational therapy was made 10 days after onset of the CVA for evaluation and intervention in ADLs, visual perceptual skills, and left UE function.

Assessment

Initial assessment revealed intact vital and related functions, such as the oral and facial musculature and swallowing. Voice production was good. Sophia had a tendency to hold her breath during activities, and subsequent decreased endurance was noted. Visual tracking was impaired, with an inability to scan past midline and apparent left-sided neglect.

Her head and neck were observed to be frequently rotated to the right and slightly flexed because of weak extensors. Her trunk was noted to be asymmetric in a sitting posture, with most of the weight supported on her right side. Sophia's posture was flexed because of weak extensors. Static sitting balance was fair and dynamic sitting balance was poor, with Sophia listing forward and to the left.

Sophia's right arm was normal in sensation and strength, although motor planning was impaired. Her left arm was essentially flaccid, with impaired light touch, pain, and proprioceptive sensation. Sophia complained of mild glenohumeral pain during passive movement at the end ranges of shoulder abduction and flexion. Scapular instability was noted. No active movement could be elicited in her left arm.

Perceptual testing showed apraxia (especially during activities requiring crossing of the midline) and left-sided neglect. Sophia was alert and oriented, with good attention span and memory. Carryover in tasks was adequate.

Sophia needed moderate assistance in ADLs and moderate to maximum assistance in transfers. Impaired balance and apraxia were the most limiting factors in performance of ADLs. She stated her immediate goal as being able to get herself ready in the morning with less time and effort.

Intervention Implementation

Following the cervicocaudal direction of development, alignment of her head and neck was the appropriate starting point for intervention. Left-sided awareness, sitting posture, and trunk balance were directly influenced by the position of her head and neck. Before the start of self-care activities, Sophia performed head and neck patterns of flexion and extension with rotation. To reinforce rotation to left, the therapist was positioned to the left of Sophia. Clothing and hygiene articles were also placed to her the left.

Lack of trunk control was another problem. During bending activities while seated, Sophia reported a fear of falling and was unsure of her ability to return to the upright position. Consequently, she had difficulty leaning forward to transfer from the wheelchair. The slow reversal–hold technique was used to reinforce trunk patterns during ADLs. For example, as a preparatory method to facilitate the trunk control needed for donning pants over legs, the therapist was positioned in front and to the left of Sophia. Manual contact was on the anterior

aspect of either scapula. The therapist moved with Sophia and applied resistance as she leaned forward. At the end of the range, Sophia was instructed to hold with isometric contraction. Manual contact was then switched to the posterior surface of either scapula. Resistance was applied as Sophia returned to the upright position. The verbal command was, "Look up and over your right shoulder." When she was upright, she was again instructed to hold with isometric contraction. In addition to reinforcing trunk control, this technique alleviated Sophia's fear of leaning forward because the therapist was in continual contact with her.

An indirect benefit of the flexion and extension patterns of the head, neck, and trunk was the reinforcement of respiration. Sophia was encouraged to inhale during extension and exhale during flexion. This approach eliminated Sophia's tendency to hold her breath.

Intervention consisted of total patterns and techniques to facilitate proximal stability in the left UE and to provide proprioceptive input. Weight-bearing activities were selected because no active movement was available in her left arm. Sophia used her right UE in diagonal patterns to perform repetitive perceptual tasks, such as a mosaic tile design, paper-and-pencil activities, and board games. These activities were performed to include the side-lying posture on the left elbow, the prone posture on elbows, the side-sitting posture with weight on the left arm, and posture on all fours. To reinforce stability at the shoulder girdle, approximation and rhythmic stabilization were used with manual contact at both shoulders and then at the shoulder and pelvis. The performance of perceptual tasks in diagonals improved Sophia's motor planning, left-sided awareness, and trunk rotation.

Sophia was instructed in bilateral asymmetric chopping and lifting patterns to support her scapula and left UE in rolling and other activities. These patterns also enhanced left-sided awareness and trunk rotation. To facilitate scapular movement during chop and lift patterns, the therapist applied stretch to initiate movement, followed by the slow-reversal technique. In preparation for the lift pattern, manual contact was placed on the posterior surface of the scapula. Stretch was applied in a lengthened range. As Sophia initiated the lifting pattern, resistance was provided and maintained throughout the ROM. This procedure was repeated for the antagonistic or reverse-of-lift pattern, with manual contact switching to the anterior surface of the scapula.

About 3 to 4 weeks after the injury Sophia was able to initiate left UE movement in synergy with a predominance of flexor tone. Weight-bearing activities and rhythmic rotation were helpful in normalizing tone, and both techniques were used with ADLs such as dressing and bathing. Wrist and finger extensions were facilitated in the D1 extension and D2 flexion patterns by using repeated contractions.

Outcomes

Re-evaluation after 5 weeks of occupational therapy revealed increased endurance and ability to coordinate breathing with activity and consistency in crossing the midline during visual scanning activities. Sophia was able to turn her head and neck to the left without cues from the therapist. The fear of falling

forward with bending had diminished, and she automatically turned her head to look up and over her shoulder to reinforce assumption of the upright position. As trunk strength continued to improve, reinforcement with head and neck rotation was no longer necessary. Visual tracking alone, in the direction of movement, was sufficient to reinforce assumption of the upright position. Eventually, Sophia was able to achieve an upright position without apparent visual or head and neck

reinforcement. Sitting balance improved with bilateral weight bearing through both hips. Shoulder pain decreased and scapular stability improved during weight-bearing activities. Sophia initiated left UE movement out of a flexor synergy pattern. Right UE motor planning was within functional limits for ADLs. Transfers and self-care required only minimal assistance, and cues were no longer needed for left UE awareness.

SECTION 3 | Neurodevelopmental Treatment Approach

JULIE MCLAUGHLIN-GRAY

Threaded Case Study Charlotte

Charlotte is a 69-year-old woman who sustained a left CVA with resultant right hemiplegia 4 months earlier. She is able to move her right arm in a synergistic manner but does not have smooth coordinated movements. When she attempts to use her right arm as an assist for functional tasks, her arm is dominated by flexor tone and it is difficult for her to extend her elbow or open her hand to grasp objects. She is able to stand and walk but tends to lean to the left side and does not stand or sit with a symmetric posture.

She is right hand dominant and is having difficulty completing both ADL and instrumental ADL skills that require the use of both hands. In particular, she reports that it is difficult for her to cook meals and dress herself. Although she was instructed in one-handed dressing techniques, she reports that it is very time-consuming and tiring to use these strategies. She would like to improve control of her right arm and hand. Charlotte reports that she misses not being able to paint or play the piano.

Critical Thinking Questions

1. What additional information would be useful in designing an intervention plan to foster improved right hand function?
2. How should the intervention plan be sequenced to foster improved skills in the right arm and hand?
3. What is limiting Charlotte's use of her right hand and arm for functional tasks?

Historical Context of the Neurodevelopmental Treatment Approach

“Neurodevelopmental treatment,” as it is currently referred to in the United States, originally began as the “Bobath concept,” a treatment approach developed by Berta and

Karel Bobath in the 1940s. Berta Bobath received her early training as a remedial gymnast at the Anna Herrmann School of gymnastics in Germany, where she stayed on as an instructor of gymnastics after graduation.⁶³ She described the focus of her educational program at Anna Herrmann:

We were taught about the analysis of normal movements and various ways of relaxation. We learned to feel and evaluate degrees of relaxation not only on tight muscles but its effect on the strength and activity of their antagonists. This was done by a special way of handling a person, inducing movements in response to being moved (p. 8).

In the 1930s, when the Nazis came to power in Germany, Berta Bobath lost her job as a gymnastics instructor because the school would not retain a Jewish teacher. Berta subsequently moved to London and eventually worked at the Princess Louise Hospital.

Based on her background and skills in analyzing normal movement, Berta Bobath was repeatedly asked to see special cases of both children with cerebral palsy and adults with hemiplegia. At the time, it was assumed that individuals with upper motor neuron (UMN) lesions could not recover from their motor deficits. Because of her background in dance, her training in posture and analysis of movement, and probably also her “heretical or eccentric” (p. viii) views,⁶⁸ Mrs. Bobath did not ascribe to this belief. She began by repositioning these clients into more neutral and symmetric alignments. She examined the impact of her handling on their tone and ability to move. Berta described the basis of her approach as “...the inhibition of released and exaggerated abnormal reflex action, the counteraction of abnormal patterns, and the facilitation of more normal automatic voluntary movements.”⁶³

After much experience and success with her techniques, Berta eventually studied to become a physiotherapist and passed the examination in 1950. Dr. Karel Bobath, Berta's husband and a psychiatrist, became interested in the approach and spent much of his career studying and explaining the neurophysiology behind Berta's observations.

Together, Berta and Karel Bobath are credited with development of the Bobath concept and the NDT approach. They established the first Bobath Centre in London in 1951 and soon began training other physiotherapists in her approach to the treatment of children with cerebral palsy and adults with hemiplegia. Today, courses on this approach

are taught both nationally and internationally to OTs and PTs, speech-language pathologists, and in some countries, nurses, physicians, and teachers.²⁷ Information regarding continuing education courses in the United States (for OTs) can be found at the Neuro-Developmental Treatment Association Website, www.ndta.org.

Several contemporary authors describe NDT as a treatment approach that is based on a hierarchic view of the nervous system, given the time period in which it was established. Although it is true that the accepted view of the nervous system at the time that the approach began was a hierarchic model, it does not appear true, or consistent with the writings of the Bobaths and other historians, that the approach was originally *based on* a hierarchic perspective. The approach was based on Berta's experiences—her skilled observations of alignment, posture, and movement—which were then interpreted in light of the reflex-hierarchic model of the time.^{54,63} This inductive sequence, from observations to development of theory, is discussed in many historical accounts of the approach. Even though dynamic models of CNS function and specifically motor control did not exist at the time, contemporary dynamic perspectives seem to support Berta's original observations and experiences more accurately than reflex-hierarchic models do. Her handling resulted in changes in tone and movement capacities that seem unlikely (or could not have resulted) if the client's tone and movement patterns were exclusively reflexive in nature. Her handling tapped into a dynamic system controlling motor output that is reflected in contemporary models.⁶⁶

Whether the original NDT approach was founded on a reflex-hierarchic perspective or simply explained in terms of that model, it was clearly suggested as a “living concept” from its inception²⁷ that consisted of concepts that were intended as “working hypotheses” (p. 9). Dr. Bobath used this terminology to stress the need for the approach to change over time with new information. Because it was grounded in an understanding of and appreciation for normal movement rather than pathology, he emphasized that the approach would continue to evolve as the understanding of normal movement advances through new discoveries and development of theories.

Berta's Developing Theory: Original Concepts and Changes over Time

The Philosophy of Neurodevelopmental Treatment

Deeply engrained in an NDT-trained therapist's methods are the philosophic underpinnings of the approach stemming from its opposition to the prevailing perspectives in the 1950s. When Berta began working with people with UMN lesions, most people believed that these individuals would not recover, and practices reflected this perspective. Individuals either were not provided rehabilitation services or were provided a compensatory approach exclusively. Any remedial intervention was from an orthopedic frame of reference—primarily stretching and strengthening—and

therefore did not address the neurologic basis underlying the movement problems.^{27,54} Contrary to these views and practices and related to her clinical observations and experiences, Berta Bobath believed that these individuals could regain control of movement if given the right opportunities.

Part of the NDT philosophy is a *belief in recovery* (i.e., in the client's potential). This belief in recovery was coupled with a belief in the influence that normal movement could have on a person's quality of life. In the Foreword to Berta Bobath's first book, Dr. P.W. Nathan very eloquently exposed some of the philosophic underpinnings of the approach, the essence of which remain today⁵⁰:

Whether the doctor knows he is doing so or not, he chooses either a policy of persuading the client to use the hemiplegic limbs and re-train his affected side, or else a policy of encouraging the client to neglect the hemiplegic side and to use the unaffected side for all tasks previously done by the limbs of both sides. The choice affects only the upper limb and the general posture of the client. There is no choice about the lower limb; the client has to learn to use it. That being so, it is best for him to learn to use it properly. If the client gives in to this neurological disorder, he will become an invalid. If he learns to retrain his hemiplegic side, he returns to life (p. v).

Key Principles of Neurodevelopmental Treatment

The NDT approach is now widely described as a problem-solving approach to the restoration of movement and participation for individuals with UMN lesions, specifically cerebral palsy and hemiplegia.²⁷ The approach is aimed at restoration of function through identifying and correcting underlying impairments that interfere with movement and participation in everyday activities. The emphasis is on regaining normal movement and postural control, as well as quality of movement in general. Compensations are discouraged.²¹ Clinicians studying the approach are instructed in Berta's belief in the potential of the hemiplegic side to recover movement and her emphasis on addressing the whole body and the whole person. According to Tallis,⁶⁸ the “fundamental ethos of Bobath [remains today as] ... the client as partner, rehabilitation tailored to the client's current situation, and rehabilitation as a 24/7 activity” (p. xi).

Although the basic principles of intervention remain the same, ideas regarding the nature of a client's movement deficits and how movement is controlled and learned have evolved over time in response to scientific advances. Primary changes in the approach can be tied to discoveries in neuroscience and motor-learning research, specifically a dynamic and interactive understanding of the way in which movement is controlled and executed and feedback is used. In the most recent edition of her book on adult hemiplegia, Bobath outlined the major problems of the client as abnormal coordination of movement and abnormal postural tone and control.⁷ Current findings suggest that deficits in motor

performance result from the combined “neurological dysfunction due to damage of the CNS, musculoskeletal changes, and learned movement strategies.”²¹ Intervention is no longer directed at reducing spasticity. Merely reducing spasticity will not foster improvements in the client’s motor control. However, there appear to be other aspects of hypertonicity that are non-neural in nature, and these non-neural influences on hypertonicity may result from muscle length, joint alignment, and recruitment patterns that tend to be amenable to handling strategies. Motor output is organized around task goals, and therefore motor skills are practiced in function as much as possible. Errors are required for motor learning, as is active participation on the part of the client; consequently, passive movement of the client is minimized and handling is graded to ensure increasing autonomy on the part of the client.

Using Neurodevelopmental Treatment to Restore Participation in Occupation

Within the last several years there has been a fair amount of controversy in the literature not only about the efficacy of NDT, which is addressed in the next section, but also about the approach itself.^{15,42,43} Given the changes in the NDT approach over time, questions arise regarding which aspects of the approach have remained constant. What are the current NDT strategies used to promote recovery of functional movement and therefore participation in occupation? What makes something NDT versus an entirely new approach to intervention? Because NDT has changed over time, other approaches have evolved from NDT, and NDT is used in combination with other approaches, it can be challenging to specify exactly which specific strategies are NDT. Physiotherapists who use the Bobath concept were surveyed and agreed that the following interventions are definitely or probably part of the approach: facilitation, mobilization, practicing motor skills for certain activities, practicing activities themselves, and teaching caregivers how to position the client.⁷⁰ Based on review of the literature and the content of Neuro-Developmental Treatment Association–approved courses (ndta.org), the next section represents a distillation of contemporary evaluation and intervention using the NDT approach.

It should also be mentioned that the NDT approach is incorporated into occupational therapy evaluation and intervention to address problems of motor control and functional movement. It does not provide a thorough lens with which to view the dynamics of occupational problems in context. NDT should be used in concert with other theoretic models to provide a comprehensive occupational therapy program. It should also be combined, as appropriate, with other interventions found to be successful in current research to effectively manage the client’s needs and responses.

Returning to Charlotte, as the OT observed her attempts to dress, including pull on pants and pull on a sweater, it was apparent that the flexor tone in her right UE compromised

performance. Even while seated, Charlotte tended to lean to the left side and did not sit with a symmetric posture. Her right scapula was downwardly rotated and she had significant lateral flexion of her trunk on the right side with a weight shift to the left in sitting and standing.

Evaluation

Based on a top-down approach to intervention, an OT using the NDT approach would begin with an occupational history interview. Grounded in the occupational profile and the client’s goals, the therapist would then observe the client’s performance in various occupations. Charlotte was unable to effectively and efficiently dress herself in a reasonable amount of time. She also had difficulty preparing a simple meal, particularly obtaining cooking equipment from the lower cupboards and spices from an upper cupboard. When reaching into a cupboard she had limited trunk extension, and her weight was shifted to the left when she was standing at the counter. Based on NDT, this observation would include assessment of not only the client’s level of assistance and the amount of movement present but also the *quality* of movement and postural control.

Specifically, the clinician would assess the following:

1. The client’s ability to maintain alignment in postures required for the occupation. As mentioned earlier, Charlotte did not use a symmetric posture in standing or sitting, and this had a negative impact on her efficiency in dressing and meal preparation tasks.
2. The “normal” or typical motor performance skills required for the tasks or activities that will be addressed. NDT-trained therapists analyze movement in terms of the whole body and the stability-mobility relationships between body segments during a task.
3. The client’s alignment and movement while performing the basic motor skills necessary for everyday activity, such as reaching, sit-to-stand, and transferring, as well as while performing occupational goals.
4. Underlying impairments that might be contributing to movement dysfunction. Ryerson and Levit outline the four primary impairments resulting from CNS lesions as “changes in muscle strength, muscle tone, and muscle activation, and changes in sensory processing” (p. 18).⁶⁰ It is these impairments that result in the compensatory movements observed following CNS lesions and also, without intervention, often result in secondary impairments such as “changes in orthopedic alignment and mobility, changes in muscle and tissue length, edema, and pain” (p. 31). Impairments are typically assessed in upright postures and during functional activity and through observation, handling, and the patient’s subjective report. A common method for assessing tone is *placing*, in which the therapist guides the limb and asks the client to hold against gravity. If tone is too low, the client cannot hold the

limb against gravity; if it is too high, the therapist will feel resistance during placing.⁶

Intervention

Because Bobath believed that you cannot “superimpose normal patterns on abnormal ones”⁶ (p. 59) and because there is a desire to minimize abnormal patterns of movement from the beginning, therapists are encouraged to overlap evaluation and intervention.³³ Although “normal” movement has been emphasized since the inception of the approach, more recent descriptions emphasize efficient and functional movement while minimizing compensations.⁴⁵ Intervention typically includes facilitation of the normal motor performance skills involved in a task, as well as practice of tasks themselves—or occupations—with manual guidance or handling.³⁸ An OT will also use the NDT framework when providing compensatory strategies to promote modified independence in necessary and valued occupations while remediating motor skills. Compensations based on an NDT approach stress incorporating the hemiplegic side as much as possible; avoiding repetition of abnormal movement patterns with the hemiplegic side, many of which lead to orthopedic impairments over time; and neutral/symmetric alignment during activities, which reinforces the other two.⁶⁰

After analyzing the client’s movement problems and tendencies, both outside of and within the occupational goal, intervention is structured according to the following sequence: preparation → movement → function. These steps overlap within an intervention session, as well as structure the series of sessions overall. Preparation encompasses all the activities that are necessary for the client to actively work on the motor skills required for the task and the task itself. Preparation might include the following:

1. Careful analysis of the movement components required for the task or occupational goal by the therapist. A helpful way to organize this analysis is by using segments of the body and analyzing the flow of movement that occurs within body segments and between body segments. The OT realized that sitting with most of the weight shifted to the left side further compromised Charlotte’s ability to easily dress herself in a front-closing blouse. This asymmetric sitting position made it difficult for Charlotte to position the sleeve of the blouse to her right side and place her right arm in the sleeve. The OT then used manual cues and handling to help Charlotte experience sitting in a symmetric posture before donning the blouse. By helping Charlotte experience this upright and symmetric posture, she was then able to hold the position for a short period before attempting to dress. Her improved sitting posture allowed greater freedom of movement.
2. Set-up of the environment to promote active participation on the part of the client, as well as

attention to the client’s starting alignment for activity. Within the kitchen, it was suggested that Charlotte place her right hand on the counter while she was preparing a meal. This position fostered a symmetric standing position at the counter. It was also suggested that Charlotte use her right arm to help stabilize a bowl when stirring food.

3. Mobilization to give the client access to the ROM required for the task. Charlotte had significant flexor tone in her right arm and downward rotation of her right scapula. Before working on various activities it was suggested that Charlotte sit at the table with her hands clasped together and forearms resting on the table. She would then lean on her elbows by shifting her trunk forward and then shift her trunk backward.⁶ This movement of her trunk effectively mobilized her scapula, particularly her right scapula, on the trunk before attempting to dress or prepare a meal.

Following preparation, the therapist will structure the session to work on specific motor skills required for the task. Frequently, these skills are partially addressed outside the occupation itself in preparation for practice of the whole task, which is congruent with the motor-learning guidelines regarding part- and whole-task practice.¹⁹ Along with verbal cues, demonstration, and structure of the environment, facilitation of motor skills is done with *handling*. In handling, the therapist uses his or her body in contact with the client’s to promote more efficient movement and avoid unwanted motor responses or alignments (Figure 31-16). Specifically, therapists use handling to add to the sensorimotor information that the client experiences during performance of task, to make the client more aware of his or her body and incorporate the hemiplegic side, and to assist in the coordination and timing of movement patterns.⁴⁵ Continuing education courses and textbooks based on the NDT approach instruct clinicians on precise choices for hand placement that result in desired movement outcomes. These

FIGURE 31-16 Key points of control. Trunk extension.

choices are referred to as *key points of control*. Although the therapist uses manual handling and guiding, the client should be active in the process. Handling and guiding should be graded to provide just enough assistance and input to give the client a feel for a more efficient movement pattern and then be gradually withdrawn as the client progresses and is able to do more of the movement pattern and task independently.²¹

Intervention for limb movements is also graded from closed chain patterns of movement to open chain patterns. A closed chain movement occurs when the distal part of a joint, or “chain” of joints, is fixed and the proximal part is moving.⁵³ An example of a closed chain pattern for the UE would be incorporating the arm in a weight-bearing alignment for postural support and to assist with balance during an activity such as standing at a counter while bearing weight on one hand for support and reaching overhead into a cupboard for an item (Figure 31-17). The weight-bearing

FIGURE 31-17 Closed chain with weight-bearing on upper extremity to support postural control.

arm must be active. Clinicians using an NDT approach would include the UE in weight bearing as part of the base of support to assist with postural control and also to promote sensory input and isometric and eccentric control in the limb. Use of the weight-bearing or closed chain strategy requires muscle activity in the arm, not passive positioning. It is often combined with movement over the base of support to encourage active extension of the UE for balance.

Positioning the UE with the hand in contact with a stable surface can also be useful for mobilization and stretching of the distal part of the UE and to grade facilitation of isolated movement patterns in the arm. During mobilization and stretching, particularly of the wrist and hand, moving the arm on a fixed hand allows the therapist to stretch the extrinsic finger, thumb, and wrist flexors (Figure 31-18). Muscle lengthening may lead to decreases in hypertonicity. In addition, when promoting isolated movement of the UE, for example, in reaching patterns of shoulder flexion with elbow extension, the distal contact offers the limb support and decreases the resistance or demand on the proximal musculature required for the task. Similar to

FIGURE 31-18 Weight bearing on the hand to mobilize and stretch wrist and finger flexors while supporting postural control.

handling and other forms of sensory input and feedback, this support must be gradually withdrawn for muscle strengthening and motor learning to occur. The sequence of facilitation should proceed to incorporation of the learned movement patterns into the occupation or functional task. Handling is gradually decreased as the patient is able to complete the efficient movement patterns.

Neurodevelopmental Treatment and Evidence-Based Practice

Evidence-based practice is a clinical reasoning process that combines the best available research, a clinician's expertise, and the client's preferences and values to make decisions about intervention in individual cases and provide the most effective and efficient care.⁶¹ The best available research for clinical decision making regarding the effectiveness of specific interventions is a systematic review of randomized clinical trials or a randomized clinical trial.¹⁸ Few studies have addressed the effect of NDT on client outcomes. At the present time, a great majority of the evidence for the effectiveness of NDT is at a lower level on the evidence scale—it is primarily the expertise of many practitioners, clients, and caregivers, who could be considered experts in their own living experiences with the condition and who report positive outcomes as a result of incorporating NDT principles and management strategies into their intervention.

The limited number of systematic reviews and clinical trials addressing the effectiveness of the NDT approach has yielded mixed results. One systematic review of the literature by Kollen and colleagues examined 16 studies encompassing 813 clients and concluded that “there was no evidence of superiority of Bobath on sensorimotor control of upper and lower limb, dexterity, mobility, activities of daily living, health-related quality of life, and cost-effectiveness”³⁷ (p. e89). Findings by Luke, Dodd, and Brock indicated that although the Bobath concept was found to have slightly better results than other approaches or no intervention at all in reducing shoulder pain and tone, the Bobath concept was one approach among several that did not demonstrate “superiority of one approach over the other at improving upper limb impairment, activity or participation”⁴¹ (p. 888). Similarly, Paci, in his review of 15 trials, found no evidence to support NDT as an optimal type of treatment, but also no conclusive support for the idea that the approach is not effective.⁵¹ Researchers agree that additional higher-level research, with more rigorous methodologies that define and detail NDT methods, is needed to provide evidence-based guidelines for practice. To systematize such research, Tyson, Connell, Busse, and Lennon outlined a “typical treatment package” for future clinical trials (p. 454) based on their study of physiotherapists using the Bobath concept.⁷⁰ The focus of the intervention package would be “facilitation, mobilization, practicing the components of movement, practicing a few whole activities, and teaching clients and carers on how to position the client” (p. 454).

It has also been suggested that researchers study specific intervention techniques, rather than the NDT concept or approach as a whole.⁷⁰

NDT is not alone in lacking evidence. As stated by Mayston, “the reality is that there is only partial evidence to support current modalities such as task-specific training, constraint-induced movement therapy, treadmill training and muscle strengthening”⁴⁴ (p. 184). The present evidence for use of the NDT approach consists of widespread clinical observations and expertise, along with limited clinical trials and systematic reviews. Despite a lack of high-level evidence supporting its efficacy, according to the authors of one systematic literature review, “in the Western world, the Bobath Concept or neuro-developmental treatment is the most popular treatment approached used in stroke rehabilitation.”³⁷ This evidence, though useful and substantial, is not enough to warrant continued and isolated use of this approach as research demonstrating more effective and/or efficient methods at higher levels of evidence becomes available. Based on dynamic models exposing the integration of multiple systems within and outside the person that contribute to the control of movement, as well as occupational performance, contemporary clinical reasoning and intervention planning for individuals with UMN lesions must consider the complex web of factors contributing to function and integrate all available resources and intervention methods, supported by evidence, that contribute to effectively restoring participation in desired occupations.

Review Questions

1. What are the four general processes of information flow related to control of movement?
2. Define motivational urge and name the locus of this function in the brain.
3. Trace the flow of information in the central and peripheral nervous systems that leads to purposeful movement.
4. What is the sensorimotor system?
5. List the areas of the sensorimotor cortex.
6. List the structures that constitute the higher, middle, and lower levels of the CNS components for movement.
7. Name the four traditional sensorimotor approaches to treatment and the theorist responsible for each.
8. Which two models of motor control form the basis for the sensorimotor approaches to treatment?
9. Briefly describe each of the four traditional sensorimotor approaches to treatment. Compare and contrast their similarities and differences.
10. List some techniques used by therapists to influence or modify motor responses in each of the traditional sensorimotor approaches.
11. How are the sensorimotor approaches used in current clinical practice?
12. In clients with pain, what tone of voice should be used when giving verbal commands?

13. Discuss the significance of auditory, visual, and tactile input in motor learning.
14. Which UE diagonal pattern is used for the hand-to-mouth phase of eating? For zipping front-opening pants?
15. Discuss the advantages of using the chop and lift patterns.
16. Which trunk pattern is used when donning a left sock?
17. List three advantages of using the diagonal patterns.
18. What is the developmental sequence of total patterns?
19. If a client needs more stability, which of the following total patterns should be chosen: side lying or prone posture on elbows?
20. Which PNF technique facilitates postural control and cocontraction?
32. Discuss the neurophysiologic principles of Sherrington on which the PNF techniques of facilitation are based.
33. What is an effective technique to prepare a client with UE flexor spasticity to don a shirt?
34. Define maximal resistance.
35. Name two PNF techniques that facilitate initiation of movement.
36. What are the key principles of the NDT approach?
37. What is the difference between a closed and open kinetic chain?
38. Identify a task in which you would use a closed kinetic chain and a task in which you would use an open kinetic chain.

■ Learning Objectives *After reviewing this chapter, the student or practitioner will be able to do the following:*

1. Describe how motor control affects occupational performance.
2. Describe dynamic systems theory and how it explains motor control.
3. Describe the task-oriented approach to motor learning.
4. Describe constraint-induced movement therapy as an intervention targeting functional use of a hemiparetic upper extremity following a neurologic insult to the brain.
5. Describe the use of robotics in the use of upper extremity motor control.
6. Describe the use of virtual reality technology in the use of upper extremity motor control.
7. Describe the use of bilateral training techniques for improving upper extremity motor control.
8. Develop client-centered and occupation-based treatment programs to facilitate motor learning.

Theoretic Foundations of Motor Learning

Motor learning is the acquisition and modification of learned movement patterns over time.⁵¹ It involves cognitive and perceptual processes to code various motor programs. Motor learning requires practice and experience, which leads to permanent changes in the person's ability to produce

movement sufficient to meet the demands of occupational performance. Motor control is the outcome of motor learning and involves the ability to produce purposeful movements of the extremities and postural adjustments in response to activity and environmental demands.⁵

The process of motor learning after a CVA, traumatic brain injury, cerebral palsy, and other neurologic insults to the brain has received a great deal of attention in research

Threaded Case Study Richard, Part 1

Richard, a 66-year-old African American man, was admitted to a rehabilitation hospital on January 21, 2011, because of the onset of a left cerebral vascular accident (CVA) with resulting right-sided hemiparesis.

Before admission, the client lived with his wife in an apartment with four steps at the entrance. They have four grown children who do not live in the area. They also have three grandchildren. Richard is a retired electrician. He was independent in all activities of daily living (ADLs) before admission. He was responsible for meal preparation, household maintenance, and finances. He enjoys gardening, playing cards, and cooking. His social participation consisted of doing the weekly grocery shopping, attending church every Sunday, and going to the theater with his wife and family.

Richard's symptoms include right-sided hemiparesis. He has selective motion at the shoulder, elbow, wrist, and hand. He is able to lift his affected arm above his head and to grasp and release objects of all sizes; however, he has difficulty manipulating smaller objects.

Richard's daily routine consisted of getting up each morning at 6:00 a.m. and walking the dog for about a mile. He then cooked breakfast for himself and his wife. After breakfast, he was responsible for cleaning the kitchen and doing basic household maintenance.

Using the Canadian Occupational Performance Measure (COPM),²³ Richard identified the following occupational performance problems:

- Inability to perform cooking tasks with both upper extremities
- Difficulty with fasteners and with the manipulation of objects of different textures and sizes greater than 1 inch
- Inability to turn the pages of a prayer book while in church
- Difficulty performing the transition movements of sitting to standing to kneeling and kneeling to standing to sitting while in church
- Inability to perform transition movements during gardening activities
- Inability to manipulate cards with the affected upper extremity

Critical Thinking Questions

1. How has Richard's motor control affected his ability to engage in meaningful occupation?
2. What motor control intervention strategies would enable Richard to more effectively engage in his daily occupations?

and occupational therapy (OT) practice. Researchers have found that 5 years after the onset of a stroke, approximately 56% of clients continue to have severe hemiparesis.¹¹ The initial degree of motor impairment is a predictor of motor recovery. Dominkus and colleagues⁹ assessed motor recovery in the upper extremity with the Motricity Index⁸ and

found that a client with initial paresis was 4.58 times more likely to achieve motor recovery than a client with initial paralysis. Furthermore, nearly 400,000 people survive with some level of neurologic impairment and disability.¹⁸ The explosion of new research on brain plasticity, or the ability of the brain to reorganize and develop new pathways, has paved the way for evolving approaches that target the ability of the individual to regain movement that enhances occupational performance, participation, and quality of life.⁵¹ Recent studies support the theory that a form of brain plasticity known as cortical map reorganization plays a major role in regaining functional use of a hemiparetic upper extremity after a CVA.^{6,25}

Dynamic Systems Theory

Modern motor control approaches are based on dynamic systems theory, which views motor behavior as a dynamic interaction between client factors (e.g., sensorimotor, cognitive, perceptual, and psychosocial), the context (e.g., physical, cultural, spiritual, social, temporal, personal, and virtual), and the occupations that must be performed to enact the client's roles.^{30,31} Dynamic systems theory is based on a heterarchic model in which each component (e.g., client, environment, and occupational performance) is viewed as being critical in a dynamic interaction to support the client's ability to engage in occupation.^{5,51} Thus, movement and motor control are the result of a dynamic interaction between each of the subsystems. In addition, any change in the system has an effect on all the subsystems. For example, a CVA can lead to changes in the client's sensorimotor, cognitive, and perceptual skills, which affects motor control, engagement in occupation, and the person's ability to master the environment.

The heterarchic model is contrasted to the hierarchic model, which views higher centers in the central nervous system as having control over the subordinate lower centers.³¹ The traditional sensorimotor approaches, such as neurodevelopmental treatment, proprioceptive neuromuscular facilitation, and the theories developed by Rood and Brunnstrom, are based on a hierarchic model. Recent research supports a dynamic systems theory approach in which motor learning plus the development of motor control is a dynamic process that involves interaction of the person, environment, and occupations that the client needs to perform or wants to perform.

Task-Oriented Approach

The task-oriented approach to motor recovery is based on dynamic systems principles in which occupational performance and motor recovery are achieved by a dynamic interaction of the person, the environment, and the occupations that the person is performing.^{30,31} In OT, this approach is occupation based and client centered and focuses on enabling the client to achieve motor recovery through occupational performance using real objects, environments, and meaningful occupations.^{47,49} Research shows that the use of

real objects from the environment versus simulated objects produces better functional movement.⁷¹ The client must also have the opportunity to attempt to solve motor problems in the context of multiple environments by using a variety of strategies. For example, Richard (see the [case study](#)) would need to be able to turn the pages in the prayer book in the spiritual context of his place of worship, in addition to using motor strategies that allow him to move from sitting to standing to kneeling. Research has shown that the environmental context plays a key role in the transfer of motor skill acquisition.^{13,29}

Occupations that the client has identified as being important through the COPM²³ can be used to motivate the client to problem-solve various motor strategies. An intervention plan that is developed collaboratively between the client and the therapist can aid the client in taking a more proactive role in making progress toward his or her outcomes and can facilitate more effective follow-through. Research has shown that a client-centered and occupation-based approach can assist clients in attaining their personal goals.^{61,62} Emerging research is also demonstrating that an occupation-based approach is more effective than rote exercise in remediating motor control impairments.^{7,14,40,41,50,60,63,72} In addition, engaging in an occupation or activity from start to finish has been shown to elicit a more efficient, forceful, and coordinated motor response than has performing only small portions of an activity.²⁸

Activity analysis must be used to analyze the necessary movements that the client must perform to complete the task successfully. Effective upgrading and downgrading of the activity must be incorporated for clients to feel that they are successfully moving toward their goals. In addition, motor learning can take place only if the client has multiple practice opportunities across several real environmental contexts.^{13,24}

Qualitative (e.g., verbal encouragement) and quantitative (e.g., concrete measures of success or failure during a motor task) analyses have been shown to produce knowledge of results, which enables the client to cognitively reflect on the strengths and weaknesses of a particular motor strategy and implement a more effective strategy for completing an activity.^{19,65,67} Through this dialogue, the client can learn to transfer various motor skills across multiple contexts.

OT Practice Notes

Feedback and analysis of factors that promote success or failure in a particular motor strategy must be a central problem-solving dialogue between the OT practitioner and the client.^{16,17,32}

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT), or forced use, is a therapeutic strategy designed to promote functional use of a hemiparetic upper extremity and has been credited with speeding up the cortical map reorganization process in nonhuman primates⁵⁷ and in humans.²² CIMT is also based on the principles of dynamic systems theory and a task-oriented approach to the acquisition of motor control. In other methods of stroke rehabilitation, clients learn to use the more functional or less involved upper extremity for daily activities. This treatment approach may foster learned nonuse of the more involved upper extremity. Learned nonuse is a phenomenon in which the individual neglects to use the affected or more involved extremity because of the extreme difficulty coordinating movement after the onset of a stroke, brain injury, or other neurologic condition.²²

As a person or animal moves through its environment and manipulates objects, it receives sensory feedback from various sources simultaneously. Vision, audition, proprioception, and kinesthesia provide important sensory information for skilled movement. The importance of sensory information on motor action was demonstrated in the classic experiment carried out by Mott and Sherrington.³⁹ The afferent (sensory) input enters the spinal cord through the dorsal roots of the spinal nerves. By selectively severing the dorsal roots, sensory input was effectively eliminated while leaving motor innervation basically intact. Experiments conducted before 1955 demonstrated that deafferentation of a single forelimb in rhesus monkeys resulted in an unused extremity when the animal is unrestricted.

Animal research has led to the discovery that cortical reorganization occurs after injury to the nervous system.²⁵ Research on somatosensory deafferentation in monkeys has shown that if a single monkey forelimb is deafferented, the monkey will not use that extremity.^{20,21} In other words, the procedure left the monkeys with intact motor nerves but no sensation in the affected upper extremity. The initial shock to the nervous system prevented movement. Even after the nervous system recovered, the monkeys failed to use their affected limb. Taub⁵⁴ theorized that use of the deafferented extremity could be retrained if the intact extremity is restrained and the monkey is forced to use the affected extremity. If the restraint was used for a specific time, between 1 and 2 weeks, the functional improvement could be permanent. These studies have shown that certain training procedures can be used to enable monkeys to regain use of their deafferented extremity.^{20,21,55,56} Experimental evidence indicates that the persistent loss of motor function caused by deafferentation was due to learned behavioral suppression, a phenomenon called learned nonuse.⁵⁴ Conditioned response techniques did not show promise in restoring use of the extremity for daily activities.

FIGURE 32-1 Client with a left cerebrovascular accident and right hemiparesis before initiation of the constraint-induced movement therapy (CIMT) program. The client demonstrates learned nonuse by using her stronger, uninjured left upper extremity during self-feeding. (Courtesy Remy Chu, OTR/L.)

Another therapeutic strategy, shaping, did result in significant improvements in motor function during ADLs. Shaping procedures are behavioral techniques that approach a desired motor outcome in small, successive increments.^{36,44,58} Shaping strategies allow subjects to experience successful gains in performance with relatively small amounts of motor improvement. Explanations from several studies have led to the development of a hypothesis that explains why the constraint and training procedures improve motor recovery after deafferentation.

The theory of learned nonuse was first described by Taub and is thought to extend to humans after central nervous system damage (Figure 32-1).^{54-56,68} Animal research has demonstrated that when the forelimb is not functional, the animal no longer uses the affected upper extremity for everyday tasks. This tendency has led to reinforcement and persistence of nonuse of the affected limb. Constraining the unaffected limb of the monkeys provided the early evidence for reversing learned nonuse.

To date, rehabilitation methods for those who have sustained a CVA or other neurologic insult to the brain have included, but are not limited to biofeedback, neuromuscular facilitation, and operant conditioning. These various forms of rehabilitation are often used in conjunction with methods that teach clients to compensate by using their intact upper extremity to perform their day-to-day functional activities. Compensatory rehabilitation strategies may improve the efficiency of the intact upper extremity, but at the same time they encourage learned nonuse of the affected upper extremity. At present, there is minimal experimental evidence demonstrating the positive benefits of these forms of therapy.

An alternative therapeutic approach, CIMT, has been used extensively for rehabilitation. Unlike more traditional

FIGURE 32-2 Constraint-induced movement therapy forces the individual to use the affected upper extremity by immobilizing the unaffected upper extremity in a mitt.

rehabilitation therapies, CIMT forces the client to use the more involved upper extremity by immobilizing the less involved or unaffected upper extremity in a sling, mitt, or a combination of both (Figure 32-2). Clients then practice using their affected upper extremity on an intensive basis for several consecutive weeks by using shaping movements with the affected upper extremity. The improvements noted in the more involved extremity after this program were attributed to the learned nonuse phenomenon described by Taub⁵⁴; thus, part of the theoretic framework of CIMT is taken from the neurophysiologic and behavioral studies of the learned nonuse of the more affected limb seen in animal experiments. Constraining the intact forelimb of these monkeys provided the first evidence of the ability to overcome the learned nonuse phenomenon. This success led to further studies involving humans with hemiparesis that developed after a stroke, brain injury, and other neurologic conditions.

Wolf^{68,69} and Miltner and associates³⁵ demonstrated the positive effects of using CIMT in individuals with stroke. Liepert and coworkers²⁵ demonstrated cortical reorganization in humans undergoing CIMT. In 1993, Taub and colleagues⁵⁹ found significant results when using CIMT in a randomized clinical trial of nine individuals after stroke. These subjects had experienced strokes from 1 to 18 years before participation in CIMT and were required to meet inclusion criteria similar to those used by Wolf and coworkers⁸ (e.g., possessing some wrist and finger extension while still demonstrating significant disability). Additionally, the subjects had to demonstrate good balance because they would be wearing a sling and would therefore be unable to use their less affected or unaffected upper extremity to protect themselves in the event of a fall. The subjects were randomly assigned to either an experimental group or a control group. The subjects assigned to the experimental group wore a sling on the less involved upper extremity for

a period of 12 days. During the 12 days the sling was worn throughout all waking hours except when specific activities were being carried out, such as when it was unsafe or extremely difficult to use the more affected arm exclusively. The study also used a behavioral contract that included an agreement from the subjects to wear the restraint device for at least 90% of their waking hours during the 12-day intervention period. The behavioral contract specifically identified activities during which the subject was to use the more involved arm exclusively, to use both arms, and/or to use the less involved arm (for safety reasons). Participants in the control group were instructed to focus attention on the more involved upper extremity and were encouraged to attempt to use the more involved upper extremity for as many new functional activities as possible at home. Activities were recorded throughout the 2-week period. Those in the control group also received two sessions involving activities requiring active movement of the more involved extremity and were provided an individualized range-of-motion exercise program. The effectiveness of treatment was measured with the Wolf Motor Function Test (WMFT) and the Motor Activity Log (MAL), a structured interview exploring functional use in the life setting. Speed, quality of movement, and functional use of the affected upper extremity were significantly improved in the research group in comparison to the control group, and functional movement was maintained over a 2-year period. In 1999, Kunkel and associates²² also demonstrated a greater than 100% increase in the amount of use of the affected upper extremity in real-world environments. The effective factor in all forms of CIMT appears to be intensive practice and functional use of the affected upper extremity repeatedly across multiple contexts for many hours a day for a period of consecutive days.⁷⁰

Over the past 30 years, numerous studies have further confirmed the effectiveness of CIMT versus traditional rehabilitation therapy in improving the client's functional motor control after stroke.⁵⁰ More recently, however, research involving CIMT has used various populations, altered the inclusion criteria, and modified the intensity of treatment and the length of the therapy program from the original research protocol. For example, Pierce and colleagues⁴⁶ found that the forced-use component of CIMT in conjunction with a home program may be effectively incorporated into the traditional outpatient setting. Furthermore, Page and associates⁴⁵ found that repeated task-specific practice is more critical than intensity in improving upper extremity function.

In the Very Early Constraint-Induced Movement during Stroke Rehabilitation (VECTORS) study, 52 subjects were randomized to one of three groups an average of 9.7 days after stroke. The three groups included the following: (1) standard CIMT in which subjects received 2 hours of shaping therapy and wore a mitt for 6 hours per day, (2) high-intensity CIMT in which clients underwent 3 hours of shaping exercise per day and wore a mitt for 90% of

waking hours, and (3) the control treatment consisting of 1 hour of ADL training and 1 hour of upper extremity bilateral training exercises. All treatment was provided for 2 weeks. The primary end point measure was the total Action Research Arm Test (ARAT) score on the more affected side at 90 days after stroke onset. In all groups the total ARAT score improved with time. Subjects in the standard CIMT and control treatment groups achieved similar gains in total ARAT score (24.2 and 25.7, respectively), whereas subjects in the high-intensity CIMT group exhibited an average gain of just 12.6 points.¹⁰ Overall, there is conflicting evidence of the benefit of CIMT over traditional therapies in the acute stage of stroke; however, there is strong evidence of the benefit of CIMT and modified CIMT over traditional therapies in the chronic stage of stroke. The benefits appear to be confined to stroke patients with some active wrist and hand movements, particularly those with sensory loss and neglect. These findings have broadened the scope and applicability of CIMT to various populations.

Although recent CIMT research has expanded the scope to include different diagnostic criteria, different treatment regimens, and different inclusion criteria, little of the current CIMT research has addressed the participant's self-reported satisfaction in life roles after completing a CIMT program. After individuals have a stroke or other neurologic condition, they experience a disruption in their life roles. This disruption can lead to feelings of ineffectiveness, incompetence, and helplessness. To restore health and quality of life, one must identify and alter one's lifestyle to improve the fit between oneself and the environment. CIMT has been proved to be effective in improving motor control in individuals who have experienced a stroke or other neurologic condition. Functional carryover of CIMT from the clinic to the natural environment has been demonstrated. Research has shown significant improvement in daily use of the affected upper extremity and an increase in the speed at which the individual carries out activities after participating in a CIMT program. Increased life satisfaction resulting from an increased ability to use the affected upper extremity has been noted in individuals who reported satisfaction in performance of meaningful daily activities and life roles.^{42,48}

To determine whether a subject meets the inclusion criteria for CIMT, a telephone screening protocol is often administered.³⁷ Many research studies use a CIMT protocol that contains typical inclusion criteria for use of this therapeutic strategy. These criteria can include (1) a first-time CVA that occurred more than 1 year earlier; (2) not currently receiving any therapeutic intervention; (3) a score of higher than 44 on the Berg Balance Test² or limited balance problems requiring an assistive device for mobility in clients who had a full-time caregiver to assist in any balance issues; (4) ability to move the affected arm in 45 degrees of shoulder flexion and abduction, 90 degrees of elbow flexion and extension, 20 degrees of wrist extension, and 10 degrees of

extension at the metacarpal phalanges and interphalanges as determined by the client's available active range of motion (Figure 32-3); (5) no significant cognitive impairments as demonstrated by a Mini-Mental State Examination score of at least 22¹⁵ or other type of cognitive test; (6) no pre-existing comorbid conditions that might interfere with mobility or function; (7) limited spasticity (score of 0 or 1) as measured by the Modified Ashworth Scale³; and (8) the ability to identify an individual or caregiver who could assist in the home program.^{37,48} In summary, potential reasons for a person to be excluded may include motor ability that is too high or too low, cognitive deficits that prevent adequate participation, and an existing high degree of functional use of the affected upper extremity.

A battery of assessments are typically administered to all clients included in a CIMT treatment program.³⁷ Results

FIGURE 32-3 The client is asked to demonstrate active wrist and finger extension in her dominant right hand. The client is able to achieve 20 degrees of wrist extension and 10 degrees of finger extension (at the metacarpal phalanges) from a flexed position. (Courtesy Remy Chu, OTR/L)

from these assessments are used to test certain research hypotheses, whereas other assessments are used for diagnostic purposes or to generate new hypotheses. Some typical assessments include the WMFT and MAL.

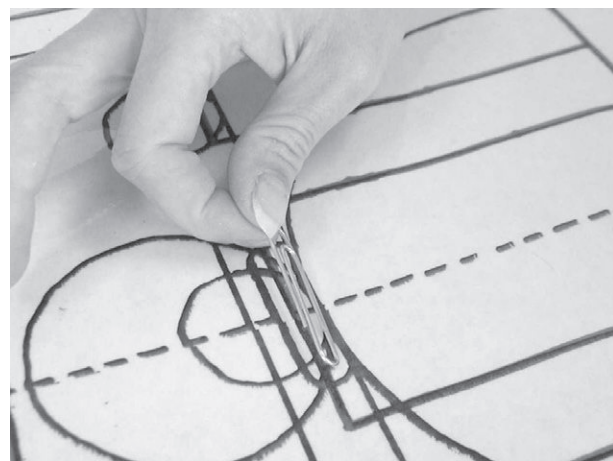

The WMFT consists of 15 motor items that examine contributions from the distal and proximal muscles of the arm. The tasks in this assessment are sequenced from proximal to distal and gross to fine motor. The majority of tasks are completed with the subject seated in a chair. Standard tasks such as lifting the forearm to the table, reaching for an object, or lifting a pencil are rated on a scale from 0 (does not attempt with the weaker arm) to 5 (movement appears normal), and the time to complete the task is measured (Figure 32-4). The WMFT uses a grid or template that is taped to the desk to specify standardized measurements. The WMFT is administered before the intervention, immediately after the intervention, and at a designated follow-up time.

The MAL was developed for the purpose of assessing activities attempted outside the clinical setting. The MAL is a self-reported, 30-item instrument administered in an interview format. Subjects are asked to rate their performance on each activity reported, and emphasis is placed on clients' functional use of the hemiparetic upper extremity in their home environment. The assessment is administered approximately 10 times throughout the course of CIMT intervention. The instrument consists of specific functional activities, such as turning on a light switch or opening a drawer. The amount of functional use of the more involved upper extremity is rated by the participant from 0 (never used) to 5 (involved arm used the same as it was before the stroke). Quality of movement (how well) is also self-rated from 0 (not used) to 5 (normal movement).

Therapeutic procedures using CIMT in the clinic are performed under the supervision of an OT practitioner (Figure 32-5). The procedures are effective only if use of the affected upper extremity is carried over to the client's home

and community environment. Clients are asked about their compliance in incorporating their affected upper extremity into functional activities as noted in a log or personal diary. The home diary is used to outline the clients' activities from the time at which they are discharged from the clinic until they return for their CIMT sessions. A typical daily schedule is often used. The schedule includes the time and length of rest periods. Furthermore, specific shaping task practice is also listed on the daily schedule. A desired motor or behavioral objective is approached in small steps with an individualized shaping plan. During shaping, explicit feedback is provided to identify small improvements in motor or functional performance. The shaping task selected depends on the specific joint movements exhibiting impairment that have the greatest chance of improving and the client's preference among tasks that have a similar potential for producing specific improvements. Applying CIMT and shaping requires repetitive, supervised, constant practice. CIMT study protocols call for 6 hours of continuous task practice per day (Figures 32-6 and 32-7).

An important component of interventions designed to enhance motor learning is the feedback received by the client while attempting a movement strategy and the results of the movement action.⁵¹ Feedback refers to the sensory experiences intrinsic to the client and the external information provided by the environment, which includes verbal comments from the OT practitioner. This combined type of feedback can be seen when a client attempts to place a hemiparetic arm into the wrong sleeve of a button front shirt and receives the visual information that something does not "look correct" along with verbal directions by the OT practitioner that placing the arm in the other sleeve will make the task easier. Knowledge of the results is a form of external feedback in which the client assesses whether the correct results were achieved after completion of the motor action. The OT practitioner assists the client by providing feedback during performance of the motor task and on completion of the motor task to assess the results. These strategies are combined with shaping to foster a higher frequency of successful motor practice for functional tasks.

A more recent study that evaluated the immediate and long-term effects of upper extremity rehabilitation approaches for stroke compared functional task practice and strength training with standard care and found that task specificity and stroke severity are important factors in rehabilitation of arm use after an acute stroke.⁶⁶ Another recent approach that involves repetitive training of the paretic upper extremity on task-oriented activities has provided evidence of efficacy in stroke survivors. The Effect of Constraint-Induced Movement Therapy on Upper Extremity Function (EXCITE) trial of individuals 3 to 9 months after stroke found that CIMT produced statistically and clinically relevant improvements in arm motor function that persisted for at least 1 year.⁶⁹

Robotics

Robot-assisted therapies involve the use of a robot to assist in initiation of movement, guidance, and resistance to movement, as well as to provide feedback. Mirror-image motion enabler (MIME) robotic devices were developed to enable unrestricted unilateral or bilateral shoulder or elbow movement. The robotic unit applies force to the more affected forearm during goal-directed movements. A randomized study involving the use of a robotic device and a control group found that there were no significant differences between the groups on either of the ADL assessments but that the clients in the robotic group exhibited a trend toward greater improvement in Fugl-Meyer scores. These

differences achieved statistical significance only if the shoulder and elbow portions of the Fugl-Meyer test were considered.⁴ Another study examined robot-assisted movement therapy versus conventional therapy in individuals with chronic hemiparesis. This study found that after the first and second months of treatment, the group using robot-assisted therapy had significantly greater improvements in the proximal movement portion of the Fugl-Meyer test. The clients using the robots also had larger gains in strength and larger increases in reach extent after 2 months of treatment. At 6 months, no significant differences were seen between the two groups on the Fugl-Meyer test, although the robot group did have significantly greater improvements on the Functional Independence Measure.²⁶ In two other studies using robotic therapy, one found that significantly greater gains were attained after treatment in the robot-combined group than in the control group; however, the gains were not maintained at 6 months' follow-up.²⁷ The other study examined 19 clients following stroke with resultant hemiplegia who underwent a standardized passive exercise program using a robotic arm targeting the upper extremity. This study found no significant changes in pre-exercise and post-exercise responses.⁴⁵ The conclusions regarding the use of robotics for rehabilitation of the upper extremity show that sensorimotor training with robotic devices improves upper extremity functional outcomes and motor outcomes of the shoulder and elbow. Overall, robot-assisted upper extremity therapy may assist in improving motor function during the inpatient period after a stroke.^{1,12,64}

Virtual Reality Technology

Virtual reality technology allows individuals to experience and interact with three-dimensional environments. Merians and colleagues^{33,34} found that computerized virtual environments have opened the doors to an “exercise environment where the intensity of practice and positive feedback can be consistently and systematically manipulated and enhanced to create the most appropriate, individualized motor learning approach. Adding computerized virtual reality to computerized motor learning activities provides a three-dimensional spatial correspondence between the amount of movement in the real world and the amount of movement seen on the computer screen. This exact representation allows for visual feedback and guidance for the patient.” Virtual reality is an innovative treatment approach that is in its infancy, but it has shown promise in improving motor function in clients following a stroke and experiencing chronic hemiparesis.

Bilateral Training Techniques

As new theories of neural plasticity have developed, the use of bilateral training techniques for the upper limb following stroke have been discussed. Bilateral upper limb training is a technique in which clients practice the same activities with

both upper limbs simultaneously. Theoretically, use of the intact limb assists in promoting functional recovery of the impaired limb through facilitative coupling effects between the upper limbs. Practicing bilateral movements allows activation of the intact hemisphere to facilitate activation of the damaged hemisphere through neural networks linked via the corpus callosum.^{38,53} In a systematic review that examined 11 clinical trials, Stewart and colleagues⁵² found that bilateral movement training alone or in combination with sensory feedback is an effective stroke rehabilitation protocol during the subacute and chronic phases of motor recovery.

Summary

Dynamic systems theory supports a heterarchic model of motor control in which motor acquisition is influenced by the client, the environment, and the occupations that the client needs to perform or wants to perform. A task-oriented approach supports the use of occupation-based and client-centered interventions to assist clients in problem solving (e.g., learning how they will perform their desired occupations in a variety of contexts to support transfer of motor learning). CIMT is a task-oriented approach that focuses on constraining use of the unaffected upper extremity to facilitate motor recovery in the affected upper extremity during occupational performance. More research is needed in OT to support the use of a task-oriented CIMT approach to motor recovery to improve participation in occupation. Sensorimotor training with the use of robotic devices improves functional and motor outcomes of the shoulder and elbow; however, it does not improve functional and motor outcomes of the wrist and hand. In virtual reality technology, preliminary evidence has shown that this form of intervention may improve motor outcomes. Finally, bilateral arm training uses the intact extremity to assist the impaired extremity through facilitative coupling effects between both upper extremities.

Review Questions

1. How does motor control affect occupational performance?
2. What is the task-oriented approach to motor learning?
3. What is dynamic systems theory and how does it explain motor control?
4. What is constraint-induced movement therapy and how does this approach increase functional use of a hemiparetic upper extremity after a neurologic insult to the brain?
5. What is robot-assisted therapy and how does this approach improve motor control of the upper extremity?
6. What is virtual reality technology and how is this used to improve upper extremity motor control?
7. How are bilateral training techniques used to improve upper extremity motor control?

Threaded Case Study | Richard, Part 2

At screening, Richard was eligible to participate in a CIMT program because his stroke occurred more than 1 year earlier. He had residual right hemiparesis with selective motion in all joints. He was able to touch the top of his head with his weaker arm, bend his wrist, and grasp or release with slow movements. He had completed an inpatient and outpatient rehabilitation program. Richard has not had any major medical complications, has not suffered any falls within the past 6 months, and is able to walk without an assistive device. After screening, an upper extremity range-of-motion assessment, tone assessment using the Modified Ashworth Scale, Berg Balance Test, and the Folstein Mini-Mental State Examination were completed. Richard met all the criteria and was therefore a good candidate for CIMT.

Richard participated in the MAL interview throughout the intervention. Each task was modeled twice before the participant's performance, and the task was videotaped for scoring purposes. Specific tasks to determine grip strength and the amount of weight added to the task of lifting a box with shoulder flexion were also scored separately. He also completed the WMFT. After completion of the pretraining assessment, Richard and his wife were taught how to don and doff the mitt and use the home diary, and they both signed a behavioral contract. Richard was then scheduled for 14 days of consecutive intervention in which his less involved left arm was constrained by a mitt so that he was required to complete his daily activities with his more affected right arm. The behavioral contract stipulated that Richard would wear the mitt for 90% of waking hours. There was also a home program contract that included exceptions to wearing the mitt, such as while bathing and sleeping. Richard also kept a diary to record which upper extremity was used and the amount of time used during various daily activities, as well as the amount of time that the mitt was worn. Richard recorded all activities completed from the time that he left the clinic until his return the following day.

In addition to the activity-based home program, Richard's intervention involved both a group setting and individual sessions. Each of the sessions lasted 6 hours. Tasks during the 6-hour sessions included shaping activities to ensure success in performance. Each small improvement in motor performance was reinforced with positive feedback. Tasks were progressively increased in difficulty as Richard's motor performance improved. To ensure that the activities were occupation based and client centered, they were developed according to the information provided and identified by the COPM.

After Richard arrived at the clinic, the therapist reviewed his diary and performed the MAL. The CIMT activities were identified through information obtained from the COPM. For example, Richard participated in group activities such as playing cards, which required him to use his more affected

hand to manipulate the cards while his less affected hand was constrained in the mitt. He further participated in activities such as cooking. He was responsible for set-up, preparation, and clean-up of the meal with his right upper extremity. His left upper extremity was constrained in the mitt, which necessitated use of his more affected right hand to chop vegetables. Richard would often attempt to use his less affected hand in the mitt and would require prompting from the therapist. To focus on activities that were meaningful for Richard, all activities during the 6-hour intervention session were based on his goals from the COPM. His CIMT activities became progressively more challenging, with repetitions of task practice requiring range of motion, strength, endurance, and coordination. Verbal acknowledgment of daily achievements was provided.

After the 2-week intervention program, Richard learned to incorporate his more affected upper extremity into meaningful daily occupations. It became routine for Richard to initiate activities with his right upper extremity, although he primarily used his left upper extremity before the intervention. Richard's level of participation grew to include gardening, attending church, and turning the pages of the prayer book with his right hand. He also resumed his roles in cooking and performing household maintenance.

How Has Richard's Motor Control Affected His Ability to Engage in Meaningful Occupation?

Because of impairments in motor control in his right upper extremity, Richard was unable to perform cooking tasks with both upper extremities. He also had difficulty with fasteners and manipulation of objects of different textures and sizes greater than 1 inch. Richard was unable to turn the pages of his prayer book while in church and had difficulty with the transitional movements of sitting to standing and standing to sitting while in church. He was also unable to perform transition movements during gardening activities and was not able to manipulate cards with the affected upper extremity.

What Motor Control Treatment Strategies Would Enable Richard to Engage More Effectively in His Daily Occupations?

Richard's CIMT program consisted of restricting movement of the unaffected upper extremity by placing it in a splint, sling, or mitt for greater than 90% of his waking hours. He complied with this protocol for a period of 14 days and participated in training of the affected upper extremity through shaping for approximately 7 hours per day during the 10 weekdays of that period. This approach enabled Richard to regain functional use of his right dominant upper extremity for occupations such as preparing meals, dressing, and opening the pages of a prayer book.

8. How would you develop a client-centered and occupation-based treatment program to facilitate motor learning?

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. List and describe evaluation procedures for survivors of a stroke.
2. Discuss the neuropathology of a stroke.
3. Identify risk factors associated with a stroke.
4. Identify multiple factors (impaired client factors, performance skills, etc.) that impede performance in areas of occupation after a stroke.
5. Describe evaluation procedures for impaired body functions related to neurobehavioral deficits.
6. Identify balance strategies (a body function) that support performance of areas of occupation.
7. Describe the motor control dysfunction (impaired body function) associated with stroke.
8. Identify standardized stroke assessments for multiple areas of dysfunction.
9. Apply a client-centered approach to stroke rehabilitation.
10. Develop comprehensive occupation-based treatment plans to remediate or compensate for underlying deficits.

Introduction

This chapter focuses on occupational therapy (OT) assessment and intervention for individuals who have sustained a stroke. Specifically, it focuses on improving participation in chosen areas of occupation. After a person has a stroke, multiple client factors and performance skills are affected and potentially limit participation and engagement in occupation.⁵ These multiple problems are addressed throughout this chapter.

Cerebrovascular accidents (CVAs), or strokes, continue to be a national health problem despite recent advances in medical technology. The American Heart Association⁴ publishes stroke statistics that demonstrate the severity of this problem. Selected statistics include the following⁴:

- Stroke ranks as the third leading cause of death behind heart disease and cancer.
- On average, a U.S. citizen suffers a stroke every 40 seconds; every 4 minutes someone dies of a stroke.
- Each year, 795,000 people suffer a new or recurrent stroke. Approximately 610,000 strokes are first attacks and 185,000 are recurrent.
- The prevalence of stroke in 2006 was 6,400,000.
- Of people who suffer a stroke, 28% are younger than 65 years. For people older than 55, the incidence of stroke more than doubles with each successive decade.
- The incidence of stroke is about 1.25 times higher in men than in women.
- The aftermath of a stroke is a substantial public health and economic problem, with stroke being a leading

Threaded Case Study | Jasmine, Part 1

Jasmine is a 39-year-old single mother of a 2-year-old boy. They live in a two-bedroom rented apartment. She has converted her dining area into a home office, where she carries out her home-based business in desktop publishing. Jasmine drives her son to preschool each morning and shops on the way home before working for the rest of the day from home. While working on her computer, Jasmine experienced tingling and “clumsiness” in her left hand. She attributed this to long work hours. Still feeling “not quite right,” she attempted to stand to go to the bathroom and collapsed on the floor. She was able to crawl to the phone to call 911.

Jasmine next remembers waking up in the emergency room, where she was told that she had just experienced a stroke. Her neuroimaging studies documented the presence of a right frontal-parietal infarct. Jasmine is unable to move or feel the left side of her body, has a left visual field cut, and tends to not respond to sensory stimuli on the left side of her body. Nurses and nurse’s aides are lifting Jasmine out of bed and providing full assistance for self-care and mobility. Jasmine was told that by the end of the week she will be transferred to the local

rehabilitation hospital and will require “aggressive” occupational and physical therapy. Her son is under the care of his aunt and uncle. Jasmine has been crying often and is concerned that she will not be able to work or take care of her son. She is also concerned about losing her apartment; she explains that she has been “just getting by” recently.

Critical Thinking Questions

1. How will Jasmine’s impaired body functions and body structures (e.g., loss of motor control, sensory loss, visual dysfunction, and neglect) affect her ability to return to her previous lifestyle and engage in chosen areas of occupation?
2. What three assessments are most critical to administer? Why?
3. Which interventions should be considered to address Jasmine’s inability to participate in self-care (e.g., toileting, dressing), mobility (e.g., bed mobility, transfers), and instrumental daily living activities (e.g., meal preparation, child care) throughout her rehabilitation stay?

cause of serious, long-term disability in the United States.

- Stroke accounts for more than half of all clients hospitalized for acute neurologic disease.
- Among long-term clients who sustained a stroke, 50% have hemiparesis, 30% cannot walk, 26% are found to be dependent in activity of daily living (ADL) scales, 19% are aphasic, 35% are clinically depressed, and 26% require home nursing care.

Obviously, stroke rehabilitation as a practice area for occupational therapists is a specialization that crosses multiple settings, from the intensive care unit to community-based programs.

Definition of Stroke

A CVA, or stroke, is a complex dysfunction caused by a lesion in the brain. The World Health Organization¹⁰⁰ defines stroke as an “acute neurologic dysfunction of vascular origin with symptoms and signs corresponding to the involvement of focal areas of the brain.” Stroke results in upper motor neuron dysfunction that produces hemiplegia, or paralysis of one side of the body, including the limbs and trunk and sometimes the face and oral structures that are contralateral to the hemisphere of the brain with the lesion. Thus, a lesion in the left cerebral hemisphere (left CVA) produces right hemiplegia. Conversely, a lesion in the right cerebral hemisphere (right CVA) produces left hemiplegia. When reference is made to the client’s disability as right or left hemiplegia, the reference is to the paralyzed side of the body and not to the locus of the lesion.

Accompanying the motor paralysis may be a variety of dysfunctions other than the motor paralysis. Some of these dysfunctions include sensory disturbances, cognitive and perceptual dysfunction, visual disturbances, personality and intellectual changes, and a complex range of speech and associated language disorders. The neurologic deficits must persist longer than 24 hours to be labeled a CVA.

Causes of Stroke

Bartels describes a stroke as “essentially a disease of the cerebral vasculature in which failure to supply oxygen to the brain cells, which are the most susceptible to ischemic damage, leads to their death. The syndromes that lead to stroke comprise two broad categories: ischemic and hemorrhagic stroke.”¹⁰ Ischemic strokes account for the majority of strokes, whereas hemorrhagic strokes account for less.

Ischemia

Ischemia refers to insufficient blood flow to the brain to meet metabolic demand. Ischemic strokes may be the result of embolism to the brain from cardiac or arterial sources. Cardiac sources include atrial fibrillation (pooling of blood in the dysfunctional atrium leads to the production of

emboli), sinoatrial disorders, acute myocardial infarction, endocarditis, cardiac tumors, and valvular (both native and artificial) disorders. Cerebral ischemia caused by perfusion failure occurs with severe stenosis of the carotid and basilar arteries, as well as with microstenosis of the small deep arteries.^{4,10}

Age, gender, race, ethnicity, and heredity are considered nonmodifiable risk factors for ischemic strokes. In contrast, a major focus of stroke prevention and education programs is on the potentially modifiable risk factors discussed in the following list^{4,50}:

1. Hypertension is considered the single most important modifiable risk factor for ischemic stroke. Those with blood pressure lower than 120/80 have about half the lifetime risk for stroke as those with high blood pressure.⁴
2. Management of cardiac diseases, particularly atrial fibrillation, mitral stenosis, and structural abnormalities (patent foramen ovale and atrial septal aneurysm), can reduce the risk for stroke.
3. Management of diabetes and glucose metabolism can also reduce the risk for stroke.
4. Cigarette smoking increases the relative risk for ischemic stroke nearly two times.
5. Although excessive use of alcohol is a risk factor for many other diseases, moderate consumption of alcohol may reduce the incidence of cardiovascular disease, including stroke.
6. Use of illegal drugs, particularly cocaine, is commonly associated with stroke. Other drugs linked to stroke include heroin, amphetamines, LSD, PCP, and marijuana.
7. Lifestyle factors such as obesity, physical inactivity, diet, and emotional stress are associated with risk for stroke.

“The realization that the probability of stroke is increased several fold by the presence of multiple risk factors may help the patient to fully appreciate the need for serious risk factor management.”⁴ The responsibility for stroke prevention education (including prevention of recurrence) falls on each member of the stroke rehabilitation team.

Hemorrhage

Hemorrhagic strokes include subarachnoid and intracerebral hemorrhages, which account for only 13% of the total number of strokes.⁴ This type of stroke has numerous causes. The four most common are deep hypertensive intracerebral hemorrhages, ruptured saccular aneurysms, bleeding from arteriovenous malformations, and spontaneous lobar hemorrhages.⁵⁸

Related Syndromes

Cerebral anoxia and aneurysm can also result in hemiplegia. Some of the treatment approaches outlined in this chapter may be applicable to hemiplegia resulting from causes other

than CVA or stroke, such as head injuries, neoplasms, and infectious diseases of the brain.

Transient Ischemic Attacks

Vascular disease of the brain can result in a completed stroke or transient ischemic attacks (TIAs). A TIA is characterized by mild, isolated, or repetitive neurologic symptoms that develop suddenly, last from a few minutes to several hours but not longer than 24 hours, and clear completely. A TIA is seen as a sign of an impending stroke.⁴ Most TIAs occur in people with atherosclerotic disease. Of those who experience TIAs and do not seek treatment, an estimated third will sustain a completed stroke, another third will continue to have additional TIAs without a stroke, and a third will experience no further attacks.^{7,8} If the TIA is caused by extracranial vascular disease, surgical intervention to restore vascular flow (carotid endarterectomy) may be effective in preventing the stroke and resultant disability.

Effects of Stroke

The outcome of a stroke depends on which artery supplying the brain was involved (Figure 33-1). Stroke diagnostic workups help localize the lesion and find a cause of the

stroke. Techniques include cerebrovascular imaging such as computed tomography (CT), magnetic resonance imaging (MRI), and more recently, positron emission tomography (PET) and single-photon emission computed tomography (SPECT).¹⁰ The information collected with these techniques (e.g., the extent of damage and location of the lesion) may help the occupational therapist identify neurologic deficits that affect function. The information may also help the therapist develop hypotheses regarding recovery and plan appropriate treatment. Initial information may be collected during a medical record review that focuses on the chief complaint of the client on admission, previous medical and surgical history, results of diagnostic tests, and current pharmacologic management. The following section and Tables 33-1 and 33-2 explain patterns of impairment resulting from stroke in both the cortical and subcortical areas.

Internal Carotid Artery

In the absence of adequate collateral circulation, occlusion of the internal carotid artery results in contralateral hemiplegia, hemianesthesia, and homonymous hemianopia.^{6,10} Additionally, involvement of the dominant hemisphere (i.e., the cerebral hemisphere containing the representation

FIGURE 33-1 Blood supply to the brain. The middle cerebral, anterior cerebral, and posterior cerebral arteries supply blood to the cerebral hemispheres. **A**, Medial surface. **B**, Lateral surface.

■ **TABLE 33-1** | Cerebral Artery Dysfunction: Cortical Involvement and Patterns of Impairment—cont'd

Artery	Location	Possible Impairments
Systemic hypoperfusion 	Watershed region on the lateral side of the hemisphere, hippocampus, and surrounding structures in the medial temporal lobe	Coma Dizziness Confusion Decreased concentration Agitation Memory impairment Visual abnormalities caused by disconnection from the frontal eye fields Simultanagnosia Impaired eye movements Weakness of shoulder and arm Gait ataxia

From Arnadottir G: Impact of neurobehavioral deficits of activities of daily living. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.

of speech/language and controlling the arm and leg used preferentially in skilled movements, usually the left hemisphere) is associated with aphasia, agraphia or dysgraphia, acalculia or dyscalculia, right-left confusion, and finger agnosia. Involvement of the nondominant hemisphere is associated with visual perceptual dysfunction, unilateral neglect, anosognosia, constructional or dressing apraxia, attention deficits, and loss of topographic memory.

Middle Cerebral Artery

Involvement of the middle cerebral artery (MCA) is the most common cause of stroke.^{7,10,21} Ischemia in the area supplied by the MCA results in contralateral hemiplegia with greater involvement of the arm, face, and tongue; sensory deficits; contralateral homonymous hemianopia; and aphasia if the lesion is in the dominant hemisphere. There is pronounced deviation of the head and neck toward the side on which the lesion is located.^{22,31} Perceptual deficits such as anosognosia, unilateral neglect, impaired vertical perception, visual spatial deficits, and perseveration are seen if the lesion is in the nondominant hemisphere.⁶

Anterior Cerebral Artery

Occlusion of the anterior cerebral artery (ACA) produces contralateral lower extremity weakness that is more severe than that of the arm. Apraxia, mental changes, primitive reflexes, and bowel and bladder incontinence may be present. Total occlusion of the ACA results in contralateral hemiplegia with severe weakness of the face, tongue, and proximal arm muscles and marked spastic paralysis of the distal end of the lower extremity. Cortical sensory loss is present in the lower extremity. Intellectual changes such as confusion, disorientation, abulia, whispering, slowness, distractibility, limited verbal output, perseveration, and amnesia may be seen.^{6,10}

Posterior Cerebral Artery

The scope of posterior cerebral artery (PCA) symptoms is potentially broad and varied because this artery supplies the upper brainstem region, as well as the temporal and occipital lobes. Possible results of PCA involvement depend on the arterial branches affected and the extent and area of cerebral compromise. Some possible outcomes are sensory and motor deficits, involuntary movement disorders (e.g., hemiballism, postural tremor, hemichorea, hemiataxia, intention tremor), memory loss, alexia, astereognosis, dysesthesia, akinesia, contralateral homonymous hemianopia or quadrantanopia, anomia, topographic disorientation, and visual agnosia.^{6,10,31}

Cerebellar Artery System

Occlusion of the cerebellar artery results in ipsilateral ataxia, contralateral loss of pain and temperature sensitivity, ipsilateral facial analgesia, dysphagia and dysarthria caused by weakness of the ipsilateral muscles of the palate, nystagmus, and contralateral hemiparesis.^{6,10,22,31}

Vertebrobasilar Artery System

A stroke in the vertebrobasilar artery system affects brainstem functions. The outcome of the stroke is some combination of bilateral or crossed sensory and motor abnormalities, such as cerebellar dysfunction, loss of proprioception, hemiplegia, quadriplegia, and sensory disturbances, along with unilateral or bilateral involvement of cranial nerves III to XII.

Medical Management

Specific treatment of stroke depends on the type and location of the vascular lesion, the severity of the clinical deficit, concomitant medical and neurologic problems, availability

TABLE 33-2 Cerebrovascular Dysfunction in Noncortical Areas: Patterns of Impairment

Location	Possible Impairments	Location	Possible Impairments
Anterolateral thalamus	EITHER SIDE Minor contralateral motor abnormalities Long latency period Slowness RIGHT SIDE Visual neglect LEFT SIDE Aphasia	Caudate	Dysarthria Apathy Restlessness Agitation Confusion Delirium Lack of initiative Poor memory Contralateral hemiparesis Ipsilateral conjugate deviation of the eyes

of technology and personnel to administer special types of treatment, and the cooperation and reliability of the client.

Early medical treatment involves maintenance of an open airway, hydration with intravenous fluids, and treatment of hypertension. Appropriate steps should be taken to evaluate and treat coexisting cardiac or other systemic diseases. Measures should be taken to prevent the development of deep venous thrombosis (DVT). DVT is the formation of a blood clot (thrombus) in a deep vein, usually in the lower extremity, a common risk in clients who have prolonged periods of bedrest and immobility. The incidence of DVT in individuals with stroke ranges from 22% to 73%. Emboli that are released from deep veins and subsequently lodge in the lungs are referred to as pulmonary emboli. Pulmonary embolism is the most common cause of death in the first 30 days after a stroke.^{10,20}

The physician oversees routine surveillance for thrombosis, which includes daily evaluation of leg temperature, color, circumference, tenderness, and appearance. Preventive treatments of DVT may involve medication, the use of elastic stockings, the use of reciprocal compression devices, and early mobilization of the client.

Respiratory problems and pneumonia may complicate the early post-stroke course. The National Survey of Stroke reported that a third of clients who had sustained strokes also had respiratory infections.⁷⁷

Symptoms are a low-grade fever and increased lethargy. Medical management involves the administration of fluids and antibiotics, aggressive pulmonary hygiene, and mobilization of the client. Ventilatory insufficiency is a major factor contributing to the high frequency of pneumonia. The hemiparesis associated with stroke involves the muscles

of respiration. Exercise programs that involve strengthening and endurance training of both the inspiratory and expiratory muscles help improve breathing and cough effectiveness and reduce the frequency of pneumonia.²⁰

Cardiac disease is another frequently occurring condition that complicates the post-stroke course. The stroke itself may cause the cardiac abnormality, or the client may have had a pre-existing cardiac condition. The former is treated in the same manner as any new cardiac diagnosis. A pre-existing cardiac condition is re-evaluated and the treatment regimen modified as appropriate. Monitoring of the heart rate, blood pressure, and electrocardiogram (ECG) during self-care evaluations is frequently indicated to determine the cardiac response to activity.

During the acute phase, bowel and bladder dysfunction is common. The physician is responsible for ordering a specific bowel program that includes a time schedule, adequate fluid intake, stool softeners, suppositories, oral laxatives, and medications or procedures to treat fecal impaction. A timed or scheduled toilet program is essential in treating urinary incontinence. Catheterization may be necessary during stroke rehabilitation.

Evaluation and Intervention Procedures for Clients Who Sustained a Stroke

Tables 33-1 and 33-2 provide information related to patterns of impairments that are typically observed and that vary depending on the area of the brain that has been damaged. The location of the stroke is determined by CT or MRI and is generally documented in the medical record. Understanding this information is the first step of the evaluation process; it should take place before meeting the client and helps the therapist focus his or her evaluation procedures and begin to understand which client factors are impaired and affecting performance in areas of occupation.

For example, Jasmine has documented damage in her right frontal and parietal lobes (most likely secondary to MCA occlusion). Patterns of impairment that are typically observed with this type of stroke include contralateral motor loss, contralateral sensory loss, difficulty interpreting spatial relationships (e.g., depth/distance, foreground from background), decreased attention or neglect of left-sided information (personal and extrapersonal), and left limb motor-planning deficits. These impairments may in turn affect Jasmine's ability to engage in meaningful areas of occupation. Her sensory-motor loss may prevent her from fulfilling her role as a mother (e.g., assisting her child in the bath, lifting her son into the crib, preparing meals) and as a worker (e.g., typing, filing). Simultaneously, her attention deficits (left-sided neglect) will make driving unsafe, interfere with self-care and care of her child, affect her computer use (e.g., finding information on the left side of the screen),

and impede her ability to manage her household (e.g., read and write bills and checks, prepare meals.)

Typically, a client's clinical findings immediately after a stroke (the acute stage) represent the worst-case scenario. In other words, once the stroke is complete and the client who sustained the stroke is medically stabilized, the lesion is considered static or not progressive. At this point, a client who sustained a stroke may exhibit little to no contralateral motor function (hemiparesis or hemiplegia) because of severe weakness, no response to contralateral sensory stimuli, and a severe attention deficit; the client may also require assistance performing his or her job. Fortunately, barring another neurologic insult, the client is usually expected to improve from both a neurologic and functional perspective. Unfortunately, predicting the amount of improvement and the length of time necessary for improvement to take place is difficult. Clinicians generally agree that the first 3 to 6 months after a stroke is the most crucial time and that the greatest improvement takes place during this period. This time frame remains controversial and should be used only as a guideline. For example, more studies⁸⁷ have documented improvements in upper extremity (UE) function in clients who sustained a stroke many years earlier. It is important to note that some clients may recover only slightly and slowly whereas others may recover fully.

Given this information, it is important to understand that neurologic recovery and functional recovery are different aspects to consider. A motor control (i.e., the process that must be performed to achieve movement) example will be used to illustrate this point. Clients A and B may share similar findings (no motor function on the left side of the body) immediately after experiencing a stroke. Client A may recover substantial motor function and resume engagement in previous occupations such as shopping and dressing with few residual impairments (perhaps a "limp" or mild clumsiness) resulting from the stroke. Client B may not benefit from the same level of neurologic motor recovery and yet still be able to resume engagement in previous occupations by using adaptive methods. Dressing may require learning new one-handed techniques, wearing clothing with a looser fit, and using equipment such as a reacher. Shopping may be accomplished with the use of powered mobility (e.g., scooter or wheelchair), an ankle-foot orthotic and a cane, or the Internet. Despite these differences, both client A and client B are able to participate in meaningful occupations.

Client-Centered Assessments

"Client-centered practice is an approach to providing occupational therapy which embraces a philosophy of respect for, and partnership with, people receiving services. Client-centered practice recognizes the autonomy of individuals, the need for client choice in making decisions about occupational needs, the strengths clients bring to a therapy encounter, the benefits of client-therapist partnership, and

the need to ensure that services are accessible and fit the context in which a client lives.⁶³

Law and colleagues⁶² and Pollack⁷³ suggest that therapists implementing this approach to evaluation include the following concepts:

1. Recognizing that recipients of OT are uniquely qualified to make decisions about their occupational functioning
2. Offering the client a more active role in defining goals and desired outcomes
3. Making the client-therapist relationship an interdependent one to enable the solution of performance dysfunction
4. Shifting to a model in which occupational therapists work with clients to enable them to meet their own goals
5. Evaluation (and intervention) focusing on the contexts in which clients live, their roles and interests, and their culture
6. Allowing the client to be the “problem definer” so that the client will in turn become the “problem solver”
7. Allowing the client to evaluate his or her own performance and set personal goals^{62,73}

Through the use of these strategies, the evaluation process becomes more focused and defined, clients become immediately empowered, the goals of therapy are understood and agreed on, and a client-tailored treatment plan may be established. The Canadian Occupational Performance Measure⁶³ (COPM) is a standardized tool that uses a client-centered approach to allow the recipient of treatment to identify areas of difficulty, rate the importance of each area, and rate his or her satisfaction with current performance. It is a particularly useful tool to use with clients who sustained a stroke because of the multiple and extensive problems that this population experiences in performance of areas of occupation.

The COPM would be a good assessment to use with Jasmine. It would give the occupational therapist insight into the occupations that should be prioritized, assist in goal writing, and facilitate treatment planning. In addition, use of the COPM would empower Jasmine as an active participant in the rehabilitation process. When Jasmine completed the COPM, the results identified toilet transfers, computer use, grooming, feeding, and child care as the occupations that she wanted to pursue first—in other words, these occupations would be the focus of her initial OT. Jasmine indicated that gaining mastery in the occupations would make her feel better about herself (“boost my self-esteem”) and give her hope that she could return to work (“and provide for my child”).

Top-Down Approach to Assessment

A top-down approach to the assessment process has been described in the literature⁹² and is applicable to the evaluation of clients who sustained a stroke. Principles of this approach include the following:

1. Inquiry into role competency and meaningfulness is the starting point for evaluation.
2. Inquiry is focused on the roles that are important to the client who sustained a stroke, particularly those in which the client was engaged before the stroke.
3. Any discrepancy of roles in the past, present, or future is identified to help determine a treatment plan.
4. The tasks that define a person are identified, as well as whether those tasks can be performed and the reasons that the tasks are problematic.
5. A connection is determined between the components of function and occupational performance.

A top-down approach to evaluation is in contrast to a bottom-up approach, which first focuses on dysfunction of client factors.⁹²

Effects of Neurologic Deficits on Performance in Areas of Occupation

Using activity analysis and keen observation allows therapists to identify errors during task performance and to analyze the errors and determine the underlying deficits blocking independent functioning. Arnadottir states that “... therapists can benefit from detecting errors in occupational performance while observing ADL and thereby gain an understanding of the impairments affecting the patient’s activity limitation. Therapists can use the information based on observed task performance in a systematic way as a structure for clinical reasoning to help them assess functional independence related to the performance and to subsequently detect impaired neurological body functions. Such information can be important when intervention methods are aimed at addressing occupational errors”⁶ (Figure 33-2).

Because performance of a single functional task (e.g., donning a shirt) requires the use of multiple underlying client factors and performance skills that may have been affected by a stroke, multiple variables may be evaluated in the context of one client-chosen activity (Figure 33-3).^{6,7}

Standardized Tools

Occupational therapists use assessment tools that are reliable, valid, and sensitive to change. In addition, assessment tools focused on task performance should be used. Tools that are focused on evaluation of client factors in isolation from performance in areas of occupation, that use novel nonfunctional tasks, and that do not consider the effect of environmental context should be interpreted with caution. Tools are available to the occupational therapist that directly relate performance dysfunction observed during ADLs to the effect of underlying skills necessary for independent performance of activities.

The Arnadottir Occupational Therapy Neurobehavioral Evaluation^{6,7} (A-ONE) objectively documents the way that dysfunction of client factors (e.g., left-sided neglect, apraxia, and spatial dysfunction) affects self-care and mobility tasks.

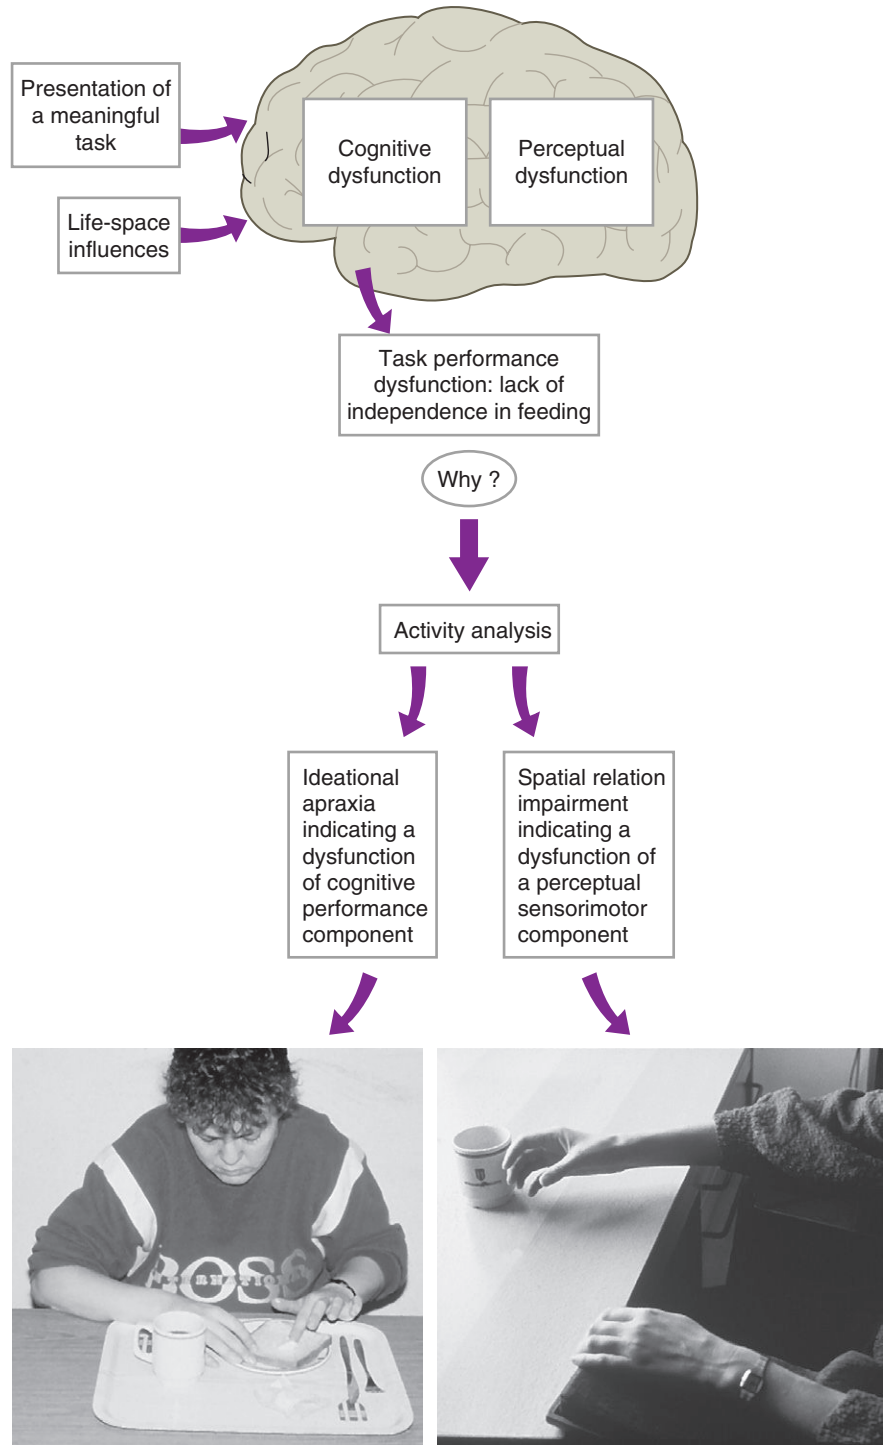

FIGURE 33-2 Dysfunction of multiple client factors such as ideational apraxia and spatial relationships can be revealed by activity and error analysis during functional tasks such as feeding.

(Modified from Arnadottir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living*, St Louis, Mo, 1990, Mosby.)

The A-ONE has more recently been referred to as the ADL-focused Occupation-based Neurobehavioral Evaluation.^{8,9} The Assessment of Motor and Process Skills⁴⁰ (AMPS) uses predominantly instrumental activities of daily living (IADLs) to evaluate underlying performance skills related to the completion of various IADLs (e.g., reaching, grasping, and posture) and process skill dysfunction (e.g., using items and searching and locating). Table 33-3 provides a summary of standardized assessments used with clients who

have sustained a stroke. The A-ONE was used to objectively document the ways that Jasmine’s various impairments (e.g., neglect, spatial relationship dysfunction, loss of motor control, topographic disorientation) affected her ability to perform basic activities of daily living (BADLs) and mobility (e.g., bed mobility, transfers, wheelchair mobility, and walking when applicable). Errors observed and documented included not dressing the left side of her body, not able to locate grooming items on the left side of the sink, and

difficulty dressing the lower part of her body and getting out of bed secondary to loss of motor control in her left limbs and trunk.

Adopting a Framework for Intervention

Therapists should consider overarching themes when deciding which interventions to use to address a client’s inability to resume meaningful roles and successfully participate in chosen occupations. Embracing evidence-based practice should serve as the foundation for all OT interventions. To be successful in this endeavor, practitioners must remain abreast of new and emerging research in the OT literature, as well as related fields. Review papers^{65,83,95} and evidence-based libraries and search engines such as the Cochrane Library are sources of up-to-date information.

Over the past several years there has been a paradigm shift related to the intervention philosophies typically used with clients who sustained a stroke. In the past, sensorimotor approaches were used to treat individuals who sustained a stroke (see Chapter 31). These approaches were developed by Rood, Bobath, Knott, and Voss (proprioceptive neuromuscular facilitation) and by Brunnstrom and are based on an understanding of central nervous system (CNS) dysfunction at the time that these clinicians were doing their research

(the mid-1900s). Although these interventions are commonly used, their effectiveness is being challenged as occupational therapists move toward models of evidence-based practice.⁷⁵ At present, there is limited research to support these neurofacilitation approaches. Indeed, the Bobath approach, or neurodevelopmental treatment (NDT), though commonly used in the clinic, has not been shown to be superior to other treatment approaches and in fact is inferior to more current models of practice. For example, a large nonrandomized, parallel group study ($N = 324$) compared the NDT approach with conventional treatment. Subjects were monitored for 12 months. The authors concluded that “the NDT approach was not found effective in the care of stroke patients in the hospital setting. Health care professionals need to reconsider the use of this approach.”⁵¹ Similarly, a systematic review of 16 studies involving 813 patients with stroke concluded that “there was no evidence of superiority of Bobath on sensorimotor control of upper and lower limb, dexterity, mobility, activities of daily living, health-related quality of life, and cost-effectiveness. Only limited evidence was found for balance control in favor of Bobath.” “This systematic review confirms that overall the Bobath Concept is not superior to other approaches.”⁵⁹

In contrast, approaches that focus on the use of functional activities as the therapeutic change agent (e.g., task-oriented approaches) show promise from both a research and a clinical

■ **TABLE 33-3** | Assessments Used with Clients Who Sustained a Stroke

Instrument	Description and Usage
NIH Stroke Scale ²³	Stroke deficit scale that scores 15 items (e.g., consciousness, vision, extraocular movement, facial control, limb strength, ataxia, sensation, speech and language)
Canadian Neurological Scale ³⁰	Stroke deficit scale that scores 8 items (e.g., consciousness, orientation, speech, motor function, facial weakness)
Rankin Scale ¹⁹	Global disability scale with 6 grades indicating degrees of disability
Canadian Occupational Performance Measure (COPM) ⁶³	Client-centered assessment tool based on clients' identification of problems in performance in areas of occupation (clients rate the importance of self-care, productivity, and leisure skills, as well as their perception of performance and satisfaction with performance) Used as an outcome measure, as well as a client satisfaction survey
Barthel Index ⁶⁶	Measure of disability in performing BADLs that ranges from 0 to 20 or 0 to 100 (by multiplying each item by 5); includes 10 items: bowels, bladder, feeding, grooming, dressing, transfer, toileting, mobility, stairs, and bathing
Kohlman Evaluation of Living Skills (KELS) ⁸⁹	Living skills evaluation that includes ratings of 17 tasks (e.g., safety awareness, money management, phone book use, money and bill management)
Functional Independence Measure (FIM) ⁵⁵	Measure of disability in performing BADLs that includes 18 items scored on a 7-point scale; includes subscores for motor and cognitive function; performance areas include self-care, sphincter control, mobility, locomotion, cognition, and socialization
Frenchay Activities Index ^{*52}	15-item IADL scale that evaluates domestic, leisure, work, and outdoor activities
PCG Instrumental Activities of Daily Living ^{*64}	IADL evaluation of telephone use, walking, shopping, food preparation, housekeeping, laundry, public transportation, and medication management
Assessment of Motor and Process Skills ⁴⁰	16 motor skills (e.g., reach, manipulation, calibration, coordination, posture, mobility) and 20 process skills (e.g., attends, organizes, searches and locates, initiates, sequences) evaluated within the context of client-chosen IADL skills; clients choose familiar and culturally relevant tasks from a list of 50 standardized activities of various difficulties
Mini-Mental State Examination ^{*41}	Mental status screening test for orientation to time and place, registration of words, attention, calculation, recall, language, and visual construction
Glasgow Coma Scale ^{*88}	Level-of-consciousness scale that includes 3 sections scoring eye opening, motor, and verbal responses to voice commands or pain
Arnadottir Occupational Therapy Neurobehavioral Evaluation (A-ONE) ⁷	Evaluates apraxias, neglect syndromes, body scheme disorders, organization/sequencing dysfunction, agnosias, and spatial dysfunction via BADL and mobility tasks; directly correlates impairment and disability levels of dysfunction
Neurobehavioral Cognitive Status Examination ^{*57}	Mental status screening test that includes the domains of orientation, attention, comprehension, naming, construction, memory, calculation, similarities, judgment, and repetition
Fugl-Meyer Test ^{*43}	Motor function evaluation that uses a 3-point scale to score the domains of pain, range of motion, sensation, volitional movement, and balance
Functional Test for the Hemiparetic Upper Extremity ⁹⁹	Arm and hand function is assessed via 17 hierarchic functional tasks based on Brunnstrom's view of motor recovery; sample tasks are folding a sheet, screwing in a light bulb, stabilizing a jar, and zipping a zipper
Arm Motor Ability Test (AMAT) ⁶⁰	Arm function evaluated by functional ability and quality of movement; test involves performance of 28 tasks (e.g., eating with a spoon, opening a jar, tying a shoelace, using the telephone)
TEMPA ^{34,35}	Upper extremity performance test composed of 9 standardized tasks (bilateral and unilateral) measured by 3 criteria: length of execution, functional rating, and task analysis; sample tasks are handling coins, picking up a pitcher and pouring water, writing and stamping an envelope, and unlocking a lock
Jebsen Test of Hand Function ⁵⁴	Hand function evaluation; includes 7 test activities: writing a short sentence, turning over index cards, simulated eating, picking up small objects, moving empty and weighted cans, and stacking checkers during timed trials

■ **TABLE 33-3** | Assessments Used with Clients Who Sustained a Stroke—cont'd

Instrument	Description and Usage
Motor Assessment Scale* ²⁵	Motor function evaluation; includes disability and impairment measures, arm and hand movements, tone, and mobility (bed, upright, and ambulation)
Motricity Index* ³³	Measures impairments in limb strength with a weighted ordinal scale
Trunk Control Test ⁴²	Trunk control evaluated on a 0- to 100-point scale; tasks used: rolling, supine to sitting, and balanced sitting
Berg Balance Scale* ¹⁴	Balance assessment of 14 items scored on a 0- to 4-point ordinal scale
Tinetti Test ⁹⁰	Evaluates balance and gait in the older adult population
Rivermead Mobility Index* ²⁹	Measures bed mobility, sitting, standing, transfers, and walking on a pass or fail scale
Functional Reach Test ³⁷	Balance evaluation; objectively measures length of forward reach in the standing posture
Boston Diagnostic Aphasia Examination* ⁴⁸	Assesses sample speech and language behavior, including fluency, naming, word finding, repetition, serial speech, auditory comprehension, reading and writing
Western Aphasia Battery* ⁵⁶	Includes an “Aphasia Quotient” and “Cortical Quotient” scored on a 100-point scale; assesses spontaneous speech, repetition, comprehension, naming, reading, and writing
Beck Depression Inventory* ¹³	21-item, self-rating scale with attitudinal, somatic, and behavioral components
Geriatric Depression Scale* ¹⁰²	Self-rated depression scale of 30 items with a yes or no format
Family Assessment Device* ³⁸	Family assessment of problem solving, communication, roles, affective responsiveness, affective involvement, behavioral control, and general functioning
Medical Outcomes Study/ Short-Form Health Survey (SF-36)* ⁹⁸	Quality-of-life measure that includes the domains of physical functioning, physical and emotional problems, social function, pain, mental health, vitality, and health perception
Sickness Impact Profile* ¹⁵	Quality-of-life measure in the format of a 136-item scale with 12 subscales that measure ambulation, mobility, body care, emotion, communication, alertness, sleep, eating, home management, recreation, social interactions, and employment
Activity Card Sort (ACS) ¹²	Uses a Q-sort methodology to assess participation in 80 instrumental, social, and high- and low-physical demand leisure activities. Clients sort the cards into different piles to identify activities that were done before their stroke, activities they are doing less, and those they have given up since their stroke. The ACS uses cards with pictures of tasks that people do every day
Stroke Impact Scale ⁶¹	A stroke-specific measure that incorporates function and quality of life into one measure. It is a self-report measure with 59 items and 8 subgroups, including strength, hand function, BADLs and IADLs, mobility, communication, emotion, memory and thinking, and participation

*Recommended in the Agency for Health Care Policy and Research’s Clinical Practice Guidelines #16, Post-Stroke Rehabilitation, 1995.
BADL, basic activities of daily living; IADL, instrumental activities of daily living.

perspective.^{67,68} A recent systematic review of task-oriented approaches concluded that “studies of task-related training showed benefits for functional outcome compared with traditional therapies. Active use of task-oriented training with stroke survivors will lead to improvements in functional outcomes and overall health-related quality of life.” The authors recommended “creating opportunities to practise meaningful functional tasks outside of regular therapy sessions.”⁷⁶ One final note on the subject is that approaches focused on the use of functional tasks are more consistent with traditional and current principles of OT.

Mathiowetz⁶⁷ has outlined a series of intervention principles based on use of the Occupational Therapy Task Oriented Approach.⁶⁸ These principles include the following:

- Help clients adjust to role and task performance limitations by exploring new roles and tasks.
- Create an environment that includes the common challenges of everyday life.
- Practice functional tasks or close simulations that have been identified as important by participants to find effective and efficient strategies for performance.

- Provide opportunities for practice outside therapy time (e.g., homework assignments).
- Minimize ineffective and inefficient movement patterns.

Functional Limitations Commonly Observed after Stroke

Multiple factors can impede effective and efficient performance of various tasks on which the client desires to focus during OT. The following section reviews problem areas that are typically observed during work with clients who have sustained a stroke.

Inability to Perform Chosen Occupations While Seated

A commonly observed deficit after stroke is loss of trunk and postural control. Impairment of trunk control may lead to the following problems⁴⁵:

1. Dysfunction of limb control
2. Increased risk for falls
3. Impaired ability to interact with the environment
4. Visual dysfunction secondary to resultant head and neck malalignment
5. Symptoms of dysphagia secondary to proximal malalignment
6. Decreased independence in ADLs

Loss of trunk and postural control (i.e., “controlling the body’s position in space for the dual purposes of stability and orientation”⁷⁹) after a stroke may be manifested as an inability to sit in proper alignment, loss of righting and equilibrium reactions, inability to reach beyond the arm span because of lack of postural adjustments, and falling during attempts to function.

Clients who sustained a stroke and lose trunk control need to use the more functional UE for postural support to remain upright and prevent falls. In these cases, the client effectively eliminates the ability to engage in ADLs and mobility tasks because lifting the more functional arm from the supporting surface can result in a fall. “Trunk control appears to be an obvious prerequisite for the control of more complex limb activities that in turn constitute a prerequisite to complex behavioral skills.”⁴² Studies have found trunk control to be a predictor of gait recovery, sitting balance,¹⁷ Functional Independence Measure (FIM) scores,⁴² and scores on the Barthel Index⁸¹ after a stroke.

Specific effects of a stroke on the trunk include the following:

1. Inability to perceive the midline as a result of spatial relationship dysfunction and leading to sitting postures that are misaligned from the vertical
2. Assumption of static postures that do not support engagement in functional activities (e.g., posterior pelvic tilt, kyphosis, lateral flexion)

3. Multidirectional trunk weakness¹⁸
4. Spinal contracture secondary to soft tissue shortening
5. Inability to move the trunk segmentally (i.e., the trunk moves as unit; examples of this phenomenon are clients using “logrolling” patterns during bed mobility and an inability to rotate the trunk while reaching for an item across the midline)
6. Inability to shift weight through the pelvis anteriorly, posteriorly, and laterally

Specific deficits in trunk control are evaluated during observation of task performance (Box 33-1). Observing tasks allows the therapist to evaluate trunk control in many directions (i.e., isometric, eccentric, and concentric control of the trunk muscle groups [extensors, abdominal muscles, and lateral flexors]) and the client’s limits of stability. The phrase limits of stability refers to “boundaries of an area of space in which the body can maintain its position without changing the base of support”⁸⁴ or “an area about which the center of mass may be moved over any given base of support without disrupting equilibrium.”³⁸ The therapist must differentiate between the client’s perceived limits of stability and the actual limits of stability. After a stroke, it is common to experience a disparity between the two because of body scheme disorder, fear of falling, or lack of insight into or awareness of disability. If the client’s perceived limits are greater than his or her actual limits, there is a risk for falls. In other cases, the client’s perceived limits are less than the actual limits. In such instances the client will not attempt

■ Box 33-1

Trunk Control Evaluation during Task Performance: Examples of Postural Adjustments That Support Participation in Chosen Activities

Feeding

Anterior weight shift occurs to bring the upper part of the body toward the table, to prevent spillage of food from utensils, and to support a hand-to-mouth pattern.

Dressing

Lateral weight shift to one side of the pelvis occurs so that pants and underwear can be donned over the hips.

Oral Care

Anterior weight shift occurs so that saliva and toothpaste may be expectorated.

Transfer

The trunk extends with concurrent hip flexion to initiate a sit-to-stand transition.

Meal Preparation

The trunk flexes into gravity in a controlled fashion to support a reach pattern to the lower shelf of the refrigerator.

more dynamic activities or will rely too greatly on adaptive equipment.

Treatment interventions aimed at increasing the client's ability to perform chosen tasks in seated postures include the following⁴⁵:

1. Establishing a neutral yet active starting alignment (i.e., a position of readiness to function). This starting alignment (similar to a typist's posture) is a prerequisite to engaging the limbs in an activity. The desirable posture is as follows:
 - Feet flat on the floor and bearing weight
 - Equal weight bearing through both ischial tuberosities
 - Neutral to slight anterior pelvic tilt
 - Erect spine
 - Head over the shoulders and shoulders over the hips
2. The client should attempt reaching activities from the above posture (Figure 33-4).
3. Establishing the ability to maintain the trunk in the midline by using external cues. Many clients have difficulty assuming and maintaining the correct posture. The therapist can provide verbal feedback (e.g., "sit up nice and tall"). Visual feedback (e.g., using a mirror or the therapist assuming the same postural misalignment as the client) may be helpful. Environmental cues may be used to correct the posture. For example, the client may be instructed to maintain contact between the shoulder and an external target such as a bolster or wall, positioned so that the trunk is in the correct posture.
4. Maintaining trunk range of motion (ROM) by wheelchair and armchair positioning that maintains the trunk in proper alignment. The therapist can provide an exercise program focused on trunk ROM and flexibility. Activities that elicit the desired

movement patterns can be chosen, and hands-on mobilization of the trunk can be used if needed.

Trunk ROM that should be addressed include flexion, extension, lateral flexion, and rotation.

5. Prescribing dynamic weight-shifting activities to allow practice of weight shifts through the pelvis. The most effective way to train the client in weight shifts is to coordinate the trunk and limbs. Randomized controlled trials have confirmed that sitting training protocols that involve practice reaching tasks beyond arm's length significantly improve function.³² Successfully engaging in meaningful occupations that require reach beyond the span of either arm requires clients to adjust their posture. The client is encouraged to reach beyond arm span in all directions while seated (preferably while reaching for an object) and to analyze the corresponding postural adjustment of the pelvis and trunk. The position and goal of the task will dictate the required weight shift (Table 33-4).
6. Strengthening the trunk, best achieved by tasks that require the client to control the trunk against gravity. Some examples are bridging the hips in the supine position to strengthen the back extensors and initiating a roll with the arm and upper part of the trunk to strengthen the abdominal muscles. Strengthening occurs within the context of an activity.
7. Using compensatory strategies and environmental adaptations when trunk control does not improve to a sufficient level and the client is at risk for injury. Examples of interventions include wheelchair seating systems (e.g., lateral supports, lumbar rolls, chest straps, tilt-in-space frames with head supports) and adaptive ADL equipment (e.g., reachers, long-handled equipment) to decrease the amount of required trunk displacement (see Chapter 10).

FIGURE 33-4 Normal and post-stroke sitting alignment.

On the floor, below the right hip

Right trunk shortening, left trunk elongation

Behind the right shoulder, at arm's length

Trunk extension and rotation (right side posteriorly)
Weight shift to the right

At shoulder level, to the left of the left shoulder

Trunk extension and rotation (left side posteriorly)
Weight shift to the left

■ **TABLE 33-4** | Effects of Object Positioning on Trunk Movements and Weight Shifts during Reaching Activities—cont'd

Position of Object	Trunk Response/Weight Shift
On floor, to left of left foot	Trunk flexion and rotation (left side posteriorly) Weight shift to the left
	
Above the head, directly behind	Trunk extension, shoulders move behind the hips Posterior weight shift
	

*These examples are for a patient with left hemiplegia. The left-hand column indicates where to position objects during a reaching task (with the right upper extremity). The right-hand column indicates the resultant trunk position and weight shift.

From Gillen G: Trunk control: supporting functional independence. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.

For Jasmine, therapy first focused on her ability to keep her trunk stable (i.e., not moving) while using her limbs to engage in occupations. Occupations that do not require substantial weight shifting while sitting (e.g., hair care, upper body washing, feeding, card playing) were chosen first, followed by those that required progressively more weight shifting in all directions (e.g., wiping after use of the toilet, lower body dressing, scooting, reaching to the floor to pick up shoes, washing her feet). As needed, the therapist provided external support at Jasmine's shoulders during these activities to increase her confidence, prevent falls, and provide necessary support to compensate for Jasmine's weakness. As Jasmine improved, more challenging seated activities were chosen and external support was diminished.

Inability to Engage in Chosen Occupations While Standing

An inability to assume and maintain a standing posture has a significant effect on the type of activities in which a person may engage; it may also play a significant role in the eventual discharge destination for a hospitalized client recovering from a stroke. Impaired upright control has been correlated with an increased risk for falls,¹⁰¹ as well as with less than optimal functional outcomes⁶⁶ on the Barthel Index. Because many BADLs and IADLs, work, and leisure skills require control of standing postures, early training in upright control is a necessary component of stroke rehabilitation programs. Postural strategies (e.g., ankle, hip, and stepping strategies) are typically impaired after a stroke.

Similar to the deficits seen while sitting, upright standing postures are characterized by asymmetric weight distribution; unlike deficits occurring while sitting, the weight distribution while standing is seen through the lower extremities,¹⁰¹ in addition to the trunk. Clients who sustained a stroke often experience an inability to bear weight through the affected leg. Reasons for this disability include fear of falling or buckling of the knee, patterns of weakness that will not support the weight of the body, spasticity impeding proper alignment (i.e., plantar flexion spasticity that effectively blocks weight bearing through the sole of the foot),⁴⁴ and perceptual dysfunction.

In addition to asymmetry and an inability to bear weight or shift weight through the affected leg, many clients who have sustained a stroke lose upright postural control and balance strategies. Effective upright control depends on the following automatic postural reactions^{36,84,85}:

1. Ankle strategies are used to maintain the center of mass over the base of support when movement is centered on the ankles. These strategies control small, slow, swaying motions such as standing in a movie line, engaging in conversations while standing, and stirring a pot on a stovetop. They are most effective when the support surface (e.g., floor) is firm and longer than the foot. Ankle weakness, loss of ankle ROM, and proprioceptive deficits may all contribute to ineffective ankle strategies and balance.
2. Hip strategies are used to maintain or restore equilibrium. These strategies are used specifically in response to larger, faster perturbations, when the support surface is compliant, or when the surface is smaller than the feet (e.g., walking on a beam).⁵³
3. A stepping strategy is used when ankle and hip strategies are ineffective or are perceived to be ineffective. This strategy results in movement of the base of support toward the center of mass movement. A step is taken to widen the base of support. Tripping over an uneven sidewalk or standing on a bus that unexpectedly stops elicits this strategy.

Both loss of postural reactions and an inability to bear and shift weight onto the affected leg will result in such functional limitations as gait deviations or dysfunction; an inability to climb stairs, transfer, and perform upright BADLs and IADLs; and an increased risk for falls. The assessment process provides the therapist with more specific information regarding the cause of the dysfunction. “Specifically, therapists should observe what happens when patients have to move their center of mass over their base of support, move their head, stand on uneven surfaces, function in lower lighting, move from one type of surface to another, or function on a narrower base of support. Therapists should also observe patients’ postural alignment, whether a bias in posture exists and in which direction that bias occurs, patients’ limits of stability, the width between

their feet during functional tasks, and what patients do after losing their balance.”³⁶

Treatment strategies aimed at improving the patient’s ability to perform chosen tasks in standing postures include the following^{36,84,101}:

1. Establishing a symmetric base of support and proper alignment to prepare to engage in occupations. This starting alignment is assumed to provide ample proximal stability and to support engagement in functional tasks. The therapist may use hands-on support or visual or verbal feedback to establish proper alignment as follows:
 - Feet approximately hip width apart
 - Equal weight bearing through the feet
 - Neutral pelvis
 - Both knees slightly flexed
 - Aligned and symmetric trunk
2. Establishing the ability to bear and shift weight through the more affected lower extremity.³⁶ The ability to bear weight may be graded at first. For example, if a client cannot assume a standing position because of postural insecurity or imbalance, sitting on a high surface (e.g., stool or raised therapy mat) allows the client to begin to bear weight but does not require bearing full body weight. As the client improves, full standing is encouraged, followed by graded weight shifts and progression to full weight bearing on the affected leg. For example, a modified soccer activity requires the client to fully shift weight to kick the ball. The environment (e.g., work surface height and placement of objects) is manipulated in conjunction with the client’s positioning to elicit the required weight shift.
3. Encouraging dynamic reaching activities in multiple environments to develop task-specific weight-shifting abilities. For example, kitchen activities that necessitate retrieval of cleaning supplies under the sink, in a broom closet, and in overhead cabinets require mastery of multiple postural adjustments and balance strategies.
4. Using the environment to grade task difficulty and provide external support. Proper use of the environment can decrease the client’s fear of falling and simultaneously improve confidence and challenge underlying balance skills. Examples include working in front of a high countertop, using one hand for bearing weight as a postural support, and using a walker for support. The client must not rely too much on external supports because balance strategies may not be fully challenged to reach optimal recovery.
5. Training upright control within the context of the functional tasks that are graded. Tasks are graded in relation to the length of required reach, speed, and progressively more challenging bases of support. Examples include making a bed, changing a pet’s food

FIGURE 33-5 Activity is positioned to elicit the desired postural strategies.

(From Donato SM, Pulaski KH: Overview of balance impairments: functional implications. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.)

bowl, setting a table, stepping up on a curb, cleaning a wall mirror, playing horseshoes or shuffleboard, and doffing slippers in a standing posture. All these activities require shifting of body weight, balance strategies, and the ability to bear weight through both lower extremities. The choice of activity is driven by the client's desires, and the therapist designs positioning and set-up of the activity to elicit the desired postural strategies (Figure 33-5).

Jasmine was quickly engaged in activities that required standing despite persistent issues related to sitting balance. Standing was first attempted in front of stable work surfaces (e.g., kitchen counter, sink) to provide a balance point, increase Jasmine's feeling of security and safety, and highlight the functional relevance of standing. As needed, the therapist stabilized the weak joints (e.g., hip and knee) with manual support, and Jasmine wore an ankle-foot orthotic to protect the integrity of her ankle. As Jasmine improved, she was asked to begin to use the upper part of her body for function while controlling her standing. Examples include wiping the counter, organizing a shelf, and grooming while standing. Progressively more demanding occupations from a standing balance perspective were chosen (e.g., modified games such as volleyball, vacuuming, emptying a dishwasher, stand-pivot transfers), and external manual and environmental support was decreased as Jasmine improved. All occupations were chosen to improve Jasmine's ability to accept and shift weight through her left lower extremity.

Inability to Communicate Secondary to Language Dysfunction

Stroke may result in a wide variety of speech or language disorders ranging from mild to severe. These deficits occur most frequently with stroke resulting from damage

to the left hemisphere of the brain. They can also occur less frequently after damage to the right hemisphere. All persons with stroke should be evaluated by a speech-language pathologist for the presence of speech and language disorders. The speech-language pathologist can provide valuable information to other members of the rehabilitation team and to the family regarding the best techniques for communicating with a particular client. The occupational therapist should continue the work of the speech therapist in the treatment sessions, as appropriate. Carryover may occur in reinforcing communication techniques that the client is learning and in presenting instruction in ways that the client is able to understand and integrate.⁸⁶

The specific speech and language dysfunctions described in the following sections can exist in mild to severe forms and in combination with one another.

Aphasia

Aphasia is an acquired communication disorder caused by brain damage that is characterized by impairment of language modalities: speaking, listening, reading, and writing; it is not the result of a sensory or motor deficit, a general intellectual deficit, confusion, or a psychiatric disorder.⁴⁹

Global Aphasia

Global aphasia is characterized by loss of all language skills. Oral expression is lost, except for some persistent or recurrent utterance. Global aphasia is usually the result of involvement of the MCA of the dominant cerebral hemisphere. A client with global aphasia may be sensitive to gestures, vocal inflections, and facial expression. Consequently, the client may appear to understand more than he or she actually does.

Broca's Aphasia

Poor speech production and agrammatism characterize Broca's aphasia. This aphasia is manifested as slow, labored speech with frequent misarticulations. Syntactic structure is simplified because of the agrammatism, sometimes referred to as telegraphic speech. A client with this form of aphasia demonstrates good auditory comprehension, except when speech is rapid, grammatically complex, or lengthy. Reading comprehension and writing may be severely affected, and a client with Broca's aphasia usually has deficits in monetary concepts and the ability to perform calculations.⁸⁶

Wernicke's Aphasia

Wernicke's aphasia is characterized by impaired auditory comprehension and feedback, along with fluent, well-articulated paraphasic speech. Paraphasic speech consists of word substitution errors. Speech may occur at an excessive rate and may be hyperfluent. The client uses few substantive words and many function words. The client produces running speech composed of English words in a meaningless sequence. English-speaking clients produce neologisms (non-English nonsense words) interspersed with real words. Reading and writing comprehension is often limited, and mathematic skills may be impaired.⁸⁶

Anomic Aphasia

Persons with anomic aphasia have difficulty in word retrieval. Anomia, or word-finding difficulty, occurs in all types of aphasia. However, clients in whom word-finding difficulty is the primary or only symptom may be said to have anomic aphasia. The speech of these clients is fluent, grammatically correct, and well articulated but accompanied by significant difficulty in word finding. This problem can result in hesitant or slow speech and the substitution of descriptive phrases for the actual names of things. Mild to severe deficits in reading comprehension and written expression occur, and mild deficits in mathematic skills may be present.^{2,86}

Dysarthria

Clients with dysarthria have an articulation disorder, in the absence of aphasia, because of dysfunction of the CNS mechanisms that control the speech musculature. This disorder results in paralysis and incoordination of the organs of speech, which causes the speech to sound thick, slurred, and sluggish.

Communication with Clients Who Have Aphasia

Although the speech-language pathologist is responsible for the treatment of speech and language disorders, the occupational therapist can facilitate communication and meaningful interaction with clients who have aphasia.

The use of gestures for communication should be encouraged. Having the client demonstrate through performance is the best way to ensure that the instructions are understood.

The occupational therapist can use routine ADLs as opportunities to encourage speech. The client should be reassured that the language disorder is part of the disability, not a manifestation of mental illness. Additional strategies for the occupational therapist to use with clients and their caregivers include the following:

- Understanding is facilitated when one person talks at a time. Extra noise creates confusion.
- Give the client time to respond.
- Carefully phrase questions to make it easier for the client to respond; for example, use "yes/no" and "either/or" questions.
- Use visual cues or gestures with speech to help the client understand.
- Never force a response.
- Use concise sentences.
- Do not rush communication because this may increase frustration and decrease the effectiveness of communication.⁸⁶

Given that Jasmine sustained a right hemispheric stroke, aphasia would not typically be expected. Jasmine did exhibit severe sensory motor loss related to her left oral structures. She had moderate dysarthria, occasional drooling, and difficulty managing food in the left side of her mouth. Jasmine was encouraged to speak slowly and overenunciate. In addition, her occupational therapist taught her safe feeding strategies, including eating slowly, alternating solids and liquids, shifting food to the right side of her mouth, tilting her head to the right at a 45-degree angle, using her finger to sweep her mouth and clear out food pocketing on the left, and performing supervised oral care after each meal.

Inability to Perform Chosen Occupations Secondary to Neurobehavioral/Cognitive-Perceptual Impairments

A neurobehavioral deficit is defined as "a functional impairment of an individual manifested as defective skill performance resulting from a neurologic processing dysfunction that affects performance components such as affect, body scheme, cognition, emotion, gnosis, language, memory, motor movement, perception, personality, sensory awareness, spatial relations, and visuospatial skills."⁶ A major responsibility of the occupational therapist treating a client who has sustained a stroke is evaluating which neurobehavioral deficits are blocking independent performance of chosen occupations.

Arnadottir⁶ proposed a relationship among the ability to perform daily activities, neurobehavioral impairments, and the CNS origin of the neurobehavioral dysfunction (a stroke, for the purposes of this chapter). She supports this theory with the following relational statements:

1. Behaviors required for task performance are related to neuronal processing at the CNS level. Therefore, a relationship also exists between the defective

behavioral responses of an individual with CNS damage during performance of ADLs and the dysfunction of neuronal processing and performance components resulting from the CNS damage.

2. Performance of daily activities requires adequate function of specific parts of the nervous system. Consequently, CNS impairment may result in dysfunction of specific aspects of ADLs. For example, a stroke caused by a lesion of the posteroinferior parietal lobe of the left hemisphere commonly results in bilateral motor apraxia. “This neurobehavioral impairment may make manipulation of objects difficult during functional activities such as combing hair, brushing teeth, or holding a spoon while eating.”⁶
3. Neurologic impairment can be observed through the client’s engagement in daily activities. Thus, by analysis of ADLs, the integrity of the CNS can be evaluated (Box 33-2).

To properly evaluate the effect of neurobehavioral deficits on task performance, the therapist must develop activity analysis skills with the goal of analyzing which components of performance are necessary to achieve an outcome that is satisfactory to the client. Even the simplest of BADL tasks challenges multiple underlying skills (Boxes 33-3 and 33-4; also see Figure 33-3).^{6,79}

Arnadottir^{6,7} proposed a system of observing clients engaged in functional activities in which errors are allowed to occur (as long as they are safe), the errors are analyzed, and finally, impairments that are interfering with performance of tasks are detected so that an appropriate treatment plan can be developed. She cautioned that when the therapist analyzes errors and observed behavior, knowledge of neurobehavior, cortical function, activity analysis, and clinical reasoning must be considered in the results of the evaluation (Table 33-5).

Treatment aimed at counteracting the effects of neurobehavioral dysfunction may be based on an adaptive and compensatory approach or on a restorative and remedial approach.^{47,70,72,79} A combination of approaches has also been suggested (Table 33-6).¹

Decisions regarding the selection of a particular treatment approach may be difficult. Neistadt^{71,72} suggested evaluating a client’s learning potential in the context of ADL evaluation and training, with a focus on such issues as the number of repetitions needed to learn new approaches to tasks and the type of transfer of learning that is demonstrated.

Toglia⁹¹ has suggested that transfer of learning from one context to another (e.g., transferring skills learned from making a cup of tea in the OT clinic to meal preparation at home) may be facilitated by the therapist through the following methods:

1. Varying treatment environments
2. Varying the nature of the task

Box 33-2

Toothbrushing Task: Treatment of Neurobehavioral Impairments

Spatial Relationships and Spatial Positioning

- Positioning of the toothbrush and toothpaste while applying paste to the brush
- Placement of the toothbrush in the mouth
- Positioning of bristles in the mouth
- Placement of the brush under the faucet

Spatial Neglect

- Visual search for and use of the brush, paste, and cup in the affected hemisphere
- Visual search for and use of the faucet handle in the affected hemisphere

Body Neglect

- Brushing of the affected side of the mouth

Motor Apraxia

- Manipulation of the toothbrush during task performance
- Manipulation of the cap from the toothpaste
- Squeezing of toothpaste onto the brush

Ideational Apraxia

- Appropriate use of objects (e.g., brush, paste, cup) during a task

Organization and Sequencing

- Sequencing of the task (e.g., removal of the cap, application of paste to the brush, turning on the water, putting the brush in the mouth)
- Continuation of task to completion

Attention

- Attention to the task (to increase difficulty, distractions such as conversation, flushing the toilet, or running water may be added)
- Refocusing on the task after the distraction

Figure-Ground

- Distinguishing a white toothbrush and toothpaste from the sink

Initiation and Perseverance

- Initiation of the task on command
- Cleaning parts of the mouth for an appropriate period, then moving the bristles to another part of the mouth
- Discontinuation of the task when complete

Visual Agnosia

- Use of touch to identify objects

Problem Solving

- Search for alternatives if the toothpaste or toothbrush is missing

Box 33-3

Examples of Environmental and Task Manipulation to Challenge Component Skills during Meal Preparation

Spatial Neglect

Place ingredients in both visual fields.
Choose a task that requires use of the right and left burners.

Figure-Ground

Place necessary utensils in a cluttered drawer.
Use utensils that match the color of the counter.

Spatial Dysfunction

Prepare items that require the client to pour ingredients from one container to another (e.g., pour pasta into a bowl or fill a pot with water).

Motor Apraxia

Choose recipes that require manipulation of food items.
Choose recipes that require control of distal extremity adjustments (e.g., using a ladle, whisking, and stirring).

Box 33-4

Sample Compensatory Strategies for Neurobehavioral Deficits Affecting Dressing Skills

Spatial Neglect

Place necessary clothing on the right side of the closet and drawers.
Move the dresser to the right side of the room.

Motor Apraxia

Use loose-fitting clothing without fasteners.
Use Velcro closures.

Spatial Dysfunction

Use shirts with a front emblem to identify proper orientation.
Lay out clothing in the proper orientation.

TABLE 33-5 | Evaluating the Effect of Neurobehavioral Dysfunction on Task Performance

Performance Area	Observed Behavior	Possible Impairment
Grooming	Difficulty adjusting grasp on a razor or toothbrush Using a comb to brush the teeth Repetitive brushing of one side of the mouth	Motor apraxia Ideational apraxia Premotor perseveration
Feeding	Not eating food on the left side of the plate Overestimating or underestimating distance to the glass, thereby resulting in knocking over the glass “Forgetting” that a glass of orange juice is in the hand, which results in spillage as the client attends to another aspect of the meal Hand placed in the cereal bowl	Spatial neglect Spatial relationship dysfunction Body neglect
Dressing	Client attempting to put socks on after sneakers Client unable to locate armholes in an undershirt Dressing only the right side of the body Client attempting to dress the therapist’s arms instead of his or her own	Organization and sequencing dysfunction Spatial relationship dysfunction Body neglect Somatognosia
Mobility	Client unable to locate the bathroom in his or her hospital room Client neglecting to lock the brakes or remove the wheelchair footrests before attempting to transfer After a transfer, only the intact buttock in contact with the seat of the chair	Topographic disorientation Organization and sequencing dysfunction Body neglect

■ **TABLE 33-6** | Treatment Approaches for Neurobehavioral Deficits after Stroke

Compensatory and Adaptive Approach	Restorative and Remedial Approach	Combination Approach
Repetitive practice of tasks	Restoration of component skills	Rejects dichotomy between compensatory and restorative approaches
Top-down approach	Bottom-up approach	Uses optimally relevant occupations and environments as the treatment modality to challenge components
Emphasizes intact skill training	Deficit specific	Choice of treatment driven by tasks relevant to client needs; tasks presented so that the underlying deficits are challenged via the task
Emphasizes modification	Targets cause of symptoms and emphasizes components	Rejects use of contrived activities
Uses environmental or task modifications to support optimal performance	Assumes that transfer of training will occur	
Choice of activity driven by performance challenges, not by component deficits	Assumes that improved component performance will result in increased skill	
Treats symptoms, not the cause	Choice of activity driven by component deficits	
Client-driven compensatory strategies	Research demonstrates short-term results with skills generalizable to very similar tasks	
Caregiver-therapist environmental adaptations		
Task specific and not generalizable		

3. Helping clients become aware of how they process information
4. Teaching processing strategies
5. Relating new learning to previously learned skills

Toglia⁹¹ has identified degrees of transfer of learning. The degree of transfer is defined by the number of task characteristics that differ from those of the original task. Examples of these characteristics are spatial orientation, mode of presentation (e.g., auditory or visual), movement requirements, and environmental context.

A near transfer of learning involves transfer between two tasks that have one or two differing characteristics. Intermediate transfer involves transfer of learning to a task that varies by three to six characteristics. A far transfer involves a task that is conceptually similar but has one or no characteristics in common. Finally, a very far transfer involves the “spontaneous application of what has been learned in treatment to everyday living.”⁹¹

From her review of the literature, Neistadt⁷⁰ reached the following conclusions:

1. Near transfer from remedial tasks to similar tasks is possible for all clients with brain injury.
2. Intermediate, far, and very far transfer from remedial to functional tasks will occur only in clients with localized brain lesions and good cognitive skills and after training with a variety of treatment tasks.
3. Far and very far transfer from remedial to functional tasks will not occur in clients with diffuse injury and severe cognitive deficits.

Using a functional and meaningful task as a treatment modality promotes the acquisition of a desired skill, and the therapist may use this task to challenge multiple underlying impairments.^{1,47,79} It is up to the therapist to present the

task by manipulating the environment in a way that challenges the underlying skills (see Box 33-3). If a compensatory approach is chosen, adaptive techniques are used to counteract the effects of the underlying neurobehavioral deficits (see Box 33-4).

Jasmine’s left-sided neglect had a substantial impact on her ability to perform relevant occupations independently and safely. A variety of strategies were used to improve her ability to attend to the left side. Organized visual scanning was taught during daily activities such as feeding and grooming. Occupations were chosen that required scanning to both the left and the right to be successful (e.g., finding ingredients in the refrigerator, locating the toothbrush on the left side of the sink and toothpaste on the right, reading, describing a room). Vanishing physical and verbal cues were used as Jasmine progressed. Another strategy that was helpful for Jasmine was the use of a left-sided anchor. A red strip of tape was placed on the left side (e.g., the left side of the computer monitor, placemat, sink, book), and Jasmine focused on scanning to the anchor to ensure that she was attending to all of the information required to be successful at performing each occupation. Because Jasmine’s neglect persisted, driving was not an option. Other modes of transportation were considered, including supervised use of public transportation, assistance with transport by friends and neighbors, and local access-a-ride companies. See Chapters 11, 25, and 26.

Inability to Perform Chosen Tasks Secondary to Upper Extremity Dysfunction

Loss of UE control is common after a stroke, with 88% of clients who sustained a stroke having some level of UE dysfunction.⁷⁴ The client’s ability to integrate the affected arm into chosen tasks may be limited by multiple factors, including the following⁴⁶:

1. Pain
2. Contracture and deformity
3. Loss of selective motor control
4. Weakness²¹
5. Superimposed orthopedic limitations
6. Loss of postural control to support UE control
7. Learned nonuse⁸⁷
8. Loss of biomechanical alignment²⁴
9. Inefficient and ineffective movement patterns

Integration into Function

UE evaluation procedures should focus primarily on assessing the client’s ability to integrate the UE into the performance of functional tasks—in other words, to use the affected UE to support performance in areas of occupation. Standardized evaluations such as the Test d’Evaluation des Membres Supérieurs de Personnes Agées (TEMPA),^{34,35} Arm Motor Ability Test (AMAT),⁶⁰ Jebsen Test of Hand Function,⁵⁴ and AMPS⁴⁰ (see Table 33-3) are available to objectively measure the client’s ability to use the affected extremity during performance of tasks. In addition, self-reported measures of UE function are recommended. Examples include the following:

1. The Motor Activity Log is a self-reported questionnaire (reported by the patient or family) related to actual use of the involved UE outside structured therapy time. It uses a semistructured interview format. Quality of movement (“how well” scale) and the amount of use (“how much” scale) are graded on a six-point scale. At present, there are 30-, 28-, and 14-item versions of the tool. Sample items include holding a book, using a towel, picking up a glass, writing/typing, and steadying oneself.^{96,97}
2. The 36-item Manual Ability Measure (MAM-36) is a new Rasch-developed, self-reported disability outcome measure. It contains 36 gender-neutral, commonly performed everyday hand tasks. The patient is asked to report the ease or difficulty of performing such tasks. It uses a four-point rating scale, with 1 indicating “unable” (I am unable to do the task all by myself), 2 indicating “very hard” (it is very hard for me to do the task and I usually ask others to do it for me unless no one is around), 3 indicating “a little hard” (I usually do the task myself, although it takes longer or more effort now than before), and 4 indicating “easy” (I can do the task without any problem). The MAM-36 can be accessed.²⁸ A look-up table from raw scores to converted 0 to 100 Rasch measures is available.²⁷

The UE may be used during functional performance in different ways (Table 33-7), including but not limited to the following⁴²:

1. Weight bearing or accepting partial body weight through a limb. Weight bearing through the hand and

TABLE 33-7 | Suggestions for Categorizing Upper Extremity Tasks

Category	Tasks
No functional use of the arm	Teach shoulder protection Self range of motion Positioning
Postural support/ weight bearing (forearm or extended arm)	Bed mobility assistance Support upright function (e.g., work, leisure, activities of daily living) Support during reach with the opposite hand Stabilize objects
Support reach (hand on a work surface)	Wiping a table Ironing Polishing Sanding Smoothing out laundry Applying body lotion Washing body parts Vacuuming Locking wheelchair brakes
Reach	Multiple possibilities to engage the upper extremity in activities of daily living, leisure, and mobility; grade tasks by height/distance reached, weight of object, speed, and accuracy

From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.

forearm with an extended elbow is a pattern used during ADLs and mobility tasks. Establishment of weight bearing is a goal of UE rehabilitation.¹⁶ Effective control of weight bearing depends on the presence of sufficient trunk and scapula stability to accept partial body weight, control of active elbow extension, and ability of the hand to bear weight without losing the palmar arches. Once weight bearing is established, the client can effectively use the arm as a postural support (e.g., by supporting upper body weight with the affected arm while wiping crumbs from the table with the more functional arm), as an aid during transitional movements (e.g., while pushing up from lying on the side to sitting), and for preventing falls (increased postural support is provided).⁴⁶

2. Moving objects across a work surface with a static grasp (supported reach). Activities such as ironing clothes, opening or closing a drawer, polishing furniture, and sliding a paper across the table are all examples of UE control of movement that does not occur with the arm in space. The hand is in contact with the objects involved in the task or is supported on the work surface; therefore, these types of tasks do

not require the same control as and may require less effort than activities performed while the client is reaching in space, such as removing dishes from a cabinet or reaching for food in the refrigerator. This movement pattern can be used for multiple tasks and at the same time strengthens the various muscle groups used to eventually support reach in space.⁴⁶

3. Reach and manipulation. Reviews of research on UE motor control^{2,46} have identified two components of function during reaching activities. The first is the transportation component, which is defined as the trajectory of the arm between the starting position and the object. The second is the manipulation component, which is the formation of grip by combined movements of the thumb and index finger during arm movement. Finger posturing anticipates the real grasp and occurs during transportation of the hand toward the object.² Shaping of the hand is independent of the manipulation itself. Trombly's reaching studies of clients with left hemiparesis documented that the ability to reach smoothly and with coordination was significantly less on the affected than on the unaffected side.⁹⁴ The continuous movement strategy was lost, movement time was longer, peak velocity occurred earlier, and weakness indicators were present.

Trombly⁹³ demonstrated that although muscular activity did not improve in the clients in her study, the discontinuity improved over time. She stated that the "level and pattern of muscle activity of these subjects depended on the biomechanical demands of the task rather than any stereotypical neurological linkages between the muscles."

Clients are commonly observed demonstrating the use of stereotypic movement patterns of the UE. These patterns are characterized by scapula elevation and fixation, humeral abduction, elbow flexion, and wrist flexion. Mathiowetz and Bass Haugen⁶⁸ suggested that the use of these movement patterns is evidence of attempts to use the remaining systems to complete tasks. They gave an example of a client with weak shoulder flexors trying to lift an arm. The client flexes the elbow when trying to raise the arm because this movement strategy shortens the lever arm and eases shoulder flexion.

The following are examples of using treatment activities to improve the client's ability to integrate the UE into tasks^{2,24,44,46,80,85}:

1. Using objects of different sizes and shapes to encourage control of the hand during reach and manipulation
2. Choosing activities that are appropriate to the client's level of available motor control
3. Using constraint-induced movement techniques (Box 33-5): techniques in which the less affected UE is constrained (e.g., with a sling and splint or similar device) to compel use of the affected extremity,

Box 33-5

Summary of Constraint-Induced Movement Therapy

- Use to counteract learned nonuse. Hypothesized causes of learned nonuse include therapeutic interventions implemented during the acute period of neurologic suppression after a stroke, an early focus on adaptations to meet functional goals, negative reinforcement experienced by patients as they unsuccessfully attempt to use the affected limb, and positive reinforcement experienced by using the less involved hand and/or successful adaptations.
- Motor inclusion criteria. Control of the wrist and digits is necessary to engage in this type of intervention. Current and past protocols have used the following inclusion criteria: 20 degrees of extension of the wrist and 10 degrees of extension of each finger; 10 degrees of extension of the wrist, 10 degrees of abduction of the thumb, and 10 degrees of extension of any two other digits; or the ability to lift a washrag from a table using any type of prehension and then release it.
- Main therapeutic factor. Massed practice and shaping of the affected limb during repetitive functional activities appear to be the therapeutic change agents. "There is thus nothing talismanic about use of a sling or other constraining device on the less-affected limb."
- Choices of activity and the therapist's interventions. Select tasks that address the motor deficits of the individual client, assist clients in carrying out parts of a movement sequence if they are incapable of completing the movement on their own at first, provide explicit verbal feedback and verbal reward for small improvements in task performance, use modeling and prompting of task performance, use tasks that are of interest and motivational to the patient, ignore regression of function, and use tasks that can be quantified related to improvements.
- Outcome measures. The Motor Activity Log (actual use outside of structured therapy or "real-world use"), Arm Motor Ability Test, Wolf Motor Function Test, and Action Research Arm Test have been used to document outcomes.
- Cortical reorganization. Constraint-induced movement therapy is the first rehabilitation intervention that has been demonstrated to induce changes in the cortical representation of the affected upper limb.
- The continued rigorous research that has been and continues to be carried out to demonstrate the effectiveness or efficacy of constraint-induced movement therapy should be used as a "gold standard" for other rehabilitation interventions that are used traditionally (e.g., neurodevelopmental therapy) but have little or no research support.
- On the basis of available evidence, constraint-induced movement therapy appears to be an effective intervention for those living with stroke and who have learned nonuse and fit the motor inclusion criteria.

From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.

FIGURE 33-6 The task is designed to elicit the desired motor pattern; the purpose of the task drives the motor output.

(From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.)

thereby providing massed practice of graded activities for the affected side to increase functional use⁸³

4. Specifically training the arm to be used in weight bearing, reach, and manipulation situations within the context of ADLs and mobility
5. Presenting the client with graded tasks related to the number of degrees of freedom, the level of antigravity control required, and the resistance involved in the task (Figure 33-6).

Jasmine had very little motor activity throughout her left UE. Therapy focused on having Jasmine position her

arm correctly (on the work surface and within her sight lines) during activities to prevent it from dangling all day, as well as use her arm as a stabilizer (e.g., using the weight of her arm to stabilize a paper while writing or holding a book open). As Jasmine improved, she was encouraged to use her arm in weight bearing as a postural support (e.g., pushing up when transitioning from the supine position to a seated position, pushing up to stand, reaching back to sit, and using the arm as support when standing at a sink or counter). Occupations were chosen that matched her available motor control and challenged her current level.

Upper Extremity Complications after Stroke

Subluxation

Subluxation, or malalignment caused by instability of the glenohumeral joint, is a common occurrence after stroke. The subluxation may be inferior (head of the humerus below the glenoid fossa), anterior (head of the humerus anterior to the fossa), or superior (head of the humerus lodged under the acromion-coracoid).⁸⁰ Cailliet²⁴ and Basmajian¹¹ described the mechanism of inferior subluxation, in which the humeral head drifts inferior to the glenoid fossa. This common subluxation occurs as a result of malalignment of the scapula and the trunk. The normal position of the scapula is one of upward rotation, an orientation that cradles the head of the humerus and stabilizes it in alignment. The weight of the arm combined with instability and malalignment contributes to subluxation.

A common misunderstanding about subluxation is that it is associated with pain. The literature does not support this relationship.¹⁰³ Because the shoulder is unstable after a stroke, care must be taken to support the flail shoulder in bed (e.g., using pillows to maintain alignment), in a wheelchair (e.g., with lap boards or pillows), and in the upright position (e.g., putting the hands in a pocket or taping the shoulder). Treatment to reduce subluxation should focus on achieving trunk alignment and scapula stability in a position of upward rotation.⁸⁰

Abnormal Skeletal Muscle Activity

A change in the resting state of the limb and postural muscles is common after stroke.¹⁶ Immediately after a stroke, a change in available, or resting, skeletal muscle activity occurs. Most commonly, the acute state is characterized by low tone (“low-tone stage”). During this low-tone stage, the limbs and trunk become increasingly influenced by the pull of gravity. Little or no muscle activity is available at this stage, thereby resulting in deviations from the normal resting alignment of the musculoskeletal system.

An inability to recruit and maintain muscle activity is generally the greatest limiting factor at this stage. Because of the generalized lack of muscle activity and the dependent nature of the trunk and limbs, secondary problems can occur,⁴⁴ including the following:

1. Edema affecting the dorsal surface of the hand and pooling under the extensor tendons, thereby effectively blocking active or passive digit flexion
2. Overstretching of the joint capsule of the glenohumeral joint
3. Eventual shortening of muscles that are passively positioned in an effort to support a weak limb (Commonly, flaccid UEs are positioned in the client's lap, on a pillow, on a lap tray, or in a sling. Although they support the arm, these static positions result in prolonged positioning of certain muscle groups [internal rotators, elbow flexors, and wrist flexors] in a shortened position, which places them at risk for mechanical shortening. Interestingly, these are the muscle groups that tend to become spastic as time progresses.)
4. Overstretching of the antagonists to the previously mentioned muscles
5. Risk of joint and soft tissue injury during ADLs and mobility tasks (Because of the lack of control associated with a low-tone stage, the arm dangles and is not positioned appropriately during dynamic activities. Common examples include an arm being caught in the wheel during wheelchair mobility, pinning of the arm during bed mobility or rest, sitting on the arm after a transfer, or weight bearing through a flexed wrist during engagement in self-care activities.)

Progression to a state of increased or excessive skeletal muscle activity (increased tone), such as clonus, stereotypic posturing of the trunk and limbs, hyperactive stretch reflexes, and increased resistance to passive limb movements that are dependent on velocity, may occur within several days or months of the stroke.⁴⁴

As spasticity increases, the risk for soft tissue shortening is heightened. This factor may lead to a vicious circle of spasticity to soft tissue shortening to over-recruitment of shortened muscles to increased stretch reflexes. Secondary problems that may occur if the spasticity is not managed in a therapy program include the following⁴⁴:

1. Deformity of the limbs, specifically the distal end of the upper limb (elbow to digits)
2. Maceration of palm tissue
3. Possible masking of underlying selective motor control
4. Pain syndromes resulting from loss of normal joint kinematics (These syndromes are usually related to soft tissue contracture that blocks full joint excursion. A typical example is loss of full passive external rotation of the glenohumeral joint. Attempts at forced abduction in these cases will result in a painful impingement syndrome of the tissues in the subacromial space.)
5. Impaired ability to manage BADL tasks, specifically UE dressing and bathing of the affected hand and axilla when flexor posturing is present
6. Loss of reciprocal arm swing during gait activities

Prevention of Pain Syndromes and Contracture Protection of Unstable Joints

During the low-tone stage, joints tend to become malaligned secondary to loss of muscular stabilization. In these cases, clients are at risk for injury to unstable joints (e.g., traction injuries and joint trauma) because of the joint instability. The glenohumeral and wrist joints are particularly at risk. The glenohumeral joint (usually already inferiorly subluxated at this stage) is at risk for a superimposed orthopedic injury if another individual unknowingly pulls on the affected arm during self-care and mobility or during unskilled passive range of motion (PROM) of the joint. The unstable glenohumeral joint is in a malaligned state, which puts the client at risk for an impingement syndrome during PROM if normal joint mechanics is not addressed. Key joint motions of concern are upward rotation of the scapula and external (lateral) rotation of the shoulder. If these motions are not present and ROM is forced, the client is at risk for the development of an impingement and pain syndrome.⁴⁴

Clients with low tone also have an unstable wrist. Care should be taken to protect the wrist if the clients are not controlling the joint during ADL and mobility tasks. Clients commonly practice a bed mobility or lower extremity dressing sequence and then complete the task while bearing weight through a malaligned flexed wrist. These clients are at risk for orthopedic injury (traumatic synovitis) and may be considered candidates for splinting to protect the wrist.⁴⁶

Maintaining Soft Tissue Length

Clients who have both increased and decreased skeletal muscle activity are at risk for soft tissue contracture secondary to the immobilization that occurs during both low-tone and increased-tone stages. Maintenance of tissue length is a 24-hour regimen. It involves frequent variations in resting postures during waking hours, teaching the client and significant others appropriate ROM procedures, daytime and nighttime positioning programs, and staff and family education so that positioning and exercise programs may be carried out in the home environment.⁴⁴

Prolonged static positioning (e.g., prolonged use of a sling) must be avoided. Rather, teaching clients to adjust their resting postures during the day will help prevent soft tissue tightness.

Positioning Programs

The same wheelchair- and bed-positioning programs should not be applied to every client. Instead, positioning should be individualized and focus on (1) promoting normal resting alignment of the trunk and limbs in an effort to maintain tissue length on both sides of the joints (2) providing stretch to muscle groups that have been identified as being prone to contracture or already shortened, and (3) placing particular focus on maintaining passive external rotation of the shoulder.³

Soft Tissue Elongation

If soft tissue shortening and length-associated changes have already developed, the treatment of choice is low-load prolonged stretch (LLPS). LLPS involves placing the soft tissues in question on submaximal stretch for prolonged periods. This technique is quite different from the common PROM with terminal stretch (high-load brief stretch) programs commonly used to treat this population.⁶⁹

LLPS can be implemented in various ways, including splinting, casting, and positioning programs. For example, during a UE assessment a client is noted to have tightness in the internal rotators, overactive internal rotation during attempts to move, and weakened external rotators. An effective LLPS program would involve having the client rest in a supine position with the arm abducted to 45 degrees and in external rotation. This position has been shown to decrease the potential for contracture.³

LLPS can also be achieved through splinting programs. A common example is the use of a splint designed to elongate the long flexors of the hand during sleeping hours.

Splinting

Commonly a controversial subject in the management of stroke, splinting should be considered on a case-by-case basis and may be quite effective for many clients.⁶⁹ The most common uses for splints during the low-tone stage are for maintaining joint alignment, protecting the tissues from shortening or overstretching, preventing injury to the extremity, and serving as an adjunctive treatment to control edema.⁶⁹ Specifically, splinting support may be needed to provide palmar arch support and maintain neutral wrist deviation and a neutral position of the wrist between flexion and extension. In most cases the fingers do not require splinting in this stage of recovery.⁶⁹

Splints may also be effective for clients in whom spasticity is developing. In these cases the splints may be used to maintain soft tissue length, provide LLPS, place muscles at their resting lengths on both sides of the joints, and attempt distal relaxation by promoting proximal alignment.⁶⁹

Client Management

In addition to the interventions already described, it is helpful to train the client to manage his or her UE. For a client with low tone, the most important information to share with the client and significant others is the method for protecting the unstable joints and maintaining full ROM. In the spastic stage, the treatment of choice is to teach positioning that will provide prolonged elongation of the overactive muscles and prevent contracture. Examples of positions that may be prescribed during leisure or self-care activities include the following⁴⁴:

1. Weight bearing on the extended arm (elongates the commonly shortened UE musculature)

2. In the supine position, hands behind the head while allowing the elbows to drop toward the bed (provides stretch of the internal rotators)
3. In the supine position, a pillow protracting the scapula and under the elbow to promote glenohumeral joint alignment
4. Lying on a protracted scapula to maintain stretch of the retractors and scapulothoracic mobility
5. Supporting the involved wrist with the more functional hand and reaching down toward the floor with both hands (This pattern will elongate muscles that tend to contract during difficult activities, which is particularly helpful after gait activities or difficult self-care activities.)
6. Cradling the affected arm with the stronger arm, lifting it to chest level, and gently raising and lowering (staying below 90 degrees) and gently abducting or adducting the arm (Figure 33-7).
Cautionary note: Clasp the hands and lifting the affected arm overhead should be discouraged because of the risk for increasing pain, causing an impingement syndrome, and stressing the carpal ligaments (Figure 33-8). Similarly, overhead pulleys should be avoided.

The keys to prescribing a proper resting posture are to identify muscle groups in the trunk and upper limb that are shortening, overactive, or at risk for the development of shortening and to select a comfortable posture that elongates the muscle group for a prolonged period.

Jasmine and her family were taught appropriate positioning when in bed and on chairs and during upright activities. In addition, Jasmine learned how to safely perform self-ROM exercises and was provided with a resting hand splint at night.

The Nonfunctional Upper Extremity

Although restoration of UE control is a realistic goal for some clients, many clients will not regain enough control to integrate the affected UE into ADL and mobility tasks. Clients who will not regain sufficient control require extensive retraining in BADLs and IADLs⁷⁴ (see Chapter 10) with one-handed techniques and prescription of appropriate assistive devices (Box 33-6). Persons in this population are also candidates for dominance retraining. Control of deformity to prevent body image issues is paramount for these clients.

Inability to Perform Chosen Tasks Secondary to Visual Impairment

Processing of visual information is a complex act that requires intact functioning of multiple peripheral nervous system and CNS structures to support functional independence. The site of the lesion determines the visual dysfunction and the effect on performance of tasks (Figure 33-9).⁷

Visual dysfunction and its treatment are detailed in Chapter 24. In general, treatment approaches may focus on

FIGURE 33-7 “Rock the baby.” The client lifts the right upper extremity to chest level (A), adducts (B), and abducts (C) horizontally to allow trunk rotation.

(From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.)

Box 33-6

Examples of Assistive Devices Used after Stroke to Improve Task Performance

- Rocker knife
- Elastic laces and lace locks
- Adapted cutting board
- Dycem
- Plate guards
- Pot stabilizer
- Playing card holder
- Suction devices to stabilize mixing bowls, cleaning brushes

remediation, such as eye calisthenics, fixations, scanning, visual motor techniques, and bilateral integration. Adaptive techniques are also used, including a change in working distance, the use of prisms, adaptations for driving and reading, changes in lighting, and enlarged print.⁸²

Psychosocial Adjustment

The psychologic consequences of a stroke are substantial. The incidence of depression in this population is 35% according to statistics collected by the American Heart Association.⁴ The highest reported incidence is found in clients in acute and rehabilitation hospitals, and the lowest is in samples of those living in the community following

FIGURE 33-8 Because of multiple biomechanical concerns (e.g., impingement), self-overhead range of motion is discouraged.

(From Gillen G: Upper extremity function and management. In Gillen G, editor: *Stroke rehabilitation: a function-based approach*, ed 3, St Louis, Mo, 2011, Mosby.)

stroke. Other psychologic manifestations that have been documented in survivors of stroke include anxiety, agoraphobia, substance abuse, sleep disorders, mania, aprosody (difficulty expressing or recognizing emotion), behavioral problems (e.g., sexual inappropriateness, verbal outbursts, aggressiveness), lability (alteration between pathologic laughing and crying), and personality changes (e.g., apathy, irritability, social withdrawal).³⁹

A critical role of the occupational therapist is to help the client adjust to hospitalization and, more important, to disability. Much patience and a supportive approach by the therapist are essential. The therapist must be sensitive to the fact that the client has experienced a devastating and life-threatening illness that has caused sudden and dramatic changes in the client's life roles and performance. The therapist must be cognizant of the normal adjustment process and must gear the approach and expectations of performance to the client's level of adjustment. Frequently, the client is not ready to engage in rehabilitation measures with wholehearted effort until several months after onset of the disability.

Family education is extremely important throughout the treatment program. Family members are better equipped to assist their loved one in adjusting to disability when they are knowledgeable about the disability and its implications.

Many clients dwell on the possibility of full recovery of function; they should gradually be made aware that some

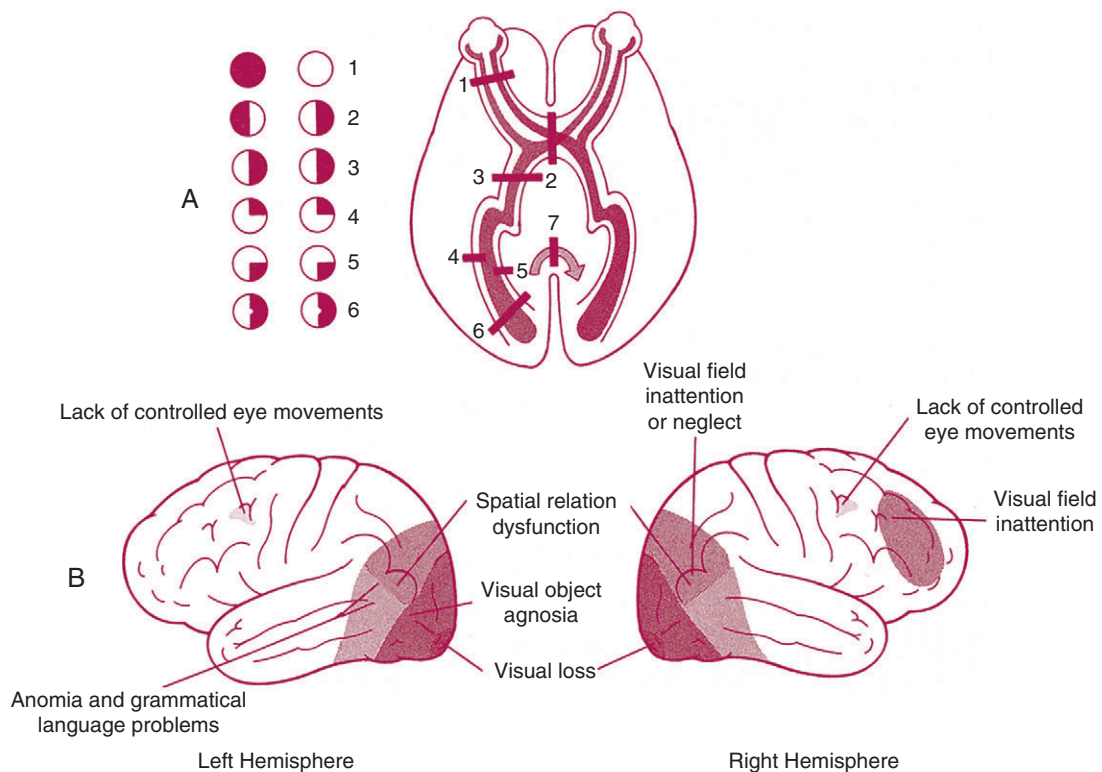

FIGURE 33-9 Visual-processing deficits.

(From Arnadottir G: *The brain and behavior: assessing cortical dysfunction through activities of daily living*, St Louis, Mo, 1990, Mosby.)

residual dysfunction is likely. The therapist may approach this probability by discussing in objective terms what is known about the prognosis for functional recovery after stroke. It may be necessary to review this information many times before the client begins to apply it to his or her recovery. This education should be done in a way that is honest and yet does not destroy all hope.

Falk-Kessler³⁹ has provided occupational therapists with guidelines related to interventions for the psychologic manifestations of stroke, including the following:

- Fostering an internal locus of control related to recovery
- Using therapeutic activities to improve self-efficacy or confidence in the performance of specific activities
- Promoting the use of adaptive coping strategies, such as seeking social support, information seeking, positive reframing, and acceptance
- Promoting success in chosen occupations to improve self-esteem
- Encouraging social support networks, such as families, friends, or support groups
- Using occupations to promote social participation

In addition to the aforementioned interventions, it is important to remember that pharmacologic interventions have been shown to be effective in this population and should not be overlooked³⁹ as part of a team approach. Such interventions include but are not limited to antidepressants for depression or for individuals with a pathologic affect, benzodiazepines for generalized anxiety disorder, and neuroleptic medications for those with post-stroke psychosis.²⁶

The OT program should focus on the skills and abilities of the patient. The patient's attention should be focused, through the performance of activity, on his or her remaining and newly learned skills. The OT program can also include therapeutic group activities for socialization and sharing of common problems and their solutions. The discovery that there are residual abilities and perhaps new abilities and success at performing many daily living skills and activities that were initially thought to be impossible can improve the patient's mental health and outlook.

Summary

Stroke is a complex disability that challenges the skills of professional health care workers. Although the number and effectiveness of approaches for the remediation of affected motor, sensory, perceptual, cognitive, and performance dysfunctions have increased considerably, many limitations in treatment remain. The occupational therapist must bear in mind that the degree to which the patient achieves treatment goals depends on the CNS damage and recovery, psychoneurologic residuals, psychosocial adjustment, and the skilled application of appropriate treatment by all concerned health professionals.

Some patients remain severely disabled despite the noblest efforts of rehabilitation workers, whereas others recover quite spontaneously with minimal help in a short period. Most patients benefit from the professional skills of occupational therapists and other rehabilitation specialists and achieve improvement of performance skills and resumption of meaningful occupational roles.

Jasmine demonstrated a clear relationship between her impaired body functions (e.g., loss of motor control, sensory loss, visual dysfunction, and neglect) and her ability to return to her previous lifestyle and engage in chosen areas of occupation. Through standardized assessments and skilled observation made while Jasmine was performing her chosen occupations of feeding, grooming, toilet transfers, computer use, and child care it was determined that several impairments were affecting Jasmine's ability to perform independently:

- Feeding: Jasmine was unable to cut or open containers secondary to unilateral UE weakness on the left, she had a tendency to eat only the food on the right side of her plate, and she was unable to locate utensils on the left side of the plate. In addition, food remained between her left gums and cheek ("pocketing") after meals, thereby resulting in oral hygiene issues and putting Jasmine at risk for aspiration.
- Grooming: Jasmine had difficulty opening and applying toothpaste with one hand. She attended only to the right side of her body while grooming, with the left side of her mouth and hair not being cared for during oral and hair care.
- Toilet transfers: Jasmine required moderate physical assistance to transfer to the toilet secondary to an inability to bear weight on her left leg and an inability to control her trunk (she falls laterally when sitting on the toilet). The occupational therapist also noted that when Jasmine "completed" the transfer to the toilet, only the right side of her body was sitting on the toilet. She neglected to include the left side of her body in the transfer and left it in the wheelchair.
- Computer use: During attempts to use the computer, Jasmine became easily frustrated and made comments such as "I feel like a failure" and "I can't even provide for my child anymore." Jasmine agreed to attempt to write a letter to her friend on the computer. Multiple mistakes were noted because Jasmine seemed to "not see" the left-sided keys, could not control the shift keys, and generally appeared disorganized in her approach to the task.
- Simulated child care: A weighted doll was used to observe Jasmine's ability to care for her child. It was quickly decided that this area of occupation would be deferred until Jasmine's status improved. Jasmine and her occupational therapist made this decision collaboratively on the basis of safety concerns and Jasmine's

emotional status. Jasmine was gravely concerned about her ability to care for her child. The occupational therapist wanted to focus on occupations that Jasmine could master, build her confidence, and upgrade her occupations systematically according to Jasmine's abilities.

The above findings were determined based on the initial assessment choices. The first assessment administered was the COPM.^{62,63} Because multiple areas of occupation are limited after a stroke, it is imperative to use a tool such as this to determine the client's priorities for intervention. These priorities then in turn become the client's initial goals. In addition, the FIM55 and the A-ONE⁶⁻⁹ were used to objectify limitations in daily function and to determine limiting factors. The FIM is typically used in inpatient rehabilitation settings and documents the level of caregiver burden related to BADLs and mobility. The A-ONE is complementary to the FIM and determines the reasons for lack of independence by evaluating client factors that result in errors in occupational performance by skilled observations of tasks performed in natural contexts.

Several interventions were considered to address Jasmine's inability to participate in chosen occupations (toilet transfers, computer use, grooming, feeding, and child care). Task-specific training of grooming, feeding, and toileting served as the basis for her initial OT. A system of vanishing physical and verbal cues was used as Jasmine relearned the tasks at hand. Jasmine had substantial motor loss in her left limbs, thus making training with adaptive equipment imperative. Examples included a rocker knife and Dycem for feeding and a grab bar and raised toilet seat. To ensure continued integration of her affected upper limb, Jasmine was taught to use her left limb as a stabilizer during tasks. She was also taught to keep her arm positioned on a surface and in her line of sight. A strategy that was used to help Jasmine overcome her neglect was use of a perceptual anchor. In addition to her left arm being positioned on the left side of a surface, a strip of red tape was placed on the left edge of work surfaces (e.g., on the table to the left of her place setting and on the left side of the sink). As Jasmine gained mastery of these tasks, task-specific training of work tasks via similar strategies was introduced.

Review Questions

1. Define stroke and list two of its causes.
2. List the disturbances that can result from occlusion of the MCA, ACA, PCA, and cerebellar arteries.
3. Name three modifiable risk factors associated with stroke.
4. Define TIA.
5. Name three functional deficits that occur as a result of loss of trunk control.
6. Besides paralysis of the limbs and trunk after stroke, what important motor disturbances can result?

7. Name two components of a "client-centered approach" to evaluation.
8. What are two frames of reference used to treat neurobehavioral impairments after stroke?
9. Name three postural reactions that support standing activities.
10. How does aphasia differ from dysarthria?

■ Learning Objectives *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the pathology underlying traumatic brain injury (TBI).
2. State current medical, surgical, and pharmaceutical interventions for acute TBI.
3. Identify levels of consciousness in individuals with TBI by using standard scales.
4. Describe the clinical picture of individuals with TBI, including common physical, cognitive, and psychosocial sequelae.
5. Identify occupational therapy evaluation methods for lower-, intermediate-, and higher-level individuals with TBI.
6. Identify several standard occupational therapy assessments for physical, cognitive, and psychosocial impairment after TBI.
7. Describe occupational therapy intervention methods for lower-, intermediate-, and higher-level individuals with TBI.
8. Describe the continuum of care services available for an individual with TBI in the acute, subacute, and postacute stages of rehabilitation.

Introduction and Epidemiology

Traumatic brain injury (TBI) is defined as damage to brain tissue caused by an external mechanical force with resultant loss of consciousness, post-traumatic amnesia, skull fracture, or objective neurologic findings that can be attributed to the traumatic event on the basis of radiologic findings or physical or mental status examination.^{25,68,73} It is the most common cause of death and disability in young people.²⁵ More than 50,000 Americans die; 235,000 are hospitalized and 1.1 million are treated and released from an emergency

department. The number of people with TBI who are not seen in an emergency department or who receive no care is unknown. The direct and indirect costs of TBI in the United States have been estimated to be in excess of \$60 billion annually.¹⁰ Survivor costs account for more than \$31 billion, and fatal brain injuries cost another \$16.6 billion.^{74,82} The Centers for Disease Control and Prevention estimates that at least 5.3 million Americans currently have a long-term or lifelong need for help to perform activities of daily living (ADLs) as a result of TBI.⁹

The etiology of TBI is closely associated with age and gender. Children younger than 5 years tend to be injured

 **Case Study**
Marisol

Marisol is an 18-year-old Hispanic woman who sustained a severe brain injury as an unrestrained passenger in a sport utility motor vehicle accident. Marisol was a high school graduate who lived with her boyfriend and worked as a waitress. A computed tomography scan of her head showed a basilar skull fracture and diffuse subdural hematoma. Approximately 2 weeks after injury she was transferred to an acute rehabilitation unit to participate in a journey-to-recovery program, which is designed for patients whose progress is expected to be slower than that of typical acute care patients. This is determined by the extent of the injury; typically, these clients are determined to be at a Rancho Los Amigos level II or III.

Results of the occupational therapy evaluation indicated that Marisol was dependent for all mobility and daily activities of living secondary to deficits in motor and process skills. She also displayed significant deficits in various client factors. Her right upper extremity had full active and passive range of motion with minimal ataxia in all joints. Her left upper extremity had decreased range of motion at her shoulder, elbow, and wrist. Severe spasticity was noted throughout her left upper extremity. Marisol was alert and able to visually attend and track. She was nonverbal and being fed through a gastrointestinal tube. When positioned at the edge of the bed, she required total assistance to maintain a sitting position, including support of her head and trunk. She did not display sitting balance.

Occupational therapy was initiated to foster Marisol's ability to engage in self-care and some instrumental activities of daily living by accomplishing the following: (1) improve left upper extremity range of motion, (2) decrease spasticity in her left upper extremity, (3) improve functional use of her right upper extremity to facilitate participation in self-care tasks, (4) improve head and trunk control to allow her to sit upright in a wheelchair, (5) participate in bed mobility and transfers, and (6) improve cognition such that Marisol could participate in a self-care and self-feeding program, as well as communicate with others.

Critical Thinking Questions

1. How should Marisol's injury be characterized?
2. What is her cognitive state?
3. How might Marisol's progress be measured?
4. How will her various problems be treated?

in falls, in motor vehicle crashes, and by adults inflicting violence. Those between the ages of 5 and 15 are also injured on bicycles, skateboards, and horses; as pedestrians; and during sports activities. Between the ages of 15 and 40, high-speed motor vehicle and motorcycle crashes are the most common causes of TBI. After the age of 40, the incidence of violence-related injury approaches that of motor vehicles, particularly in metropolitan areas.

Young and middle-aged adult men are 1.5 times more likely to be injured than their female counterparts. The two age groups at highest risk for TBI are 0- to 4-year-olds and 15- to 19-year-olds.⁹ Elderly individuals are injured just as often by a fall or during a pedestrian mishap as they are in motor vehicles accidents.^{21,46} Blasts are a leading cause of TBI in active duty military personnel in war zones.⁹

Nontraumatic brain injuries include toxicity from drug overdose, chronic substance abuse, carbon monoxide poisoning, or environmental exposure; anoxia from cardiopulmonary arrest or near-drowning; brain abscess, meningitis, and encephalitis from bacteria, viruses, acquired immunodeficiency syndrome, fungi, or parasites; nutritional deficiencies; genetic and congenital disorders; chronic epilepsy; and degenerative diseases such as dementia.⁴⁹

Although the aforementioned conditions often have characteristics similar to those resulting from TBI (particularly with regard to rehabilitation approaches), this chapter's primary focus is assessment of and intervention for individuals with traumatic injury.

Substance abuse is strongly linked to TBI and many nontraumatic causes. Use of alcohol close to the time of injury is prevalent in more than 50% of adults with TBI.⁴¹ An even greater number of individuals have a previous history of alcohol or other substance abuse in the year preceding the injury. As defined by the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, substance abuse is defined as follows: (1) failure to fulfill major role obligations at work, school, or home; (2) use in situations in which it is physically hazardous; (3) substance-related legal problems; or (4) continued use despite having persistent or recurrent social or interpersonal problems related to use.^{3,17,41,47} Therefore, knowledge of the acute and chronic sequelae of substance abuse disorders is crucial in assessing and treating individuals with brain injuries.

Recovery from any type of brain injury depends on the patient's age and preinjury capabilities, the severity of the injuries incurred, and the quality of intervention and support available during the patient's recovery. Recurrent brain injury is unfortunately all too common and occurs in those who have previously sustained trauma, have developmental disabilities, or have acquired disabilities associated with other causes.

Prevention of secondary complications is critical throughout all stages of the recovery process: at the time that the person is resuscitated (i.e., at the site of injury), in acute medical care settings, during acute and postacute rehabilitation programs, and when the individual is trying to reintegrate into his or her family and community. Many of the available medical and therapeutic interventions target these secondary complications. A well-coordinated team of knowledgeable professionals, family members, and supportive community caregivers can optimize the outcome for a given individual.¹²

Pathophysiology

Neuropathologists and neurosurgeons currently categorize the early stages of TBI as primary (occurring at the moment of impact) and secondary (occurring in the days to several weeks after the injury). Prevention of primary injury includes the use of safety belts, protective helmets, air bags, and roadside barriers, all of which can minimize the impact of the initial injury-causing agent. Prevention of secondary injury typically begins at the point of contact with those providing first aid at the scene of the trauma. It continues with emergency medical services, resuscitation and transport, and acute medical and surgical management and carries over to rehabilitation settings. It is particularly the secondary interventions that will be discussed later in the section on medical interventions. An individual with TBI will typically have some combination of primary focal and diffuse brain injury, depending on the cause and mechanism of the initial injury; in best-case scenarios, there is a minimal amount of secondary brain damage and functional disability that occurs as a result of brain swelling, hypotension, hypoxia, and systemic injury. Prompt recognition of these complications improves survival and functional outcome when an appropriate intervention is implemented.²⁵

Focal Brain Injury

Focal brain injury is caused by a direct blow to the head after collision with an external object or fall, a penetrating injury resulting from a weapon, and collision of the brain with the inner tables of the skull. The bones of the face or skull may or may not be fractured. Common findings in individuals with focal injury resulting from falls include intracerebral and brain surface contusions, particularly in the inferior and dorsal-lateral frontal lobes, anterior and medial temporal lobes, and less commonly, the inferior cerebellum. Assaults and missile wounds can occur anywhere in the brain depending on the direction of force. Other surface areas of the brain, including those not directly below the blow to the head, can also suffer contusions as a result of collision of the brain with the inner tables of the skull. The directly injured area is referred to as the coup, and the site of the indirect injury is known as the contrecoup.^{29,30}

If there are injuries to the coverings of the brain, especially the dura, pia, and arachnoid, other focal hemorrhages occur. Epidural hematomas (EDHs) are associated with skull fractures in adults with disruption of the integrity of the meningeal arteries; children may have arterial disruption with or without a skull fracture. Individuals with an EDH may initially be alert after the blow to the skull; as the hematoma develops between the skull and the dura, it can cause pressure on underlying brain tissue (secondary injury) with rapid deterioration in mental and physical status. Prompt recognition and neurosurgical treatment can save lives and limit morbidity.³⁶

Subdural hematomas (SDHs) occur between the dura and the brain surface through tearing of bridging veins. The rate of hemorrhage is often slower than that of an EDH because venous bleeding is more gradual than arterial. An SDH may occur just as frequently on the side of the head opposite the direct blow; therefore, an EDH can occur on one side of the brain adjacent to the trauma and an SDH on the other. SDHs tend to spread around the entire surface of one hemisphere or less commonly in the posterior fossa. Acute SDH is diagnosed within 48 hours of injury, subacute SDH within 2 to 14 days after injury, and chronic SDH after 2 weeks. The fall or blow to the head in individuals with subacute or chronic SDH may have occurred days before the person arrives at the hospital, with symptoms being typical of changes in mental status. The urgency of treating SDH depends on the clinical condition of the individual and the extent of adjacent brain tissue affected as observed on radiology.⁶⁷

Multifocal and Diffuse Brain Injury

With multifocal and diffuse brain injuries, there may be sudden deceleration of the body and head with variable forces transmitted to the surface and deeper portions of the brain. Motor vehicle, bicycle, and skateboard crashes are typical etiologic factors, but falls from a high surface or off a horse or bull can also result in multifocal and diffuse injuries.

Intracerebral hemorrhage (ICH) is nearly always present as a focal injury with missile wounds and is common after falls and assaults. Within the first week after TBI, particularly in clients with blood-clotting abnormalities, ICH may appear on follow-up computed tomography (CT) scans. With high-speed deceleration injury, multiple small, deep ICHs occur throughout the neuraxis; on high-resolution CT or magnetic resonance imaging (MRI), they are typically visible at the junction between gray and white matter and in the basal ganglia, corpus callosum, midbrain, and/or cerebellum.

Subarachnoid hemorrhage (SAH) and intraventricular hemorrhage (IVH) occur when the pia or arachnoid is torn. SAH caused by trauma is less frequently associated with vasospasms than is SAH caused by rupture of an aneurysm. A large IVH can block the flow of cerebrospinal fluid (CSF) and result in acute hydrocephalus. Thus, clinical evaluation of the possibility of a ruptured aneurysm causing brain dysfunction, which may result from a fall or motor vehicle crash, is important with either of these entities.

Diffuse axonal injuries (DAIs) are prototypic lesions caused by rapid deceleration. The degree of injury may vary from primary axotomy, with complete disruption of the nerve, to axonal dysfunction, wherein the structural integrity of the nerve remains intact but there is loss of ability to transmit normally along neuronal pathways. The clinical severity of DAI is measured by the depth and length of coma (i.e., the time from onset of the injury until the

individual performs purposeful activity) and associated signs such as pupillary abnormalities.⁴⁷

Prevention of Secondary Brain Injuries

The brain, like any body tissue, reacts to injury with swelling or edema, neurochemical injury cascades, changes in blood flow, and inflammation. Unlike other tissues, the brain is confined in a closed container, the skull, which protects it from outside injury but also confines the amount of swelling or blood accumulation that can occur. The brain is also the organ least able to tolerate loss of blood flow or oxygen. Secondary injury occurs as a result of the effects of brain swelling in a closed space, loss of perfusion, and decreased delivery of oxygen to healthy and damaged tissue. Recovery is related to the extent of the initial pathology and secondary injury.²⁵

Guidelines for the management of severe TBI to minimize the impact of secondary injury have been developed over the last 10 years by the American Association of Neurological Surgeons (AANS) and the Brain Trauma Foundation. Some of these areas include resuscitation of blood pressure and oxygenation, management of elevated intracranial pressure (ICP) or hypertension, nutrition after acute trauma, and seizure prophylaxis. These care recommendations are based on a critical review of the available literature on the management of individuals with TBI and are categorized into the following groups: *standards*, which represent a high degree of clinical certainty; *guidelines*, which represent a moderate degree of clinical certainty; and *options*, which represent a low degree of clinical certainty.¹¹ Each of these terms—standards, guidelines, and options—are used as labels for forms of intervention in individuals who have sustained a TBI.

Areas of intervention that are considered standards are relatively few and relate to interventions that may be more harmful than helpful. They include the following:

- In the absence of increased ICP, chronic prolonged hyperventilation should be avoided.
- Steroids are not recommended to reduce ICP.
- Prophylactic anticonvulsants are not recommended for preventing late (i.e., after the first week) post-traumatic seizures (PTSS).

Guidelines, which have a moderate degree of certainty regarding efficacy, include the following for individuals with severe TBI: (1) all regions should have an organized trauma care system; (2) hypotension (systolic blood pressure <90 mm Hg) or hypoxia (apnea, cyanosis, oxygen saturation <90% in the field, or a Pao₂ of 60 mm Hg) must be monitored and corrected immediately; (3) ICP monitoring is appropriate for injuries in individuals younger than 40 years with a systolic blood pressure lower than 90 mm Hg, with Glasgow Coma Scale (GCS) scores between 3 and 8, or when CT scans show hematomas, contusions, edema, or compressed basal cisterns; (4) intervention should be initiated to lower ICP if it exceeds 20

to 25 mm Hg; (5) effective ICP treatments include mannitol, high-dose barbiturate therapy, ventriculostomy for drainage of CSF, and craniectomy (i.e., removal of portions of the skull to allow external brain swelling [bone flap]); and (6) enteral or parenteral nutritional support at 140% of the basal rate in nonparalyzed and 100% in paralyzed individuals, with 15% of calories provided as protein within 7 days of TBI.

PTSS are classified as immediate when they occur during the first 24 hours after injury, early when they occur during the first 7 days, and late after the first 7 days. Prophylactic treatment with phenytoin or carbamazepine during the first week after TBI is an intervention option recognized by both the AANS and the American Academy of Physical Medicine and Rehabilitation. Both organizations recognize that the efficacy of prophylactic treatment diminishes greatly after the first week and thus recommend discontinuation of anticonvulsant medication as standard treatment after the first week.^{10,11} If late PTSS develop, treatment is warranted because the reoccurrence rate is greater than 80%.³³ All patients and caregivers should learn recognition of and first aid for seizures, as well as risk modification. Avoidance of alcohol, street drugs, and prescribed medications that lower the seizure threshold is important for clients recovering from TBI. The groups at highest risk are those with penetration of metal and bone into the brain substance, biparietal contusions, multiple intracranial operations, and any injury that causes more than a 5-mm lateral shift on CT.²⁰

Implementation of the aforementioned standards and guidelines more typically takes place in designated trauma centers, where physicians, nurses, and allied health providers are accustomed to treating large numbers of individuals with TBI. Studies in both academic and community hospital settings have shown that morbidity and mortality can be reduced appreciably by following the AANS guidelines.⁵⁹

After survival from the initial injury, ongoing optimal medical and health management can facilitate an individual's recovery and ability to participate in his or her own rehabilitation. Early detection and prompt management of sleep and mood disorders, pain, hydrocephalus, heterotopic ossification, and endocrinopathies, which are all common sequelae of TBI, must be addressed. Medical therapeutic interventions should be based on behavioral, cognitive, and functional performance factors that are observable and measurable by members of a rehabilitation team.

Coma and Levels of Consciousness

A TBI typically results in an altered level of consciousness. The continuum of consciousness includes coma at one end and conscious awareness at the opposite end. After a brain injury, an individual's progression along this continuum of consciousness depends on age; previous health status;

Case Study Dewayne

Dewayne, an 18-year-old with multiple cerebral contusions, has right arm and leg tremors with intentional movement and severe rigidity. He also has increased tone in his left arm and leg. He is dependent for all self-care and mobility.

After baseline evaluation conducted over a period of 2 days, both occupational and physical therapists note that the tremors increase with any voluntary movement. Medication is introduced to reduce the tremors, and feedback is provided to the prescribing physician regarding Dewayne's performance of self-care activities and bed mobility. Over the next 2 weeks, Dewayne can use his right hand to wipe his face with minimal assistance, which takes 10 seconds, and his medication dose is tapered, with no worsening of the tremor. Meanwhile, the flexor tone on his left side is increasing, especially at the elbow; this prevents progress in upper body dressing. A temporary musculocutaneous nerve block with bupivacaine results in increased ability to extend his left arm so that dressing now requires only moderate assistance; the next day, a phenol nerve block is performed at the therapist's suggestion for longer-term relief of the elbow flexion tone.

This intervention is directed toward a focal area of difficulty for the patient, which is his ability to use his left arm for upper body self-care. Alternative interventions include systemic tone-reducing medications, which may have adverse side effects, or inhibitive casting of the elbow, which may help but makes the limb less useful while casted.

severity of the injury; and the methods of medical, therapeutic, and environmental management.

Consciousness is a state of environmental awareness and self-awareness. Coma involves the absence of awareness of self and the environment despite maximal external stimuli. No periods of wakefulness occur in the coma state.⁶⁰ When sedating and hypnotic medications are discontinued, the coma rarely lasts more than 4 weeks. When the coma resolves, the person becomes either partially aware of self and the environment ("minimally conscious") or, if no awareness is present, "vegetative."

The GCS has been the traditional method used by health care professionals to assess levels of consciousness after TBI (Table 34-1). The GCS has been used to quantify the severity of brain injury and predict outcome. The three behavioral areas assessed in the GCS are motor responses, verbal responses, and eye opening. The most reliable is the motor score; when it reaches 5, which signifies a purposeful response to pain, such as pushing away noxious stimuli, or 6, which represents an ability to follow simple commands, the injured individual is no longer in a coma or vegetative state. This is an important landmark in recovery from TBI.⁷⁴

The vegetative state is most succinctly described as wakefulness without awareness. A person in a vegetative state has the following characteristics: (1) no awareness of self or the environment and an inability to interact with others; (2) no sustained, reproducible, or voluntary behavioral responses to sensory stimuli; (3) no language comprehension or

■ TABLE 34-1 | Glasgow Coma Scale

Examiner's Test		Individual's Response	Assigned Score
Eye opening	Spontaneous	Opens eyes on own	4
	Speech	Opens eyes when asked to in a loud voice	3
	Pain	Opens eyes when pinched	2
	Pain	Does not open eyes	1
Best motor response	Commands	Follows simple commands	6
	Pain	Pulls examiner's hand away when pinched	5
	Pain	Pulls a part of body away when pinched by examiner	4
	Pain	Flexes body inappropriately to pain (decorticate posturing)	3
	Pain	Body becomes rigid in an extended position when examiner pinches victim (decerebrate posturing)	2
	Pain	Has no motor response to pinch	1
Verbal response (talking)	Speech	Carries on a conversation correctly and tells examiner where and who he or she is and the month and year	5
	Speech	Seems confused or disoriented	4
	Speech	Talks so examiner can understand but makes no sense	3
	Speech	Makes sounds that examiner can't understand	2
	Speech	Makes no noise	1

From Rosenthal M: *Rehabilitation of the head-injured adult*, Philadelphia, Pa, 1984, FA Davis.

expression; (4) sleep-wake cycles of variable length; (5) ability to regulate temperature, breathing, and circulation to permit survival with routine medical and nursing care; (6) incontinence of bowel and bladder; and (7) variably preserved cranial nerve and spinal reflexes. A persistent vegetative state refers to a condition of past and continuing disability with an uncertain future; the typical onset is within 1 month of a traumatic or nontraumatic brain injury or after a month-long metabolic or degenerative condition. The condition may improve and the client may achieve a minimally conscious state (MCS) over time. If the client does not improve, the term permanent vegetative state is appropriate and signifies that the chance of regaining consciousness before death is exceedingly small.⁷¹ Recovery of consciousness is rare for individuals in a persistent vegetative state 12 months after a TBI or 3 months after a nontraumatic brain injury.⁷²

Practice parameters regarding the care of individuals in a persistent vegetative state indicate that appropriate diagnosis of the condition is crucial; a physician with experience in this area should participate in the determination. Once the diagnosis is established, the prognosis should be explained in detail to the family, surrogates, and caregivers. Appropriate care respects the individual's comfort, hygiene, and dignity. Careful observation of any signs of emergence to MCS is important in determining the intensity of therapeutic interventions. Positioning and other interventions to manage tone and prevent contractures should be included. The amount of extraordinary care will be guided by the advanced directives or presumed directives supplied by the patient's surrogate.⁶²

Many individuals emerge from a persistent vegetative state to MCS in which there is definite behavioral evidence of awareness of self, environment, or both. Clearly discernible, reproducible behavior in one or more of the following areas must be demonstrated: (1) ability to follow commands, (2) gestural or verbal yes/no responses (regardless of accuracy), (3) intelligible verbalizations, and (4) purposeful movements or affective responses that are appropriate reactions to environmental stimuli. Examples include reaching for objects; touching or holding objects and accommodating for their size and shape; engaging in eye pursuit movements or sustained fixation in direct response to stimuli; and smiling, crying, vocalizing, or gesturing in response to relevant stimuli. Convenient ways to assess for MCS are to test an individual with situational orientation questions (e.g., "Are you standing? Are you in a chair?") and giving the individual an object of common use, such as a washcloth or comb, and seeing whether the patient tries to use it. Testing for MCS should occur in a quiet environment when the patient is alert (i.e., not under sedating medication or in a physical position that encourages inattention). Requested commands should not exceed the patient's physical capabilities and not involve reflexive movements.²⁶ Serial assessment tools are available that can be useful for measuring the cognitive progress of individuals in MCS, such as

■ **TABLE 34-2** | Duration of Post-traumatic Amnesia and Severity of Injury

PTA Duration	Severity
Less than 5 min	Very mild
5 to 60 min	Mild
1 to 24 hr	Moderate
1 to 7 days	Severe
1 to 4 weeks	Very severe
More than 4 weeks	Extremely severe

the JFK Coma Recovery Scale (JFK), Wessex Head Injury Matrix (WHIM), Coma–Near Coma Scale, Sensory Stimulation Assessment Measure, and the Western Neuro Sensory Stimulation Profile.^{14,57}

Another important landmark in recovery is post-traumatic amnesia (PTA), which is probably the single best measurable predictor of functional outcome in the research literature (Table 34-2). PTA is the length of time from the injury to the moment when the individual regains ongoing memory of daily events. Some evidence suggests that the duration of PTA is highly correlated with individual outcomes. Longer PTA is associated with poorer long-term cognitive and motor abilities and a decreased ability to return to work and school. PTA lasting 4 weeks or longer is correlated with significant long-term disability.⁵³ Measurement of PTA is performed with the Galveston Orientation and Amnesia Test or the Orientation Log.⁴⁸ The latter test is easier to administer to individuals with moderate to severe TBI in which the examiner may not know the details of circumstances that took place immediately before the injury and in which the injured individual has begun to remember events.^{39,48}

The Rancho Los Amigos Scale of Cognitive Functioning is a descriptive measurement of levels of awareness and cognitive function.⁶³ Progression through the various levels occurs most typically with traumatic injuries. However, the recovery curve of some individuals who are very severely injured may actually skip a level, typically Rancho IV, an agitated confused state. Others may never be as low as Rancho level I or II but may be agitated and confused for several weeks (Rancho IV). These individuals may experience periods during which they also function at Rancho V or VI levels. Thus, this scale can be helpful to treating staff and family members in designing specific behavioral interventions for a given patient. Box 34-1 contains a complete description of the scale.

Box 34-1

Rancho Los Amigos Levels of Cognitive Functioning

Level I. No response. The individual appears to be in a deep sleep and is completely unresponsive to any stimuli presented to him or her.

Level II. Generalized response. The individual reacts inconsistently and nonpurposefully to stimuli in a nonspecific manner. Responses are limited in nature and are often the same, regardless of the stimulus presented. Responses may be physiologic changes, gross body movements, or vocalization. Often, the earliest response is to deep pain. Responses are likely to be delayed.

Level III. Localized response. The individual reacts specifically but inconsistently to stimuli. Responses are directly related to the type of stimulus presented, as in turning the head toward a sound or focusing on an object presented. The individual may withdraw an extremity or vocalize when presented with a painful stimulus. He or she may follow simple commands in an inconsistent, delayed manner, such as closing the eyes, squeezing, or extending an extremity. After the external stimulus is removed, the individual may lie quietly. He or she may also show a vague awareness of self and body by responding to discomfort by pulling at a nasogastric tube or catheter or resisting restraints. The individual may show bias by responding to some persons (especially family, friends) but not to others.

Level IV. Confused, agitated. The individual is in a heightened state of activity with a severely decreased ability to process information. He or she is detached from the present and responds primarily to his or her own internal confusion. Behavior is frequently bizarre and nonpurposeful relative to the immediate environment. The individual may cry out or scream out of proportion to the stimuli even after removal and may exhibit aggressive behavior, attempt to remove restraints or tubes, or crawl out of bed in a purposeful manner. The individual does not, however, discriminate among persons or objects and is unable to cooperate directly with treatment effort. Verbalization is frequently incoherent and inappropriate to the environment. Confabulation may be present; the individual may be euphoric or hostile. Thus, gross attention is very short and selective attention is often nonexistent. Being unaware of present events, the individual lacks short-term recall and may be reacting to past events. He or she is unable to perform self-care (e.g., feeding and dressing) without maximal assistance. If not disabled physically, the individual may perform motor activities such as sitting, reaching, and ambulating, but as part of the agitated state and not as a purposeful act or on request.

Level V. Confused, inappropriate, nonagitated. The individual appears alert and is able to respond to simple commands fairly consistently. However, with increased complexity of commands or lack of any external structure, responses are nonpurposeful, random, or at best fragmented toward any desired goal. The individual may exhibit agitated behavior, not on an internal basis (as in level IV) but rather as a result of external stimuli and usually out of proportion to the stimuli. He or she has gross attention to the environment but is highly distractible and lacks the ability to

focus attention on a specific task without frequent redirection back to it. With structure, the individual may be able to converse on a social, automatic level for short periods. Verbalization is often inappropriate; confabulation may be triggered by present events. Memory is severely impaired, with confusion of past and present in his or her reaction to ongoing activity. The individual lacks initiation with regard to functional tasks and often shows inappropriate use of objects without external direction. He or she may be able to perform previously learned tasks when they are structured for him or her, but the individual is unable to learn new information. He or she responds best to self, body, comfort—and often family members. The individual can usually perform self-care activities with assistance and may accomplish feeding with maximal supervision. Management on the ward is often a problem if the individual is physically mobile because he or she may wander off either randomly or with the vague intention of going home.

Level VI. Confused, appropriate. The individual shows goal-directed behavior but is dependent on external input for direction. The response to discomfort is appropriate, and the individual is able to tolerate unpleasant stimuli (e.g., nasogastric tube) when the need is explained. The individual follows simple directions consistently and shows carryover for tasks that have been relearned (such as self-care). He or she is at least supervised with old learning but is unable to maximally assist in new learning with little or no carryover. Responses may be incorrect because of memory problems, but they are appropriate to the situation. Responses may be delayed, and the individual shows a decreased ability to process information with little or no anticipation or prediction of events. Past memories have more depth and detail than recent memory. The individual may show beginning awareness of his or her situation by realizing that he or she doesn't know an answer. The individual no longer wanders and is inconsistently oriented to time and place. Selective attention to tasks may be impaired, especially with difficult tasks and in unstructured settings, but the individual is now functional for common daily activities (30 minutes with structure). He or she shows at least vague recognition of some staff members and has increased awareness of self, family, and basic needs (e.g., food), again in an appropriate manner, in contrast to level V.

Level VII. Automatic, appropriate. The individual appears appropriate and oriented within the hospital and home settings and goes through the daily routine automatically but is frequently robot-like. The individual exhibits minimal to absent confusion but has shallow recall of what he or she has been doing. He or she shows increased awareness of self, body, family, foods, people, and interaction in the environment. The individual has superficial awareness of but lacks insight into his or her condition, demonstrates decreased judgment and problem solving, and lacks realistic planning for the future. He or she shows carryover for new learning, but at a decreased rate. He or she requires at least minimal supervision for learning and for safety purposes

■ Box 34-1

Rancho Los Amigos Levels of Cognitive Functioning—cont'd

and is independent in self-care activities and supervised in home and community skills for safety. With structure the individual is able to initiate tasks in social and recreational activities in which he or she now has interest. Judgment remains impaired such that the individual is unable to drive a car. Prevocational or avocational evaluation and counseling may be indicated.

Level VIII. Purposeful and appropriate. The individual is alert and oriented, is able to recall and integrate past and recent events, and is aware of and responsive to his or her culture. He or she shows carryover for new learning if it is acceptable to him or her and his or her life role. The individual needs no supervision after activities are learned within his or her physical capabilities. He or she is independent in home and community skills, including driving. Vocational rehabilitation, to determine ability to return as a contributor to society (perhaps in a new capacity), is indicated. The individual may continue to show decreased ability, relative to premorbid abilities, in reasoning, tolerance for stress, judgment in emergencies, or unusual circumstances. His or her social, emotional, and intellectual capacities may continue to be at a decreased level but are functional for society.

The following additional Rancho Los Amigos levels are used at some outpatient facilities to identify higher-functioning clients.

Level IX. Purposeful, appropriate: stand-by assistance on request

- Independently shifts back and forth between tasks and completes them accurately for at least 2 consecutive hours.
- Uses assistive memory devices to recall daily schedule and “to do” lists and to record critical information for later use with assistance when requested.
- Initiates and carries out steps to complete familiar personal, household, work, and leisure tasks independently and unfamiliar personal, household, work, and leisure tasks with assistance when requested.
- Aware of and acknowledges impairments and disabilities when they interfere with task completion and takes appropriate corrective action but requires stand-by

assistance to anticipate a problem before it occurs and take action to avoid it.

- Able to think about the consequences of decisions or actions with assistance when requested.
- Accurately estimates abilities but requires stand-by assistance to adjust to task demands.
- Acknowledges others' needs and feelings and responds appropriately with stand-by assistance.
- Depression may continue.
- May be easily irritable.
- May have low tolerance for frustration.
- Able to self-monitor appropriateness of social interaction with stand-by assistance.

Level X. Purposeful, appropriate: modified independent

- Able to handle multiple tasks simultaneously in all environments but may require periodic breaks.
- Able to independently procure, create, and maintain own assistive memory devices.
- Independently initiates and carries out steps to complete familiar and unfamiliar personal, household, community, work, and leisure tasks but may require more than the usual amount of time and/or compensatory strategies to complete them.
- Anticipates impact of impairments and disabilities on ability to complete daily living tasks and takes action to avoid problems before they occur but may require more than the usual amount of time and/or compensatory strategies.
- Able to independently think about the consequences of decisions or actions but may require more than the usual amount of time and/or compensatory strategies to select the appropriate decision or action.
- Accurately estimates abilities and independently adjusts to task demands.
- Able to recognize the needs and feelings of others and automatically respond in appropriate manner.
- Periodic periods of depression may occur.
- Irritability and low tolerance for frustration when sick, fatigued, and/or under emotional stress.
- Social interaction behavior is consistently appropriate.

From Adult Brain Injury Service: *Original scale, levels of cognitive functioning*, Downey, Calif, 1980, Rancho Los Amigos Medical Center.⁶³

Although many studies have analyzed factors such as age, severity, cause of the injury, substance abuse, and psychosocial status in predicting outcomes after TBI, they have definite limitations regarding the recovery of an individual patient.^{8,12,17,22,35,78} Individuals with TBI improve over a period of months to years, especially once the individual becomes aware of his or her altered capabilities.⁶¹ Monitoring an individual's personal rate of recovery is probably more predictive of future recovery than any other factor.

Clinical Picture

Physical Status

An individual with TBI may exhibit a variety of symptoms, depending on the type, severity, and location of the injury. Individuals may have limitations in most of the areas listed in the following sections, or they may have subtle deficits evident only during more complex activities. [Table 34-3](#) shows some of the most common clinically diagnosed physical signs and symptoms of a client who has suffered a TBI.

■ TABLE 34-3 | Motor Signs

Motor Sign	Lesion Localization	Clinical Characteristics	Interventions
Decerebrate rigidity	Midbrain, pons, diencephalon	Extended internally rotated shoulders; extended elbows; flexed wrists, fingers; extended internally rotated hips, extended knees, ankle plantar flexion, inversion; increased rigidity when awake	Positioning, ROM, neuromuscular blocks, early casting
Decorticate rigidity	Cortical white matter, internal capsule, thalamus, cerebral peduncle, basal ganglia	Internally rotated shoulder; flexed elbow, wrists, fingers; extended, internally rotated hips; knee flexion; ankle plantar flexion, inversion; increased rigidity when awake	Positioning, ROM, neuromuscular blocks, early casting
Bruxism		Persistent jaw clenching, teeth grinding ± temporomandibular dislocation or subluxation	Neuromuscular blocks, oral orthotics
Spasticity	Upper motor neuron syndrome; cortical spinal pathways	Velocity-dependent resistance, hyperreflexia/clonus, muscle shortening; present in face, neck, trunk, limbs; worse when awake and with effort	Bed/chair positioning, ROM, weight bearing, neuromuscular blocks, inhibitive casting, enteral and intrathecal medications, tendon releases, relaxation techniques
Rigidity and bradykinesia; “parkinsonism”	Substantia nigra, extrapyramidal pathways; also with medications that block dopamine	Velocity-independent resistance; “lead pipe,” “cogwheeling” worse when awake	Positioning, ROM, functional activities, medications
Torticollis		Dystonic posture of the neck; spasticity and/or contracture of the sternocleidomastoid, splenius muscles	Positioning, modalities and ROM, medications, neuromuscular blocks
Myoclonus	Variable	Abrupt, shocklike involuntary jerks in large (limb) or small muscles when sleep or awake	Medications, neuromuscular blocks
Tremor	Variable	Involuntary rhythmic oscillations while awake	Weighted devices, weight bearing, medications, neuromuscular blocks, appropriate assistive devices
Dystonia	Variable	Dynamic contraction/relaxation of muscles with slow, writhing or repetitive twisting movements or sustained contortions; usually distal limb(s)	Positioning, ROM, neuromuscular blocks, medications, appropriate assistive devices
Athetosis	Basal ganglia, medications with effect on dopamine	Slow sinuous movements of the face, tongue, or limbs	Relaxation techniques, taper offending medications
Chorea	Contralateral neostriatum, thalamus	Involuntary dancelike or jerky movements without rhythmic pattern; distal	Medications
Hemiballismus/ballismus	Contralateral subthalamic nucleus, thalamus, cerebellum	Sudden irregular flinging movements starting in the hip or shoulder, occasionally facial or oral ± rotator component, worse with arousal/excitement, absent in sleep	Medications
Tics	Variable	Sudden stereotypic coordinated automatic movements or vocalizations while awake	Medications, behavioral management, relaxation techniques
Pseudobulbar athetoid syndrome	Bilateral pyramidal tract	Postural dystonia with fragmentary athetosis, ± bradykinesia; often preserved intellect/personality	Positioning, appropriate assistive devices

ROM, range of motion.

Data from Mayer NH, Keenan MAE, Esquenzi A: Limbs with restricted or excessive motion after traumatic brain injury. In Rosenthal M, Griffith ER, Kreutzer JS, Pentland B, editors: *Rehabilitation of the adult and child with traumatic brain injury*, ed 3, Philadelphia, Pa 1999, FA Davis; Mayer NH: Choosing upper limb muscles for focal intervention after traumatic brain injury, *J Head Trauma Rehabil* 19(2):119, 2004; Zafonte R, Elovic E, Lombard L: Acute care management of post-TBI spasticity, *J Head Trauma Rehabil* 19(2):89, 2004.

Decorticate, Decerebrate, and Motor Rigidity

Rigidity is the presence of increased resistance to passive movement throughout most of the range that is independent of stretch velocity.⁵¹ Comatose individuals often display one of two common positions: decorticate rigidity and decerebrate rigidity. In decorticate rigidity, the upper extremities (UEs) are in a spastic flexed position with internal rotation and adduction. The lower extremities (LEs) are in a spastic extended position but also internally rotated and adducted. Decorticate rigidity results from damage to the cerebral hemispheres (particularly the internal capsules) that causes an interruption in the corticospinal tracts—those that emerge from the cortex and send voluntary motor messages to all extremities.

In decerebrate rigidity, both the UEs and LEs are in a position of spastic extension, adduction, and internal rotation. The wrist and fingers flex, the plantar surfaces of the feet flex and invert, the trunk extends, and the head retracts. Decerebrate rigidity occurs as a result of damage to the brainstem and extrapyramidal tracts—the tracts that send involuntary motor messages from the brainstem to the extremities. Individuals with decerebrate rigidity have a poorer prognosis than do those exhibiting decorticate rigidity.^{15,29}

Cogwheel or lead pipe rigidity resembling Parkinson's disease can occur, typically in individuals with severe TBI. It may respond to dopamine agonists such as levodopa/carbidopa or amantadine. Dystonia of the neck (torticollis), jaw, or distal ends of the limbs can also occur and may require treatment with motor point blocks.⁵¹

Abnormal Muscle Tone and Spasticity

Although decorticate rigidity and decerebrate rigidity are associated with the most severe types of abnormal muscle tone and tend to occur in comatose individuals, hypertonicity may range from minimal to severe in any muscle group. Individuals who are functioning at a higher cognitive level than coma generally display a combination of both hypotonicity (i.e., decreased tone, or flaccidity) and hypertonicity (i.e., increased tone, or spasticity). Flaccidity, or hypotonicity, is a decrease in normal muscle tone. It is usually attributed to peripheral nerve injury resulting in soft muscle feel, in which the muscles offer no resistance to passive movement. Spasticity, also known as hypertonia, is an involuntary increase in muscle resistance that is dependent on velocity.⁴⁷ Because individuals with spasticity cannot voluntarily relax their limbs, voluntary movement of an affected limb may be impossible. Spasticity can be seen as early as a few days after brain injury, or it may take between 3 and 6 months to develop. In as little as 2 weeks, spasticity may cause muscles to shorten permanently, which in turn can cause joints to lose motion. The condition of permanent shortening is called a muscle contracture.

OT Practice Notes

It is important to instruct all members involved in the client's care that tone can fluctuate as a result of changes in position, volitional movement, medication, infection, illness, pain, environmental factors (i.e., ambient temperature), and emotional state.⁷

Primitive Reflexes

If damage to the midbrain has occurred, impaired righting reactions are commonly observed. Similarly, damage to the basal ganglia can result in the absence of equilibrium reactions and protective extension. The absence of righting reactions, equilibrium reactions, and protective extension places the individual at a significant risk for further injury from falls during such activities as transfers, getting out of bed, toileting, bathing, and dressing.

Muscle Weakness

A decrease in muscle strength without the presence of spasticity can occur as a result of peripheral nerve or plexus injuries and lack of physical activity caused by secondary factors associated with TBI (e.g., compromised respiration, fractures, and infection). A functional muscle and sensory test may be indicated when an individual exhibits decreased strength in the limbs. Additionally, impaired gross and fine motor coordination will be evident and should be assessed.

Decreased Functional Endurance

Decreased endurance and vital capacity usually accompany reduced muscle strength as a result of medical complications such as infections, poor nutrition, or prolonged bedrest. Increasing the individual's muscle strength and endurance is a primary goal in the acute stage and in the initial stages of rehabilitation.

Ataxia

Ataxia results from impairment of the cerebellum itself or the motor pathways leading to and from the cerebellum; it can also occur with impaired proprioception. Ataxia is a movement abnormality characterized by incoordination, impaired sitting and standing balance, or both.⁷ Ataxia can occur in the entire body, in the trunk, or in the UEs and LEs. An individual with ataxia has lost the ability to perform the small adjustments in the distal and proximal ends of extremities that are necessary for smooth, coordinated movement. The degree of ataxia ranges from mild to severe. An individual with ataxia in the trunk displays impaired postural stability when sitting and standing. He or she has difficulty maintaining the trunk in a stable position to free the UEs or LEs for activities. The individual may compensate for this deficit by grasping a stable surface such as a tabletop. Ataxia in the UEs causes dysfunction in activities

in which the individual attempts to perform a combination of gross and fine motor movements, such as bringing a glass of water to the mouth. The UE oscillates back and forth, thus causing the water to spill. Ataxia in the LEs results in an impaired ability to ambulate while maintaining balance; falls can easily occur with this condition.

Postural Deficits

Postural deficits develop as a result of an imbalance in muscle tone throughout the body. An individual may inadvertently accentuate the postural deficits by using ineffective strategies to compensate for impaired motor control, delayed or absent righting reactions, or impaired vision, cognition, or perception. Therapists must possess thorough knowledge of the postural deficits of their clients to position them properly in a wheelchair with the appropriate seating system, which is necessary to obtain an upright posture, maintain good postural alignment, and prevent further postural deformities. Frequently exhibited abnormal postures include the following:

1. Pelvis. Posterior pelvic tilt is often due to prolonged bedrest in the supine position, which causes loss of range of motion (ROM) in the lower part of the back. Posterior pelvic tilt results in sacral sitting and facilitates kyphosis. Pelvic obliquity is observed when one side of the pelvis sits lower than the other side as a result of hypertonicity of the quadratus lumborum on the involved side.
2. Trunk. Kyphosis, scoliosis, and lordosis may all be present secondary to weak or spastic trunk muscles (e.g., pectoralis, abdominal, spinal, and paraspinal). It is also common to observe lateral flexion toward the involved side (trunk shortening) with elongation of muscle on the opposite side.
3. Head and neck. Forward flexion or hyperextension of the neck and lateral flexion of the head often accompany lateral flexion of the trunk.
4. Scapula. The scapula may be depressed, protracted or retracted, downwardly rotated, or all of these at once. This results from an imbalance in scapular muscle tone; some muscles are hypertonic, whereas others are hypotonic.
5. Upper extremities. UEs may be bilaterally or unilaterally involved. In unilateral involvement, it is common to see variations in ROM, tone, and strength in each muscle group and joint of the arm, forearm, wrist, and hand.
6. Lower extremities. Severe extension patterns are often observed in both LEs, which can pose a problem with wheelchair positioning; this is evident when the individual thrusts forward and slides out of the seating system. Hip adduction, internal rotation, knee flexion, plantar flexion, and inversion of the feet can all be observed.

Limitations of Joint Motion

Loss of ROM in the joints is a common problem. It is often difficult to distinguish between several possible causes of decreased ROM, such as increased muscle tone, volitional resistance, contractures, heterotopic ossification, fractures or dislocations, and pain. Because the intervention addressing decreased ROM depends on the cause, the therapist should consult a physician to determine the cause of the decreased ROM before initiating intervention. Distal limb fractures are often overlooked in acute trauma settings when patients are unable to communicate because of cognitive deficits. Therapists are typically the first to detect the hard end feeling of joints with limited ROM typical of heterotopic ossification, the formation of lamellar bone in soft tissue.³⁴

Sensation

Clients with TBI may exhibit signs of absent or diminished sensation, including problems with light touch, differentiation between sharp and dull sensations, proprioception, temperature, pain, and kinesthesia. Additionally, impaired senses of taste and smell, caused by cranial nerve injury, may be observed.⁷ Lost or diminished stereognosis, two-point discrimination, and graphesthesia (i.e., the ability to interpret letters written on the hand without visual input) may be present. Hypersensitivity, which can often interfere with postural alignment, may also occur.

Integration of Total Body Movements

Total body movements involve the integration of head, neck, and trunk control with dynamic sitting and standing balance while reaching, bending, stooping, and ambulating. To perform total body movements, the individual must coordinate and modulate gross and fine motor movements of the trunk, head, neck, and limbs while performing ADLs. An individual with severe physical involvement often displays poor sitting and standing balance and is unable to maintain an upright position to free the UEs for activities. Individuals functioning at a more advanced level may exhibit subtle deficits in total body movements that make it difficult to bend down, reach overhead to retrieve items in a cabinet, or stoop to retrieve an item that has fallen to the floor. Integrated total body movements are necessary for the performance of all ADLs.

Dysphagia

Dysphagia, or difficulty completing the four stages of chewing and swallowing, is caused by cranial nerve damage (see Chapter 27). There is a higher incidence of oral preparatory-, oral-, and pharyngeal-stage dysphagia than esophageal-stage dysphagia. Typically, more than one stage of chewing and swallowing is impaired.^{5,6}

An individual may display oral muscular hypotonicity or hypertonicity, instability of the jaw, and abnormal oral reflexes such as rooting, biting, sucking, gagging, and coughing, which prevent or impair the activity of speaking

or eating. As a result of cognitive deficits, the individual may experience difficulty in sequencing chewing, swallowing, and breathing.

Self-Feeding

Clients with TBI may be unable to sustain attention long enough to feed themselves. If impulsivity is apparent, these clients will have difficulty monitoring the amount and rate of food brought to the mouth, thus causing coughing and possibly aspiration. Oral apraxia, an inability to perform an intended action or execute an act on command with the mouth or lips, may occur. If clients have ideational apraxia, they will have difficulty understanding the demands required of the self-feeding activity and will be unable to recognize utensils as tools for eating. Because they may also have lost the motor plan for self-feeding (ideomotor apraxia), they may be unable to gain access to the neurologic motor pattern for bringing food to the mouth. Hemianopia (visual field cut) or visual neglect may prevent them from seeing half of the plate of food.

Cognitive Status

Cognitive deficits are always evident to varying degrees and can affect many aspects of the individual's quality of life, as mentioned in previous sections. The most common include decreased attention and concentration, impaired memory, impaired initiation and termination of activities, decreased safety awareness and poor judgment, impulsivity, and difficulty with executive functions and abstract thinking (e.g., problem solving, planning, integration of new learning, and generalization).

Attention and Concentration

Reduced attention and concentration impair the ability to maintain focus on an activity without becoming distracted and the ability to resume an activity when interrupted. Clients with TBI often lose the ability to concentrate for a length of time and the ability to filter out distractions from the surrounding environment. The inability to attend to and concentrate on activities severely impedes the ability to function at work and school and complete ADLs. Although deficits in attention and concentration can diminish as neurologic recovery progresses, such deficits can remain to varying degrees throughout an individual's life. Even patients who experience mild TBI can demonstrate subtle deficits in attention and concentration that often linger for years after the injury and can affect their everyday functioning.

Memory

Impaired memory, the most frequently observed cognitive deficit in patients with TBI, can remain a lifelong problem. Memory impairment ranges from forgetting several words just heard (immediate memory), to forgetting which family members visited the night before (short-term memory), to forgetting events that occurred years before the injury (long-term memory). Despite neurologic recovery, most of these

patients continue to demonstrate difficulty in learning new information. Safety concerns include getting lost, leaving doors unlocked, and leaving a stove on; patients with impaired memory typically require supervision if compensatory methods cannot be used. This loss of independence can be emotionally devastating because patients with TBI often have insight into who they were before the injury, as well as their accomplishments, goals, and plans for the future—many of which are severely disrupted and perhaps lost as a result of TBI.

Memory losses are also labeled in relation to the time of the injury or brain damage. Loss of memories for events before the time of the specific injury is referred to as retrograde amnesia. The client may forget events that occurred just before the accident or forget events that happened several days, weeks, and even months before the accident. Following TBI the client is often unable to form new memories, and this is referred to as anterograde amnesia. This period when the client cannot form new memories can last for days, weeks, or even months after the injury.

Initiation and Termination of Activities

Impaired initiation and termination of activities affect the ability to start and end activities. An inability to initiate activities without assistance affects the individual's ability to live independently. In general, patients who exhibit deficits in initiation will demonstrate the greatest progress in a rehabilitation setting that provides assistance and structure. After returning home, patients may regress and have difficulty completing basic daily activities if the necessary structure has not been set up. Similarly, patients may exhibit difficulty terminating an activity once it is started, which is a type of perseveration. For example, patients may initiate brushing their teeth and be unable to end the task because they feel compelled to continue. Perseveration sometimes involves a thought process. Clients may be unable to concentrate on one activity because they are perseverating on the idea that another activity (e.g., the laundry) must be completed.

Safety Awareness and Judgment

Frontal lobe damage often results in an impairment in insight regarding a person's limitations, as well as in impulsivity, or the inability to consider consequences before acting. Such individuals demonstrate poor safety awareness and judgment. For example, the client may attempt to rise out of a wheelchair without locking the brakes or moving the footrests. A more mobile client who has been reintegrated into the community may attempt to cross streets without observing traffic signals or remove pots from the stove or oven without using protective oven mitts or pot holders. It is important for the occupational therapist to structure the client's environment to reduce accidents and increase the client's awareness of his or her limitations through repeated opportunities to practice and relearn safe and appropriate behavior.

Processing of Information

Most people with TBI experience some degree of difficulty processing external information from the environment. A delay in response time is often noted and can range from a few seconds to several minutes. It is important for the therapist to recognize the presence of delayed processing and distinguish the delay from the absence of function. For example, during sensory evaluation a client may exhibit a delay in response to a dull stimulus. The therapist may mistakenly interpret the individual's delayed processing time as an absence seizure or impairment of sensory awareness. A delay in the processing of external information from the environment can involve visual, auditory, sensory, and perceptual processing.

Executive Functions and Abstract Thought

Executive function skills include the ability to plan, organize, set goals, understand the consequences of one's actions, and modify behavior in accordance with environmental responses. Abstract thinking is the ability to hold and manipulate a concept in one's mind by using critical reasoning and analytic skills. Many clients with TBI exhibit concrete thinking, in which they are able to interpret information only at the most literal level. For example, individuals with impaired executive and abstract functions may be able to complete a meal preparation activity accurately and safely only if step-by-step directions are provided. If the directions do not specifically direct the reader to modify the cooking temperature, these individuals may burn the food because they are unable to foresee the consequences of maintaining the stove on a high setting.

Generalization

Generalization of new learning is the ability to learn a specific task and transfer the skills needed for that task to a similar activity. Deficits in executive function skills, abstract thinking, and short-term memory significantly impair the generalization of new learning. For example, an individual who has learned in a day treatment setting the skills for completing a laundry task may be unable to transfer the skills at home or at a different laundromat. Such deficits often occur as a result of concrete thinking and the inability to form abstractions. Although the cognitive pattern for completing laundry tasks with the laundry machine in the clinical setting is established, the individual cannot transfer that cognitive pattern to a similar but unfamiliar laundry machine in a different environment. Impaired generalization of new learning is one of the most significant problems impeding the individual's ability to resume independent functioning in a community setting.

Visual Status

Visual skills involve the ability to accurately see stimuli from the external environment (see [Chapter 24](#)). Visual skills do not involve the identification of objects, which is a function of perception. Among the many deficits in visual skills that

may result from TBI are accommodative dysfunction (causing blurred vision), convergence insufficiency (the inability to maintain a single vision while fixating on an object), lateral or medial strabismus, nystagmus, hemianopia, and impairment of scanning and pursuits. Saccades (fast, jerky movements of the eyes as they change from one position of gaze to another, as needed to read a book) may also be compromised by TBI. Reduced blink rate, ptosis (drooping of the eyelid), and lagophthalmos (incomplete eyelid closure) are also common visual deficits resulting from damage to the oculomotor nerve.⁷

Dysfunction in any of these visual elements can profoundly affect daily life function. Individuals rely on vision indirectly in social and interpersonal interactions. Vision is used as a cueing and feedback system for motor skills such as ambulation and for eye-hand coordination activities. Deficits in vision can affect all daily life activities, including the areas of hygiene and grooming, meal preparation and eating, wheelchair mobility, reading and writing, and driving.

Perceptual Skills

Perception is the ability to interpret stimuli from the external environment (see [Chapter 25](#)). Perception is a function of the secondary cortical areas of the right hemisphere, including the secondary visual area, the secondary somatosensory area, the secondary auditory area, and the multimodal parietal-occipital-temporal area. Perceptual deficits are more often a result of right hemisphere damage but may also occur with lesions in the left hemisphere. Perception can be grouped into the following categories: visual perception, body schema perception, motor perception, and speech and language perception. An individual with impairments in visual perceptual may exhibit difficulty in right-left discrimination, figure-ground discrimination, form constancy, position in space, and topographic orientation. Visual perceptual deficits also include visual agnosia, in which the individual displays difficulty recognizing familiar objects and people. For example, prosopagnosia is the inability to connect faces with names. Prosopagnosia results from damage to the multimodal association area.⁷

Body schema perception is awareness of the spatial characteristics of a person's own body. This awareness is derived from the neural synthesis of tactile, proprioceptive, and pressure sensory associations about the body and its individual parts. A common problem in persons with TBI is anosognosia, a failure to recognize deficits or limitations. This may lead to the body schema perceptual dysfunction of unilateral neglect syndrome, in which the individual has lost the ability to integrate perceptions from one side of the body or environment (usually the left). Unilateral neglect is commonly caused by a lesion in the right parietal lobe but can also occur as a result of frontal and occipital lobe damage. Patients with left unilateral neglect may disown their left extremities and treat them as though they belong

to someone else. For example, these individuals may shave only the right side of their face or dress only the right side of their body.⁷

Aphasia is a disturbance in comprehension or formulation of language (or both) caused by dysfunction in specific brain regions, typically the left hemisphere.¹⁹ A few left-handed individuals have language dominance in the right hemisphere. Establishing reliable communication is crucial in treating anyone with aphasia. If auditory comprehension is compromised, gestural demonstration of instructions or activities will be more reliable. Common types of aphasia involving disorders of comprehension include the Wernicke and transcortical sensory types. Affected individuals will have longer periods of PTA because they do not understand orientation questions, and although their spoken language is fluent, it includes verbal paraphasias, or word substitutions. Clients with aphasia may also misinterpret speech and become suspicious and agitated. Insight into their communication deficit may be limited.

The nonfluent aphasias (Broca's aphasia and transcortical motor aphasia) are characterized by relatively preserved comprehension but effortful or explosive speech with phonemic paraphasias (e.g., "bork" for "fork"). Conduction aphasia (i.e., intact comprehension, fluent speech, impaired repetition) and anomic aphasia are characterized by circumlocution and frequently paraphasias. Individuals with these types of aphasia are typically aware of their problems and are often frustrated by their limitations. They should be encouraged to use gestures to express their immediate desires and needs.

Dyslexia (disturbance in reading), agraphia (disorder of writing), and dyscalculia (disturbance in calculation) frequently accompany the aphasias. However, with traumatic aphasias, these capabilities may be better preserved than with stroke; treating therapists should always attempt alternative modes of communication.

Dysprosody or aprosody is impaired production or comprehension of the tonal inflections or emotional tone of speech. Executive dysprosody is an inability to inflect one's voice to convey emotion. It can occur with cerebellar, basal ganglia, or right frontal lobe injury. Receptive dysprosody is an inability to perceive the emotional content of other people's spoken language. It occurs with right temporal or parietal injury and less often with left hemisphere injury. Individuals with this disorder may miss the point of a joke or story because they cannot comprehend the subtle innuendoes and implicit meanings conveyed through tonal qualities and inflections.⁷⁵ Even more disabling is the inability to interpret anger, humor, or sarcasm during communication with others.¹⁸ Perceptual-motor dysfunction is impairment in motor planning, or an apraxia. It is a disorder of learned movement that cannot be explained by weakness, lack of sensation, inattention, or comprehension of the requested task.¹⁸ The apraxias are usually a result of impairment of the premotor cortex, corpus callosum, or connections between the temporal/parietal lobes and frontal motor

cortex.³⁷ It is in these cortical areas that established motor patterns for specific activities are stored and accessed for the execution of common movement patterns. Ideational apraxia is an inability to understand the demands of a task or use of the wrong motor plan for a specific task. For example, individuals suffering from ideational apraxia may not understand that a shirt is an item of clothing to be placed on the torso and UEs. Not understanding the demands of the task, they may be unable to activate the motor plan for UE dressing or may activate the wrong plan and attempt to place their legs through the sleeve holes. This deficit is sometimes referred to as a dressing apraxia. Ideomotor apraxia is loss of the kinetic memory of a movement pattern for a specific activity. Individuals with this disorder may understand that a shirt is an item of clothing to be placed on the torso and UEs but be unable to execute the appropriate movement plan because it is no longer accessible. Constructional apraxia is an inability to accurately assemble pieces of an object to form a three-dimensional whole. For example, a former carpenter who suffers from constructional apraxia may be unable to put together the wooden pieces of a basic birdhouse kit.

Psychosocial Factors

Researchers have found that the greatest concerns of clients 1 or more years after TBI are the psychosocial deficits that prevent them from rebuilding a satisfactory quality of life. As the time after injury increases, clients and family members view such psychosocial factors as being more detrimental than both the physical and cognitive sequelae of TBI.

For example, in Marisol's case, it was initially difficult to assess her psychosocial status because she was nonvocal. The team was able to assess her mood on the basis of her level of participation and affect during therapy. Marisol would laugh appropriately and become visibly more interactive, with brighter affect, when her boyfriend arrived to visit.

Marisol continued to engage in positive interactions throughout her 4-month inpatient and day treatment stay. Her discharge plan involved moving to Georgia with her mother. When the move was discussed with Marisol, it was evident that she was quite saddened by the knowledge that she would no longer be able to see her boyfriend. The team observed her closely to assess whether her sadness would eventually culminate in depressive symptoms.

Self-Concept

One of the most difficult psychosocial sequelae of TBI is alteration of the individual's self-concept. Self-concept is the internal image that a person holds regarding personal human identity, sexual and gender identity, body image, personal strengths and limitations, and position in the family, peer group, and community systems. An individual's self-concept changes drastically after TBI. One of the most difficult characteristics of TBI is that although short-term memory is often impaired, long-term memory commonly remains intact. Persons with TBI often have a clear memory

of who they were before their injury and must now resolve the emotional conflict of having to replace their preinjury self-concept with a postinjury self-concept that is both meaningful and satisfying. Affected individuals sometimes describe this process as an unwanted death and rebirth. They say that the person who lived before the injury is now gone, replaced by someone who is very different from the person that they remember themselves to be.⁵⁸

Social Roles

Self-concept is derived largely from the social roles that the person attains in the family, peer group, and larger community systems. Frequently, an individual with TBI loses most preinjury roles and the activities that supported those roles. Family and peer group roles change. Family members and friends are often readily visible during the acute and subacute stages of TBI rehabilitation. However, as the time after injury increases, family and friends become progressively less involved with the individual, which frequently leads to feelings of isolation and abandonment. Many individuals with TBI report that the feeling of isolation and the inability to form and maintain social relationships are their most troubling postinjury concerns. Loss of the role of dating partner or spouse commonly leaves clients with TBI with a deep sense of loss and failure if they cannot rebuild a postinjury life that includes intimacy with another human being, partnership in a committed relationship, and parenting of children. Loss of the work role and inability to support oneself are intimately tied to feelings of dependence and lack of personal control.⁴⁴

Independent Living Status

As a result of the physical, cognitive, and psychosocial sequelae of TBI, many affected individuals find that they require supportive living arrangements or must live with their parents. Loss of the ability to live independently in the community further reinforces feelings of dependence and decreased personal control. As a result of these role losses, adults who sustain TBI commonly experience role strain and feel that they cannot re-enter their communities. The TBI, particularly if it occurred between the ages of 18 and 30, disrupts the developmental transition from adolescence to adulthood and leaves individuals feeling inadequate and unable to attain a postinjury adult status. Depression, withdrawal, and apathy are common psychosocial sequelae of the alterations in self-concept discussed earlier and of the loss of desired social roles.⁵²

Dealing with Loss

Persons with TBI and their family members often go through a process that resembles the stages of death and dying experienced by the terminally ill.⁴⁵ These stages begin with denial, in which affected individuals deny that they are experiencing physical, cognitive, or psychosocial deficits. Denial can impede therapy because these clients may refuse to participate in the belief that it is unnecessary. Denial

gradually subsides as they continually confront their limitations in ADLs. Anger follows denial. Clients grow increasingly aware of their deficits and become frustrated and angry because recovery is slower than desired. Bargaining is the next stage. Clients strike a deal with the Creator or the fates and offer to work as diligently as possible in therapy if only their preinjury lifestyle could be restored. The bargaining stage is often marked by increased motivation and optimism. Depression tends to emerge next. Eventually, clients begin to realize the severity of the injury and its effect on the rest of their lives. Acceptance of the injury and resultant limitations, the next stage in the process, is necessary for clients to become sufficiently motivated to attempt to build a postinjury life that although drastically different from their preinjury goals and expectations, is nevertheless meaningful and personally valuable. These stages may require years of transition. Frequently, denial, anger, and bargaining occur in the first few months to a year after the injury. Depression sets in as the individual is able to let go of some of the denial and becomes aware of the effect that the injury will have on the future. It may take years before he or she can truly accept the injury and alterations in personality, skill, and lifestyle and move on to rebuild a new life.

The process of denial, anger, depression, and acceptance does not generally proceed in a linear fashion. Clients with TBI commonly experience repeated periods of denial, anger, and depression throughout their years of rehabilitation. Renewed denial, anger, and depression may occur in response to a new environmental demand, such as a change in life condition (e.g., a need to move from the parental home to a community group home) or the development of further physical, cognitive, or psychosocial deterioration over time (e.g., the need for increased ambulatory assistance because of deterioration in visual skills).

Affective Changes

Depression, increased emotional lability, and decreased affect can result from the neurologic damage itself. Individuals with left hemisphere damage tend to exhibit increased depression and emotional lability. Lesions of the left orbitofrontal lobe often cause severe depression and heightened affect (including excitement, agitation, and tearfulness). Lesions of the left dorsolateral frontal lobe commonly result in a decreased or flat affect. Individuals with these lesions may appear depressed even though they feel fine. Neurologic damage to the right hemisphere frequently causes a strange sense of euphoria or lack of emotional response to the severity of injury.⁵⁸

Behavioral Status

Behavioral impairments are a natural part of the recovery process. The Rancho Los Amigos cognitive level IV is typically described by the rehabilitation team as the “agitated, confused” level.⁶³ During this stage of recovery, affected individuals can be described as restless and combative. They

may be responding to internal body experiences, or some external environmental stimuli may be provoking the agitation. Commonly observed behavior includes yelling, swearing, grabbing, and biting. Behavioral problems can be disturbing to both the individual's family and the intervention team; therefore, behavioral management is an essential component in TBI rehabilitation.

Ethical Considerations

Working with clients who have behavior problems can be frustrating and sometimes frightening. Untrained staff members can become injured and often reinforce the client's negative behavior through their own actions and responses.

A comprehensive behavior management program should be established for anyone who exhibits behavior that interferes with active participation in therapy and achievement of goals. The goals and objectives of a comprehensive program include maintaining a safe environment for individuals and staff at all times, developing and consistently implementing behavior management techniques, minimizing the use of all restrictive modalities, and providing an environment that facilitates participation and appropriate behavior in the hospital setting and after discharge.⁶⁵

Interventions used in an effective behavior management program include one-on-one coaching, intervention with psychotropic medications, and individually designed behavior management guidelines and interventions. One-on-one coaching, usually performed by a trained nursing assistant or rehabilitation technician, is especially necessary for clients who are at risk of harming themselves or others. In many cases, implementation of a behavior management program is necessary 24 hours a day, 7 days a week. A coach will help reinforce the client's behavior plan and redirect inappropriate or maladaptive behavior. Medications are required to regulate sleep and minimize agitation and combative behavior until clients can control the behavior on their own. Because pain may often provoke agitation, assessing patients' level of pain and providing appropriate medication may resolve the restlessness, agitation, and/or inability to sleep. Medications must be chosen carefully to prevent side effects such as clouding of awareness and psychomotor slowing. Clients should have specific behavioral end points, such as establishing adequate sleep at night, facilitating attention during functional activities, and decreasing the frequency of verbal or physical outbursts.

Environmental modifications are a proactive approach to prevent and minimize undesirable behavior. Such modifications may include use of a cubicle or net bed, an alarm system, a helmet, and walkie-talkies. A drug and alcohol policy is frequently necessary; it is well documented that many individuals with TBI have pre-existing alcohol or drug problems (or both).⁶⁶

The first step in becoming more comfortable when working with clients who have behavior problems is to understand why they occur and how they manifest themselves.

Clients who are exhibiting agitation, combativeness, disinhibition, and refusal to cooperate and participate in activities typically have difficulty filtering distractions and can become agitated in noisy environments. Providing a quiet room during interventions and use of a cubicle bed may help minimize noise and reduce outbursts.

A disinhibited individual may lack awareness of the external environment and may make indiscriminate sexual remarks or gestures to others. Ignoring comments, redirecting inappropriate behavior, and modeling acceptable behavior are typical therapeutic interventions.

Clients who refuse to cooperate and participate in intervention can be the most challenging because this attitude may affect their ability to remain in an acute rehabilitation program. The lack of participation is typically organically based and due to cognitive deficits such as impaired initiation and lack of insight into their disability. It is important to document such behavior throughout the course of care; however, when clients refuse to participate, documenting progress can be challenging.

Interventions include providing consistent structure through daily schedules and goal sheets that provide visual cues for expectations, as well as visual and physical guidance through activities until clients are capable of completing tasks without assistance.

OT Practice Notes

Behavior management is essential in all TBI rehabilitation programs. It is important to develop and implement a behavioral program whether the behavior is passive (decreased initiation), active (agitation), or somewhere along the continuum.

An effective program includes comprehensive staff training, tools that track and monitor behavior and techniques, and consistent multidisciplinary communication (behavior management meetings) to ensure that the individualized behavior plan is effective and goal oriented.⁶⁶

Evaluation of the Lower-Level Individual

Clients emerging from coma and at the beginning stages of the injury (Rancho Los Amigos level I to III) may exhibit minimal arousal and limited purposeful movements. It may be necessary to evaluate such individuals in short sessions and at different times of the day. A quiet environment with minimal distractions will enhance the client's ability to attend to and follow commands. Evaluation includes assessment of the following:

1. Level of arousal and cognition—Can the client visually attend to the speaker and follow commands such as “open your mouth” and “squeeze your eyes closed”? Can he or she communicate through verbalizations, gestures, or eye movements? Does he or she demonstrate purposeful movements such as pulling at vital tubes? How easy/difficult is it to wake the client, and how long can the client stay awake?
2. Vision—Is the client able to visually scan or attend to a person, object, or activity? Can the client maintain eye contact?
3. Sensation—Does the client respond to external stimulation such as pain, temperature, and movement of the joints?
4. Joint ROM—Has the client lost ROM in certain joints as a result of decorticate or decerebrate posturing, increased tone or spasticity, contractures, or heterotopic ossification?
5. Motor control—Does the client exhibit decorticate or decerebrate posturing? Is there an increase in tone and spasticity? Is there decreased tone and hypotonicity? Are deep tendon responses present, diminished, or absent? Does the client exhibit the presence of primitive reflexes? Does the client engage in spontaneous motor movements, such as scratching the face?
6. Dysphagia—Does the client handle his or her own secretions, drool, or swallow spontaneously? Does the client demonstrate poor oral-motor control? Answers to these questions provide valuable information on whether a swallowing evaluation is indicated.
7. Emotional and behavioral factors—Is the client’s affect flat or expressive? Are responses such as crying or laughing observed in response to interactions with the rehabilitation team or family members?

Evaluation of lower-level individuals with TBI is generally accomplished with tools such as a goniometer, clinical muscle and tone testing, traditional neurologic screening, and clinical observations. Many acute TBI rehabilitation facilities have developed their own initial evaluation forms. A variety of scales can be used to establish a baseline and predict recovery. The GCS and Rancho Los Amigos Scale are common; however, newer cognitive scales such as the JFK and WHIM are also being used.⁶² Some clients tend to emerge quickly and move expeditiously through the Rancho levels, whereas others (e.g., those with anoxia) may demonstrate limited or slow recovery. A subacute program or a rehabilitation center that specializes in slow-to-recover clients may be necessary. In either case, a rehabilitation program with active therapeutic intervention is necessary to prevent contractures, encourage activity, and facilitate the client’s progress through the rehabilitative process.

In the case of Marisol, the team decided to address her spasticity and joint contractures first by providing appropriate medical interventions, including blockade of her

musculocutaneous nerve to decrease her left UE spasticity. This was followed by casting to reduce her elbow contracture. The team also gave Marisol a comprehensive activity schedule in a multistimulus environment. This schedule involved transferring her out of bed and into a customized wheelchair, in which she would remain between 6 and 8 hours a day, getting up into a standing frame daily, and requiring active participation in all therapies 4 hours per day. Her cognitive level was assessed weekly with the JFK scale, as well as assessment of her ability to follow-through with basic mobility and self-care tasks.

Intervention for the Lower-Level Individual

The general aim of intervention for those at Rancho levels I through III is to increase the individual’s level of response and overall awareness of self and environment. All stimulation should be well structured and broken down into simple steps and commands. Allotting sufficient time for an individual’s response is necessary because cognitive processing is often significantly delayed during this phase of recovery. Intervention at this stage can be grouped into six areas: sensory stimulation, bed positioning, casting or splinting, wheelchair positioning, management of dysphasia, and emotional and behavioral management, as well as family and caregiver education. Interventions may occur simultaneously to optimize progress. Each intervention affects and enhances the next. Because clients often respond more to the familiar and routine, it is important to incorporate close family members and friends into sessions.

Sensory Stimulation

Intervention for clients emerging from coma should start as soon as they are medically stable. Intervention generally begins in the intensive care unit. At this stage, clients frequently lack responsiveness to pain, touch, sound, or sight. They may exhibit a generalized response to pain that appears reflexive (e.g., attempting to pull away from painful stimuli). The goal of intervention is to increase the client’s level of awareness by trying to increase arousal with controlled sensory input. Sensory regulation increases neurologic signals to the reticular activation system, the structure of the brainstem that alerts the brain to important sensory input from the external environment.

Sensory stimulation can be introduced in a variety of ways and methods. Introducing isolated visual, auditory, tactile, olfactory, and gustatory stimulants to the individual may heighten arousal. For example, a flashlight may be used to elicit eye opening and visual tracking. Playing familiar music may facilitate autonomic responses, such as a change in the respiratory rate or changes in blood pressure. Introducing olfactory stimulation through a variety of scents may elicit eye opening or head turning. Gustatory stimulation involves the controlled presentation of taste to the client’s

lips and tongue through use of a cotton swab. Such stimulants may include salty, sweet, bitter, and sour tastes. Any response from the client is noted.

OT Practice Notes

The most effective types of sensory stimulants are those that have personal meaning to the client, such as favorite songs or stories. Family members often bring in familiar objects and pictures that can facilitate responses from the client. It is helpful to learn about the client's preinjury history to incorporate familiar items and routines into his or her intervention plan.

Kinesthetic input is incorporated early in the intervention. One of the most effective ways to facilitate volitional movement is by actively guiding movements in a normalized fashion while performing functional activities. The therapist actively helps the client perform simple movements, such as rolling from side to side, and perform simple functional activities such as wiping the mouth with a washcloth, combing hair, and applying lotion to the skin. The theoretic aim of functional sensory stimulation is to reactivate highly processed neural pathways that had been established before the injury. Other activities related to functional sensory stimulation include sitting the individual up at the edge of the bed and having the client stand by using a tilt table or a hydraulic standing frame. During all these activities, the therapist observes the client for any changes such as visual tracking, turning of the head, physical responses, vocalizations, and ability to follow verbal commands.

Wheelchair Positioning

Seating and positioning are important components of treatment in lower-level patients. Being properly positioned in a wheelchair allows these patients to interact with their immediate environment in an upright, midline posture. Proper positioning aims to facilitate head and trunk control so that clients can see and interact with people and objects in the environment. A proper wheelchair seating position helps prevent skin breakdown and joint contractures, facilitate normal muscle tone, inhibit primitive reflexes, increase sitting tolerance, enhance respiration and swallowing function, and promote function (Figure 34-1).

Effective seating and positioning require a stable base of support at the pelvis, maintenance of the trunk in the midline, and facilitation of the head in an upright, midline position. This position frees the UEs for use and allows the client to visually scan the environment. Once the client has a seating system that encourages and promotes function, therapy sessions can be more effective and beneficial. For example, clients generally find it easier to handle their secretions in this position, so swallowing trials may be safer and more effective.

FIGURE 34-1 Proper wheelchair seating position.

Marisol required a wheelchair and specific positioning devices when she entered the acute rehabilitation program. Given her motor abilities and deficits, what type of wheelchair set-up would you prescribe?

Pelvis

Wheelchair positioning should begin at the pelvis. Poor hip placement adversely alters trunk and head alignment and influences tone in the extremities. Because sling-seat wheelchairs contribute to internal rotation and adduction of the hips, it is important to insert a firm, solid seat (padded with foam and covered by vinyl) to facilitate a neutral to slightly anterior pelvic tilt. A lumbar support may also help maintain the natural curve in the lumbar spine. A wedged seat insert (with the downward slope pointing toward the back of the chair) can be used to facilitate hip flexion and inhibit extensor tone in the hips and LEs. The individual's buttocks should bear weight evenly, with both ischial tuberosities firmly resting on the wheelchair seat. A seatbelt angled across the pelvis helps maintain this desired position. Since patients have spent a significant amount of time in bed, loss of anterior pelvic tilt is present. Before positioning clients in a wheelchair, significant pelvis and trunk stretching is often necessary to achieve neutral pelvic alignment and upper trunk extension. These stretches often facilitate upright, symmetric trunk alignment, which may have occurred secondarily to prolonged bedrest and abnormal tone, reflexes, and patterns.

Trunk

The trunk should be positioned after the pelvis because it is the next most proximal body structure. A solid back insert or firm contoured back should be placed behind the client's back to maintain the spine in an erect posture. A back insert

that is contoured to the curves in the spine will maintain the lumbar and thoracic curves. Lateral trunk supports can be used to reduce scoliosis and lateral trunk flexion caused by imbalanced tone of the intrinsic muscles of the back. A chest strap (with easily opened Velcro fasteners) can be used to decrease kyphosis, facilitate shoulder retraction and abduction, and expand the upper part of the chest for proper diaphragmatic breathing and UE use.

Lower Extremities

An abductor wedge placed between the LEs just proximal to the knees may be used to decrease hip adduction and internal rotation. If hip abduction is present, a padded abductor wedge can be placed along the lateral aspect of the thigh to reduce LE abduction. Ideally, the knees should be positioned at 90 degrees, with the heels slightly behind the knees while sitting. It is desirable to maintain both feet securely on the foot plates to provide proprioceptive input and facilitate weight bearing in both heels to normalize tone.

Upper Extremities

The UEs should be positioned with the scapulae in a neutral position (neither elevated nor depressed), the shoulders slightly externally rotated and abducted, the elbows in a neutral position of slight flexion with forearm pronation, and the wrists and digits in a functional position. This position is often difficult to achieve because of severe spasticity and soft tissue contractures of the UEs. A splint or cast may be applied to decrease spasticity and facilitate a functional position of the UEs. Frequently, a lap tray is used to provide support for the UEs and encourage bilateral UE weight bearing and use.

Head

Clients with TBI at a lower functioning level often have little or no active head control. Attaining a neutral-midline head position, which allows optimal visual contact with the environment, is difficult. A dynamic head-positioning device (Figure 34-2) can be used to maintain neutral head alignment and facilitate head control. A contoured headrest that cradles the head posteriorly and laterally may be used to support the head in a midline position. A forehead strap (fabricated from soft, padded material) may be used to prevent the head from falling forward. Slightly reclining the wheelchair also prevents the client's head from falling forward and facilitates visual interaction with the environment. The client should be reclined between 10 and 15 degrees; reclining the client beyond this point reduces weight bearing through the trunk and pelvis and tends to encourage extensor tone, a posterior pelvic tilt, and sacral sitting. If the patient has had a portion of the skull removed, a helmet is necessary to protect the brain during all mobility and when getting the patient out of bed into a wheelchair.

As the client progresses in rehabilitation, wheelchair seating and positioning should be continually re-evaluated

FIGURE 34-2 A dynamic head-positioning device maintains neutral head alignment and facilitates head control.

to better meet his or her specific needs. Devices should be modified gradually or removed as the client begins to control his or her body actively and manipulate more items in the environment. A schedule is necessary to indicate the length of time that the client can tolerate being seated in the wheelchair. Keeping the client in a wheelchair longer than can be tolerated may result in fatigue, which can subsequently interfere with active participation in therapy.

Bed Positioning

Proper bed positioning is critical in the early stages of TBI. Because the client tends to spend a lot of time in bed, proper bed positioning is crucial to prevent pressure sores, facilitate normal muscle tone, and prevent loss of pelvis and trunk ROM and mobility. It is often difficult to maintain optimal positioning because of spasticity and abnormal posturing. Other complications that may interfere with proper positioning are casts or splints, intravenous tubes, nasogastric tubes, fractures, or any other medical precautions that must be maintained while in bed.

If the client exhibits abnormal tone or posturing, a side-lying or semiprone position is preferable. This position assists in normalizing tone and providing sensory input. A supine position may elicit a tonic labyrinthine reflex and extensor tone. A supine position with the head in a lateral position could elicit an asymmetric tonic neck reflex. Clients with TBI generally have bilateral involvement requiring a program for side-lying on both sides. The

traditional bed-positioning techniques used for patients who have suffered a cerebrovascular accident may require modification depending on the extent of bilateral involvement. Pillows, foam wedges, and splints may be incorporated into the bed-positioning program to facilitate normal positions and prevent abnormal postures such as extreme elbow flexion, head and neck extension, and footdrop deformity.

OT Practice Notes

Because all clients have unique needs, each should be assessed and set up with an ideal positioning program. It often helps to take a photo of the client once positioned and post it to ensure that it can be easily duplicated and carried out by staff and family members.

Splinting and Casting

Splinting or casting may be indicated when (1) spasticity interferes with functional movement and independence in ADLs, (2) joint ROM limitations are present, and (3) soft tissue contractures are possible. Splints have been thought to provide elongation and inhibition by positioning the joint in a static position with the muscles and soft tissues on stretch. Splinting of the elbows, wrists, and hands is often implemented to maintain a functional position at rest and to reduce tone. Serial casting is a more aggressive intervention to increase ROM in the joints when contractures have formed or spasticity is present (or both). Splinting and casting not only reduce contractures and increase ROM but also prevent skin breakdown. Because clients with TBI often have limited active ROM, the UE joints often assume a position of flexion (particularly when severe finger flexor spasticity has caused the fingers and nails to embed in the palmar surface of the hand), and this may cause moisture, redness, and breakdown of the skin.

A resting or functional position splint (Figure 34-3) is one that is worn when the client is not involved in active movements or functional tasks. Once the splint has been fitted, a wearing schedule must be established for the rehabilitation team and caregivers to follow. A typical splint schedule during the day requires the client to wear the splint for repeated, alternating 2-hour periods (2 hours on, followed by 2 hours off). The client must be monitored frequently for any skin breakdown or tonal changes that may change the initial fit of the splint. The team and caregivers should be trained in proper application and removal of each splint.

Other common splints worn at this stage of recovery are cone splints, used in the palm of the hand to keep the fingers from digging into the palmar surface. Frequently, rolled cloths are put into the clenched hand; however, because this may facilitate increased spasticity, a hard cone

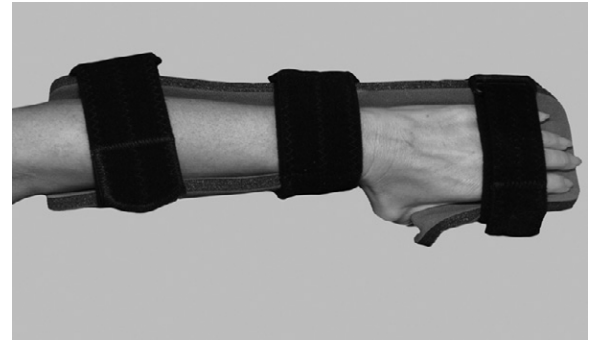

FIGURE 34-3 Resting splint.

FIGURE 34-4 Antispasticity splint.

splint is more appropriate. An antispasticity splint (Figure 34-4) not only positions the hand and wrist in a functional position but also abducts the fingers to further decrease spasticity. Splints are modified as needed and may eventually be discontinued if the individual's motor control and tone improve.

A serial casting program is indicated when moderate to severe spasticity cannot be managed by splints. The goal of casting is to increase ROM and decrease tone gradually by using a progressive succession of separately fabricated casts, each worn continuously for a period of weeks. Casts are often left on for 5 to 7 days, which places the muscle and tendons on prolonged stretch and reduces tone. Successive casts are designed to increase ROM further until a functional joint range is achieved and maintained. A common difficulty that prevents serial casting from being successful is skin breakdown. If skin breakdown occurs because of a cast that is worn for several days, the cast must be removed until the skin has healed. While wound healing is occurring, spasticity again increases and any gain in joint ROM is often lost.

The most common UE casts are the elbow cast, which is used for loss of passive range of motion (PROM) in the elbow flexors, and the wrist-hand cast, which is used for loss of PROM in the wrist and finger flexors. Other variations of these casts include elbow dropout, wrist, thumb, hand,

and individual finger casts. However, casting of more than one joint at a time often leads to skin breakdown as a result of multiple pressure points. It is thus recommended that casting be applied to one joint at a time.²⁸

Casting is frequently used in conjunction with motor point, nerve blocks or botulinum toxin injections. Blocks involve the injection of a chemical substance (e.g., lidocaine, bupivacaine, phenol) into the nerve or motor point to inhibit the innervation of spastic muscles temporarily. Botulinum toxin is injected directly into the target muscle and works by causing presynaptic blockade of acetylcholine release.

Indications for termination of a casting program include achieving functional ROM or plateauing (e.g., the individual has not gained significant improvement in ROM after two consecutive casts). When improvement in ROM has been made and the goal has been achieved, the final cast is cut in half lengthwise, the edges are finished, and the cast is used as a bivalve splint to maintain the functional position. Velcro straps or elastic wrap bandages are used to secure them in place (Figure 34-5). A wearing schedule is then established.

Casting is an advanced intervention technique that carries some risk. Competent use of the technique requires knowledge and advanced clinical training. Marisol had increased spasticity and reduced function in her UEs. What splint or cast (or both) would best suit her needs initially?

Dysphagia

Patients emerging from coma are fed through a nasogastric or gastrointestinal tube. Once the patient is alert and more oriented, the physician decides when evaluation for dysphagia is indicated. Dysphagia programs usually begin in the

FIGURE 34-5 Spasticity splint.

intermediate- to advanced-level stages of rehabilitation (see Chapter 27).

Behavioral and Cognition

As clients emerge from coma and become more alert and aware of their surroundings, it is important to track their improvement and attempt to establish a form of communication. In acute rehabilitation, tracking the level of arousal and awareness is important because it demonstrates progress. Several scales and assessments are available, including the WHIM, JFK, and Orientation Log. These measurement tools will document improvements in visual attention, visual tracking, and ability to follow commands.

Establishing a way for the client to communicate wants and needs is of the utmost importance because it helps guide intervention. It also allows the team to more accurately assess the client's cognitive level. A reliable yes/no system should typically be implemented. Examples include eye blinks, eye gaze, head nods, and motor movements such as thumb up and down. Once a system is established, communication is possible. In the case of Marisol, she gained some active movement of her right UE and with guiding was able to use large colored buttons to answer yes and no to questions. The yes/no buttons were positioned on the lap tray of her wheelchair and provided a buzz sound when touched. She was effectively able to answer simple questions such as do you need to use the bathroom or are you in pain when asked.

Family and Caregiver Education

Education of family members and caregivers starts immediately because they are an integral part of the intervention team. Family members often play an essential role in eliciting the client's responses and implementing the sensory regulation program, positioning the client in bed, and contributing to the ROM program. At the earliest stage after the injury, therapy may be limited; therefore, setting up a simple intervention plan for the family to implement is important in fostering the client's recovery and maintaining passive joint motion. Family members often feel helpless, and allowing them to be actively involved helps alleviate their feelings of helplessness and focus their array of emotions. Later, when the individual is more alert and mobile, family members can be involved in transfers, wheelchair positioning, feeding programs, and ADL retraining. Providing several education materials is helpful for family members. Brain injury patient education booklets and Internet Websites are effective tools in educating patients and family members.

Evaluation of the Intermediate- to Higher-Level Individual

During the intermediate to advanced level of recovery (Rancho Los Amigos Scale level of IV to VIII), the client is alert but often displays confused, agitated, and

inappropriate responses. The client may be able to follow simple two- to three-step verbal commands but is easily distracted. Minimal or moderate cues are often necessary to assist intermediate- to higher-level clients in the performance of ADLs. In general, they can complete most components of the occupational therapy evaluation; however, they may require several breaks during the evaluation process because of distractibility or agitation. The evaluation is similar to that for beginning-level clients in that physical status, dysphagia, psychosocial and behavioral factors, vision, sensation, and perception are assessed. Additionally, these patients require more extensive evaluation of ADLs (including driving), work readiness, and ability to reintegrate into the community.

Physical Status

The physical status evaluation includes an assessment of joint ROM, muscular strength, sensation, proprioception, kinesthesia, fine and gross motor control, and total body control (i.e., dynamic sitting or standing balance). Limitations in physical status are usually the result of abnormal tone, spasticity, and muscle weakness without abnormal tone, heterotopic ossification, fractures, soft tissue contractures, and peripheral nerve compression. Tools to assess physical status include goniometers, dynamometers, manual muscle testing, and clinical observation. Standard assessments may include the Jebsen Hand Function Test,⁴⁰ the Minnesota Rate of Manipulation Tests,⁵⁴ the Minnesota Manual Dexterity test,⁵⁴ and the Purdue Pegboard.⁷⁰

Dysphagia

Dysphagia assessment may include both clinical (bedside) evaluation and videofluoroscopy. The bedside examination provides the therapist with a variety of information. For example, aspiration can be caused by impulsivity because the client may gulp large portions of food quickly. Pocketing food and drooling may be apparent and are a result of impaired oral motor control. The dysphagia examination can also provide the therapist with information regarding cognitive status. Does the client appear to understand what to do with the utensils and food items? Is neglect present and causing the client to leave one side of the plate untouched? Does the client know the names of the utensils and food items, or is aphasia suspected?

Performed by a speech pathologist or a trained occupational therapist, videofluoroscopy provides information regarding the anatomy and physiology of the oral, pharyngeal, and esophageal stages of swallowing. Videofluoroscopy is the only dysphagia assessment tool that can provide information on the individual's ability to manage liquids and solid foods. This information will be used to design a feeding program that may require a diet of thick liquids and pureed foods. Swallowing status should be re-evaluated as the individual improves in rehabilitation and can progress to thin liquids and solid foods. (See [Chapter 27](#) for more information on dysphagia.)

Improper positioning, behavioral disorders, and cognitive-perceptual impairment have all been implicated as factors contributing to swallowing disorders. Dysphagia intervention must address seating and positioning and cognitive-perceptual distortions. Formal assessments to evaluate dysphagia include the Dysphagia Evaluation Protocol 4 and the Evaluation of Oral Function in Feeding.⁶⁹

Cognition

Cognitive skills are assessed within functional tasks (e.g., ADLs, meal preparation, money management, and community skills). Tasks that involve paper and pencil can also provide valuable information, although they are only part of the equation. Assessment of a client's cognition during preparation of a cold meal may include the following skills: (1) following two- to three-step written or spoken directions, (2) correctly sequencing the order of steps, (3) attending to the task with minimal distraction, and (4) displaying good safety and judgment. The therapist may evaluate the client's cognitive status by measuring any of the following: (1) counting the number of errors and correct responses, (2) assessing the amount of assistance or cueing required (minimal, moderate, or maximal), and (3) determining the percentage of the task that was completed correctly. Assessment of the complexity of the activity (simple versus multistep or basic to complex) and the conditions of the environment (isolated versus multistimulus or quiet to distracting) is also important.

When assessing an individual's cognitive skills, the therapist must consider and document other factors that may affect performance. Such factors include language barriers (e.g., the presence of aphasia, a primary language other than English), visual-perceptual deficits, the effects of medication on cognitive level, educational and cultural background, and previous experience with the task. Formal cognitive assessments that may be used with a TBI population include the Allen Cognitive Level Test,² the Loewenstein Occupational Therapy Cognitive Assessment,⁵⁰ the Rivermead Behavioral Memory Test,⁷⁷ Kohlman Evaluation of Living Skills,⁴³ and the Cognitive Assessment of Minnesota.⁶⁴

Vision

Clients with TBI should undergo vision screening. The vision screening should be completed as early as possible in the rehabilitation process because early detection of visual deficits will allow the intervention team to obtain more reliable information regarding the client's overall health status. For example, diplopia (double vision) or accommodative dysfunction (inability to adjust focus for changes in distance) will probably influence the results of the neuropsychology or speech-language pathology assessments.

Vision screening is a tool that allows therapists to identify potential deficits in vision. Although therapists cannot diagnose conditions of vision dysfunction, they can determine whether an individual passes or fails a visual screening based on standard criteria. The screening is a means of

determining which clients require a referral to an optometrist or ophthalmologist for a complete evaluation and intervention. A comprehensive vision intervention program is designed by an optometrist and implemented by an occupational therapist or vision therapist. A visual history questionnaire should be completed as well. The questionnaire should contain an ophthalmologic history, questions regarding the use of glasses and contact lenses, and questions about the presence of blurred vision, dizziness, headaches, eyestrain, diplopia, and visual field loss.

Common areas evaluated in a vision screening include visual attention, near and distant acuity, ocular movement (e.g., pursuits and saccades), convergence, accommodation, ocular alignment, depth perception (stereopsis), and visual field function. Visual dysfunction can also be identified during clinical observation of the individual's performance in functional activities. Tilting the head as a result of a field deficit, closing or covering one eye to decrease blurred vision, and bumping into walls or objects in the environment because of a field deficit or unilateral neglect are all easily observed behavior indicative of visual dysfunction.

Perceptual Function

Perceptual evaluation should be performed when the therapist has obtained a clear understanding of the individual's cognitive, sensory, motor, and language status because deficits in these areas may skew the client's performance on a perceptual evaluation. Evaluation of visual perception should include right-left discrimination, form constancy, position in space, topographic orientation, and naming of objects. Evaluation of perceptual-speech and language function should assess for aphasia, and anomia. Evaluation of perceptual motor function should include the functions of ideational praxis, ideomotor praxis, three-dimensional constructional praxis, and body schema perception (including identification of unilateral neglect). Formal perceptual assessments that can be used for a population of adults with TBI include the Hooper Visual Organization Test,³⁸ Motor-Free Visual Perception Test—Revised,¹⁶ Rivermead Perceptual Assessment Battery,⁷⁶ and Loewenstein Occupational Therapy Cognitive Assessment.⁵⁰

Activities of Daily Living

Intermediate-level clients should be assessed in all basic ADLs (e.g., grooming, oral hygiene, bathing, toileting, dressing, functional mobility, and emergency response). Advanced-level clients should also be assessed with regard to instrumental activities of daily living (IADLs), such as hot and cold meal preparation, money management, community shopping (Figure 34-6), household maintenance, cleaning and clothing care, safety procedures, medication routine, and work readiness. The therapist will have ample opportunity during assessment to observe cognitive skills, perceptual skills, and behavioral appropriateness.³¹ Formal assessments that can be used for a population with TBI to

FIGURE 34-6 Community shopping.

assess ADL skills include the Arnadottir OT-ADL Neurobehavioral Evaluation,⁴ Assessment of Motor and Process Skills,²³ Functional Independence Measure,³⁵ and the Klein-Bell Activities of Daily Living Scale.⁴²

Clients with a history of alcohol abuse require assessment of leisure patterns. An interest history and interest checklist may reveal healthful leisure interests that can replace alcohol use. The combination of leisure skills development and substance abuse rehabilitation will help clients manage time more effectively and thereby refrain from using alcohol after discharge.

Driving

Many states require physicians to report anyone to the Department of Motor Vehicles who has lapses of consciousness, seizure disorders, and cognitive, visual, and perceptual dysfunction caused by TBI. Regulations regarding such disorders often mandate that the driver's license be revoked until further assessment confirms that the person can drive without posing a safety risk to self or others.

Advanced-level clients with TBI who do not have seizure disorders or severe cognitive deficits must undergo a comprehensive driving evaluation to assess their ability to resume driving. Two types of driving evaluation can be completed: a clinical assessment (evaluation of the individual's visual, cognitive, perceptual, and physical status as it relates to driving) and an on-road assessment. Both types of evaluation are necessary because the client may fail the clinical assessment but pass the on-road assessment by using compensatory strategies. Conversely, the client may perform successfully on the clinical assessment but fail the on-road assessment (see Chapter 11).

Clients with TBI frequently exhibit deficits (e.g., visual processing disorders, figure-ground discrimination dysfunction, and impulsivity) that significantly affect their ability to drive safely. When visual processing is delayed, affected persons hesitate during driving maneuvers and stop in an unsafe manner (e.g., in the middle of the road or at a corner) to allow themselves adequate time to process visual

information. Those with figure-ground impairments may be unable to identify stop signs and traffic signals at intersections or locate the gearshift near the dashboard. Impulsive individuals may respond aggressively rather than defensively when driving, thereby increasing the risk for accidents. They may use poor judgment when making driving decisions and be unable to inhibit inappropriate responses. The Elemental Driving Simulator²⁷ and Driving Assessment System²⁷ are off-the-road clinical driving assessments that can be used with an on-road assessment to determine a client's ability to resume driving after brain injury. Occasionally, individuals have a strong desire to drive and poor insight into whether they possess safe skills to resume driving. Since most rehabilitation centers and outpatient settings do not have an adaptive driving program and expensive driving simulators, occupational therapists need to use low-tech options to determine driving readiness and educate patients on whether they are safe to drive. There are many commercially available computerized driving assessments and training tools that are easy to download and inexpensive. One option is the Roadwise Review distributed by the American Automotive Association (AAA).¹ This computer-based tool measures the functional abilities scientifically linked to risk for crashing in older drivers. Since it assesses useful field of view, visual-perceptual skills, and reaction times, it is an excellent tool that can be used in the TBI population.

Vocational Rehabilitation

Advanced-level clients may be evaluated to determine whether they are ready to return to work. It has been well documented that return to work after moderate to severe TBI is generally unsuccessful. High unemployment rates have been attributed to the adverse emotional, behavioral, and neuropsychologic changes arising from TBI. Substance abuse in the TBI population is also a major factor inhibiting the ability to return to and maintain employment.²⁶

Vocational assessment for advanced-level clients must involve assessment in the actual work setting because psychometric tests and job simulations in themselves do not accurately determine work potential. The client is often able to compensate in a familiar work setting for deficits that may appear to be significant impairments on a psychometric test. The therapist's vocational evaluation should summarize the individual's interests, strengths, and areas of deficit. The report should conclude with recommendations stating the modifications required, realistic job goals, and a plan for achieving these goals with professional assistance as needed.

Psychosocial Skills

Advanced-level clients who will be discharged to the home setting or a community-supported living residence should also undergo a psychosocial skill evaluation. Such an evaluation should assess role loss, social conduct, interpersonal skills, self-expression, time management, and self-control.

The therapist should also assess the client's social support system, ability to form and maintain friendships, and resources to decrease feelings of isolation (such as TBI support groups). The ability to form and maintain intimate and sexual relationships after TBI will be of paramount concern to single clients who sustained their TBI between the ages of 18 and 30. Child rearing and care of family members will be of concern for clients who are responsible for children and other family members.

Assessment of psychosocial skills in clients with TBI is critical. For 1 or more years after injury, clients with TBI report that their psychosocial deficits significantly diminish life satisfaction and are a greater problem than the physical and cognitive deficits combined. Psychosocial impairment is often neglected in the rehabilitation setting, which prioritizes intervention for acute physical, cognitive, and perceptual deficits. Psychosocial difficulties are more apparent after discharge, when the individual has left the structured and safe setting of the rehabilitation hospital to re-enter the community. It is important to address psychosocial difficulties before the individual is discharged. Psychosocial assessment tools that can be used for this population include the Assessment of Communication and Interaction Skills,⁶⁵ the Occupational Role History,²⁴ and the Role Checklist.⁵⁶

Marisol received skilled occupational therapy intervention throughout a 3-month inpatient rehabilitation stay, followed by 6 weeks in a day treatment program. Marisol participated in a multifaceted spasticity reduction program and neuromuscular re-education, which improved ROM and functional use of her right UE. As her ROM and selective movement improved, Marisol learned how to feed, dress, and bathe herself with minimal assistance. As Marisol's head and trunk control improved, she was able to participate in all aspects of bed mobility and transfers. Daily guided self-care tasks were a critical part of her morning schedule. Performing meaningful, routine tasks allowed Marisol to work on her basic cognitive abilities. Spontaneous neurologic recovery, cognitive re-education, and memory strategies improved Marisol's ability to plan, organize, and sequence her ADLs and recall her daily therapy schedule with occasional verbal cues. Marisol was referred to an outpatient occupational therapy program after discharge from the day treatment program.

Intervention for the Intermediate-to Higher-Level Individual

Intervention for intermediate- to higher-level individuals involves two primary approaches: the rehabilitative model and the compensatory model. The rehabilitative model is supported by the theory of neuroplasticity, which holds that the brain can repair itself or reorganize its neural pathways to allow relearning of functions that had been lost as a result of neural damage sustained in the accident. The compensatory model holds that repair of damaged brain tissue either

has occurred to its fullest extent or cannot occur, with the individual being left unable to perform lost functions without external assistance. Tools used in the compensatory model are adaptive equipment, environmental modification, and compensatory strategies that allow the client to perform ADLs. It is valuable to approach intervention via both the rehabilitative and compensatory approaches through addressing neuromuscular impairment, cognitive deficits, perceptual deficits, vision dysfunction, and behavioral disorders. In general, a rehabilitative approach is used in the acute stage of TBI recovery until the client has plateaued or progress has slowed, at which time a compensatory approach is attempted.

Neuromuscular Impairments

As in beginning-level individuals with TBI, numerous types of neuromuscular impairment can be present in intermediate- to advanced-level individuals. Spasticity, rigidity, soft tissue contractures, the presence of primitive reflexes, diminished or lost postural reactions, muscular weakness, and impaired sensation affect the ability to perform activities independently and with normal control (see [Table 34-3](#)). The prerequisites for normal movement include normal postural tone, balanced integration of flexor control (reciprocal innervation), normal proximal stability, and the ability to implement selective movement patterns.

The common principles of intervention for neuromuscular impairment are to facilitate control of muscle groups, progressing proximally to distally; encourage symmetric posture; facilitate integration of both sides of the body into activities; encourage bilateral weight bearing; and introduce a normal sensory experience. Effective rehabilitation techniques for such individuals include neurodevelopmental treatment (NDT), proprioceptive neuromuscular facilitation (PNF), myofascial release, Rood techniques, and some physical agent modalities (see [Chapters 29 and 31](#)). These clinical interventions require education beyond the entry level and must be either incorporated into or followed by a meaningful functional activity that requires the same movement. The following brief overview of principles is merely an introduction and cannot substitute for training in the specific techniques.

Intervention for impaired neuromuscular control should begin at the pelvis because positioning of the pelvis affects the motor control of all other body parts. A variety of approaches may be used to normalize pelvic positioning. For example, clients with TBI commonly have a posterior pelvic tilt. To move the client to a more functional erect pelvic position, a therapist trained in NDT might use anterior pelvic tilt mobilization. A therapist with a different approach might use a bedsheet behind the pelvis to lift and rotate the pelvis forward over the heads of the femurs. In either case, individuals would be directed to raise their head and sit up tall.

The trunk is positioned after the pelvis. Proper positioning of the trunk frees the UEs for functional activities.

Major principles include the following: (1) facilitating trunk alignment, (2) stimulating reciprocal trunk muscle activity, (3) encouraging the individual to shift weight out of a stable posture into all directions (bending forward, bending backward, reaching to each side while laterally flexing the trunk), and (4) helping the individual move the lower part of the trunk on a stable upper trunk or move the upper trunk on a stable lower trunk. Once trunk control improves, intervention should progress to the UEs.

Competent practitioners may apply rehabilitative techniques in a variety of ways. A client with soft tissue contractures or spasticity in a particular muscle group may benefit from NDT mobilization and inhibitory techniques for the agonistic muscle group. A client with low tone or weak muscles (without the presence of spasticity) may benefit from NDT, PNF, Rood, and physical agent modalities. Kinesio-taping can assist in providing stability to weak muscle groups. Neuromuscular electrical stimulation can effectively stimulate UE muscle groups, including the triceps, pronators, supinators, and wrist and finger extensors, to enhance muscle strength, increase sensory awareness, and assist in motor learning and coordination.¹³

Many advanced-level clients have fairly intact motor control and are able to ambulate independently and use both UEs in functional activities. However, close observation reveals subtle trunk and extremity deficits related to coordination and speed of movement. The intervention for trunk control focuses on developing full isolated movements of the trunk and extremities, good dynamic standing balance for all activities (including reaching and bending to high and low surfaces), and the ability to shift weight naturally from one LE to the other during activities. UE intervention programs are designed to increase scapular stability and improve fine motor control. A goal of intervention is to improve the client's speed while maintaining good coordination and minimizing compensatory strategies ([Figure 34-7](#)).

FIGURE 34-7 Use of both hands during meal preparation.

Ataxia

Ataxia is a common motor dysfunction that occurs primarily as a result of damage to the cerebellum or to the neural pathways leading to and from the cerebellum. Ataxia develops early in the acute stage of recovery and may remain permanently. It is a clinical problem for which rehabilitation methods are generally ineffective. More often, therapists train the client in use of compensatory strategies to control the effects of ataxia. For example, weighting of body parts and the use of resistive activities often improve control during the performance of tasks but show inconsistent carryover of muscular control when the resistance is removed. When applying weights to clients, the therapist must identify at which joint (or joints) the tremor originates. Applying weights to clients' wrists when the tremor emerges from the trunk and shoulders is ineffective. Weighted eating utensils and cups are also used as compensatory aids to reduce the effects of ataxia on the UEs; however, these assistive devices are limited in their effectiveness.

Cognition

Intervention designed to enhance cognitive skills should be implemented through functional ADLs and IADLs. A common impairment in cognition is concrete thinking, in which the individual is likely to have difficulty with abstract concepts. Activities that require generalization of skills from one task to another will be difficult for clients with TBI. It is best to engage these clients in activities that they need to participate in everyday life. For example, if the client will return to a community environment in which it is necessary to use public transportation, interpreting bus schedules is a meaningful and relevant activity that addresses many critical cognitive skills, including problem solving, planning, organization, concentration, tolerance of frustration, sequencing, money management, and categorization. Another way to address the aforementioned cognitive skills is by planning a trip to the hardware store to purchase supplies necessary to install a hand-held showerhead.

Clients at an advanced level of recovery who demonstrate high-level cognitive skills often display subtle cognitive deficits in the areas of organization, planning, sequencing, and short-term memory.

Generally, neuropsychologists and cognitive educators have implemented the use of computers in cognitive retraining. However, use of computer programs has not been shown to generalize to the cognitive skills needed to improve performance in IADLs.⁵⁵ Computers can be used in therapy if they are meaningful in the client's daily life; the therapist should address the client's specific computer needs. For example, by simplifying tool bars and menus and programming step-by-step written directions that appear on screen, therapists may reprogram a client's home computer to make it less complicated to use. Software programs that do not represent functional activities should be avoided. Since 36% of Americans with a disability use a computer at home (U.S.

OT Practice Notes

Activities such as establishing a monthly budget to live independently and negotiating the community public transportation system to pay a utility bill provide a context for cognitive retraining to address subtle cognitive deficits. Activities should be challenging, age appropriate, and relevant to the individual's real-life needs. Compensatory strategies may include the use of a schedule, memory book, electronic hand-held device, monthly budget chart, and the use of simplified maps of the client's community. For optimal success, the system chosen must take into account the client's familiarity with and motivation to use the given strategy. For example, a client may have used a high-tech cell phone as a day planner before the injury and may prefer to use this system after the injury as well.

Census, 2008) and 60% of working-age adults are likely to benefit from the use of accessible technology because of disabilities, it is important to introduce computers into treatment as a therapeutic modality. The occupational therapist can not only set up a computer by using the built-in accessibility options and utilities but also provide specialty assistive technology products such as voice recognition, alternative keyboards, and trackballs to allow patients successful access and use.³² Computer access not only facilitates cognitive retraining opportunities but can also be a source of communication and address visual, perceptual, and motor deficits.

Vision

Intervention alternatives for clients with TBI and visual dysfunction include the use of corrective lenses, occlusion (e.g., patching one eye), prism lenses, vision exercises, environmental adaptations, and corrective surgery. An optometrist or ophthalmologist can evaluate the client's vision and prescribe glasses to address any accommodative dysfunction caused by brain injury. However, the glasses should not be prescribed until the client has passed the subacute phase of rehabilitation because an accommodative dysfunction that appears in the acute stage of brain injury may improve during the recovery process.

A common technique to eliminate double vision (diplopia) is patching, or occlusion. The client wears a patch over one eye to block the image seen by that eye and eliminate diplopia. Patching is a temporary compensatory strategy. An optometrist may prescribe prism glasses or binasal occluders for clients with consistent diplopia resulting from permanent oculomotor nerve damage. The prisms assist the eyes in fusing images. Prism glasses are not effective for those with significant lateral strabismus or exotropia (outward eye turn). Binasal occluders encourage the malaligned eye to fixate centrally. Prism glasses and binasal occluders are used conjointly with vision exercises. The goal of this

intervention is to decrease the diplopia and eventually eliminate the need for prisms or occluders.

Vision exercises consist of a series of activities that (1) maximize residual vision, (2) enhance impaired vision skills (the rehabilitative approach), (3) increase the client's awareness of his or her visual deficits, and (4) help the client learn compensatory strategies. Intervention progresses from monocular to binocular vision and follows a developmental progression (supine to sitting to standing). Exercises initially address basic skills such as visual attention, pursuits, and saccades and may progress to more difficult skills such as fusion and stereopsis. These vision exercises are based on the rehabilitative model, which holds that impaired visual skills can improve with training.

Environmental adaptations for visual deficits are based on the compensatory model. Compensatory strategies for visual deficits include using a colored border along one side of a page to facilitate reading. A colored strip of tape along one side of a plate or meal tray to promote self-feeding is one option. Use of large objects, such as a clock with bold numbers or a telephone with enlarged buttons, is another compensatory technique. Contrasting colors to highlight controls and knobs (e.g., marking TV/VCR remote control buttons with fluorescent paint) may be helpful. Increasing lighting in an environment and using textures as cues (e.g., placing textured tape on a banister by the bottom step to alert the individual that the bottom step is coming and thereby reduce falls) may be used for clients with low vision. The latter compensatory strategy is also valuable for clients with vertical gaze paralysis who can look neither up nor down. Those who have lost pupil constriction should wear sunglasses whenever they are in bright light.

Corrective surgery performed by an ophthalmologist may be indicated to align the eyes and eliminate double vision; however, the individual must wait at least a year after the injury to allow any improvement that may occur naturally in the course of recovery.

Perception

Treatment of perceptual deficits involves both rehabilitative and compensatory intervention. For example, impairment of figure-ground perception might be treated via a rehabilitative approach through the repeated practice of locating objects against a similar background (e.g., finding a white shirt on a bed with white sheets or finding a spoon in a drawer of similar stainless steel utensils). Using a compensatory approach, the therapist would help the client arrange the kitchen drawers so that utensils are categorized (perhaps color-coded) and distinctly divided to facilitate identification.

Aphasia (a perceptual-speech disorder) can also be treated by both rehabilitative and compensatory approaches. Expressive aphasia may be treated rehabilitatively through repeated conversation exercises in which clients are given feedback regarding their incorrect spoken words and challenged to express the words that they meant to verbalize. If

the client has not made significant gains in expressive speech through use of the rehabilitative approach, the compensatory approach should be used to help the client articulate his or her needs to caregivers. For example, a chart with letters, words, or pictures (or a combination of the three) of important items in the client's environment can be used to help the client identify needs such as eating, toileting, and medications. Such a chart may be used concomitantly with rehabilitative approaches.

Through a rehabilitative approach, apraxia can be treated by helping the client perform specific tasks (e.g., hair combing) hand over hand (i.e., the therapist's hands guide the client's hands during hair combing). The rehabilitative approach holds that through repeated hand-over-hand exercise, the client's brain can repair the neural pathways that mediate specific motor patterns, such as those needed for hair combing, or can reorganize pathways so that different, undamaged areas of the brain can establish new pathways for specific motor patterns. Using a compensatory approach, the client may comb his or her hair by following steps through the visual interpretation of pictures sequentially depicted (pictures) or listed (words) on a poster or note card.

Neglect syndrome (a disorder of body schema) can also be addressed by using rehabilitation and compensatory strategies. Severe neglect syndromes tend to decrease as a natural part of the recovery process. However, some neglect syndromes may continue into the postacute rehabilitation stage. With a rehabilitative approach, the client is encouraged to use the neglected extremity for all ADLs. The client's room may be rearranged to encourage interaction with the neglected part of the environment (e.g., placing the television or standing bed tray in the left side of the room if the client has left-sided neglect). A compensatory model is used when the client has not demonstrated significant improvement in attending to the neglected side of the body or environment. The meal tray may be placed within the client's field of vision to maximize success. A colored border may be placed on the left side of book pages to cue the individual to scan the entire line while reading.

Behavioral Management

The types of intervention strategies used to decrease and eliminate problem behavior may be divided into two categories: environmental and interactive. Environmental interventions alter objects or other environmental features to facilitate appropriate behavior, inhibit unwanted behavior, and maintain individual safety. Agitated clients should be placed in a quiet, isolated room without a roommate. All extraneous stimuli (e.g., radios and televisions) should be removed. Similarly, therapy is provided in a private, quiet room away from other people and extraneous stimuli.

An agitated client who demonstrates severe behavioral problems may require one-to-one care. The client is assigned a rehabilitation aide who remains with the client throughout the day (including during therapy) to monitor and

regulate his or her behavior. The rehabilitation aide may wear an alarm bracelet that signals staff when the client attempts to wander away from the appropriate floor or out of the building. Walkie-talkies and pagers may be used with those who are at risk of eloping. One walkie-talkie or pager remains in the nursing station; the other is held by the therapist or staff member who is providing one-to-one care to the client. If the client begins to act aggressively or attempts to elope, the rehabilitation aide can alert the staff that assistance is needed.

Interactive interventions are the approaches that staff and caregivers use to interact with the client. The entire team should implement these interventions in a consistent way. Consistent implementation includes speaking in a calm and concise manner and deliberately refraining from detailed explanations that will only increase the client's confusion and frustration. For safety's sake, therapists should also keep the door open when working with the client at the bedside and should always maintain awareness of the individual in relation to self.

A client who is in the postacute stages of rehabilitation and who continues to exhibit behavioral problems should be placed in a behavioral management program. Such a program should allow the client to experience the natural consequences of inappropriate behavior (e.g., losing community recreational privileges) in an effort to encourage more appropriate responses. Drug therapy may be used for those who do not make significant improvements in their behavior and who present a safety risk to themselves and others.

Dysphagia and Self-Feeding

Intervention strategies for dysphagia follow the same guidelines as for other neurologic impairments; intervention, however, may be more complex in this population as a result of bilateral neurologic involvement, cognitive and behavioral issues, and severe neuromuscular impairments.^{5,6} A self-feeding program may begin in a quiet area, such as the client's room. Eating is then advanced to more social situations, such as the hospital dining room. Common pieces of adaptive equipment, such as a rocker knife, plate guard, and nonspill mug, may be used if the client demonstrates diminished strength, coordination, or perceptual deficits. If the client displays decreased attention, introducing one piece of adaptive equipment at a time may help. Clients with heightened impulsivity may benefit from the strategy of placing the fork down after each bite to ensure that they completely chew and swallow before initiating the next bite. Depending on the client's level of dysphagia (i.e., pre-oral, oral, pharyngeal, and esophageal), a diet of thick liquids or puréed foods may be indicated until the client makes progress toward recovery.

Functional Mobility

Mobility training can be subdivided into bed mobility, transfer training, wheelchair mobility, functional ambulation during performance of ADLs, and community

mobility. The NDT principles of bilateral extremity use, equal weight bearing, and tone normalization are used in intervention strategies that address functional mobility. The rehabilitation model, based on the principles of NDT and PNF, should be used for intermediate-level clients with TBI in the acute and subacute stages of rehabilitation. Allowing a client with loss of function to use compensatory strategies, such as grabbing a bed rail with one hand and rolling or standing on one leg to transfer, may appear to enable the client to function more independently earlier. However, use of such strategies diminishes the client's ability to perform activities with a bilateral UE pattern at a later point. In time, unilateral performance of activities results in hemiplegic postures, contractures, and abnormal gait deviations. Compensatory strategies should be used only in the later stages of recovery and when the client has not been able to demonstrate significant improvement in functional mobility skills and thus must learn compensatory strategies to enhance the ability to live independently in the community.

Bed Mobility

An intermediate-level client with TBI may require training in bed mobility skills, including (1) scooting up and down in bed, (2) rolling, (3) bridging, and (4) moving from a supine position to and from sitting and standing positions.

Wheelchair Management

Wheelchair management includes the ability to manage wheelchair parts (e.g., removing footrests and locking brakes) and propelling the wheelchair both indoors and outdoors on a variety of surfaces (e.g., low-pile carpeting, sidewalks, and ramps). Customized wheelchairs may be ordered for a client who is in the postacute stage of rehabilitation and continues to exhibit neuromuscular impairment that requires the use of a wheelchair for long-term mobility needs. A custom wheelchair provides a seating and positioning system that contours the client's body for comfort and skin protection, includes adaptive supports for proper pelvic and trunk alignment, and offers a seating position that enhances the client's ability to interact with the environment. Clients who cannot propel or control a manual wheelchair may require an electric wheelchair for independent home or community mobility.

Functional Ambulation

Functional ambulation refers to the ability to walk during functional activities. Whereas physical therapists address gait training, occupational therapists facilitate the carryover of ambulation skills into ADLs. Ambulation during performance of ADLs often requires the integrated use of UEs and LEs to carry and manipulate objects (e.g., carrying a plate to a table, holding a book bag or purse, sweeping with a broom or vacuum cleaner, carrying an infant). Functional ambulation also requires the ability to negotiate an ambulatory device (e.g., straight or quad cane and walker) with one

or both UEs during performance of ADLs. This is a high-level activity that requires eye-hand coordination and the integration of total body movements. Compensatory aids to improve the client's ability to negotiate an ambulatory device while performing ADLs include walker bags and baskets, wheeled carts (to provide balance and support while transporting items such as plates to a table), canes with built-in reachers, pouch belts (to hold keys, wallet, and memory books), and an apron during meal preparation (see also Chapter 10).

Community Travel

For clients who will be discharged to home or a community supportive living arrangement, the ability to negotiate their environment must be considered. Negotiating uneven sidewalks and curb cutouts and correctly interpreting traffic light signals, as well as the direction and speed of oncoming traffic, are important skills to practice for safe and independent community mobility. Functional ambulation in the community requires the client to respond and initiate actions quickly—for example, to cross the street after the light turns green and before it turns red. Clients must perceive depth and spatial relationships (to correctly judge the distance and speed of oncoming and turning traffic) and visually identify and avoid environmental hazards that could cause falls (e.g., potholes and cracks in the sidewalk). Power mobile scooters or power wheelchairs are often recommended for clients who must perform long-distance mobility in the community but who fatigue easily or are unable to walk independently. Use of a power mobile scooter or power wheelchair requires good static sitting balance and the ability to quickly integrate UE hand control and cognitive decisions regarding the environment. Practicing with clients during the wheelchair evaluation is crucial to determine whether they are able to safely propel a power system within the community.

Transfers

Because individuals with TBI commonly have memory deficits and limited carryover of information, transfer training should be consistent (in technique and sequence) among all staff members treating the client. It is preferable that transfers for intermediate- and advanced-level clients be practiced while moving to both the right and the left sides. Without such practice, clients who become proficient in a transfer toward the uninvolved side (in the hospital) may be dismayed to find that the home setting or public restroom requires transfers toward the opposite side. Additionally, teaching them to transfer to both sides provides weight bearing on both LEs, the use of bilateral trunk muscles, and bilateral sensory input.

Family members and caregivers should be trained in proper transferring techniques (including proper body mechanics) and cleared by a therapist before transferring the individual alone. The decision about when to begin caregiver training depends on the client's functional level and

ability to cooperate, the discharge date, and the caregiver's physical and cognitive abilities.

Home Management

As the client's skills and independence in self-care, dressing, self-feeding, and functional mobility increase, intervention is expanded to include home management skills in preparation for discharge to the community. Home management skills include meal preparation, laundry, cleaning, money management (e.g., balancing a checkbook, paying bills, and budgeting), home repairs (e.g., changing a washer in a leaking faucet), and community shopping (which includes making a shopping list, locating the correct items in the store, and paying the correct amount of money at the cash register). Examples of high-level activities include planning a monthly budget, organizing a file cabinet, ordering from a catalog or the Internet, and filing income taxes. These are skills that adults need to live independently in the community and are thus relevant for most clients with TBI.

The degree to which clients participate in home management activities varies. For example, some prepare only simple meals using a microwave oven. For those who must prepare meals to live independently in the community but who are not interested in cooking, the goal is to help them safely prepare simple hot and cold meals at home. Some clients perform no household cleaning activities other than making their bed and doing the laundry. Common sense dictates that therapeutic interventions first address the activities that the client performed before the injury.

As in all other areas of intervention, home management skills are graded to accommodate the client's functional level. Beginning meal preparation tasks may involve making a cold sandwich, whereas beginning money management skills may involve learning to perform basic cash transactions. As clients progress in home management skills, the meal preparation task may be graded to preparing a two-item hot meal using a stovetop, oven, or microwave oven. Money management skills may be graded to writing checks and balancing a checkbook. As the client continues to gain skills, activities requiring higher-level demands are performed until the client reaches the desired goals.

Child care, if appropriate, must not be overlooked as an area of intervention. Family involvement is critical if a mother or father is to return effectively to his or her role as a spouse and parent. Sensory overload and its resultant agitation in a parent with TBI are a commonly reported problem for families. Occupational therapy sessions should gradually reintroduce parents to their role of caring for their children. Some hospitals have a family suite in which family members can practice ADLs and interpersonal skills with the client on weekends in preparation for discharge. This allows family members to gain a greater awareness of their loved one's impairments and need for assistance. It also makes the transition from hospital to home less stressful for both clients and family members.

The occupational therapist can also assist parents with TBI in the adaptation of strollers, cribs, and child care equipment to make handling of such items easier. Safely bathing or carrying a baby, preparing a meal while simultaneously caring for children, and one-handed diapering and dressing techniques are all examples of areas that could be addressed by occupational therapy services.

Community Reintegration

Clients who will be discharged from the acute rehabilitation hospital to home or to a postacute, residential supportive living arrangement should receive training to facilitate the transition from the hospital to the community. Clients who achieve a maximal level of independence in the protected and structured environment of the rehabilitation hospital may find that community reintegration holds even greater challenges. Community trips—in which an advanced-level client with TBI is accompanied in the community by the occupational therapist (and perhaps a family member) to practice IADLs in the natural environment—should be implemented to provide the client with the opportunity to rebuild daily life skills. Depositing or withdrawing money from the bank or ATM, using the public transportation system, planning a shopping list, and purchasing items at the grocery or hardware store are activities that will facilitate initiation of the client's re-entry into the community. Having the client perform ADLs within the community setting will also allow the therapist to observe the client's ability to interact successfully or otherwise with the environment. The client will be provided a chance to receive valuable feedback from others in the community regarding his or her behavior.

Some clients are discharged from the acute rehabilitation center to a transitional living center. Transitional living centers are designed to develop daily life skills by providing the client an opportunity to temporarily live in a community group setting with 24-hour staff supervision and assistance. The goal of transitional living centers is to facilitate progression from supervised living to greater independence in community living. The client is usually discharged from the transitional living center to a relative's home or to a residential supportive living facility that provides various levels of living arrangements (e.g., community apartments and shared community group homes). Because long-term residential community facilities for people with TBI are expensive and not covered by most insurance companies, many are discharged home, where they receive continued intervention in outpatient rehabilitation or in day treatment programs that provide community, work, and school re-entry training.

Psychosocial Skills

Individuals with TBI commonly report 1 or more years after the injury that psychosocial impairment is the greatest obstacle to rebuilding a meaningful lifestyle. Many report feeling a deep sense of isolation and loneliness. Loss of roles

such as partner or spouse, worker or student, independent home maintainer, friend, and community member often leaves individuals feeling as though they have lost their identity. The goal of the occupational therapist, particularly in postacute TBI centers (e.g., day treatment programs, outpatient rehabilitation, transitional living sites, and long-term community supportive living arrangements), is to help rebuild desired occupational and social roles. This involves a three-step process: (1) identifying the desired roles that were lost secondary to TBI, (2) identifying activities that would support the desired roles, and (3) identifying rites of passage that were either lost or never transitioned through as a result of TBI. Rites of passage are socially recognized events that mark the transition from one life stage to another. Common rites of passage in Western society include obtaining a driver's license, graduating from secondary school or obtaining a higher education degree, securing full-time employment, living independently in the community, dating, marrying, and parenting.

Once the desired occupational and social roles, activities, and rites of passage have been identified, the therapist facilitates the client's use of adaptation, compensatory strategies, and integration of new learning. The therapist will also help the client enhance or regain interpersonal skills, self-expression, social appropriateness, time management, and self-control. Such psychosocial skills will be critical if the client is to re-enter the community—to live in a neighborhood setting, hold a job, perform volunteer work in the community, and participate in desired recreational opportunities along with other adult community members.

Group intervention is beneficial because it enables the client to meet others experiencing the same life concerns (thereby decreasing feelings of isolation). Groups can offer exposure to peer reactions, which is particularly helpful if the client exhibits socially inappropriate behavior. Groups may also facilitate problem solving by providing the opportunity to speak with others who have successfully dealt with the same or similar problems. Participants who have been in the group longer can become peer mentors to new group members. The opportunity to help others—to share one's experience of having a brain injury with others who can benefit from that knowledge—has been shown to enhance an individual's life satisfaction, feelings of competence, and sense of usefulness. Many states have support groups for individuals with TBI that are run by state associations for brain injury.

Substance Use

If the client's preinjury history includes substance use, the client should receive drug and rehabilitation services specifically designed for individuals with TBI. Clients with a history of substance use may not display any signs of a desire to return to substance use while in the structured and protective environment of the subacute rehabilitation facility. Substance use may become a problem only after the client is discharged to home, a community-supported living

arrangement, or any residential situation in which long periods may be spent alone and unsupervised. Drug rehabilitation services are critical for clients with a substance abuse history because return to substance use after brain injury has been closely implicated in the occurrence of a second TBI.

Discharge Planning

Planning for discharge from occupational therapy services begins at the initial evaluation and continues until the last day of intervention. Components of discharge planning include a home safety evaluation (if the client will be discharged home), equipment evaluation and ordering, family and caregiver education, recommendations for a driver's training program (if indicated), and recommendations for successful return to school or vocational retraining and work skills.

Home Safety

If the client is to be discharged home, the therapist should visit the home (or transitional living setting) to recommend modifications for increased safety. For example, clients with balance difficulties should have grab bars in the shower stall. Increased lighting should be provided as necessary for clients with visual deficits because low lighting has been linked to falls. Recommendations should also be made regarding the client's ability to handle sharp items (e.g., knives or glass items that could shatter easily), use the stove, and remember to turn off the faucet and other appliances. The temperature setting on the hot water system should be set at or below 120° F to prevent scalding. Anything that could be tripped over (e.g., throw rugs, appliance cords, furniture legs, objects placed on steps) should be removed. If feasible, nonslip flooring should be added to slippery surfaces (e.g., bathroom and kitchen tiles). If a wheelchair is indicated, the therapist should recommend modifications to doorways and bathroom spaces and should suggest replacement of high-pile carpeting with tile, wood, or other surfaces that can easily be traversed by a wheelchair. Additionally, family members and caregivers should be educated in the appropriate steps to follow during a seizure, should understand how to evacuate the individual in case of emergency, and should practice methods by which to transfer the individual safely. Caregivers should be able to identify unsafe activities in which their loved one should not participate and should know the length of time that he or she can be left alone safely (if possible at all).

Equipment Evaluation and Ordering

Clients who will be discharged from the acute rehabilitation facility will require an evaluation of the equipment needed in the next setting. This may necessitate re-evaluation of the client's equipment needs because many of the adaptive devices that were valuable in the beginning and intermediate stages of rehabilitation may be discarded as the client improves. For example, a tub bench or shower chair may

have been needed initially because of dynamic standing balance difficulties. The client may have progressed sufficiently during the course of rehabilitation to stand in the shower while using only a grab bar.

Family and Caregiver Education

Family members and caregivers should be involved in the client's rehabilitation from the beginning of treatment and should be considered members of the intervention team. Education of caregivers in such activities as transfers, wheelchair mobility, ADLs, bed positioning, splint schedules, use of equipment, ROM exercises, and self-feeding techniques will facilitate follow-through with the skills that have been learned in the rehabilitation hospital. Individual safety is of primary importance for caregiver education. The caregiver should be trained in implementation of the home program (in either written or videotape form). Home programs may include the areas listed previously, as well as specific activities for the improvement of cognition, vision, perception, and motor control.

Recommendations for Driver's Training

If the client passes the clinical driver's evaluation, the occupational therapist may recommend a specific number of hours of driver's training. An occupational therapist or a driving instructor who has experience working with individuals with TBI (see [Chapter 11](#)) should implement the driver's training.

Recommendations for Vocational Training and Work Skills

If indicated, an occupational therapist may make recommendations for vocational training if the client is discharged to a day treatment program, outpatient rehabilitation center, or a transitional living site. Vocational training is an extended process that requires the involvement of an occupational therapist and possibly a vocational counselor. The client's eventual return to work may require the assistance of a job coach. The success of a client's return to work depends highly on the environment to which he or she is returning and the supportiveness of the environment. These are all aspects that must be considered when evaluating a client's potential.

Summary

Treatment of adults with TBI is challenging and requires flexibility, stamina, and creativity. Behavioral and psychosocial deficits greatly influence recovery. Substance abuse, a possible contributing factor, must be assessed and addressed. Most clients have a multitude of problems requiring intervention. Coordination of evaluation and goal setting with the interdisciplinary team (including the client and family) is assumed. Intervention should be individualized and oriented toward functional outcomes that are meaningful to the client. An effective transition from acute care to

intermediate-level care and then to the community requires the therapist to plan thoughtfully and communicate clearly. For persons with TBI, recovery and adjustment may be a lifelong challenge. Since these individuals face challenges throughout their lives and their needs continue to evolve, providing resources throughout the continuum is essential for an ongoing productive outcome.

Review Questions

1. What are two important measurable landmarks of recovery from TBI?
2. Name five types of neuromuscular impairment that may be present in a client with TBI.
3. Describe the types of care settings available for clients with TBI in the acute, subacute, and postacute stages of rehabilitation.
4. Describe the psychosocial deficits that may be present in a client with TBI.
5. List two components of a behavioral management program.
6. Name three standard assessments for a population with TBI and describe the performance components and areas that they assess.
7. List four visual skills that are evaluated in a vision screening.
8. Why is it important for a client with TBI to complete an on-road driving assessment?
9. What are the goals of a proper wheelchair-positioning program?
10. What are the indications for splinting? Casting?
11. Describe three areas that should be addressed during discharge planning.
12. Why is it important to address substance use in populations with TBI?

■ **Learning Objectives** *After studying this chapter, the student or practitioner will be able to do the following:*

1. Describe the course of amyotrophic lateral sclerosis.
2. Describe the differences between familial and sporadic amyotrophic lateral sclerosis.
3. Describe the role of the occupational therapist for a client with amyotrophic lateral sclerosis.
4. Describe the three subtypes of amyotrophic lateral sclerosis.
5. Identify the symptoms and incidence of Alzheimer's disease.
6. Describe the pathophysiology of Alzheimer's disease.
7. Describe the overall model of medical management of Alzheimer's disease used by primary care providers and other health professionals.
8. Describe an approach to evaluation used by occupational therapists.
9. Identify stages of disease progression and general methods of treatment interventions associated with stages of dementia.
10. Describe the course and stages of Huntington's disease.
11. Identify current research regarding the etiology of the disease.
12. Describe the medical management of Huntington's disease.
13. Describe the purpose of occupational therapy for a client with Huntington's disease.
14. Describe the three typical forms of multiple sclerosis.
15. Describe current research regarding the etiology of the disease.
16. Describe the symptoms of multiple sclerosis.
17. Describe complications that may occur as a result of the disease.
18. Describe the role of the occupational therapist for a person with multiple sclerosis.
19. Describe the course and stages of Parkinson's disease.
20. Identify current research on the etiology of the disease.
21. Describe the medical management of Parkinson's disease.
22. Describe the role of the occupational therapist for a client with Parkinson's disease.

Case Study | Marguerite

Marguerite is a 35-year-old woman who was diagnosed with multiple sclerosis (MS) when she was 26. Although Marguerite was initially identified as having the relapsing-remitting form, the secondary progressive form of multiple sclerosis was recently diagnosed by her neurologist, who referred her for occupational therapy. Marguerite now uses an ankle-foot orthosis on her right lower extremity when walking and has diminished sensation and dexterity in her nondominant left hand.

An occupational profile revealed the following background information about Marguerite. She is married and has two boys aged 8 and 6. Both children are involved in soccer and swimming on a weekly basis. Her husband travels every month in his job as a sales manager for an insurance company. Marguerite is a special education teacher in an elementary school and works full-time, although she was unable to work during relapses. She cares for her 69-year-old mother, who has been diagnosed with Alzheimer's disease. Her mother lives alone in her own apartment in the same city. Although Marguerite has two sisters, neither lives within driving distance; Marguerite has the primary responsibility of caring for her mother and her children.

Marguerite was asked to identify what areas of occupational performance were problematic or successful. She quickly replied that being a chauffeur for her children, a manager of her mother's medical care, and a housekeeper for her family was problematic. She felt as though she were constantly juggling schedules; recently, her children's swimming class changed to a different day, which caused a big change in her

schedule. Even though she wants her children to have the opportunity to pursue sports, Marguerite finds it difficult to supply snacks every month for these extracurricular activities, an obligation that each participant's mother is expected to fulfill. Her husband does try to help with household chores when he is home, but he works long hours and does not have time to shop for the family's groceries. Marguerite is also responsible for arranging all her mother's medical appointments; shopping for her mother, who no longer drives; and visiting her mother daily. Marguerite reports that she often feels so tired after teaching all day and running all her errands that she has trouble making dinner when she returns home.

Marguerite was most comfortable with her work situation and reported that many of her colleagues had offered to help with various tasks such as playground duty or monitoring the students during lunchtime. This allowed Marguerite to have a brief break during the day to rest.

Critical Thinking Questions

1. What evaluations would you perform to collect additional data for developing an intervention plan?
2. Where would you start your intervention plan in light of Marguerite's report of her occupational profile?
3. How would the change in Marguerite's diagnosis from the relapsing-remitting form to the secondary progressive form of multiple sclerosis affect her current occupational roles?
4. How would the strategies that you select for Marguerite be applied to other clients who have degenerative neurologic disorders?

Introduction

This chapter addresses the impact of degenerative neurologic disorders on a person's occupational performance and outlines the role of occupational therapy (OT) in providing services to clients with these disorders. The specific disorders discussed in this chapter are amyotrophic lateral sclerosis (ALS), Alzheimer's disease (AD), Huntington's disease (HD), multiple sclerosis (MS), and Parkinson's disease (PD).

In degenerative neurologic disorders, the disease progresses and an individual's occupational performance is often increasingly compromised. OT aims to help the client compensate and adapt as function declines secondary to the disease process. Environmental adaptations and modifications are frequently necessary to maintain functional skills for as long as possible.

Degenerative neurologic diseases may occur because of structural or neurochemical changes within the central nervous system (CNS).⁷² In the disorders discussed in this section, the client's CNS usually functions normally during childhood and adolescence. After these years, the client experiences signs and symptoms indicating that CNS functions are deteriorating. The progressive nature of the disorder varies from person to person. Some clients have a rapid decline in function, whereas others maintain functional skills for many years.

The decline in function may compromise the individual's sense of self-efficacy in performing various tasks.¹⁹⁵ No longer is the individual able to perform personal or instrumental activities of daily life at the same level of independence. Dependence on others can alter the client's concept of self-worth and self-control. The OT practitioner serves an important role in reframing the client's sense of self even though functional independence may be deteriorating. A man with PD who is unable to dress independently may now direct a personal care attendant or home health aide to perform these tasks. A woman with MS who was previously responsible for household finances may need to instruct a member of the family to complete these activities.

The disorders discussed in this chapter are most often diagnosed during adult or later adult life, after habits, routines, and patterns of independent behavior are well established. A client may encounter a significant change in social relationships and interactions secondary to a decline in functional abilities. The OT practitioner must consider the ways in which progressive loss of function affects the client's social and occupational roles, whether those roles are as husband, wife, parent, adult child, worker, sibling, or friend. OT must address the needs of the client within the context of his or her social, physical, and cultural environment.

OT intervention aims to support the client's ability to function within his or her environment. The rate at which the client's symptoms progress influences the intervention plan. A client who displays progressive loss of fine motor skills over a 20-year period has a much different profile than

one who loses all upper extremity function within 2 years. Use of adaptive equipment must be weighed carefully against the rate of deteriorating skills.

The OT practitioner must be knowledgeable about the support services and respite care available to clients with a degenerative neurologic disorder. A PD support group may provide the necessary social support for both a man with this disorder and his family. MS support groups may offer clients information on new intervention methods available, along with the opportunity to share life experiences.

An OT intervention plan should address not only the physical limitations associated with various disorders but also their cognitive, social, and emotional implications. Many individuals with neurodegenerative disorders have concomitant depression. Depression can be a reaction to the loss of function associated with some disorders or the primary symptom of other disorders. Occupational therapists should regularly screen for depressive features. An instrument such as the Beck Depression Inventory can effectively evaluate this component.^{25,26} In addition to evaluation of depression in clients with neurodegenerative disorders, cognitive abilities should be assessed. Clients may have concomitant cognitive problems because of the destruction of neurologic structures, and these deficits can have a dramatic effect on intervention. Brief assessments such as the Mini-Mental State Examination (MMSE)⁶⁵ or the Cognistar¹⁵⁴ can be used to determine cognitive abilities and establish a baseline of performance.

In most cases, the occupational therapist is a member of a team providing services to the individual with a degenerative neurologic disorder.⁹⁸ As a team member, the occupational therapist must consider the roles that other professionals and family members play in the client's life and incorporate this knowledge into the intervention plan. OT practitioners provide a unique and needed service to individuals with degenerative neurologic disorders. A client who is able to engage in meaningful occupations despite deteriorating skills reflects the significant contribution of OT.

Two case studies are presented to illustrate the similarities and differences among clients faced with degenerative neurologic disorders. The first case concerns a woman who has MS. That case is presented at the beginning of the chapter. The second case concerns a man with PD and is presented at the end of the chapter to serve as a review. The cases should serve to prompt clinical reasoning and decision making as you read this chapter.

SECTION 1: | Amyotrophic Lateral Sclerosis

DIANE FOTI

This section of the chapter focuses on both areas of occupation and performance skills. Diagnosis and progression of disease are described in terms of the loss of performance

skills, whereas Box 35-1 describes the OT interventions in relation to both occupation and performance skills as identified in the Occupational Therapy Practice Framework.

The term *amyotrophic lateral sclerosis* is used to identify a group of progressive, degenerative neuromuscular diseases. The underlying neurologic process involves destruction of motor neurons within the spinal cord, brainstem, and motor cortex.^{28,35} Affected individuals exhibit a combination of both upper motor neuron (UMN) and lower motor neuron (LMN) deficits at some point in the progression of the disease.

In the United States, ALS is also known as Lou Gehrig's disease; in France, it is referred to as Charcot's disease.²⁷ The term *motor neuron disease* refers to a group of diseases that includes ALS, progressive bulbar palsy, progressive spinal muscular atrophy, and primary lateral sclerosis.^{106,151} Table 35-1 provides a description of each of these distinct subtypes of ALS. The classic forms of ALS are presented in this section.

The incidence of ALS is about 2.0 per 100,000 people, and it is diagnosed in approximately 5000 people in the United States each year.¹⁴⁶ Two forms of ALS are recognized: sporadic and familial. Sporadic ALS makes up about 90% to 95% of the ALS population. Between 5% and 10% of individuals with ALS are found to have a family history of the disease. There is no difference in the symptoms of clients with the familial and sporadic types.

The diagnosis is primarily determined by clinical symptoms and ruling out other neurologic disorders.²⁷ Multiple tests and a thorough neurologic examination provide a differential diagnosis. Tests include electromyography and nerve conduction velocity; blood and urine studies, including high-resolution serum protein electrophoresis, thyroid and parathyroid hormone levels, and 24-hour urine collection to assess for heavy metals; spinal tap; radiographs;

■ Box 35-1

People with Cognitive Dysfunction Benefit from the Following Approaches

- Use simpler tools for communication than you would use for patients who do not have cognitive deficits.
- Use simpler and more straightforward language and communicate clearly and directly.
- Supervise eating more closely. Patients with frontal lobe abnormalities and poor swallowing ability may have difficulty following medical advice to limit solid foods, or they may place too much food in their mouth.
- Assess patients' ability to make decisions by talking with them and the caretaker because patients with neurologic disorders are faced with complicated medical, financial, and sometimes legal issues.
- Even patients with subthreshold cognitive deficits who do not meet the criteria for dementia may lack the ability to make sound judgments about their care. Poor insight is very common, so caregiver involvement may be appropriate.
- Supervise walking. Patients with cognitive deficits often have a loss of impulse control and may make poor decisions about where to walk, how far to walk, or when to use equipment such as a walker.
- Remind caregivers and family to try to avoid taking the person's behavior personally.
- Help them understand that there is a physiologic cause for the behavior.
- Encourage the caregiver and the family to try to build an atmosphere of comfort and love with a calm and orderly environment.

■ TABLE 35-1 | Clinical Subtypes of Amyotrophic Lateral Sclerosis

Name	Area of Destruction	Symptoms
Progressive bulbar palsy (bulbar form)	Corticobulbar tracts and brainstem motor nuclei involved	Dysarthria, dysphagia, facial and tongue weakness, and wasting
Progressive spinal muscular atrophy (lower motor neuron form)	Lower motor neurons in the spinal cord and sometimes the brainstem	Marked muscle wasting of the limbs, trunk, and sometimes the bulbar muscles
Primary lateral sclerosis (upper motor neuron form)*	Destruction of cortical motor neurons; may involve both the corticospinal and corticobulbar regions	Progressive spastic paraparesis

*The World Federation of Neurology classification of spinal muscular atrophy and other disorders of the motor neurons does not identify primary lateral sclerosis as a subtype of amyotrophic lateral sclerosis.²⁷ This author is including primary lateral sclerosis in the list in recognition of the many other articles and books that recognize it as a subtype of amyotrophic lateral sclerosis. From Belsh JM, Schiffman PL, editors: *ALS diagnosis and management for the clinician*, Armonk, NY, 1996, Futura; and Guberman A: *An introduction to clinical neurology, pathophysiology, diagnosis, and treatment*, Boston, Mass, 1994, Little, Brown.

magnetic resonance imaging; myelography of the cervical spine; and muscle and/or nerve biopsy.^{1,27,28,35}

Pathophysiology

The etiology of ALS has not been established. Multiple theories have been proposed as the cause of the motor neuron destruction, including metabolic disorders of glutamate insufficiency, metal toxicity, autoimmune factors, genetic factors, and viral infection.¹⁸⁷

Clinical Picture

The symptoms of ALS are variable, depending on the initial area of motor neuron destruction. An individual with ALS typically has a focal weakness beginning in the arm, leg, or bulbar muscles. The individual may trip or drop things and may have slurred speech, abnormal fatigue, and uncontrollable periods of laughing or crying (i.e., emotional lability). As the disease progresses, marked muscle atrophy, weight loss, spasticity, muscle cramping, and fasciculations (i.e., twitching of the muscle fascicles at rest) ensue. The individual may have greater difficulty with walking, dressing, fine motor activities, swallowing, and breathing. In the end stages the individual may require tube feedings and the support of a ventilator for respiration. ALS is a rapidly progressive disease with the majority dying of respiratory failure in 3 to 5 years after the onset of symptoms if no tracheostomy is performed. Approximately 10% of the population will live 10 years or longer.¹⁴⁶ As ALS progresses, the disorder does not affect a person's eye function, bowel and bladder function, or sensory function. Recent research has found that cognitive changes occur in 20% to 25% of the population with ALS. Specific cognitive deficits have been identified such as frontal temporal lobe dysfunction. As many as half may have mild to moderate cognitive or behavioral abnormalities. "Risk factors for developing cognitive problems, behavior changes or a full-fledged dementia syndrome may include: older age, bulbar onset ALS, a reduction in FVC (functional vital capacity) and a family history of dementia."^{1,125,177}

The prognosis is difficult to predict. Generally, individuals with early bulbar involvement have a poorer prognosis. A more positive prognosis is usually associated with the following factors: younger age at onset; onset involving LMNs located in the spinal cord; deficits in either UMNs or LMNs, not a combination of both areas; absent or slow changes in respiratory function; fewer fasciculations; and a longer time from the onset of symptoms to diagnosis. In some cases, the client's condition stabilizes, with little progression of the disease.⁸⁶

A client with ALS differs from a client, such as Marguerite, with MS; with ALS the loss of function is more rapid, without episodes of remission. A person with ALS must cope with a fatal disease, whereas a person with MS must cope with a chronically disabling condition.

Medical Management

The American Academy of Neurology has established practice parameters and standards to address major management issues for persons with ALS. An OT practitioner working with this population should be familiar with the standards to better understand the approaches and rationale for intervention. The parameters cover the following topics: how to inform the client of the diagnosis, when to consider non-invasive and invasive ventilator support, evaluation of dysphagia and intervention with a feeding tube, management of saliva and pain, and use of hospice services.¹³³

Symptoms such as muscle cramping, excessive saliva, depression, and pain are managed with medication. The client's respiratory status should be re-evaluated frequently to determine when noninvasive and invasive ventilator support is necessary. Swallowing function should also be evaluated frequently to prevent aspiration and to determine when and whether a feeding tube should be placed.

The Food and Drug Administration approved the drug riluzole (Rilutek) in 1995. Riluzole, an antiglutamate, was the first drug used specifically to alter the course of the disease by prolonging survival. In addition to inhibiting the release of glutamate from nerve endings, it blocks amino acid receptors on the cell bodies.¹⁸⁷ Researchers believe that the success of riluzole indicates that an excess of glutamate leads to the death of motor neurons. Research has shown that riluzole prolongs the life of clients with ALS by at least a few months.¹⁴²

Other medications and stem cell research²⁰⁴ for the treatment of ALS are currently in clinical trial.^{28,217} The clinical trials are focused on extending survival and slowing the decline associated with the disease.
