- **Acute pain** has a biological function; it lasts from seconds to days, acting as a warning that injury has occurred or that something is wrong. Acute pain is closely associated with tissue damage and nociception occurring with a rapid onset. Physical agents are indicated as a part of the treatment approach in patients with acute pain.
- **Chronic pain** recurs or persists for a long time. It may be associated with anguish, apprehension, depression, or hopelessness. Chronic pain is often poorly localized, without an underlying cause being fully identifiable. Chronic pain pervades the individual's life. Chronic pain affects an individual's occupational functioning, affecting society, the economy, employment, and health care systems. Physical agents are usually ineffective in consistently relieving chronic pain.
- **Referred pain** occurs at an area different from the source of the injury or disease, that is, not where the nociceptors were stimulated. These irritable areas, sometimes known as trigger points, can be located through palpation and are electrically active and facilitate current flow into the tissue. Trigger points can also be identified by using TENS to locate and stimulate these areas.

Physical agents such as heat, sound, compression, cold, or electricity may all reduce the effects of pain and can influence healing in soft tissue injuries. Selection of the correct intervention or physical agent is based on a thorough evaluation of the patient and on the diagnosis, treatment goals, clinical experience of the therapist, and the goals of the patient.

INCORPORATING PHYSICAL AGENTS INTO A TYPICAL OCCUPATIONAL THERAPY TREATMENT

Physical agents are used as a precursor to functional activity to facilitate occupational performance. The therapist determines which physical agents will help achieve the patient's goals. For example, a patient with rheumatoid arthritis may have pain and limited movement. Paraffin to both hands and wrists may alleviate the patient's pain and stiffness prior to training with adaptive equipment for self-care activities.

Before administration of any modality, the therapist questions the patient as to any untoward negative response to physical agents applied in previous treatment and reviews whether the patient has any contraindications for the selected agent. Prior to administration of the physical agent, the therapist informs the patient as to the procedure, expected outcome, and subjective sensation that the patient may feel during the treatment. Skin integrity is always evaluated prior to administration of physical agents and immediately following the intervention. Documentation should be clear and concise, stating the modality applied, parameters or settings, sequence in the course of treatment, and patient's response (Procedures for Practice 20-1). Therapists also assess the effectiveness of the modality on a session-by-session basis. If the modality fails to provide the desired outcome or if the patient has discomfort or negative results, the modality should be discontinued.

PROCEDURES FOR PRACTICE 20-1

Documenting Physical Agent Interventions

Documentation of physical agent interventions should include the following:

- Physical agent applied and treatment parameters
- Site of application or placement
- Treatment duration
- Physiological responses elicited from treatment
- Subjective responses from the patient, such as tolerance, reaction, and clinical effectiveness

SUPERFICIAL THERMAL AGENTS

A superficial thermal agent is any modality applied to the skin that can increase or decrease skin and superficial subcutaneous tissue temperature. Thermotherapy is the term used to describe the therapeutic application of heat. The objectives of heating agents are to decrease pain and stiffness, improve range of motion and tendon excursion, improve viscosity of synovia, and promote healing and relaxation. Conditions that may benefit from heat include muscle spasm, subcutaneous adhesion, sympathetic nervous system disorders, contractures, neuromas, chronic arthritis, trauma, wounds, and subacute and chronic inflammation. Superficial heat has a therapeutic effect at depths of up to 1 cm (Kaul, 1994). If a depth greater than 1 cm is desired, ultrasound should be considered.

Treatment Planning

In planning treatment that involves heat, one typically considers general and specific **dosage** guidelines, primary effects, and modality selection.

Dosage Guidelines

Thermotherapy is used when an increase in tissue temperature is the intended goal of treatment. General dosage guidelines provide a starting point for selection of an agent and for application parameters. Dosage refers to the amount of heat applied to the tissue, which then elevates the tissue temperature. When the temperature of soft tissue is increased between the range of 102 and 113°F, it can have a positive therapeutic effect. If the soft tissue is heated to a temperature less than 102°F, cell metabolism may not be stimulated adequately enough to elicit a therapeutic response. If tissue is heated too vigorously, to a temperature greater than 113°F, catabolism and cell death may occur. Physiological response in thermal applications is dependent on the extent of the temperature elevation within the tissue. Elevation of tissue temperature in turn depends on the rate the temperature is applied to the tissue, the duration of the application, and the volume or area of tissue exposed to the heat. Consideration of dosage intensity guides application based on specific characteristics of the patient.

The dosage of a thermotherapy can be described as mild to vigorous. Application of a mild dose of heat implies a minimal elevation in tissue temperature. The primary benefits of a mild application of heat is related to the somatosensation of warmth. Many conservative home remedies provide this mild dosage. A moderate dose causes an increase in tissue temperature of approximately 6°F and a moderate increase in blood flow. A vigorous dose implies a marked increase in blood flow with substantial tissue

SAFETY NOTE 20-1

Superficial Thermal Agents

Precautions

- Edema
- Diminished sensation
- Compromised circulation
- Use of anti-coagulant medications

Contraindications

- Impaired sensation due to skin graft or scar
- Tumors, cancer
- Advanced cardiac disease (body inadequately dissipates heat)
- Acute inflammation, acute edema
- Deep-vein thrombophlebitis
- Pregnancy (systemic effects of circulating blood on fetus are unclear)
- Bleeding tendencies
- Infection
- Primary repair of tendon or ligament
- Semicoma or impaired cognitive status
- Rheumatoid arthritis: vigorous dosages of heat can exacerbate joint inflammation

Adapted from Schmidt, 1979.

temperature elevation (up to 14°F). Safety Note 20-1 lists precautions and contraindications of thermotherapy. One should be especially vigilant with moderate and vigorous doses of heat and monitor skin color and respiratory status.

Primary Effects of Thermotherapy

The four primary effects of thermotherapy are analgesic, vascular, metabolic, and connective tissue responses. Each has different dosage guidelines.

- The analgesic effect influences pain symptoms. Heat acts selectively on free nerve endings, tissues, and peripheral nerve fibers, which directly or indirectly reduces pain and elevates pain tolerance (Behrens & Michlovitz, 2005). A mild to vigorous dose is required to obtain an analgesic effect.
- Vascular effects aid in pain relief and in decreasing muscle spasm. At 6°F of tissue temperature elevation, substances such as histamines are released in the bloodstream, resulting in vasodilation. This increased blood flow reduces ischemia, muscle spindle activity, and tonic muscle contractions, decreasing pain. Moderate dosage is needed to obtain these effects.

- Thermal agents affect the components of inflammation and healing due to changes in the rate of circulation and chemical reactions. Metabolic effects influence tissue repair and aid pain relief. Increases in blood flow and oxygen within the tissues bring a greater number of antibodies, leukocytes, nutrients, and enzymes to injured tissues. Pain is reduced by the removal of byproducts of the inflammatory process. Nutrition is enhanced at the cellular level and repair occurs. A mild to vigorous dosage of heat is needed to facilitate the metabolic effects, depending on the acuity of the wound or soft tissue condition.
- Collagen is the primary component protein of skin, tendon, bone cartilage, and connective tissue. Those tissues containing collagen can become shortened due to immobilization or limited range of motion as a result of weakness, injury, or pain. Improvement in the properties of collagen and extensibility of tissues occurs when heat is combined with passive or active mobilization and/or engagement in occupation. This connective tissue response occurs during an 8- to 10-minute window after the application of heat (Norkin & Levangie, 1992). Reduced joint stiffness and increased range of motion also occur. A moderate to vigorous dose is needed to achieve these benefits.

Selection of Superficial Thermal Agents

Regardless of the mechanism of heat application to the tissue (paraffin, hot pack, etc.), the biophysiological effects will be the same. There are three primary mechanisms of heat transfer within the body: **conduction**, **convection**, and radiation. Conduction occurs when there is direct contact between tissue and the heat or cold source. Convection occurs when particles or molecules, such as air or water, move across the body part thereby creating a temperature variation. Radiation occurs when there is a transfer of heat from a warmer source to a cooler source, such as through air in application of infrared lamps.

The choice of modality depends on the treatment objective, the location and surface area of the involved structure, and the desired dosage and tissue temperature. Other considerations include whether moist or dry heat is desired, the positioning of the extremity in a non-dependent or intermittently dependent position, and whether active or passive participation by the patient is desired (Earley, 1999). The acuity or chronicity of the patient's condition is also an important factor. Injuries in the inflammatory or acute phase (24–48 hours) should be treated with cryotherapy, not heat. Wounds in the **remodeling** stage of recovery would be treated with higher dosages of heat to facilitate the remodeling process of collagen alignment and differentiation.

Clinical Use of Thermotherapy

As previously mentioned, superficial heat is primarily transmitted through conduction and convection. Hydrotherapy and fluidotherapy are examples of convection agents, whereas hot packs and paraffin are categorized as conduction agents.

Whirlpool Baths and Hydrotherapy

The whirlpool bath is effective with open wounds, status post fractures, inflammatory conditions, peripheral vascular disease, and peripheral nerve injuries. An advantage for whirlpool use is that the therapist can see and have immediate access to the body part being treated, and the client can actively move the extremity. Water temperature can be set to the desired temperature (100–104°F), and the degree of agitation of the water can be controlled to act as a soft tissue massage or resistance for exercise or to cleanse and debride a wound. With any open wounds or lesions, proper disinfecting of the whirlpool bath is necessary.

Fluidotherapy

Fluidotherapy uses fine particles of ground corn husks suspended in a hot air stream to heat the extremity (Borrell et al., 1980). Temperature is controlled by a thermostat, with most conditions requiring a temperature between 105 and 118°F. Temperature settings depend on the dosage of heat needed and the area of the extremity being treated. The force of the air and particles circulating within the machine can be graded via the blower speed, facilitating mobilization and desensitization through its impact on nerve conduction (Kelly et al., 2005). The advantage of fluidotherapy is the ease of implementation and the therapist's access to the client's extremity while in the unit, allowing for passive or active assistive range of motion or manual therapy.

Hot Packs

Hot packs, or hydrocollator packs, are forms of moist heat that come in a variety of sizes. They heat large areas of the body and adequately cover contoured areas of the body, such as the shoulder. The temperature of the hot pack is typically between 104°F and 113°F. Hot packs are stored in a thermostatically controlled container of hot water kept at approximately 158–167°F. Hot packs are generally easy to use and require minimal maintenance. It is important to ensure that a dry padding is used between the hot pack and the skin to avoid burns, even though it cools as the treatment progresses. Continued use of the hot pack covers between patients during the day will decrease their effectiveness as an insulator and may cause burns. The hot pack should be wrapped in six to eight layers of dry towels or two to three layers of hot pack covers. More layers

should be used if the towels or pack covers become worn or damp. Hot packs help to reduce pain and muscle spasms and to improve connective tissue extensibility. The extremity can be placed in a positional sustained stretch of the tissue being treated to facilitate extensibility.

Paraffin

Paraffin is used to provide a high degree of localized heat to smaller joints. The paraffin is mixed with mineral oil in a 6:1 or 7:1 ratio to effectively lower the melting point of the paraffin to between 113 and 122°F. The paraffin is kept in a thermostatically controlled unit, and the temperature of the paraffin should be checked before it is applied to a patient. Paraffin is primarily used to decrease stiffness, improve range of motion, and relieve pain. Healed amputations, arthritis, strains, and sprains are a few conditions that benefit from paraffin. Paraffin allows for an even distribution of heat to the treatment surface, reducing the viscosity of the synovia and, hence, decreasing stiffness and pain associated with arthritis.

The wrap or glove technique is the most popular method of application. **The therapist should always check the temperature of the paraffin before use to ensure a safe temperature and avoid burns.** The client immerses the extremity in the bath and withdraws it to allow the paraffin to harden. This gloving process is repeated approximately 10 times, depending on the client's tolerance to heat. The extremity is then wrapped in a plastic bag followed by a towel to retain the heat and is left on for 20 minutes (Fig. 20-2). At the end of treatment, the paraffin is removed and discarded.

Figure 20-2 Application of paraffin to increase pain-free AROM of the interphalangeal joints. The extremity will be wrapped in a plastic bag and then a towel.

Passive stretching of joints can be accomplished with an elastic wrap or Coban tape, which is secured prior to the dipping. This form of treatment facilitates tissue extensibility and can maximize the benefits of mobilizing and remodeling connective tissue.

CRYOTHERAPY

Cryotherapy is the application of a cold agent to relieve pain and to reduce edema and inflammation following trauma. Cryotherapy involves the application of any substance to the body that results in withdrawal of heat from the body, lowering the temperature of the tissue. Tissue temperature change and biophysical effects of cooling are related to the time of exposure, the method used to cool the tissue, the conductivity of the tissue, and the size or area being treated. Care must be used when determining the length of exposure to the cold agent because changes in skin temperature occur quickly and tissue may be damaged before the desired biophysical effects are achieved.

Purpose and Effects

The clinical use of cold is based on physiological changes resulting from tissue temperature reduction. Cold is used in the management of acute trauma because it affects arteriolar vasoconstriction, reducing bleeding; decreases metabolism and vasoactive agents such as histamine, thereby reducing inflammation and swelling; and elevates the pain threshold. In most acute traumas, cold is used with compression and elevation.

There are four primary methods for administering cold treatment: cold packs, ice cubes, cold baths, and controlled cold-compression units. Application of cold provides an anesthetic or numbing effect, and the patient may initially report a cold, aching, or burning sensation. As with any thermal agent, monitoring of the skin is essential to avoid damage to the tissue, and caution is advised for patients with decreased sensation or mentation.

Indications and Precautions

Cryotherapy is easy to apply and is indicated for a number of treatment conditions. The most common use for cryotherapy is in the treatment of acute injury and inflammation (Fig. 20-3). Other conditions and indications for the use of cold include edema, exercise-induced muscle soreness (combined with compression, exercise, and massage), arthritic exacerbation, acute bursitis or tendinitis, spasticity, and acute or chronic pain secondary to muscle spasm.

Figure 20-3 Application of cryotherapy for distal extremity edema and inflammation.

The physiological effects of cold can last for several hours. Rewarming of the tissue takes approximately 20 minutes. Care should always be used when applying cold, and the skin condition should be monitored to avoid frostbite and tissue damage. Safety Note 20-2 lists contraindications to cryotherapy.

THERAPEUTIC ULTRASOUND

Therapeutic ultrasound is classified as a deep-heat modality and works via acoustic energy that is inaudible to the human ear. Ultrasound is acoustic energy that is used in medicine for diagnosis and tissue destruction and in rehabilitation to help restore and heal soft tissues. The ultrasound beam in therapeutic ultrasound itself does not transmit heat. Heat accumulates in the tissue

SAFETY NOTE 20-2

Cryotherapy

Avoid cryotherapy with patients who exhibit the following:

- Peripheral vascular disease or any circulatory compromised area
- Cold sensitivity, Raynaud's phenomenon
- Multiple myeloma, leukemia, systemic lupus (cryoglobulinemia is a disorder of abnormal protein formation that can lead to ischemia in these individuals)
- Cold urticaria/intolerance; can occur with rheumatic diseases or after crush injuries and amputations

because of the conversion of energy absorbed from the sound wave in continuous-mode ultrasound. Therapeutic ultrasound has two primary effects on tissue: thermal and non-thermal (or mechanical). Thermal effects refer to those biophysiological changes produced by cellular heating, while non-thermal, or mechanical, effects refers to biophysiological changes produced by the cellular effects of cavitation, microstreaming, or acoustic streaming. Both can be used to facilitate healing and ultimately improve occupational function (Bracciano, 1999; Bracciano, 2000).

Physical Principles

Standard ultrasound units consist of a power supply, oscillator circuit, transformer, coaxial cable transducer, and ultrasound applicator. The generator uses alternating current as a power source, converting electrical energy into ultrasonic energy. Inside the applicator, a crystal contracts or expands in response to alternating current (Fig. 20-4). The vibration of the crystal generates the sound waves, which are transmitted to a small volume of tissue, causing the tissue molecules to vibrate. Ultrasound travels poorly through air, so a lubricant is used to maintain contact between the transducer and the tissue, ensuring that the energy is dispersed into the tissue (Fig. 20-5).

When the sound waves are generated rapidly and dispersed into the tissue, the molecules in the waves' path are pushed back and forth by the alternating phases of successive waves until the wave runs out of energy. This type of wave, moving in one direction and compressing and decompressing the molecules in its way, is termed a *longitudinal wave*. When the wave encounters bone, the sound energy is transferred along the periosteum and is then deflected up at a right angle causing a *shear wave*. Shear waves occur when the sound energy strikes a solid

Figure 20-4 Production of ultrasound.

Figure 20-5 Application of non-thermal ultrasound for acute elbow lateral epicondylitis.

substance. This may cause heating of the outer covering of the bone but is negligible in terms of tissue temperature elevation (Bracciano, 1999; Bracciano, 2000; Cameron, 2003). A *standing wave* occurs when the sound head isn't moved adequately enough, and the incoming sound waves encounter the reflected sound waves moving back up toward the surface, creating hot spots and potential overheating of tissue.

Each tissue in the body transmits and absorbs ultrasound energy according to its unique properties, known as absorption coefficients. The rate at which the sound wave travels depends on the density of the molecules of the tissue, with body fluids such as blood and water having the lowest **impedance** (or resistance to ultrasound waves) and lowest acoustic absorption coefficient. Bone possesses the highest impedance and absorption coefficient, making it a good absorber of ultrasound energy (Kimura et al., 1988) along with other protein-dense structures, such as scars, joint capsules, ligaments, and tendons.

Energy Distribution

The spread of ultrasound waves into tissue is affected by the frequency and size of the crystal. The frequency of the ultrasound (the number of wave cycles per second) determines the depth of penetration of the ultrasound energy. A frequency of 1 megahertz (MHz) provides deeper penetration (up to 5 cm) than 3 MHz, which penetrates approximately 1–2 cm.

The intensity of the beam of energy varies within the sound wave; this phenomenon is called the beam non-uniformity ratio (BNR) (Allen & Batye, 1978; Kimura et al., 1988). The BNR of a transducer refers to the ratio between its spatial peak intensity and spatial average intensity.

These higher areas of intensity are in part responsible for hot spots, which can be prevented by moving the sound head during treatment. Smaller ratios refer to a more uniform ultrasound beam (Hekkenberg, Reibold, & Zeqiri, 1994). The intensity of the beam of energy is a significant factor in determining tissue response. In general, there is greater tissue temperature elevation with higher intensities. Intensity is documented as watts per square centimeter (W/cm^2).

The duty cycle determines the overall amount of acoustic energy a patient receives and plays a role in determining tissue response (Fig. 20-6). The duty cycle is a percentage or ratio of time that the ultrasound energy is actually being introduced into the body. A 50% duty cycle provides twice as much acoustic energy as a 25% duty cycle because the on-time is twice as long (Kollmann et al., 2005). Consider a hose with a squeeze nozzle as analogous to the ultrasound transducer. If the handle is squeezed and held, water is released in a constant stream from the hose, which is comparable to a constant flow of sound energy. If the handle is squeezed and released rapidly, the water is turned on and off, or pulsed. The same concept holds for ultrasound. When the sound wave is on 100%, the sound wave and energy are constant. When the sound energy is turned on and off rapidly, the sound wave is pulsed and is described in terms of a ratio of the cycle. Whether to use continuous or pulsed ultrasound depends on the pathology, stage of wound healing, and amount of area being treated (Bracciano, 2000; Fyfe & Parnell, 1982).

Effects on Tissue: Thermal Versus Non-Thermal Ultrasound

As previously mentioned, ultrasound has thermal and non-thermal effects on tissue. In the thermal mode, ul-

Figure 20-6 Duty cycles determine the on time of the ultrasound.

trasound is a deep-heating agent capable of elevating tissue temperatures to a depth of 5 cm. Thermal effects are typically achieved with continuous sound waves (as in a 100% duty cycle). Non-thermal ultrasound exerts mechanical effects at the cellular level but does not elevate tissue temperature. It typically involves delivering the ultrasound at a 20% duty cycle and provides secondary cellular effects, such as increased cellular permeability and diffusion. Clinicians may use ultrasound to achieve thermal or non-thermal effects and must select the effect considering a patient's given problem and the therapeutic effect that is desired.

A number of physiological effects occur with thermal ultrasound. They include increased metabolic rates, increased blood flow and tissue permeability, increased viscoelasticity of connective tissue, elevation of pain thresholds, and increased enzymatic activity, which may stimulate the immune system. Thermal ultrasound may increase joint range of motion, facilitate tissue healing, decrease muscle spasm and pain, and decrease chronic inflammatory processes (Enwemeka, 1989; Fabrizio, Schmidt, & Clemente, 1996; Gan et al., 1995; Hsieh, 2005).

The heating effects of ultrasound can be decreased by pulsing the sound waves or by decreasing the intensity or strength of the sound wave. Pulsing the ultrasound refers to modification of the ultrasound wave. Rather than the sound waves being produced continuously, the sound wave is intermittently turned on and off (pulsed), leading to a non-thermal effect.

Non-thermal ultrasound causes increased cellular permeability and diffusion and a variety of second-order effects that facilitate tissue repair (Dyson & Pond, 1970; Dyson & Suckling, 1978).

The effects of non-thermal ultrasound on tissue healing occur with short treatment duration along with lower intensities (0.1 and 0.2 W/cm² pulsed at 20% duty cycle). Treatment sessions should be repeated every 24–48 hours to facilitate tissue repair.

Non-thermal effects of pulsed ultrasound occur at the cell membrane due to stable cavitation, acoustic streaming, and micromassage (Apfel, 1989). Acoustic streaming occurs with the unidirectional movement of the body fluids that cause currents, which exert force and structural changes in the cell membrane along with increased permeability. Second-order effects of non-thermal ultrasound are due to the destabilization of the cellular membrane. Secondary effects of pulsed ultrasound may include an increase in phagocytic activity; increase in the number and motility of fibroblasts, resulting in enhanced protein synthesis; increased granular tissue; and improved angiogenesis, facilitating wound contraction. Low-intensity pulsed ultrasound may also accelerate fracture healing in tibial and Colles fractures (Doyle, 2004; Lehmann & Guy, 1971).

Clinical Use of Ultrasound

A thorough evaluation of the patient is necessary to identify problems and to set treatment goals prior to using ultrasound. It is essential to determine the location, stage of healing, depth, and anatomical location of the injury and the area and type of tissue to be treated. Superficial conditions, for example epicondylitis, are best treated using a frequency of 3 MHz. If a thermal effect is not needed, such as in a subacute condition or superficial pathology, low intensities can be used with a pulsed sound wave. Acute conditions should be treated for shorter periods than chronic conditions, and smaller areas of tissue require less time than larger areas (Bracciano, 1999).

Acute conditions are best treated with very low-intensity dosages (0.1 to 0.5 W/cm²); the patient is unlikely to feel any warmth at this low level. Subacute conditions can be treated using a low-intensity dosage (0.5 to 1 W/cm²); chronic conditions and those requiring a thermal effect require a setting between 1 and 2 W/cm². Patients may report some degree of warmth during the treatment but should not report any pain, discomfort, or burning. If these symptoms occur, the intensity should be reduced, the sound head should be moved more quickly, or ultrasound gel should be added if an inadequate amount is causing an uncomfortable tingling, vibration, or burning sensation.

Ultrasound may also be used before functional activity for prophylactic pain-relieving effects. Thermal ultrasound (100% duty cycle, high intensities) can be used to heat tissue and increase its length. Combining thermal ultrasound with positional stretch, splinting, functional activities, or manual therapy may be effective in stretching the heated tissue through a pain-free range of motion following application of ultrasound.

Phonophoresis

Phonophoresis is the use of ultrasound to facilitate the delivery of topically applied drugs or medication to selected tissue. Although it is frequently used, there are questions as to the effectiveness of phonophoresis because of variability in outcomes associated with inconsistent treatment parameters, such as intensity of sound waves and transmission characteristics of the conducting gel. Many hydrocortisone creams commonly used in the clinic (1% or 10% hydrocortisone in a thick, white cream base) do not transmit ultrasound, and this method of delivery is ineffective (Henley, 1991; Masse, 1996). Dexamethasone sodium phosphate mixed with a sonic gel transmits ultrasound effectively and can be formulated by a pharmacist. Following phonophoresis, a dressing can be used to seal the area and prevent moisture from escaping. Intensities of 1.5 W/cm² are effective for both the thermal and non-thermal effects of ultrasound as part of phonophoresis. A

low intensity (0.5 W/cm^2) may be more effective for treating acute injuries (Bracciano, 2000).

Precautions for Use of Ultrasound

Patients should be monitored during ultrasound, and any pain or discomfort may indicate that the intensity is too high or there is an inadequate amount of gel. Ultrasound should never be applied over the eye, the heart, the pregnant uterus, or the testes. Sonification to malignant tissue should also be avoided. Caution must be used when applying ultrasound over areas of decreased circulation and avoided over areas of thrombophlebitis. High intensities and application over the growth plates in children should also be avoided (Sicard-Rosenbaum, Lord, & Danoff, 1995). When using ultrasound as a thermal agent, one must follow general contraindications and precautions for any thermal modality. Safety Note 20-3 lists precautions and contraindications for ultrasound.

SAFETY NOTE 20-3

Ultrasound

Precautions

- Unhealed fracture sites
- Primary repair of a tendon or ligament
- Marked demineralization/osteoporosis
- Plastic and metal implants

Contraindications

- Suspected deep-vein thrombophlebitis
- Bleeding and edema; areas with tendency to hemorrhage
- Where sensation is reduced or if a person cannot report heat sensations accurately
- In the very old and very young because of compromised body temperature regulation
- Skin or lymphatic cancers; tumors or malignancies
- Over a cardiac pacemaker or surrounding adjacent tissue
- Pregnancy
- Infected areas
- Epiphyses of growing bone
- In conjunction with radium or radioactive isotopes treatment for cancer within 6 months
- Over the heart, eyes, or testes
- Over carotid sinus and cervical ganglion
- Over the spinal column or where there is inadequate protection over the spinal cord, such as after laminectomy

LOW-LEVEL LASER THERAPY

Low-level laser therapy (LLLT) is also known as “cold laser” because it will not increase the thermal temperature of the tissue. Laser is an acronym for light amplification by stimulated emission of radiation (LASER). Low-level laser, although gaining popularity with many clinicians, has been generating an increase in research regarding its overall effectiveness and mechanism of action. Many of the early studies evaluating the use of lasers supported their use with promotion of tissue repair in experimental animals and with human wounds and ulcers, although other studies were less conclusive (Conlan, Rapley, & Cobb, 1996; Reddy, Stehno-Bittel, & Enwemeka, 1998).

Light is another form of radiant energy with wavelengths that vary between 100 and 10,000 nm within the electromagnetic spectrum. Different wavelengths of light have been shown to promote healing of skin, muscle, nerve, tendon, cartilage, bone, and dental and periodontal tissues. These tissues respond to appropriate doses of light, which may vary within 600- to 1000-nm wavelengths. This low-energy light appears to facilitate the stages of healing by accelerating inflammation, promoting fibroblast proliferation, and enhancing revascularization of wounds and bone repair and remodeling (Abergel et al., 1987; Whelen et al., 2001). The mechanism of action appears to be through facilitation of the ATP cycle, the form of energy that cells use to facilitate metabolic processes, and through histochemical changes used to repair and regenerate cell and tissue components (Gum et al., 1997; Reddy, Gum, Stehno-Bittel, & Enwemeka, 1998; Reddy, Stehno-Bittel, & Enwemeka, 1999).

LLLT is a relatively recent addition to the therapeutic tools for occupational therapy and rehabilitation, although it has been used in Europe for the past decade. There are three primary types of laser in use by therapists: HeNe (helium neon), GaAs (gallium arsenide), and gallium-aluminum-arsenide (GaAlAs) lasers. The laser “beam” is produced by electrical or mechanical stimulus to the type of matter in the specific laser. When the stimulation is applied to the matter, there is a change in the position of the electrons of an atom, causing a release of photons. Photons are the energy component of light and are absorbed as energy when they collide with other atoms, which make them “unstable.” Within the laser itself, the molecules being stimulated are in an enclosed chamber that has a reflective surface. As the photons continue to collide with other atoms and thus releasing more photons, a chain reaction occurs, causing emission of radiation. As the energy is released from the chamber and directed toward tissue or an object, the laser is emitted as a coherent beam of light. The light wave streams in the same parallel direction and phase (coherence) and possesses the other unique characteristics of monochromaticity (a single wavelength) and collimation (a defined, concentrated beam).

It has been proposed that the mechanism of action of LLLT is due to biostimulation of the tissue. This stimulation is dependent on the dosage of the energy, which can either facilitate or inhibit the biochemical, physiologic, and proliferative activities of cells. The mechanism of action of LLLT appears to be at the cellular level, with the biophysiological effect related to the wavelength, depth of penetration, and dosage. There is an expanding body of evidence that indicates low-energy light may increase the healing process. LLLT may accelerate the inflammatory process, promote fibroplasias (Akai et al., 1997), enhance chondroplasia (Akai et al., 1997), upregulate the synthesis of type I and type III procollagen mRNA (Saperia, Glassberg, & Lyons, 1986), facilitate bone repair and remodeling and revascularization of wounds, and accelerate tissue repair (Houghton et al., 1999). The variable in most studies and the question that needs to be answered relates to determining the appropriate energy density that is needed to facilitate the healing response (Enwemeka et al., 2004).

LLLT uses low-power laser. Thus, it is essentially safe, unless the laser beam is directed toward the eye, where it may cause damage to the retina or cornea. Care should also be used over areas with active bleeding or hemorrhage, over cancerous tissue, during pregnancy, or in individuals with photosensitive skin. Research appears to support the use of LLLT to facilitate tissue healing through the stimulation of collagen formation and vasodilation, to modulate pain through decreased nerve conduction velocity, and to influence the histochemical changes that occur during inflammation (Akai et al., 1997; Chow, 2002; Halevy et al., 1997; Houghton et al., 1999; Ozawa et al., 1998). As research continues in the area of laser therapy, greater acceptance and use of the modality will likely occur.

ELECTROTHERAPY

Electrotherapy has been used since the time of the early Romans. The growth of electrical stimulation in recent years is due to the research of Melzak and Wall (1965) and their gate theory of pain and to advances in technology. Electrotherapy is the application of electrical stimuli to accomplish any of a variety of therapeutic purposes and goals. Frequently used applications include neuromuscular electrical stimulation (NMES), transcutaneous electric nerve stimulation (TENS), electrical stimulation for tissue repair (ESTR), functional electrical stimulation (FES), electrical muscle stimulation (EMS), and iontophoresis. Surface electromyography (sEMG) biofeedback monitors the level of electrical activity in muscles and is often paired with neuromuscular electrical stimulation. (Clinical application of commonly used modalities will be discussed later.)

- NMES uses pulsating, alternating current to activate muscles through stimulation of intact peripheral

nerves to cause a motor response. Stimulation of the nerve is used to decrease muscle spasm, for muscle strengthening, and for its effect on muscle pumping, which can reduce edema. NMES stimulation of innervated muscle can also be used for muscle reeducation and to prevent atrophy.

- FES is neuromuscular electrical stimulation to activate targeted muscle groups for orthotic substitution or to facilitate performance of functional activities or movements (Fig. 20-7). FES is often used with individuals who have shoulder subluxation or foot drop after a stroke.
- TENS describes the wide variety of stimulators used for pain control. TENS uses surface electrodes with the goal of sensory analgesia rather than a motor response.
- EMS is electrical stimulation of denervated muscle to facilitate viability and to prevent atrophy, degeneration, and fibrosis of the fibers. EMS may facilitate nerve regeneration and muscle reinnervation while decreasing muscle atrophy.
- Iontophoresis is the use of low-voltage direct current to ionize topically applied medication into the tissue. Iontophoresis is often used in the treatment of inflammatory conditions or for scar formation and management.
- ESTR, also known as high-voltage galvanic stimulation (HVGS) or HVPC, has been used for wound healing. There is a “current of injury” that occurs when the skin is disrupted by injury. Electrical stimulation has been correlated with accelerated healing by stimulating cell processes during the phases of tissue repair, by

Figure 20-7 FES for the extrinsic flexor and extensor muscle groups to facilitate grasp for self-feeding.

inhibiting bacterial growth, and by increasing oxygen perfusion through localized vasodilation. Due to its complexity for entry-level clinicians, it is not reviewed in this chapter.

Principles of Electricity

To use electrotherapy in occupational therapy practice, clinicians need working knowledge of the principles of current, duration, rise and decay time, frequency, duty cycle, and current modulation and ramp time.

Current

Electric current is the movement of ions or electrons, which are charged particles, from one point to another to equalize the charge. Current, measured in amperes, occurs when there is an imbalance in the number of electrons in two distinct locations. Voltage is the potential or electromotive force that drives the current and is measured in volts. Current flows from an area of high electron concentration (cathode, or negative pole) to an area of less concentration (anode, or positive pole). Opposition or resistance to current flow is measured in ohms. Ohm's law states that voltage is proportional to both current (I) and resistance (R), such that $V = I \times R$. For clinical application, three specific forms of currents, direct current (DC), alternating current (AC), and pulsatile current, are used (Fig. 20-8).

Direct Current

Direct current (DC) is unidirectional, with the electrons moving continuously in one direction and the electrodes maintaining their polarity. DC flow, characterized by the square wave, can cause chemical reactions in the body and facilitate the ionization of medication through the skin.

Alternating Current

Alternating current (AC) is characterized by periodic changes in the direction of the current flow. The current is uninterrupted and bidirectional, without any true positive or negative pole. Household electricity uses AC. Hertz is the number of times the current reverses direction in 1 second (cycles per second).

Pulsatile Current

Pulsed current is the term used when the electron flow is periodically interrupted. These interrupted currents can flow in one direction (monophasic) or two directions (biphasic). In pulsed current, the current is interrupted for very short

Figure 20-8 Commonly used electrotherapeutic current wave forms. **A.** Direct current. **B.** Monophasic pulsed. **C.** Biphasic pulsed. **D.** Interferential beats. **E.** Russian bursts.

periods of milliseconds or microseconds. Most stimulators can be classified under one of three wave forms: monophasic, biphasic, or polyphasic.

- Monophasic wave forms have a single phase to each pulse, with the current flow being unidirectional and either negative or positive. A monophasic pulse has a pulse duration averaging 40–60 msec.
- Biphasic currents have two opposing phases in a single pulse, with the lead phase of the pulse above the baseline and the final phase below. Biphasic pulses may be symmetrical or asymmetrical and have a phase duration between 25 and 250 sec.

- Polyphasic waveforms consist of a burst of three or more phases, a series of pulses delivered as a single charge. This current is also known as interferential or Russian current. There have been many claims as to the uniqueness of this type of current, although there are no confirmed physiological advantages to this type of waveform.

Duration

For monophasic current, phase and pulse duration are synonymous and refer to the length of time between the beginning and end of one phase of the pulse. For biphasic currents, the pulse duration is equal to the total of the two phase durations, including the intra-pulse interval. As phase duration increases, comfort levels decrease. Shorter pulse and duration result in better conductivity of the current with less impedance (Currier, 1993).

Rise Time and Decay Time

Rise time is the amount of time needed for the amplitude to go from 0 volts to peak. The rate of rise is related to the ability of the amplitude to excite nervous tissue. The depth of current penetration is related to the peak amplitude. With biological tissue, the higher the voltage applied, the larger the current that will be passed through the tissue.

Frequency

The number of pulses or wave forms repeated at regular intervals is the pulse or stimulus frequency. The pulse frequency consists of the number of pulses or cycles per second delivered to the body. The rate of successive electrical stimuli is adjustable and may range from 1–120 stimuli per second (1–120 Hz). Frequency may also be labeled as the pulse rate.

Duty Cycle

Duty cycle is the amount of time between the stimulation period and the rest period. That is, it is the ratio of the time the current is on to the time the current is off. The duty cycle may be expressed as a percentage or a ratio. For example, a treatment protocol in which electrical stimuli are delivered for 10 seconds followed by a 50-second off period is expressed as a 1:5 duty cycle. Duty cycle is important in determining muscle fatigue. As the patient's condition improves, the duty cycle can be gradually increased.

Current Modulation and Ramp Time

Changes to the current or to the pulse characteristics are referred to as modulation. Current can be modulated by modifying the frequency, amplitude, or duration. Ramping is a

change of the pulse intensity or duration of the pulse. Ramp time is the time required for successive current stimuli to reach the desired amplitude. Ramp-down, the gradual decrease of the intensity, describes the movement of the peak amplitude back to zero.

Physiology of Nerve and Muscle Excitation

In addition to a working knowledge of electrical principles, clinicians using electrotherapy must understand the physiology of nerve and muscle excitation. The application of electrical current causes physiological changes at both a local and cellular level; these changes can occur segmentally or systemically. The application of electrical current modifies the body's physiological response and physiochemical effects (Hess, Howard, & Attignger, 2000).

Human tissue is either excitable or non-excitable. Excitable tissues, such as nerves and muscles, can initiate and propagate an action potential if the stimulation parameters are sufficient. Stimuli must be sufficiently intense and long lasting to cause the ions to shift across the resting membrane and depolarize the cell. Depolarization of the neural or muscle cell occurs quickly, and the sudden alteration in the cell membrane's electrical potential is known as an action potential. Action potentials are an all-or-none occurrence and, once started, are carried along the cell membrane. Following depolarization, if a membrane becomes hyperpolarized, it may be unable to discharge an action potential, and accommodation occurs.

Propagation

Tissues with high water content, such as muscle and nerve, transmit electricity better than those with lower water content, such as bone, fascia, and adipose tissue. The diameter of the fiber and degree of myelination are also factors affecting the rate of propagation of action potentials. Conduction is faster in myelinated fibers and in large-diameter fibers, which offer less resistance to the conduction of current. More intense stimuli, which are achieved by increasing the stimulus duration and amplitude, are needed to depolarize smaller diameter nerves and denervated muscle membrane (Mehreteab & Weisberg, 1994). Large-diameter nerves are associated with non-noxious cutaneous sensory modalities and motor nerves linked to large motor units. The small-diameter cutaneous sensory nerves are associated with pain pathways. As the amplitude and pulse duration increase, so do the number of nerve fibers recruited. The strength-duration curve in Figure 20-9 describes the relationship between the amplitude and duration of the stimulus needed to depolarize the membranes of various types of nerves to achieve a response (Mehreteab & Weisberg, 1994).

Figure 20-9 Strength–duration curve of an electrical stimulus. MST, maximum sensory threshold.

When the cell membrane or tissue receives an unchanging stimulus over time, the cell membrane begins to adapt to the stimulus and requires higher levels of stimulation to trigger an action potential; this is termed accommodation. Following stimulation and generation of an action potential in a nerve cell membrane, the membrane needs a short period to recover its excitability. This recovery time is known as the absolute refractory period.

Electrically Stimulated Movement

The diameter of the nerve, depth of the nerve, and duration of the pulse affect a nerve's response to electrical stimulation. Sensory nerves are stimulated first, followed by motor nerves, then pain fibers (Fig. 20-9), and finally muscle fibers. Although pain fibers are superficial in relation to motor nerves, they also have a smaller diameter and a greater resistance to electrical current flow. Motor nerves reach threshold, and if there is sufficient intensity, contraction of all muscle fibers attached to that nerve (motor unit) occurs. Stimulation of the skin surface causes an activation of sensory receptors before motor or pain nerves (Baker, Bowman, & McNeal, 1988). Smaller motor units are recruited at varying and slowly increasing frequencies, followed by larger motor units. If the stimulus frequency is sufficient, the muscle twitch contractions become fused in synchronous rapid succession, and the contraction becomes tetanic, leading to a complete contraction of the muscle and movement at the specified joint.

In a voluntary contraction, smaller motor units are recruited first, followed by the larger motor units as contraction strength increases. This gradual, asynchronous sequence allows for fine motor control, with larger fibers recruited as increased strength or speed is needed. This type of recruitment allows smooth, controlled movement.

In electrically stimulated movement patterns, however, the reverse occurs, with larger motor units recruited first in a synchronous pattern. This causes electrically stimulated muscle to fatigue more rapidly and limits the finely controlled quality of functional movement.

Treatment Planning Specific to Electrotherapy

Before incorporating electrotherapy into treatment, clinicians make decisions about the type of electrical stimulator to use and placement and size of electrodes.

Parameters of Electrical Stimulation Devices

The many stimulators available are offered with a variety of poorly supported claims by both manufacturers and clinicians. Research has been equivocal, and the clinician must critically evaluate the claims against the research-based outcomes of electrotherapeutic interventions. Prior to use, the therapist should be familiar with the specific capabilities of the available stimulators and their stimulation parameters.

Electrodes

Electrodes are the contact point providing the current flow from the stimulation device to the body. The electrode acts as an interface with the skin surface, the point where the electron-ion conversion occurs. Electrodes should offer little resistance to the current flow. A variety of electrodes are commercially available. Common electrode material includes carbon-rubber electrodes, which are silicon rubber impregnated with small carbon particles; metal- or foil-backed electrodes; sponges over metal plates; karaya gum electrodes; and self-adherent polymer electrodes. The self-adhering electrodes may be reusable and do not require strapping or taping, making them convenient to use. Adequate contact with the skin is crucial, and complete coverage of the electrode with gel, if used, is necessary.

Electrodes should be examined before each use and changed when necessary. Electrodes degrade with use and become unable to conduct the current efficiently. Therapists should look for cracking and worn spots in the carbon-rubber electrodes or excessive dryness in self-adhering electrodes and replace them as needed. With frequent use, carbon-rubber electrodes may develop non-conductive areas because of the absorption of dirt, skin oil, or electrode gel and depletion of the carbon-rubber. This may cause “hot spots,” areas of high current density that may be uncomfortable for the patient and cause skin burns. A biting or stinging sensation during electrical stimulation may be caused by uneven conductivity, and the electrodes should be replaced.

Regardless of the type of electrode used, proper skin care and hygiene is necessary to prevent skin irritation or breakdown. This factor becomes critically important for patients who are using the stimulators on a home program or when there is prolonged placement and use of the electrodes.

Electrode Size

Current density is inversely related to the electrode size. As the electrode size decreases or the contact area of the electrode decreases, the current density increases, which can cause “hot spots,” as mentioned earlier. As the current density increases, there is a greater perception of the stimulation beneath the electrode along with a greater physiological response due to the charge transfer. Excessive current density under an electrode can lead to discomfort or skin burns.

The inverse relationship between electrode size and current density means that smaller electrodes require less current to stimulate tissue, and large electrodes generally produce a stronger contraction with decreased pain or discomfort. Electrode size is determined by the size of the targeted tissue.

Electrode Placement

As the current density is greater in superficial layers of the skin, the distance between the electrodes also influences the depth of the current flow. When the electrodes are close together, the current passes superficially, and when the electrodes are farther apart, the current penetrates deeper. Location and orientation of electrodes must also be considered when stimulating muscles. Small electrodes can be used to obtain an isolated contraction from smaller muscles, such as those of the hand. Larger electrodes disperse the current into the tissue and are less specific in stimulating isolated muscles. Care should be taken when applying and selecting location of the electrodes because closely spaced electrodes may increase discomfort.

There are two primary methods of electrode placement for electrical stimulation: monopolar and bipolar. Simply put, the terms identify whether one lead and electrode is placed over the targeted tissue or if both leads and electrodes are placed over the area. The monopolar technique uses one stimulating electrode, which is placed over the targeted area. The other lead and electrode are placed over an area that is not affected by stimulation; this is the dispersive, or non-treatment, electrode. In the monopolar technique, only one pole or side of the circuit (active electrode) of the electrical stimulator is used to stimulate the target area. The dispersive electrode completes the electrical circuit and can be placed away from the target area on the same side of the body so as not to affect cardiac conduction. The dispersive electrode is often larger, minimiz-

ing the current density and perception of sensory stimulation. Monopolar techniques are most often associated with trigger and acupuncture-point stimulation.

Bipolar techniques consist of both electrodes placed over the target area to cause stimulation of the tissue. Since both electrodes or sides of the circuit are in contact with the targeted area, the current flow is more local, and the stimulation is perceived under both electrodes of the circuit. Most often, the electrodes are the same size, and this technique can be used to stimulate large muscles or muscle groups. Bipolar techniques are often used to activate muscles atrophied because of disuse, for muscle reeducation, or to obtain stronger contraction (neuromuscular facilitation) to increase limited movement.

Clinical Use of Electrotherapy

The unique applications and indications for each type of electrotherapy are discussed in turn.

Electrical Stimulation

Electricity has been advocated in the treatment of a variety of body systems and for a plethora of conditions, including joint swelling and inflammation, joint dysfunction, tissue healing, muscle reeducation, circulatory disorders, postural disorders, **pelvic floor** disorders, fracture healing, and pain management. There are a number of claims for electrical stimulation along with a variety of protocols and applications; some are objective, but many are unsubstantiated or anecdotal. The clinician should take a systematic and objective approach to the use of electrical stimulation.

Neuromuscular Electrical Stimulation

Neuromuscular electrical stimulation (NMES) has a variety of clinical uses as an adjunct to occupational therapy treatment. NMES is defined as the “use of electrical stimulation for activation of muscle through stimulation of the intact peripheral nerve” (American Physical Therapy Association, 1990, p. 29). NMES is often erroneously referred to as “functional” electrical stimulation. Functional electrical stimulation is a subcategory of neuromuscular electrical stimulation and refers to the use of NMES as a substitute for an orthosis to assist with a functional activity, such as standing or holding an object, or as a substitute for a sling. NMES can be used for strengthening and endurance, range of motion, facilitation of muscle function, management of muscle spasms and spasticity, edema reduction, and orthotic substitution (Cahe, Yu, & Walker, 2004). Clinical use of NMES requires a partially intact or intact peripheral nerve, and its use with primary muscle disease or muscular dystrophy is questionable.

Biofeedback/NMES

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>M.J. is a 36-year-old female who suffered a stroke affecting her left side. The stroke occurred while she was camping with her two sons (ages 12 and 9) and her husband. When her condition stabilized, she was referred to an inpatient rehabilitation program where she stayed for 5 weeks. She was discharged home with the recommendation for outpatient treatment. Prior to the cerebrovascular accident (CVA), she was employed as a nurse. She was right-hand dominant and independent for ADLs. She was accompanied by her husband for the initial evaluation. She was alert and oriented, but somewhat apprehensive and subdued. The following problems were identified during the occupational therapy assessment: (1) decreased initiation of IADL; (2) decreased functional use of the left upper extremity (active shoulder flexion/abduction to 95°); (3) increased tone in the left upper extremity with active grasp and weak release; (4) impairment in sensation, stereognosis, and proprioception in the left upper extremity; and (5) dependent for community mobility on public transportation.</p>	Appreciate the context	“M.J. is a young, vibrant woman whose entire occupational roles have been affected by her CVA. She has gone from total independence to a state of greater dependence on her family and husband. She seems apprehensive and concerned over whether she will regain function in her upper extremity.”
	Develop intervention hypotheses	“M.J. seems worried about whether she will be able to return to work and is also concerned about the financial impact her disability will have on the family. Her husband and family seem extremely supportive of her, and I am pleased that they are very engaged in her rehabilitation and in facilitating her independence.”
	Select an intervention approach	“I am proposing an intervention plan that emphasizes compensatory techniques but also remediation and neuro-reeducation techniques to facilitate the return of function in the upper extremity. M.J. is anxious to continue to re-learn to use her affected arm and hand. Because of her nursing background, she seems to want to ‘try everything and anything to get better.’
	Reflect on competence	“I have to admit that M.J. is a challenging case because she is about my age and extremely active prior to her CVA. She wants to try to return to work and recognizes the fact that she ‘has’ to get her ‘hand and arm to work.’ I know that we can use neuromuscular electrical stimulation to facilitate movement and strength in the upper extremity, but we also need a mechanism to provide her with feedback as to the level of volitional activity that she has in the arm and hand. Because of her motivation and progress to date, I recommend the use of biofeedback synchronized with NMES to strengthen the volitional control that she demonstrates and to facilitate the full ROM of the extremity. I do have concerns about safety issues related to ADL independence and am concerned that M.J. could injure her left upper extremity because of impaired upper extremity sensation and proprioception.”
<p>Recommendations</p> <p>The occupational therapist recommended three outpatient treatment sessions each week for 4 weeks. In collaboration with M.J. and her family, the occupational therapist established the following long-term treatment goals: (1) M.J. will display full AROM in the left upper extremity; (2) M.J. will display active grasp and release patterns of the upper extremity to manipulate large objects; (3) M.J. will be independent for IADLs; (4) M.J. will return to work; (5) M.J. will drive independently.</p>	Consider the patient's appraisal of performance	“M.J. seems highly motivated to attempt to return to work, and her family was supportive of this goal. In addition, because of the school and church activities that her sons were involved in and the fact that public transportation is negligible in the county that she lives in, M.J. really wants to return to driving independently. I know that this goal would strengthen her independence and ability to engage in those IADLs that are so vital to an active and involved family.”
	Consider what will occur in therapy, how often, and for how long	
	Ascertain the patient's endorsement of plan	

Summary of Short-Term Goals and Progress

1. MJ will display full AROM in the left upper extremity.
2. MJ will display active grasp and release patterns of the upper extremity to manipulate large objects.

The therapist began treatment using biofeedback and NMES to isolate shoulder flexion and abduction greater than 110°. The biofeedback parameters were set to register the amount of volitional muscle activity and provide the patient with auditory and visual feedback. She engaged in a variety of reaching activities that initially required active shoulder movement slightly below the point that would stimulate her flexor synergy pattern to override her active extension. When M.J. would volitionally reach this point and “get stuck,” the NMES would trigger and stimulate the targeted muscle groups to contract, completing the movement for her. As her strength and control continued, the parameters were adjusted, requiring her to volitionally control more of the movement and to strengthen functional movements. To stimulate shoulder movements, electrodes were placed over the supraspinatus/upper trapezius, the anterior deltoid, and, to ensure elbow extension, the triceps. As greater proximal control developed, the electrodes were placed more distally on the arm, providing feedback and stimulation at the elbow (triceps), the wrist extensors, and then finally, alternating between the wrist extensors and flexors as needed.

Assess the patient’s comprehension

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

“In the initial evaluations and subsequent visits in the first week of therapy, it was clear to me that M.J. was developing active control in the extremity. Due to the strong flexor synergies prevalent, however, when she attempted to move beyond the range of motion she could control, the flexor patterns predominated in the upper extremity. She is anxious to learn how to override the synergy patterns and strengthen the volitional control in her arm and hand. The use of the auditory and visual feedback of the motor activity is reinforcing to her and provides her with the input she needs to determine which muscles are active and which need to relax. When synchronized with the NMES, the electrical stimulation of the weaker extensor patterns is reinforced and provides her with visual and neurological feedback to strengthen the movements. M.J. is a perfect candidate for this kind of intervention. She quickly learns how to use the feedback and stimulation to reinforce the distal control that she needs. I need to keep track of the degree of volitional movement she can demonstrate and monitor fatigue and synergy patterns that seem to vary depending upon M.J.’s emotional and physical state.”

“I am pleased to see M.J. translate her gains in upper extremity function into expansion of her IADLs. She recently began testing to determine if she could resume driving independently and ultimately succeeded. This will further her independence and resumption of IADLs and eventually enable her to attempt to return to her work.”

Next Steps

Continued outpatient occupational therapy for 1 month but with declining contact is recommended. Intervention will focus on weaning M.J. away from the biofeedback and NMES and ensuring that she continues to use the extremity for functional movements. Occupational therapy will incorporate educating the patient’s family members and spouse on the returning function and importance of a home program of exercise and movement as crucial to ensure continued strength, independence, and function. The patient will also be assisted in resuming many of her social and religious activities and reintegrating her into meaningful community organizations and activities.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Because of the patient’s background as a nurse, M.J. seems well aware of challenges and potential limitations based on her initial prognosis. She has always been highly motivated to ‘try almost anything’ if it would ‘work.’ But I am impressed at her insight into the possible risks and difficulties she will face returning to her career as a surgical nurse, and she is starting to prepare herself for other options that might require less fine motor dexterity and endurance as her condition improves. I expect that she will work closely with her employer and physicians to adapt her work site and work requirements.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Identifying Appropriate Therapeutic Goals and Interventions

M.J. was a young, active, healthy individual prior to her devastating stroke. Overnight, her life and roles changed, impacting not only her immediate family but the community in which she lived and her patients and employer. She was highly motivated to return to some semblance of her pre-morbid activities and life. The difficulty she faced was in determining short-term, realistic goals and objectives (which the therapist had to assist her to prioritize) and expanding those into long-term functional goals. As functional return and movement occurred in her upper extremity, refining and strengthening the motor patterns and movements available to the patient became a motivating factor for her. There are a variety of neuromuscular facilitation techniques that can be used as part of neuromuscular reeducation. What other therapeutic techniques and interventions could have been used with this patient? What were the components of NMES and biofeedback that were motivating and intrinsically rewarding to the patient? Could only NMES have been used? What are some of the complications that occur with cerebrovascular accidents in terms of the shoulder and upper quadrant?

Maintain Muscle Mass

NMES can be a successful adjunct to conventional treatment in individuals with limited traumatic or orthopedic injuries. There is a relationship between training intensity and strength gains, and improving muscle strength is based in part on the overload principle. The overload principle refers to the fact that, for strength gains to occur, the body must be subjected to greater levels of stress than it is accustomed to. To accomplish this, the therapist must increase the load, frequency, or duration of the exercise or activity. Patients who are deconditioned or have areas of weakness may benefit from NMES to improve endurance of the targeted muscle. Isometric strengthening using NMES produces better results than conventional isometric exercises alone but is most effective when paired with functional goals and movements (Baker, 1993).

Maintain or Gain Range of Motion

Neurologically impaired patients often develop spasticity as a consequence of their injury. Range-of-motion techniques and positioning are often part of the overall training and education program for family members and caregivers. Unfortunately, patients with moderate to severe spasticity often have difficulty following through on these techniques and can develop limitations affecting their occupational function. Hemiplegic patients with chronic moderate spasticity in the wrist or finger flexors may be appropriate candidates for this intervention (Powell et al., 1999). For these individuals, the stimulus should ramp up and be sufficiently intense to allow for a slow stretch without increasing spasticity due to a quick stretch or jerk (Baker, 1993). Ramp-up times should be extended to 6–8 seconds or longer, and proper positioning or blocking of other muscles should be considered. Serial casting or splinting of the extremity can be an ef-

fective adjunct to NMES. The use of NMES is effective as part of a home program because it reduces the spasticity and allows the caregiver to carry out passive range of motion several times daily.

For the orthopedic patient, range of motion may be limited by contractures secondary to immobilization or pain. NMES may be used to improve joint range of motion if the limitation is due to intrinsic soft tissue shortening as opposed to a bony block or biomechanical limitation. The technique should maintain a low-intensity stretch for a few seconds.

Management of Spasticity

The effectiveness of NMES for the treatment of spasticity depends in part on the underlying disease causing the spasticity. The response of NMES in a patient with a spastic spinal cord injury may be different from the response in a patient with a brain injury or multiple sclerosis. The variability of abnormal tone may only result in a temporary interruption of the motor neuron excitability, with short-term treatment effects. Stimulation of a spastic muscle in the neurologically impaired client using a high frequency causes a response similar to fatiguing the muscle (Vodovnik, Bowman, & Hufford, 1984).

NMES also affects spasticity by stimulating the muscle antagonist to the spastic muscle, which inhibits the spastic muscle, allowing range-of-motion exercise (Wang, Tsai, & Chan, 1998). Heat or ice and serial casting or splinting paired with functional movements and activities may enhance the therapeutic response.

Orthopedic patients may have pain-spasm cycles caused by local spasm of a particular muscle or group. Decreasing the pain-spasm cycle through the application of NMES to the area improves and enhances range of motion and occupational performance.

Facilitate Voluntary Control

NMES has been used frequently for muscle reeducation and facilitation, particularly with neurological injuries and orthopedic injuries after surgery. Facilitation and retraining can be effective for patients suffering from disuse atrophy, muscle weakness, and pain (Lewek, Stevens, & Snyder-Maackler, 2001). In neurologically involved patients, the sensory feedback loop becomes distorted or impaired.

The goal of NMES for facilitation and reeducation is to incorporate the stimulation with voluntary contraction, functional movement and activity, and sensory feedback (Bracciano, 2000). The intent of NMES for facilitation and reeducation is to flood the central nervous system with sensory and kinesthetic information linked to an anticipated motor response. A variety of functional activities incorporating the desired motor response should be used to ensure adequate carryover of the response. For example, a stroke patient who is working on grasp and release should be provided with a variety of objects consisting of various shapes, sizes, and weights to hold and release. Placement of the objects should require movements to various heights and locations.

Functional Electrical Stimulation

Functional electrical stimulation (FES), the use of NMES as a replacement for orthoses, has been an effective adjunct in facilitating occupational function, most notably positional stability and mobility. Stimulation of innervated paretic or paralyzed muscles can decrease dependence on slings, splints, or orthotics through the development of increased strength and endurance of the paretic musculature.

FES has been effectively used with hemiparetic patients who display shoulder subluxation during the flaccid phase of recovery and also to facilitate grasp-and-release activities (Eckerson & Axelgaard, 1984; Phillips, 1989). In the hemiplegic patient, gravity stresses the shoulder capsule, stretching the ligamentous capsule. When muscle tone and voluntary control develop at the shoulder, normal glenohumeral alignment may not recur when the arm is at rest because of ligamentous laxity (Yu, Cahe, & Walker, 2001). Slings may be helpful to establish glenohumeral alignment, but stimulation of the posterior deltoid and supraspinatus muscles may be more effective in improving normal shoulder integrity (Lin, Granat, & Lees, 1999; Wang, Chan, & Tsai, 2000). Use of FES for maintaining shoulder integrity by preventing subluxation and reeducating muscles can be an effective adjunct to splinting and facilitate occupational function. Clearly outlining and teaching the client and caregivers in a home program is vital to ensure continuity and carryover.

Transcutaneous Electrical Nerve Stimulation

Pain is one of the most common complaints that cause patients to seek medical care. Adequate pain manage-

ment facilitates occupational function (Fig. 20-10). Transcutaneous electrical nerve stimulation (TENS) can be used to manage pain in musculoskeletal disorders. The two primary theories on which the modulation of pain with TENS is based are the gate control theory (Low and Reed, 2000) and the endorphin theory (Bonica, 1990).

Treatment applications using electrical stimulation for pain control employ pulsed or alternating current with a variety of stimulation patterns. The type of stimulation is based on the neurological response to the stimulation. The four primary types of stimulation frequently employed include subsensory level, sensory level, motor level, and noxious level. Stimulation sites for electrode placement are based on the problem areas and goals for the patient. Optimal electrode placements should correlate with the structures and sources of pain and include motor points, trigger points, and acupuncture points. TENS units are often used at home, and the therapist should explain the purpose of the equipment and instruct the patient in its operations and precautions, with written and pictorial instructions. Through application of TENS for sensory analgesia, the patient may better perform functional activities and movements that foster independence and function.

Figure 20-10 Application of TENS to the shoulder for acute pain.

Iontophoresis

Iontophoresis is a method of topically delivering a medication or ionized drug to an area of tissue by using direct electrical current. Iontophoresis is non-invasive, essentially painless, and an effective way to administer medications to local targeted tissues. Occupational therapists frequently use iontophoresis in the treatment of inflammatory conditions such as epicondylitis, carpal tunnel syndrome, glenohumeral bursitis, ulnar nerve inflammation, and wrist tendinitis and tenosynovitis. Therapists using iontophoresis should thoroughly understand the

pathophysiology of the condition, the wound healing process, medications being used, and any potential drug interactions. Caution must be used whenever using iontophoresis because medications may cause an allergic or anaphylactic reaction, which is a life-threatening condition and medical emergency. Patients should *always* be asked for a list of current medications and whether they have any known allergies, sensitivities, or reactions to foods or medications. Documented orders should always be obtained from the patient's physician prior to using iontophoresis (Bracciano, 2000).

Iontophoresis

Occupational Therapy Intervention Process

Patient Information

Laura is an active and athletic 47-year-old female who was referred to occupational therapy by her family physician. She relates that she was “painting her kitchen and family room” in the “new house” they recently purchased. After 3 days of painting, she developed pain in her right elbow (dominant hand), increasing inability to “hold” onto objects such as a gallon of milk, and further difficulty with cooking and self-care activities requiring her to use her right hand in static “hold” positions, along with “tingling and numbness” in her right hand. She reports pain being “constantly a 4–5 out of 10” and increasing to “7–8 out of 10” with use. Cozen's test was positive, with patient displaying pain on the lateral epicondyle with resisted wrist extension. Laura also displays point tenderness over the right lateral epicondyle. Grip and pinch strengths are decreased in the right hand and are less than normal for women her age. The patient also displays an extension lag of 10° and lacks full flexion by 12° (pain in both distal ranges).

Clinical Reasoning Process

Examples of Therapist's Internal Dialogue

Appreciate the context

“It seems that Laura's signs and symptoms are consistent with a diagnosis of lateral epicondylitis. Her symptoms developed quickly after apparently overusing the right upper extremity to paint her house.”

Develop intervention hypotheses

“Because of the rapidity with which her symptoms developed, the quick referral by her physician, and lack of previous difficulties in her right upper extremity, Laura's condition is considered an acute episode. I believe that she will require a multi-faceted approach to treat her condition.”

Select an intervention approach

“Laura's problems and clinical presentation are consistent with a diagnosis of acute lateral epicondylitis. I expect that her physician will recommend some form of NSAIDs or other anti-inflammatory medications. I will be recommending static splinting of the right wrist in neutral, ROM and gradual strengthening of the upper extremity, use of physical agent modalities to facilitate the healing process of the tissue, and modification of her daily activities to avoid further exacerbating her condition.”

Reflect on competence

“There are a number of therapeutic approaches that can be used with lateral epicondylitis. I will need to consistently monitor Laura's response to the interventions used, which will assist in modifying the treatment as needed. I will also want to monitor her level of use of the right upper extremity, compliance with the splint-wearing schedule, and modifications to her daily routine to prevent further exacerbation of her condition.”

Recommendations

The occupational therapist recommended three treatment sessions per week for 3 weeks. The following long-term goals were established: (1) decrease pain in the right upper extremity; (2) improve pain-free ROM; and (3) improve pain-free pinch and grip in the right hand.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"From the beginning, it was apparent that Laura would follow through on all recommendations. She was highly motivated and had been very active and participated in a number of athletic activities prior to her injury. She was anxious to return to her pre-morbid activities, and there was more concern that she might 'overdo it' as she progressed in treatment and her symptoms began to subside. Because her children were also older, I wasn't concerned with her having to 'lift' any babies or infants. Additionally, she could ask her family members to help her with those activities that required heavy lifting or static hold and release patterns."

"Laura agreed with the goals and was anxious to begin treatment to decrease the pain and loss of function in her right upper extremity. "

Summary of Short-Term Goals and Progress

The treatment approach and intervention included: (1) static splinting of the right hand; (2) iontophoresis with dexamethasone to decrease the inflammatory process and pain (2–3 out of 10); (3) friction massage to the lateral epicondyle, and icing as needed; (4) ROM to the right elbow; (5) and modification of ADLs and movements to prevent exacerbation of her condition.

Laura was instructed in different methods of modifying activities that required her to lift or manipulate objects as part of her daily activities. She was also provided with a static positioning splint for her right hand that she was to wear at night and initially during the day. She was aware of skin and splint care and her wearing schedule.

Laura's condition responded to the iontophoresis, and she reported a decrease in pain by 50% after the fourth treatment (every other day). As she responded to the iontophoresis and her treatment, her dosage was increased from 40 mA/min to 60 mA/min and, for her final three treatments, to 80 mA/min. (Using a gradually increasing 40/60/80 milliamp protocol as the patient improves allows a greater number of ions to be delivered to the underlying tissue and may hasten healing.) All activities and interventions were graded and gradually increased in resistance and/or intensity as her condition and symptoms improved.

Assess the patient's comprehension

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

"I noticed that Laura was apprehensive to ask for assistance at home, but after we talked about the importance of 'resting' the elbow the first 2 weeks or so, her family took an active role in assisting her with her activities and responsibilities. Because she was responding so positively to the treatment interventions, I recommended that she begin wearing her splint only at night but resume wearing the splint during the day if she noticed any return of her symptoms or pain. I know how important it is for me to monitor Laura's condition closely and to note any changes in pain or symptoms during each treatment visit, modifying the treatment and interventions as needed. If she reports a reversal back to earlier levels of pain and symptoms, I'll have to figure out whether or not the interventions are effective or whether she is impacting the injury somehow in the performance of her daily occupations and activities."

Next Steps

Revised short-term goals (2 weeks):

1. Laura will display decreased pain (1–2 out of 10) with use of her hand to lift "light" objects.
2. Laura will display full active ROM in the right elbow (she will be able to fully extend her arm to reach for and manipulate objects).
3. Laura will wear her splint at night.
4. Laura will improve her grip and pinch strength within functional limits without pain.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide whether the patient should continue or discontinue therapy and/or return in the future

"I am pleased with Laura's response to the initial course of treatment. She was compliant with her splint wearing and modified her routine and activities to avoid using the right upper extremity. She noticed a marked decrease in pain 'by at least 50%' and a decrease in her other symptoms after the fourth treatment using iontophoresis. Because she responded so well to the treatment, I recommend that we continue with the iontophoresis, begin gentle strengthening activities and exercises, and allow her to begin using the right upper extremity in more activities requiring a static hold and release pattern."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Determining Progress in Physical Agent Modalities

Laura’s “injury” occurred following her engagement in a rather normal activity, painting her house. The signs and symptoms that she exhibited, such as pain in her elbow, difficulty holding onto objects and performing routine activities, and numbness and tingling, are all diagnostic clues that an occupational therapist needs to use to determine a differential diagnosis and select an appropriate treatment plan and physical agent. Establishing a realistic “starting point” based on the evaluative and assessment components provides a mechanism for determining progress and efficacy of the therapeutic interventions, guiding modifications to the treatment.

What clues, both subjective and objective, did Laura provide to the therapist to guide him in his thinking and treatment plan? What other physical agents could have been used with Laura to achieve the identified goals and objectives? What was the primary factor that indicated to the therapist that the iontophoresis should be continued?

SURFACE ELECTROMYOGRAPHIC BIOFEEDBACK

Biofeedback is an often overlooked modality that therapists can use for neuromuscular reeducation, relaxation techniques, and behavioral modification. The general term “biofeedback” refers to those procedures or techniques that are used to provide an individual with an auditory or visual cue or “feedback” to learn and gain volitional control over a physiological response. Biofeedback equipment provides the individual with an external mechanism for monitoring a specific physiological function and response and, through instant feedback, allows the individual to attempt to control or modify the behavior or response.

The term biofeedback was first used by researchers to describe procedures that were being attempted to train subjects to alter brain activity, blood pressure, heart rate, and other physiological functions not controlled volitionally. Biofeedback was given its initial impetus by the work of Basmajian and his research on single motor unit training of the neuromuscular system. Clinically, biofeedback techniques and equipment continue to develop and are used to treat a variety of conditions including migraine headaches, tension headaches, pain, disorders of the digestive system, hyper- and hypotension, cardiac arrhythmias, Raynaud’s disease, seizures, and paralysis and movement disorders (Foster, 2004; Engel, Jensen, & Schwartz, 2004; Smania et al., 2003; Middaugh et al., 2001). Specialists in a variety of fields use biofeedback to control pain, anxiety, muscle tone, behaviors, and muscle function and movement. Since the primary use of biofeedback in

physical medicine and rehabilitation is in the form of sEMG or surface electromyographic feedback for muscle reeducation and training, we will focus on this dimension of biofeedback in this chapter.

Clinical use of sEMG biofeedback for neuromuscular dysfunction was demonstrated to be an effective education method for a variety of conditions, and later research used sEMG to improve function in hemiplegic patients (Booker, Rubow, & Coleman, 1969; Johnson & Garton, 1973). Research using sEMG neuromuscular reeducation has also demonstrated success when compared to traditional methods of treating stroke (Moreland, Thomson, & Fuoco, 1998). sEMG uses electronic instrumentation to measure and display muscle activity. Surface electrodes are placed on the skin over the muscles being retrained or examined. These electrodes and the associated computer electronics sense the electrical activity associated with muscle tension or relaxation and quantify and display the activity. Electromyography can demonstrate asymmetrical muscle activation during symmetrical movements, co-contraction of antagonists during movement, difference in onset or timing of muscle firing during specific movements, and failure of the muscle activity to “shut off” following movement. These can all lead to musculoskeletal pain, spasm, contractures, or loss of functional movement and are considerations for incorporating sEMG as part of the treatment regimen. Using sEMG, a spastic muscle, for example, would be treated with relaxation and “calming” of the targeted muscle. Contractures would be treated with mobilization and stretching. Paralysis would be treated with activation and mobilization, with the patient “attempting” to move the affected muscle to increase biofeedback activity. As

the desired control or movement is developed by the patient, he or she should be weaned from the biofeedback with an emphasis on volitional movement and activity being reinforced. Some sEMG equipment can be linked or synchronized with neuromuscular electrical stimulation to facilitate motor unit activity or to increase motor unit recruitment and movement. sEMG and paired NMES can be used for patients who are, for example, unable to fully complete a movement through partial or full range of motion. The therapist can set the threshold so that the patient receives auditory and visual feedback with activation of a selected muscle, which, when achieved, activates the NMES to complete the movement, thereby reinforcing and strengthening the response (Pullman et al., 2000; Seo et al., 2005).

Muscle Reeducation

sEMG enables the therapist and patient to objectively measure and visually determine muscular activity patterns. Depending on the equipment, the therapist is also able to quantify and track changes in motor performance and function. Use of biofeedback for muscle reeducation or strengthening most often uses auditory and visual feedback. Depending on the device, the feedback is set to an all-or-none response or to a specific threshold that the patient must achieve to activate the auditory or visual response. The threshold can be raised or lowered depending on the need and allows the therapist to grade the activity and response, allowing the patient to achieve higher levels of performance based on earlier training sessions. If the goal is muscle inhibition, the threshold is set so that the device will either turn on or turn off when the level of motor activity decreases below the specific setting. One disadvantage to using surface electrodes is that they are susceptible to movement artifacts or electrical noise. Electrodes are placed over the bulk of the targeted muscle belly parallel to the muscle fibers. As with neuromuscular electrical stimulation, placing the electrodes further apart increases the amplitude of the EMG signal.

sEMG is motivating for patients because they are provided instantaneous feedback in the form of visual and auditory modes. With many patients who have suffered a cerebrovascular accident, along with disruption of motor control, there is a concurrent impairment in proprioception and kinesthesia, which impacts functional abilities because of the loss of sensory input and feedback. Incorporating sEMG into the therapeutic mix provides the central nervous system and patient with additional feedback and input. As the patient's condition improves and muscle function and performance are normalized, conditioning and engagement in functional tasks and activities reinforces and strengthens the "learned" movement patterns (Procedures for Practice 20-2 and 20-3).

PROCEDURES FOR PRACTICE 20-2

EMG Biofeedback Session for Muscle Reeducation

- Begin with large, widely spaced electrodes over the muscle belly.
- Initially set the threshold at an attainable level.
- During a 10- to 15-minute treatment session, the patient voluntarily contracts the muscle to reach the threshold level.
- When possible, incorporate purposeful activities to facilitate the muscle activity desired.
- Gradually raise the threshold during the treatment session to challenge the patient to contract the muscle more strongly.

Biofeedback in the Treatment of Incontinence

Biofeedback has also been used in the treatment of pelvic floor disorders (Dannecker et al., 2005; Kielb, 2005). Although men may suffer from pelvic floor disorders, the vast majority of patients with this condition are women because of the anatomy and function of the pelvis in women. Pelvic floor disorders refers to the pelvic diaphragm, the sphincter mechanism of the lower urinary tract, the upper and lower vaginal supports, and the internal and external anal sphincters. This complex of muscles, tissue, and ligaments holds up the organs of the pelvis, the vagina, rectum,

PROCEDURES FOR PRACTICE 20-3

EMG Biofeedback Session to Decrease Spasticity

- Begin with small, closely spaced electrodes over the muscle belly.
- Initially set the threshold at an attainable level.
- Place the limb in midrange, and keep the environment free of distractions.
- During a 10- to 15-minute treatment session, the patient attempts to maintain relaxation of the muscle below the threshold level.
- Gradually decrease the threshold as the patient learns to relax the muscle.
- In subsequent sessions, challenge the patient to maintain relaxation of the spastic muscle while contracting the antagonistic group.

Evidence Table 20-1 Best Evidence for Interventions Used in Physical Agent Modalities Case Examples

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability	Reference
Functional Electrical Stimulation (FES)	Use of functional electrical stimulation to wrist and finger extensor muscles to improve grip acquisition and grip processing speed.	38 patients with hemiplegia.	FES to affected extremity 2 times per week for 6 months.	IIIb3b; Pre-post only.	Yes. FES administered twice weekly for 6-month increased grip speed.	Statistically significant improvement in grip speed after treatment ($p = 0.0309$).	Lourencao et al., 2005
Iontophoresis	Iontophoresis of corticosteroids (compared with local corticosteroid injection).	30 patients (48 median nerves) with clinical and electrophysiological evidence of carpal tunnel syndrome.	1 session only. One group received 40 mg of methylprednisolone acetate injected into the carpal tunnel; the second group received iontophoresis of dexamethasone sodium phosphate.	Random assignment of median nerves to 1 of 2 groups; unblinded. IC2b.	Yes. At 2 weeks and 8 weeks after therapy, there was a statistically significant improvement in pain, symptom severity scale, and functional status in both groups compared with baseline ($p < 0.05$). But symptom relief was greater at 2 and 8 weeks with injection of corticosteroids.	Statistically significant ($p < 0.05$).	Gokoglu et al., 2005

uterus, and bladder. This system of support often becomes weak following vaginal delivery of several children or in women who have had perineal or pelvic floor tears during delivery. As they age or reach menopause, these women may develop symptoms of pelvic floor disorders, which are caused, in part, by the organs shifting, bulging, and pushing against each other. This may lead to urinary or fecal incontinence, obstruction, vaginal pain or prolapse, sexual dysfunction, and other difficulties (Jundt & Friese, 2005; Kielb, 2005).

The nature of the pelvic floor musculature provides individuals with voluntary control. These muscles contract and relax with the action becoming automatic. If the normal contract-relax coordination of the pelvic floor muscles becomes disrupted, bowel and bladder disorders may occur. Since these muscles can be controlled voluntarily, however, they can be “retrained” using sEMG. Special EMG sensors are available that can be placed in the anal canal or vagina and measure and display the amount of electrical activity. The therapist can provide instruction and training to assist the patient in regaining control and changing abnormal muscle activity. If the patient is unable to isolate muscle contraction, pelvic floor exercises can be paired with electrical stimulation to provide proprioceptive feedback and strengthen the muscular contraction. Portable electrical stimulation units can be used at home, and a variety of internal and external electrodes are available. Some pelvic floor biofeedback devices are also linked to neuromuscular electrical stimulators; these are called pelvic floor stimulators. These biofeedback-triggered stimulation units provide both active and passive strengthening of the weakened musculature. The patient contracts the pelvic floor muscles to a specific threshold, which, when reached, triggers the electrical stimulation to further strengthen the response. These devices provide the patient with additional assistance in developing volitional control, changing muscle tone, or increasing muscle activity through the administration of electrical current at a specific threshold (Lin et al., 2004; Seo et al., 2005). Treatment of pelvic floor or urogynecological and colorectal systems requires advanced training and clinical practice. There may also be specific requirements related to state practice acts that must be met prior to developing or implementing these programs and interventions, and the clinician is cautioned to review both institutional and state regulatory guidelines before using these techniques.

Physical agents like the ones discussed in this chapter should never be the single method or treatment approach in occupational therapy treatment. When used judiciously after taking into account the diagnosis, healing process, and phase of recovery, physical agents can make a valuable contribution to occupational therapy, facilitating outcomes and occupational performance.

SUMMARY REVIEW QUESTIONS

1. Identify and discuss the three phases of wound healing. Why is the phase of wound healing a significant factor in selection of a specific physical agent modality as an adjunct to treatment?
2. Discuss the types of pain and their effect on occupational function.
3. Define and discuss superficial and deep thermal agents. Identify indications and contraindications for application of deep thermal agents and their effect on occupational function.
4. List the most frequently used applications of electrotherapy.
5. Discuss AOTA’s position on physical agents and how physical agent modalities can be incorporated into a comprehensive treatment program.
6. Define and discuss therapeutic ultrasound and its thermal and non-thermal effects.
7. List precautions and contraindications for superficial thermal agents and cryotherapy.
8. Identify indications for use of sEMG biofeedback.

SECTION V: Treatment of Occupational Function

CHAPTER 21

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. State the biomechanical and physiological mechanisms that underlie therapeutic exercise and occupation.
2. Apply the methods of movement, positioning, and compression to prevent limitation of range of motion.
3. Apply the principles of the biomechanical approach to increase range of motion, strength, and endurance as needed for occupational performance.
4. Apply these principles to the selection of occupations as a means for treating range of motion, strength, and/or endurance problems.
5. Design treatment goals and therapy for clients who have problems with range of motion, strength, and/or endurance to enhance occupational performance.

Optimizing Abilities and Capacities: Range of Motion, Strength, and Endurance

Nancy A. Flinn, Jeanne Jackson, Julie McLaughlin Gray, and Ruth Zemke

Glossary

Ankylosis—Pathological stiffening of a joint due to fibrotic changes in the bones and/or tissues surrounding the joints.

Concentric contraction—Muscle contraction that moves a limb segment in the direction of the muscle pull.

Contracture—Static shortening of muscle and connective tissue that limits ROM at a joint.

Cross-bridge—ATP segment that moves and reconnects actin and myosin fibrils during muscle contraction.

Eccentric contraction—Muscle contraction that applies a braking force to a movement produced by an opposing force (e.g., gravity) or resistance because the direction of the muscle pull is opposite the actual movement.

Guillain-Barré—An inflammatory disorder in which the body's immune system attacks the peripheral nervous system, resulting in weakness and numbness in the arms, legs, trunk, and face. Most patients make substantial improvements, but

about one third of patients still have some residual weakness 3 years after onset.

Heterotopic ossification—Formation of new bone material in an abnormal site, such as adjacent muscle (Salter & Cheshire, 2000).

Kinematics—Study of the form of motion, describing movement paths in terms of the amount and direction of displacement of body segments in meters, velocity or speed in meters per second, and acceleration or rate of change of speed in meters per second squared. Joint angle changes in a given direction are also kinematic characteristics.

Kinetics—Study of forces, including static forces that balance or stabilize and dynamic forces that mobilize.

Parameter—Variable that can be manipulated.

Torque—Product of force \times perpendicular distance between the force and the axis of rotation.

According to the Occupational Functioning Model, a goal of occupational therapy is to foster competency and self-esteem through participation in life occupations (see Chapter 1). Biomechanical and physiological principles that relate to movement can provide guidelines for treatment when participation in occupation is threatened because of limitations in the capacities of range of motion, strength, or endurance. For example, occupational therapists use these principles to assist in remediating impairments from acute injuries or compensating for chronic disability to enable occupation. Occupational therapists also use these principles in preventing illnesses and conditions such as cumulative stress trauma and back injuries, which often result from occupations requiring a sustained position or repetitive motions. In this chapter, we will address treatment methods to increase range of motion, strength, and endurance.

MUSCULOSKELETAL SYSTEM

The following is a simple overview of the biomechanical and physiological elements of the musculoskeletal system that underlie range of motion (ROM), strength, and endurance. This basic understanding enables occupational therapists to analyze and prescribe therapeutic occupations and exercise to promote occupational function.

Biomechanical Aspects

The biomechanical aspects of human movement are described in terms of the path of a limb in time or space or the forces that influence that motion, either making it

persist or making it cease. These two ways of describing motion are called kinematics and kinetics, respectively.

Kinematic analysis describes the amount and direction of movement, speed, and acceleration of body segments and joint angles (Levangie & Norkin, 2005). Researchers have used these quantitative kinematic descriptors to describe the reaching movements in children with cerebral palsy (Chang et al., 2005), the influence of instructions on reach in adults with and without cerebrovascular accidents (Fasoli et al., 2002), and the effect of wheelchair handrim size on manual wheelchair propulsion (Guo, Su, & An, 2005). Therapists use this information for structuring occupation and designing exercise programs.

Kinetics addresses the forces that cause motion or maintain stability (Hall & Brody, 2005). These forces may be internal to the body, such as muscle contraction or the elasticity of structural and connective tissue, which enable us to engage in our daily occupations. Forces of movement or stability may also be external to an individual, such as wind that moves a sailboat, the friction of grass slowing down a golf ball, the friction of the carpet against a moving wheelchair, or the weight of a spoon, which may limit self-feeding in an individual with muscle weakness. Gravity is perhaps the greatest external force, unnoticeable and constant to most of us, that affects all human movement. It is the gravitational pull on the body, body segments, and other objects that gives them weight and is often the biggest challenge to the patients we treat (Baechle & Earle, 2000). Therapists must be aware of these various forces when developing treatment plans using therapeutic occupations and/or exercise programs.

The following is an example of forces, stability, and motion in occupation. While dining, a person grasps a glass

RESEARCH NOTE 21-1

Abstract: Vuillemin, A., Boini, S., Bertrais, S., Tessier, S., Oppert, J., Hercberg, S., Fuillemin, F., & Briançon, S. (2005). Leisure time physical activity and health-related quality of life. *Preventive Medicine, 41*, 562–569.

Abstract

Background: Intensity, frequency, and duration of physical activity may contribute in various ways to health related quality of life.

Methods: The relationship of frequency and vigorosity of leisure time physical activities and health related quality of life was studied in 2333 male participants aged 45 to 60 years of age, and 3221 female participants aged 35 to 60.

Results: Leisure time physical activity (LTPA) was related to all categories of health related quality of life, including physical functioning, bodily pain, mental health, emotional and physical role performance, social functioning, vitality, and general health. LTPA was divided into four categories: Inactive, Irregular (some activity, but not meeting the next category), Moderate activity (more than 150 minutes/week, but less than the next category), Vigorous activity (more than 60 minutes/week, at high energy cost). Individuals whose leisure time physical activity fell into the “vigorous” category had even better scores in health related quality of life. For all participants, meeting the public health recommendations of 30 minutes of vigorous or moderate activity on a regular basis led to better health related quality of life scores on all dimensions, except for bodily pain in women, which was not affected.

Conclusion: Regular leisure time physical activity of 30 minutes per day, even at a moderate level, can significantly improve health related quality of life.

Implications for Practice

A unique expertise of occupational therapy is the design and prescription of purposeful and meaningful activity (occupation) to enhance and promote health. Along these lines, occupational therapists frequently use therapeutic occupation to improve an individual’s ROM, strength, and endurance. This study supports the notion that a variety of daily activities, if performed at moderate or vigorous level, have the potential to improve a client’s health-related quality of life.

Occupational therapists should be aware of the variety of activities available for strengthening, endurance building, fitness, and overall health promotion. They should complete a thorough occupational history to learn which activities in the patient’s background may provide interest and exercise benefits. Through careful activity analysis and monitoring, occupational therapists can frequently use meaningful and purposeful activity to enhance strength and endurance, achieving the additional cognitive, psychosocial, and spiritual gains these activities may be designed to provide.

filled with a beverage and lifts it to take a sip. This task requires both stability and motion. Initially, muscles in the trunk and shoulder girdle (internal forces) co-contract to provide proximal stability, allowing for controlled distal mobility. To raise the glass, muscle contractions of the elbow flexors act as an internal force that overcomes the weight of the forearm and hand and the glass (external forces). The biceps contraction causes rotary motion, or flexion, of the elbow joint. When rotary motion occurs, each point on the bone segment (ulna and radius) moves through an arc at the same time at a constant distance from the axis (elbow joint) (Levangie & Norkin, 2005). The arc formed by that rotary movement is called the ROM of that joint. To cause rotation, the biceps must have enough strength to overcome the external forces created by gravity.

To analyze the movement in this scenario, one must also consider **torque**. Torque is the effectiveness of a force in causing rotary movement (Levangie & Norkin, 2005). In rotary movements, torque depends on (1) the amount of force applied and (2) the distance of the force from the axis of movement. Thus, in mathematical terms, the torque of a force is equal to the amount of force applied times the perpendicular distance between the line of force and the axis of rotation [$T = (F)(D)$] (Levangie & Norkin, 2005; Neumann, 2002). In relation to the example of taking a sip, the torque of the biceps (effort force) is equal to the force the muscle can produce times the perpendicular distance from its insertion on the radius to the axis of motion or elbow joint (Fig. 21-1A). The torque of resistance force (the glass and forearm) is equal to the resistance force (weight of glass and forearm) times the perpendicular distance between the glass and the axis of movement or elbow joint (Fig. 21-1B). In this case, biceps torque is greater than the torque of the forearm and glass, so flexion can occur.

The concept of torque shows that the placement of an object either closer to or farther from the axis of rotation changes the effort needed to make the movement, even though the object’s weight remains constant. Therapists use this concept in a number of situations. For example, a short reacher as opposed to a long one requires less force of the patient’s upper extremity muscles to pick up an object. With a long reacher, the object provides more resistance torque because the distance between the object and the person’s joint (axis of movement) is greater than with the short reacher. Likewise, when assisting a patient to perform a stand-and-pivot transfer from the wheelchair to bed, a therapist stands close to the patient as they both pivot, and the therapist lowers the patient to a sitting position. The patient provides less resistance torque (the weight of the patient times the perpendicular distance between the patient and the therapist’s back) when he or she is close to the therapist. This in turn requires less effort force by the therapist’s back muscles for raising, maintaining the position during the pivot, and lowering the patient to the bedside. This body mechanic principle for protecting stress on one’s back (i.e., holding objects close

Figure 21-1 **A.** Torque of effort force. *a*, Line of pull of effort force (elbow flexors). *b*, Perpendicular distance between the insertion of the elbow flexors and the axis of rotation. **B.** Torque of resistance force. *a*, Line of pull of resistance force (weight of glass and forearm). *b*, Perpendicular distance between the resistance force and the axis of rotation.

to one's center of gravity when lifting or transporting) can be explained by this principle of torque.

In biomechanical terms, rotary movement is analyzed as one of three types of lever systems. A lever system consists of a rigid bar (such as a bone), an axis of rotation (such as a joint), and two forces, effort and resistance. Effort is the force that causes movement, and resistance is the force that tends to keep the object from moving.

A first-class lever is a system in which the effort and resistance forces lie on either side of the axis of rotation (Levangie & Norkin, 2005). A common example of a first-class lever is the seesaw (Fig. 21-2A). As one can see, a seesaw would remain in balance, with no movement, if two children of the same weight sat the same distance from the axis. This balance, or equilibrium, is maintained because the torque (weight of child 1 times the perpendicular distance from child 1 to the axis of rotation) on one side of the seesaw equals the torque (weight of child 2 times the perpendicular distance from child 2 to the axis of rotation) on the opposite side of the seesaw. In essence, they balance, and there is no movement. If one of the children is heavier, he or she must move closer to the axis to maintain that balance (Fig. 21-2B).

In second- and third-class levers, the effort and resistance force lie on the same side of the axis (Baechle & Earle, 2000). A second-class lever system, such as a bottle opener or a wheelbarrow used to carry compost in a garden, is a system in which the resistance force lies closer to the axis of rotation than does the effort force (Fig. 21-3). With a bottle opener, the resistance force is the force of the cap that is tightly connected to the bottle. The effort force is a person's hand lifting the end of the opener to release the cap. This lever system allows a relatively small amount of force to overcome strong resistance. Second-class lever systems explain the tools used frequently in occupations when mechanical advantage is required, such as an extended handle on a faucet.

In third-class lever systems the effort force lies closer to the axis than does the resistance force (Levangie & Norkin, 2005) (Fig. 21-4, top). The example of bringing a glass to

Figure 21-2 **A.** First-class lever system. Balanced equilibrium depicted by children on a seesaw. Both children weigh 60 pounds, and they are equidistant from the axis. **B.** First-class lever system. The heavier child must be closer to the axis of the seesaw to maintain the equilibrium.

Figure 21-3 Top, Schematic drawing of a second-class lever. Bottom, Second-class lever depicted by using a bottle opener to remove the cap from a bottle. *A*, axis; *R*, resistance force (tightly secured cap); *E*, effort force (force from bottle opener to open cap).

one’s mouth represents a third-class lever. The elbow joint is the axis; the biceps is the effort force; and the combined weight of the forearm and glass is the resistance force (Fig. 21-4, bottom). In contrast to the stability of first-class levers and the mechanical advantage of second-class levers, third-class levers produce greater speed and ROM. For this reason, most of the muscles in the human body

Figure 21-4 Top, Schematic drawing of a third-class lever. Bottom, Third-class lever depicted by lifting a filled glass. *A*, axis; *E*, effort force (elbow flexors); *R*, resistance force (weight of glass and forearm).

work in third-class lever systems when they contract concentrically to produce the speed and ROM needed to engage in occupation.

The mechanical aspects of the musculoskeletal system promote both stability and mobility to provide the basis for action in occupation. The potential work capacity of the various muscles of the body also depends on the force they can generate and the distance over which they can shorten. In other words, the resulting work depends not only on biomechanical factors but also on physiological factors.

Physiological Aspects

The contractile portion of skeletal muscle is within the myofibrils of the muscle, where adenosine 5+ triphosphate (ATP) creates **cross-bridges** between the actin and myosin filaments. According to the sliding filament theory, muscle contraction occurs when the ATP cross-bridges are broken, actin is pulled over the myosin, and new cross-bridges are developed (Fig. 21-5) (Levangie & Norkin, 2005; Baechle & Earle, 2000). As this sequence continues, tension is generated, and the muscle shortens (**concentric contraction**). In a lengthening contraction (**eccentric contraction**), the opposite process occurs (Definition 21-1).

Figure 21-5 Schematic of actin and myosin cross-bridges during muscle relaxation and contraction. **A.** Relaxed muscle. **B.** Contracted muscle. (Adapted with permission from Hall, C. M., & Brody, L. T. [1999]. *Functional approach to therapeutic exercise for physiological impairments*. In C. Hall & L. Brody [Eds.], *Therapeutic exercise: Moving toward function* (pp. 45–46). Philadelphia: Lippincott Williams & Wilkins.)

DEFINITION 21-1

Types of Muscle Contractions

Concentric

Muscle shortens to move a limb section in the direction of the muscle pull. In a concentric contraction, the internal force of the muscle overcomes the external resistance.

Eccentric

Contracted muscle lengthens to act as a brake against an external force to allow for a smooth controlled movement.

Isometric

External and internal forces are in equilibrium, and the length of a contracted muscle remains the same.

Example

In Figure 21-6, lowering a filled 10-pound cookie jar from the top of the refrigerator uses an eccentric contraction of the shoulder flexors and, concurrently, of the scapula upward rotators. Returning the cookie jar to the top of the refrigerator before mom finds out you have eaten the cookies requires concentric contractions of the shoulder flexors and, concurrently, the scapula upward rotators. Maintaining a grasp on the cookie jar exemplifies isometric contraction of the shoulder horizontal adductors and the distal upper extremity muscles.

A muscle's strength and endurance depend on multiple factors. Muscle strengthening results in both muscle hypertrophy and the development of more effective neural patterns and neuromotor connections (Hall & Brody, 2005; Kraemer et al., 2002). Muscle size is increased when an activity stresses the muscle's ability to produce tension and force. As the load or duration increases, some motor units fatigue, requiring recruitment of others. The demand for recruitment of motor units ultimately leads to neural adaptation and the growth of the muscle fiber through myofibrillar changes. Those myofibrillar changes include an increase in the number of sarcomeres or myosin and actin filaments. The more actin and myosin filaments available, the more cross-bridges can develop, creating more tension or strength in the muscle. For example, violinists increase finger strength by practicing musical pieces that stress (through vigor or duration) their hand musculature. As a violin player continues, or more challenging fingering is used, actin and myosin filaments are generated to increase strength as needed. In contrast, when muscles are not used, myosin and actin filaments are lost, resulting in weakness.

Neural change, namely increased number of motor units activated and increased synchrony of motor unit activation, also contributes to muscle strength (Elbert et al., 1998; Kisner & Colby, 2002; Kraemer et al., 2002). Individual motor units, which make up muscles, fire according to the

Figure 21-6 Getting a cookie jar down from the top of the refrigerator and putting it back requires eccentric, concentric, and isometric muscle contractions.

all-or-none principle of neural propagation. When all of the required motor units of the hand and finger muscles needed to press a string on the violin fire in synchrony, more tension is generated than when those same motor units fire asynchronously. Remember that, in addition to muscle size and synchrony of motor unit firing, psychological factors, such as motivation to perform an occupation, affect effort exerted, which contributes to muscle strength.

Muscle endurance is the ability of a muscle to sustain or perform repeated contractions over time (American College of Sports Medicine, 2000; Hall & Brody, 2005). Muscle endurance relies on a number of factors, such as the ability of the central and peripheral nervous system to relay messages from the limbic, premotor, and association cortices to the muscles and the ability of the lungs, capillaries, and muscles to transport and uptake oxygen, which is needed for metabolic and enzymatic processes (American College of Sports Medicine, 2000; Hall & Brody, 2005).

In general, improvement in muscle endurance requires availability of more oxygen. When heart rate increases, so does the amount of oxygen the person can take in during a given amount of time and dispense to the muscles (VO_2). The muscles require oxygen to break down ATP into the

Figure 21-7 Fishing is an occupation that requires both muscular strength and muscular endurance.

chemical energy needed for actin and myosin to form cross-bridges and thus create a muscle contraction (American College of Sports Medicine, 2000; Baechle & Earle, 2000). Local muscle fatigue is often related to impaired capillary systems interfering with the transportation of blood (oxygen) to the muscles, insufficient storage of glycogen, and/or a disruption of the metabolic process that breaks ATP into chemical energy (Hall & Brody, 2005).

Muscle endurance is intricately related to muscle strength. In fact, most occupations that require muscular endurance, such as tennis, also require muscle strength. For example, in Figure 21-7, muscular strength was required to hold up the fish for the picture, but muscular endurance was also required to get the fish into the boat. For many of our clients, endurance and strength are related problems, although some occupations, such as those requiring maintained postural control, require muscle endurance more than muscle strength. (For a more detailed understanding of the cardiac and pulmonary systems, see Chapter 47.)

BIOMECHANICAL APPROACH TO TREATMENT

Based on these biomechanical and physiological principles, occupational therapists can design treatment programs to address ROM, strength, and endurance problems affecting occupation. Ultimately the remediation or prevention of these limitations is aimed at ensuring the individual's occupational functioning.

Maintaining or Preventing Limitation in Range of Motion

ROM assessments provide guidelines for the typical ranges available at various joints in the human body, but an individual's actual ROM at any joint is determined by the physical constitution of the body and the person's typical occupations. For example, a waiter who carries platters of food with one hand throughout the work shift probably has greater wrist extension ROM than most others. Functional ROM is the range necessary to perform daily occupations. Occupational therapists are concerned with preventing ROM limitations that interfere with daily occupations.

Immobilization Reduces Range of Motion

Many ROM limitations can and should be prevented. When a joint remains immobilized, changes in the muscle through loss of muscle fiber, changes in the number and length of sarcomeres, and changes in the connective tissue through disorganized synthesis of new collagen, ligament weakness, and elastic stiffness result in shortening of the muscle itself. These changes, along with disruption of the workings of the synovial fluid, synovial membrane, and articular cartilage, create limitations in ROM (De Deyne, 2001; Hall & Brody, 2005). Tendons and ligaments change biochemically and lose tensile strength in the absence of motion and stress. With immobilization, muscle filaments lose their ability to slide, which is necessary for contraction. Edema and developing viscosity of fluid can increase the circumference of a joint and limit ROM (Hall & Brody, 2005; Kisner & Colby, 2002; Wong, 2002). Prolonged swelling leads to fibrotic changes and adhesions in the edematous tissue that result in **contractures** (Wong, 2002). Changes begin at as early as 24 hours of immobilization. As a result of these underlying changes, a joint maintains only the range through which it is moved on a regular basis.

Patients who cannot move their own joints and for whom motion is not contraindicated need passive ROM exercises and proper positioning to maintain their available ROM. For example, when a patient is in a coma or unable to move because of paralysis, ROM should be maintained to enable a return to occupations when recovery occurs. Also, when an agonist muscle is significantly weaker than its antagonist, the uneven tension between the two muscles may create a contracture. Furthermore, maintaining ROM can prevent discomfort, skin breakdown, hygiene problems, and difficulty in caring for the person. Occupational therapists are ultimately concerned with limitations in ROM that affect a client's ability to perform occupations.

Methods

The methods occupational therapists use to prevent limitations in ROM include compression, positioning, and movement through full ROM.

Compression

Compression is used to prevent ROM limitations secondary to edema. Edema can be controlled by compression with elastic strip or tubular bandages. The occupational therapist must take care to apply these correctly so they do not constrict circulation in the more distal part of the extremity. *Skin color is observed regularly to confirm that circulation is preserved.* Coban (3M, St. Paul, MN), a self-adhesive elastic bandage, is wrapped around the part spirally in a distal to proximal direction, and the edges are overlapped by at least 25% of the width of the material so that the fluid can flow evenly back toward the body and not be trapped in pockets of unwrapped tissue (Lowell et al., 2003; Salter & Cheshire, 2000). Tubigrip (Mark One Health Care Products, Philadelphia, PA) is a tubular elastic support bandage that provides graduated constant pressure support when the correct size is applied. Compression is most effective in eliminating edema when combined with positioning and passive or active movement of the limb.

Positioning

When a person's limb is too weak to resist gravity, positioning in a resting or functional position is essential to avoid development of deformities, minimize edema, and maintain ROM gained in treatment. Positions of function are encouraged, and all non-functional positions are avoided throughout the day and night. In particular, positions that are opposite of normal patterns of tightness should be encouraged for at least periods of the day. For example, patients often develop tightness in the shoulder internal rotators after stroke. So, positioning the patient with the arm in at least neutral rotation will help prevent that tightness from developing. In addition, elevating a patient's edematous hand by use of a pillow assists the fluid to drain back to the body.

In spite of prevention, sometimes contractures and consequent **ankylosis** are unavoidable because of the disease process. In these instances, positioning, splinting, and bracing are used to ensure that ankylosis occurs in as nearly a functional position as possible. A functional fixed position is one that allows the person to manage self-care and other functional tasks. For example, the functional position of the hand and wrist is slight (10–30°) extension of the wrist, opposition and abduction of the thumb, and semi-flexion of the finger joints. If a patient's hand contracts in that position, the person can still use it to hold objects. If, however, the hand contracts in a fully flexed position, it not only is non-functional but also presents a hygiene problem. Likewise, a hand that fuses in an extension contracture has no holding capacity. When positioning a patient, the occupational therapist must be vigilant in anticipating eventual outcomes of prolonged immobilization that may compromise occupational performance.

Movement through Full Range of Motion

The methods used for movement through full ROM, referred to as ranging, are (1) teaching the patient to move the joints that are injured, immobilized, or edematous and (2) passively moving the joints if the patient cannot. The ranging technique for active ROM (AROM) and passive ROM (PROM) are similar. Twice daily each involved joint is slowly and gently moved three times from one limit of motion to the other. In AROM, the patient actively performs the desired motion. In PROM, the therapist gently moves the patient's limb through the desired motion, paying particular attention to planes of motion and joint biomechanics. For example, the therapist pays special attention to the scapulohumeral rhythm when ranging the shoulder girdle. By moving the scapula with one hand and the humerus with the other, the therapist ensures that they are moving in synchrony (Fig. 21-8). Attention to this alignment during movement of the scapula and humerus eliminates injury to the glenohumeral joint, bursae, capsule, and ligaments. As previously mentioned, the joint maintains only the range through which it is moved and, therefore, the

Figure 21-8 Facilitation of glenohumeral rhythm during passive ROM.

therapist or patient must move a limb through the full available range or it will not be maintained. **Exception: A person who has tetraplegia and will rely on tenodesis action for grasp (see Chapter 43) must be ranged in the following manner to allow finger flexor tendons to develop necessary tightness for grasping. When flexing the fingers, the wrist must be fully extended, and when extending the fingers, the wrist must be fully flexed.**

PROM can also be performed by external devices, such as continuous passive motion (CPM) machines. CPM machines are commercial orthoses used to maintain ROM and prevent postoperative swelling by continually moving the joint from one limit of motion to the other (Griggs, Ahn, & Greene, 2002; Salter & Cheshire, 2000). See O'Driscoll and Giori (2000); Michlovitz, Harris, and Watkins (2004); and LaStayo et al. (1998) for additional information on the use of CPM with the upper extremities.

AROM is preferred to PROM for reduction of edema because the contraction of the muscles helps pump the fluid out of the extremity. If AROM is not possible, however, PROM can aid in reducing edema. Positioning of the edematous extremity above the heart during distal PROM is recommended to aid in venous return.

Occupational therapists often structure activities to provide AROM to prevent limitations in ROM. For example, the patient may use his or her hemiplegic upper extremity in weight bearing for balance and postural stability while having to maintain the ROM in wrist and finger extension. Another example is the *ROM Dance Program* devised by Harlowe and Yu, which is a 7-minute movement program modeled after Tai Chi Chuan that incorporates joint motion in all ranges while the dancer listens to a poem that is meant to evoke pleasurable images. Although the ROM dance was developed for people with rheumatoid arthritis, it has been used with other populations, including the well elderly (Mandel et al., 1999).

Increasing Range of Motion

If limitations in ROM impair a patient's ability to function independently in occupations or are likely to lead to deformity, treatment to increase ROM is indicated. Whereas some significant limitations of ROM can be ameliorated or corrected by occupation and exercise, some cannot. Problems that can be changed include contractures of soft tissue, such as skin, muscles, tendons, and ligaments. Problems that cannot be changed through these means include bony ankylosis or arthrodesis, longstanding contractures in which there are extensive fibrotic changes in soft tissue, and severe joint destruction.

Occupational therapists may treat ROM limitations, using the principle of stretch, to help a patient develop the capacities needed to perform occupations. If ROM limitations cannot be reduced, occupational therapy

becomes compensatory, focusing on providing techniques and/or equipment to enable participation in life occupations.

Stretching

Stretch is a process by which tissue is lengthened by an external force, usually to eliminate tightness that has the potential to cause a contracture. Stretch produces change only if done to the point of maximal stretch, defined as a few degrees beyond the point of discomfort, and held there for between 15 and 30 seconds (Bandy & Sanders, 2001). The force, speed, direction, and extent of stretch must be controlled (Kisner & Colby, 2002; Salter & Cheshire, 2000). The force must be enough to put tension on the tissue but not enough to rupture it. Different tissues tolerate stretch differently; tight muscles can be stretched more vigorously than tight joints (Kottke, 1990). The speed should be slow to allow the tissue to adjust gradually. The direction of stretch is exactly opposite to the tightness. The stretch is applied to the point of maximal stretch.

Gentle stretching that achieves small increments of gain over time is more effective than vigorous stretching aimed at large, rapid gains. As a protective mechanism, connective tissue resists quick, vigorous stretching, which is therefore ineffective or injurious (Kisner & Colby, 2002; Kottke, 1990; Salter & Cheshire, 2000). The method of moving gently to the point of maximal stretch and holding that position allows connective tissue, which has plasticity, to adapt to new requirements and adjust its length gradually over time. **Residual pain after stretching indicates that the stretch was too forceful and caused tearing of soft tissues or blood vessels.** It is clinically recognized that maintained stretching is most effective; however, gains are also noted using a briefly held stretch, usually 15–30 seconds (Bandy, 2001; Kisner & Colby, 2002). A study of healthy subjects found that 30 seconds of passive stretch was as effective as 120 seconds (Ford, Mazzone, & Taylor, 2005).

Methods

There are two types of stretching, active and passive. In active stretching, the muscle contraction is the source of the force, and in passive stretching, an external force is applied.

Active Stretching

An occupational therapist's expertise lies in using occupations for treatment, in this case as a means of reaching the goal of increasing ROM. The use of occupation for stretching is empirically based on the idea that a person involved in an interesting and purposeful activity will gain greater range because he or she is relaxed, is not anticipating pain, is motivated to complete the task, and therefore is likely to move as the activity demands.

The therapist and patient choose a life occupation that has significance to the patient. Occupations can be performed using a number of muscle patterns, thus, the therapist must determine how the patient completed the activity prior to injury. If the activity, as naturally performed by the patient, requires stretching the soft tissues that are shortened, it can be used as a form of active stretching. Occupations used as a means to increase ROM must provide a gentle active stretch by use of slow, repetitive isotonic contractions of the muscle opposite the contracture or by use of a prolonged passive stretched position of the contracted tissue. In both types of stretch, the requirement is that the range be increased slightly beyond the limitations. If the contracture existed before the limb was immobilized, active stretch is not likely to be effective; that is, if the patient was free to move and did not during daily activities, it is unlikely that gains will be made using activity to correct the contracture. People move in individually characteristic ways and frequently compensate by using available range in adjacent joints, so the therapist must carefully monitor the patient's motions. The therapist cannot assume that the activity itself will evoke the desired response in all persons. Reasonable adaptations of the occupation may sometimes be used to elicit the desired motions. Examples of adaptations are adjusting the size of a handle to stretch finger flexors or extensors or placing an object on a higher shelf to increase the amount of shoulder ROM during daily activities (Fig. 21-9). See Evidence Table 21-1 for support for occupationally based range of motion exercises.

Exercises that increase the range of shortened tissue are the proprioceptive neuromuscular facilitation (PNF) techniques called contract-relax (CR) and agonist contraction (AC) (Bonnar, Deivert, & Gould, 2004; Feland, Myrer, & Merrill, 2001) (Chapter 26). CR involves a maximal isometric contraction of the tight muscle, usually performed at the point of limitation. The muscle is contracted maximally for approximately 3–10 seconds against resistance provided by the therapist and then relaxed. During the relaxation phase, the therapist moves the part in the direction opposite to the contraction and holds it. For example, if there is a contracture of elbow flexors, the elbow is extended to its limit. The patient is instructed to contract the flexors isometrically and maximally and then relax, at which moment the therapist smoothly extends the elbow into greater range. The CR is repeated until as many increments of gain as possible are achieved.

Therapists have typically used a variety of stretching techniques, including those described here. Based on a review of studies spanning 20 years, Hall and Brody (2005) concluded that no one technique has been demonstrated to have greater benefit over any other.

Passive Stretching

Although passive stretching is often done by a physical therapist, occupational therapists may have to perform

Figure 21-9 Placing an object on a higher shelf can help incorporate greater active range of motion into the daily activity of cooking.

passive stretching prior to engagement in occupation. Techniques for passive stretching may include manual stretch and the use of orthotic devices, such as splints or casts, to provide controlled passive stretching (see Chapter 16). The procedures for manual stretching by the therapist are outlined in Procedures for Practice 21-1. Safety Note 21-1 lists precautions.

Some patients can perform passive stretching of soft tissue contractures themselves. Activities such as the ROM dance, which includes some passive stretching, can be integrated into their daily occupations. Occupational therapists can modify the ROM dance to provide the necessary active and passive stretches to meet the patient's needs. Therapists must remember that with any method to increase rather than maintain ROM, the patient's limb must move to the point of maximal stretch.

Strengthening

If limitations in a patient's strength prevent participation in occupations or may lead to a deformity, treatment aimed at increasing strength is warranted. Weakness can be deforming if the muscles on one side of a joint are significantly weaker than their antagonists, as in a patient

PROCEDURES FOR PRACTICE 21-1

Manual Stretching Methods

- Provide a relaxing environment for the patient.
- Describe manual stretching, noting that it involves tolerable pain.
- Use motions identical to motions used in ROM evaluation (see Chapter 5).
- Stabilize the bone proximal and distal to the joint that is to be moved to avoid any compensatory movement.
- Move the bone smoothly, slowly, and gently to the point of maximal stretch (mild discomfort indicated verbally or facially by the patient).
- Make sure the movement is in the line of pull of the muscle.
- Encourage the patient to assist in moving the limb if possible.
- Hold the limb at the point of maximal stretch for 15–30 seconds (Kisner & Colby, 2002).
- Relief of discomfort should immediately follow the release of stretch.
- If the patient complains of residual pain, future stretches should be performed more slowly and with less force.

after a stroke, in whom there is activation of the biceps (elbow flexor) but no activation of elbow extensors. These patients often develop an elbow flexion contracture if stretching is not done. If the weakness prohibits the person from moving the limb or maintaining a functional position, the lack of regular active range of motion will lead to contracture.

Muscle strength increases when the muscle is stressed to the extent that additional motor units are recruited through increased efficiency of the neuromotor system, and the muscle hypertrophies (Hall & Brody, 2005; Kraemer et al., 2002). For muscles to hypertrophy and strengthen they must be stressed to the point of fatigue. Occupation or exercise **parameters** that may be manipulated to increase stress to a muscle include type of contraction, intensity or load, duration of contraction, rate or velocity of contraction, and the frequency of exercise. It is important to realize that strengthening is a very specific process, that muscle will only gain strength within the range of motion that is exercised, and that the speed of contraction is quite specific. Therefore, if there are specific activities that the strengthening is being designed to address, the types of contractions, ranges of motion, and speed of contraction of the strengthening program should be similar to the performance environment. If the patient needs general strengthening, then

SAFETY NOTE 21-1

Safety Precautions Related to Passive Stretching

- Inflammation weakens the structure of collagen tissues; therefore, those tissues must be stretched cautiously with slow, gentle motion (Kottke, 1990).
- Sensory loss prevents the patient from monitoring pain; thus, the therapist must pay particular attention to the tension of the tissues being stretched.
- Overstretching must be avoided because it causes internal bleeding and subsequent scar formation that may eventually ossify. Overstretching can lead to **heterotopic ossification**.
- Resistance can be provided by weights either held in patient's hand or strapped around the moving part. Resistance can also be provided by tools and materials of activity. The greater the resistance that is provided, the more aggressive the stretch will be, so the therapist must take care that the stretch is slow and gentle.

the types of contractions, ranges of motion, and strength of contraction should be varied (Hall & Brody, 2005; Kraemer et al., 2002).

Methods

Occupations and Exercise

Occupations, exercise, or both can be used to increase strength. Therapists may find that various occupations provide sufficient opportunities for muscle strengthening and are more effective at maintaining the patient's interest and motivation than exercise alone. At other times, therapists may develop an exercise program specifically targeted to strengthen certain muscles needed for occupation. This exercise may also be combined with occupation in a number of ways. Exercise may be used as a warm-up to occupation, or occupation may be introduced to enhance carryover of the strength gained by exercise. Carefully prescribed therapeutic occupations can strengthen muscles in situations closely approximating their intended uses.

For some individuals, an exercise program may be a valued occupation in and of itself. In these cases, exercise can be used as a therapeutic occupation designed to address the individual nature of the performance, the meaning of exercise for that person, and the context in which that person typically exercises. In this instance, the occupational therapist may use the therapeutic occupation of exercise to remediate any performance component. For example, weightlifting can be used with a patient who has a brain injury not only to increase strength but also to enhance attention, memory, and organizational skills (see Chapters 29 and 39).

Grading Muscle Strength Parameters

When prescribing a strengthening program, therapists can manipulate the exercise or occupational parameters. DeLorme (1945) and DeLorme and Watkins (1948) developed exercise programs based on principles of resistance and repetition to increase muscle strength. DeLorme's classic method, progressive resistive exercise, continues to be used today in a modified form. Progressive resistive exercise is a program in which a person lifts 50%, then 75%, and finally 100% of his or her 10-repetition maximum (RM) (Baechle & Earle, 2000). Ten RM is the maximum weight a person can lift with coordination through full ROM 10 times. Each exercise set (50%, 75%, and 100%) is done 10 times, with a rest break between sets. For example, if a client's 10-RM was 10 pounds, the client would repeat 10 repetitions with 5 pounds, 10 repetitions with 7.5 pounds, and 10 repetitions with 10 pounds. Procedures for Practice 21-3 has guidelines for setting up a therapeutic exercise or occupation program. Although these guidelines are for exercise programs, the principles can be used in designing a routine of occupations to be used for strengthening.

More recently, a simplified strengthening protocol has been identified (Rhea et al., 2003.) In this protocol, the patient's 1-repetition maximum (1-RM) is established by determining the maximum weight a warmed-up muscle can move smoothly through the range of motion one time, but not two times. The amount of resistance provided during strengthening is determined by the patient's strength training history. For patients who are untrained or who have not lifted weights consistently in the past year, 60% of 1-RM is moved through the full ROM 10 times, followed by a rest break. For individuals who are considered trained or who have been doing strength training consistently for more than 1 year, 80% of the 1-RM is moved through the full ROM 10 times, followed by a rest break. Four sets of the 10 repetitions are completed for each muscle's strengthening program, regardless of whether the patient is trained or untrained. This strengthening program should be repeated three times a week for untrained individuals and two times a week for trained individuals. The advantage of this simplified strengthening protocol is that there is less changing of weights required and it can be more easily integrated into occupation.

The use of elastic bands for strengthening exercise provides an inexpensive method of strengthening and is often used when patients will be doing strengthening on their own, as in a home program or in community-based programs, where resources are often limited (Gill et al., 2003; Rogers et al., 2002). The elastic bands are color coded for different levels of resistance and have been shown to be an effective method of providing isotonic strengthening (McCann et al., 1993). The elastic bands are cut to length and tied into a loop. The loop is stabilized on one end by one limb of the client, or it can be attached to a stable object in the environment. The occupational therapist designs the exercises so that the joint moves through the full

range of motion against the resistance provided by the elastic band. The client is asked to move the joint through the full range of motion against the resistance of the loop. In Figure 21-10, the subject is strengthening her right triceps by holding the loop against her chest with her left hand, while her right arm goes through full elbow extension. In addition, in this case, a small piece of plastic pipe has been added to the loop to provide a handle for the client to use.

The type of contraction—concentric, eccentric, or isometric—is established by the demands of the task and assistance provided by the therapist (see Definition 21-1). Isometric contraction of a muscle at resting length can produce the most forceful contraction. *When the patient has hypertension or cardiovascular problems, however, isometric contraction should be avoided because isometric contraction of either large or small muscles increases blood pressure and heart rate (Kisner & Colby, 2002; Hall & Brody, 2005) (see Chapter 47).* More weight can be lowered by a given muscle during an eccentric contraction than can be lifted concentrically or held at any one point. A corollary is that less effort is exerted when lowering a given weight than when lifting it. Regardless, the type of contraction should mirror what is required by the patient's occupations because transfer of ef-

Figure 21-10 The patient is strengthening her triceps by moving her arm from elbow flexion to elbow extension against the resistance of the elastic band.

PROCEDURES FOR PRACTICE 21-3

Guidelines for a Strengthening Program

Type of Exercise	Definition	Muscle Grades	Procedures
Isometric	Exercise in which a weak muscle is isometrically contracted to its maximal force 10 times with rest periods between each contraction	Trace (0) The force of contraction is not sufficient to move the part.	<p>Provide a stimulating environment.</p> <p>Explain procedures.</p> <p>Instruct the patient to contract the weak muscle (“hold”). External resistance applied by the therapist may help the patient isolate the contraction to the weak muscle or muscle group.</p> <p>Patient holds contraction at maximum effort as long as possible while breathing normally.</p> <p>Repeat 10 times with a rest between each contraction.</p> <p>Increase duration of maximal contraction as patient improves.</p> <p><i>Maximal isometric contraction is contraindicated for patients with cardiac disease.</i></p>
Isotonic Assistive (Active Assistive ROM)	Exercise in which a weak muscle is concentrically or eccentrically contracted through as much ROM as patient can achieve; therapist and/or external device provides assistance to complete motion	Poor minus (2–) Fair minus (3–) The muscle can move only through partial available range in either a gravity-eliminated or against-gravity plane.	<p>Provide a stimulating environment.</p> <p>Explain procedures.</p> <p>For a 2– muscle, position limb to move in a gravity-eliminated plane.</p> <p>For a 3– muscle, position the limb to move against gravity.</p> <p>Patient moves weak muscle through as much range as possible.</p> <p>Therapist provides external force to complete motion.</p> <p>Although this seems similar to PROM, it differs because patient actively attempts to contract weak muscle.</p>
Isotonic Active (Active ROM)	Patient contracts muscle to move part through full ROM. ^a Resistance can be provided by weights either held in the patient's hand or strapped around the moving part. Resistance can also be provided by tools and materials of activity.

fects of training is unlikely between isometric and isotonic training programs (Hall & Brody, 2005; Kraemer et al., 2002). Occupational therapists commonly use occupation to build strength.

In the context of strengthening, the intensity of occupation or exercise refers to the amount of resistance offered and includes gravity. The intensity or resistance should be increased over time for strengthening. For example, Ms. C. (see Case Example 1), who has poor musculature but needs upper extremity strengthening to accomplish her daily tasks, can begin by washing her face side-lying in bed (reduced effect of gravity) until she can complete the task upright. Ms. C.'s occupational therapist can set up the task to be accomplished in bed and assist Ms. C. to bring her hand to her face so that she washes with her muscles in a gravity-eliminated plane. Ms. C. may

next attempt to wash her face sitting upright in a chair in the bathroom, moving the extremity against the resistance of gravity. The therapist can further increase the intensity by adding various weighted tools, such as a light puff, a washcloth, and a washcloth and bar of soap. The therapist can continue to increase the intensity through more resistive occupations, such as dressing, making a bed, washing a car, gardening, or playing basketball, to increase strength gradually.

In this situation, resistance is graded by adding a load to the extremity (i.e., tools such as a washcloth, different textured clothing, or the resistance of dirt on a car) or by changing the plane of movement (i.e., gravity eliminated to against gravity). The duration of occupation can also be graded by increasing the need for muscle contraction through time spent in activity. A patient who is very weak

Occupational Therapy Assessment Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

Ms. C. is a 40-year-old woman who was the executive administrator of a large computer company. She lives at home with her partner and her high school-aged son from a previous marriage. Her partner is a lawyer in a small law firm that requires at least 10- to 12-hour work days. Ms. C. is a high-powered, motivated woman who not only enjoyed but was energized by the various people with whom she interacted at her job and the diverse assignments she supervised. When Ms. C. returned home from work, she often used household occupations as a means of changing from her high-energy level to a more relaxed state. Ms. C. shared household tasks equally with her partner and also her son. Relationships are essential in her life.

Ms. C. began to complain of tingling in her legs about 3 weeks ago. This progressed to her trunk and then to weakness in her legs and arms about 2 weeks ago. She was admitted to the hospital at that point and was then diagnosed with **Guillain-Barré**. She was in intensive care for about 10 days and has now been admitted to the rehab unit. At this point, she is extremely weak and has poor endurance. She is unable to lift her arms against gravity and has been up in a reclining wheelchair for about 30 minutes before she needs to go back to bed. Following an occupational therapy evaluation that included this history, the following problems were identified by Ms. C. and the therapist: (1) loss of independence in all occupations including all self-care activities and use of the phone and computer; (2) weakness throughout her arms, trunk, and legs, with manual muscle testing scores of 2–3, but very limited endurance, so that she is able to do only 3–4 repetitions of a motion before she is fatigued; (3) depression and anxiety due to an unpredictable future; and (4) inability to communicate with her employees, employer, and her son, which is causing considerable anxiety.

Appreciate the context

See Chapter 3, 4, 5, 10, and 11 for description of the assessment process and patient's background.

Develop intervention hypotheses

"I think if Ms. C. reestablished some of her more important activities, such as being able to communicate with work, she would feel that she was making progress. In addition, with her endurance and strength both so low, repetition of any movements would help to increase them both."

Select an intervention approach

“Ms. C. would benefit from remediation to increase strength and endurance in her extremities, which would allow her to regain independence in her occupations. However, I also think she would benefit from compensation through the use of adapted equipment to help her resume some important activities.”

Reflect on therapist’s competence

“Ms. C. is really having difficulty being separated from work. I think that if she could communicate with her workplace, she would feel that she was back in some control. In addition, it is difficult for her to see her son because he can only come after school, and at that point, she is usually exhausted. But if she could have some other means to communicate with both work and her son, she might begin to see that she is making progress. I will need to see if she is willing to use adaptive equipment as a bridge to independence; some patients don’t tolerate ‘gadgets,’ so I will have to check that out.”

Recommendations

The occupational therapist recommended three treatment sessions each day for 4–6 weeks. Ms. C. and the therapist established the following long-term treatment goals: (1) Ms. C. will carry out her hygiene, self-care, dressing, and showering independently, which would prepare her for being at home during the day; (2) Ms. C. will prepare a light meal for lunch, which will also ready her for discharge; (3) Ms. C. will learn skills and develop strategies to be able to work from home when she is discharged, for at least a few hours a day; (4) Ms. C. will be independent in a home exercise program for strengthening and endurance; and (5) Ms. C. will resume an active role as the mother of her son.

Consider the patient’s appraisal of performance

“I think that Ms. C. is so overwhelmed with what has happened that she really isn’t aware. It is such a change from her previous life of being in charge of everything. I think that we will need to start with things that are very important to her and that she can succeed at. Since work and her son are so important, I think that, if we used an overhead sling, she might be able to operate both a speakerphone and email and that would allow her to be involved. My one concern is that she might overdo it, so we will have to talk about that. I will need to maintain her passive range of motion, particularly in those antigravity positions that she cannot move into. Daily PROM will be necessary until she gains enough strength to move herself. In addition, care will need to be taken to ensure that she is not developing imbalances of muscle strength around joints that would lead to contractures. Once she has had some success, we can begin to do other activities such as strengthening activities and self-care.”

Consider what will occur in therapy, how often, and for how long

Ascertain the patient’s endorsement of plan

Summary of Short-Term Goals and Progress

- Ms. C. will start assisting with hygiene and grooming activities and then advance to independence in daily self-care.
Ms. C. was fitted with overhead slings, so that she could move her arms without lifting them against gravity. With that equipment, Ms. C. was able to wash her face and brush her teeth and was able to drive a power wheelchair, which greatly improved her independence.

Assess the patient’s comprehension

“Ms. C. seems to understand that any activities she does with her arms will help with strengthening and endurance and is motivated to do more. Now that she can access her email and use the phone and feed herself, she is beginning to think about what she needs to do to be home alone for periods of time after discharge.”

2. Ms. C. will access a speakerphone and email to make working from home possible.
With the overhead slings, she was able to operate both a speakerphone and her laptop computer in her room. She was able to work for about 25 minutes before she fatigued.
3. Ms. C. will feed herself and get food in and out of the refrigerator.
Ms. C. was able to feed herself with a set up using the overhead slings and progressed to feeding herself without equipment. Using the power wheelchair, she was able to get items out of the refrigerator.
4. Ms. C. will develop ways to communicate with her son more frequently.
She was able to access her email account and sent an email to her son. She also was able to call him on his cell phone over the noon hour, and he was really excited to talk to her when she was alert and awake.
5. Ms. C. will begin an upper extremity strengthening and endurance program.
As she gained endurance, she was able to begin doing resistive exercises to some muscles, as well as assume some responsibility for stretching. She will have to be independent in some parts of the program when she goes home.
The therapist and Ms. C. discussed that it was important that she not overdo it, and she seemed to understand that. Her endurance for activity increased considerably over the first week, as she had the opportunity to do things that were important to her on her own schedule.

Understand what the patient is doing
Compare actual to expected performance
Know the person
Appreciate the context

“Ms. C. is accepting of the use of adaptive equipment as a bridge to independence, so that opens up a lot of opportunities. She is doing better than I expected, and she is tolerating all the activity well.”

“We will continue to advance her to more complex activities, such as meal preparation, and more work-related tasks, such as handling files, organizing a work station, etc.”

“I need to check with her partner and her son to see how things are going at home. If the partner is working 10–12 hours a day and her son is home alone, we may need to come up with a new plan.”

Next Steps

We are also going to need to assess the accessibility of her home, since she will probably be using her wheelchair most of the time at home, particularly when she is alone.

At some point in the next several weeks, we will remove the overhead slings, progress her to a manual wheelchair, and then begin doing more activities in standing, as she can tolerate. This may be frustrating for her because occupations she is currently doing will become more difficult, so I’ll have to be careful of that. We will need to plan out a typical day and make sure that Ms. C. can do all the things she will need to do at home.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Ms. C. is making very good progress and will be able to leave the hospital in several more weeks. Since her partner works and they don’t have any family nearby, Ms. C. will need to be home alone for periods of time after discharge. I’m not sure Ms. C. is anticipating how isolating that can be. Although she will probably be walking short distances at that time, she will likely spend most of her time in her wheelchair. I will need to be sure that she has an emergency plan, can operate a cell phone that she has with her, and has anticipated as much as possible what things she needs to be able to do. Home care may be a very feasible option for Ms. C. for a while, and then she can consider outpatient therapy when she is no longer homebound. Transportation to and from rehab will be a challenge. She will also need to check with her doctor about when he might allow her to drive.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of Endurance and Strength on Performing Occupations

The therapist developed an exercise program to assist Ms. C. in building the strength and endurance needed to carry out her daily occupations. How would the strengthening program differ from the program to build endurance? How could Ms. C. use occupation to build strength? How could Ms. C. use occupation to increase her endurance?

may not even be able to finish washing his or her face in bed. The therapist can manipulate the rest breaks during the activity or complete a portion of the activity to increase the duration of the patient's participation. In this example, the treatment goal may be for the patient to take an entire bath or complete other occupations that take longer.

The rate or velocity of contraction, described as the number of repetitions per period of time, must be gradually increased according to the patient's abilities and comfort. As specified in the literature, the velocity of muscle contraction in training should eventually match the velocity of muscle contraction that is required in the patient's occupational routine (Kraemer et al., 2002). Finally, the frequency of exercise periods can also be graded for added strength benefit.

Increasing Endurance

Exercise programs designed to increase muscle endurance rather than muscle strength require somewhat different design. The following describes the underlying principles and guidelines for those modifications.

Less Than Maximal Resistance Over Time

In ordinary daily occupations that are lightly resistive, motor units are activated asynchronously. After a motor unit ceases activity, the muscle fibers recover to some degree while fellow units take their turn. Fatigue occurs more slowly with light resistive movements than with maximal contraction, in which many more units must contract simultaneously without the opportunity to recover. Doing repetitive concentric or eccentric contractions against less than maximal resistance increases endurance through less glycogen depletion and improved oxidative capacity of muscle fibers. Exercise to increase muscle endurance therefore uses moderately fatiguing activity for increasingly longer periods with intervals of rest to allow metabolic recovery (Kisner & Colby, 2002; Kraemer et al., 2002).

Methods

Grading Occupations to Increase Endurance

One of the most dramatic examples of adaptability of the muscular system is the extent to which muscle endurance can be improved by engaging in mild activity with increased numbers of repetition. To increase endurance, therapists guide patients to engage in longer periods of occupation at 40–60% of their repetition maximum (RM) (Kisner & Colby, 2002; Kraemer et al., 2002). Occupation or exercise used to build muscular endurance is graded by increasing the exercise period, which is done either by raising the number of repetitions of a contraction or by lengthening the time an isometric contraction is held. The

occupational therapist can also increase the frequency of engaging in occupation or exercise if patients are not ready to increase duration times.

Occupational therapists provide the patients with interest-sustaining occupations that can be graded along the dimension of time or repetition. For example, patients who are interested in board games, such as backgammon or chess, may increase the number of games they play or the length of time they play. Occupational therapists can also work with patients to schedule their everyday routines so that they gradually increase the amount of time they engage in occupations throughout the day and/or gradually increase the duration of engagement in one particular occupation. For example, in Figure 21-11, increasing the time working in the garden or the amount of muscular effort put forth (picking tomatoes vs. pulling weeds) is an effective way to increase muscular endurance. Remember, to increase muscle endurance, the therapist must increase the number of repetitions of a specific motion. Programming for cardiovascular endurance specifically with patients who have cardiopulmonary problems is discussed in Chapter 47.

Figure 21-11 Muscular endurance can be increased by adding to the time spent on a task or adding to the resistance of the activity. In gardening, picking tomatoes could advance to weeding the garden.

Occupational Therapy Assessment Process

Patient Information

Mr. G., a 46-year-old man with a landscaping career, sustained a back injury when he tripped over his 2-year-old son's play lawnmower, lost his balance, and fell on the grass. Initially he had pain in his lower back and a sharp tingling sensation down his leg. Medical examination revealed that he had severely sprained his back muscles in the fall and had exacerbated pain because of previous bone spurs on the lumbar spine and a degenerating disc at L5-S1. Mr. G. was prescribed a brief period of bed rest and given medication for pain and muscle relaxation. Following this medical intervention, Mr. G. was referred to outpatient occupational therapy for exercises and instruction in how to perform his daily occupations so that his back pain would be relieved or minimized and further back injury would be prevented.

Mr. G. described two main roles in his life, work (landscaping) and childcare. Mr. G. explained that he and his partner both work outside the home and share the childcare and household responsibilities. Mrs. G. works part time at a travel agency. Although she has a flexible schedule, she usually goes to the office at least two evenings per week, and Mr. G. takes care of their three children, Eliza, aged 4, and Tom and Pat, aged 2.

Mr. G. is performing his self-care occupations with moderate assistance from his wife and with severe discomfort. He requires maximal assistance for all home and childcare occupations. He had not performed any other leisure or work occupations at the time of the evaluation.

Mr. G. is the sole owner of his landscaping business and has five experienced gardeners working for him. The occupations of his job include the following: (1) manage the finances, which requires sitting at a computer for approximately 5 hours, two to three times per month; (2) design landscapes, which requires sitting at a drawing table for 3–4 hours at a time; (3) consult with the client and nursery personnel to design the landscape and buy the plants; these tasks require driving, creativity, communicating, and, at times, bending and lifting heavy pots; and (4) supervise the gardeners, which often entails working with them to plant or lay down cement, stones, birdbaths, and other heavy garden fixtures.

Mr. G.'s evening schedule consists of cooking dinner, changing diapers, bathing the children, dressing them for bed, playing with them, and emotionally supporting them. The children love to play rough-and-tumble with their daddy. Multiple piggy-back and horsey rides are an expected part of playtime. Furthermore, each parent has developed a special bedtime activity. Mrs. G. reads a book and Mr. G. pulls them on a cardboard train around the house and deposits each child in his or her bed.

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist's Internal Dialogue

See chapter 3, 4, 5, and 10 for description of the assessment process and patient's background.

Mr. G.'s therapist conducted an interview and observed him to determine which occupations were particularly significant in Mr. G.'s life, which occupations created pain, and how he performed the occupations.

Develop intervention hypotheses	“Mr. G. has a very physically demanding life; landscaping is hard physical work, and picking up and playing with 3 small children is demanding, too. I wonder how much flexibility he has at work. To decrease his symptoms, he will need to make changes in body mechanics in both his home and work life.”
Select an intervention approach	“Mr. G. will need to learn how to apply body mechanic principles on his own so that he can solve problems as they arise. This will involve compensation by using equipment and adapted movement techniques. I can use situations with his children as teaching tools and make some specific suggestions about his work, but he will need to learn the principles and be able to apply them on his own. I wonder if Mr. G. can make some changes at work to reduce the physical demands. I know that we can work out some changes in handling his children at home, but the work situation may be more difficult.”
Reflect on therapist’s competence	“Mr. G. is like a lot of other patients I’ve worked with, and his success will depend on how well I teach him to adopt the principles of body mechanics. I also don’t know a lot about the landscaping business, and although I assume there is a lot of hard work, I’m not very sure about the specifics. I will need to learn more about landscaping and also about equipment that might be helpful for him to use.”

Recommendations

The occupational therapist recommended two treatment sessions per week for 5 weeks. In collaboration with his wife and the therapist, Mr. G. set the following long-term goals: (1) change or delete certain daily occupations to prevent further injury; (2) learn proper body mechanics during daily occupations to relieve strain on his back; and (3) perform self-care, home, childcare, and landscaping occupations independently without pain.

Consider the patient’s appraisal of performance	“I think that Mr. G. knows that he needs to make changes to get better. He seems very motivated to make changes, and his wife is very supportive of those changes.”
Consider what will occur in therapy, how often, and for how long	“Mr. G. and I, and his wife if she can come to the sessions, will spend each session reviewing the principles of body mechanics and why they work and then apply them to a variety of daily activities. At the end of each session, I will give him homework to do before he comes back to the next session so he can evaluate how it is working and we can continue problem solving.”
Ascertain the patient’s endorsement of plan	“Mr. G. seems optimistic about the plan and so does his wife. I think they are both willing to make the changes that are going to be needed to make this work.”

Summary of Short-Term Goals and Progress

Mr. G. will explore his options for avoiding some of the physically stressful occupations at his landscaping business and will enact a reasonable plan. The therapist and Mr. G. discussed various scenarios about his business. The most feasible option was to increase the responsibilities of two of the gardeners and give them a pay raise so that he would no longer purchase or carry heavy plants or help with planting. By eliminating these tasks and using proper body mechanics for the other tasks, Mr. G. can maintain his landscaping business.

Mr. G. will pick up his children, incorporating good body mechanics 75% of the time. Initially, Mr. G. stopped his childcare and household responsibilities. The therapist taught Mr. G. the principles of body mechanics, such as holding objects close to the body when lifting, keeping the back straight and using the leg muscles to lift, and avoiding simultaneous bending and twisting when moving items from one place to another. Mr. G. practiced and was successful with these techniques with various items around the house. He applied these principles to lifting his children, paying close attention to facing his child, being close to his child, and lifting with his legs. Although this technique worked, Mr. G. also taught his children to climb up on his lap, where he could position them well and use his leg muscles to stand up.

Assess the patient's comprehension

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Mr. G. has been very good at following through on his homework. He is learning the principles of body mechanics very well and has been creative about coming up with solutions to avoid problematic movements. Mr. G. seems to be pleased and relieved that he is able to care for his children and run his business with decreased pain and that he is in control of the situation. Being able to resume his work and taking care of his children are the most important things for Mr. G.”

Next Steps

Mr. G. will analyze his body movements and change them to reflect good body mechanics during cooking, diapering, and playing with the children.

Mr. G. will perform his computer work and landscape designing independently, incorporating proper body mechanics, pacing, energy conservation, and joint protection.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. G. has been able to anticipate activities that might be problems and avoid them, which is an indication that he's really learning the principles and techniques. Even when he had a flare up of pain last week, he was able to identify the activity that had probably increased his pain, and that seemed to help him manage the situation. I think that one concern might be that he will follow the movement adaptations while his back is flared up but may revert to old habits if they don't cause him pain. We've discussed his desk arrangement in addition to all the activities at work and home, so I think it is time to discharge him. I do want him to know that he should return to therapy if he gets into trouble again or if his activities change and he needs information about equipment or techniques.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Prevention of Back Injuries While Lifting**

While alone at work, Mr. G. had to lift a large, heavy box of office supplies from the floor to his desk. How might a therapist instruct Mr. G. to position the box to lessen the force on his back when lifting the box? Using the concept of torque, how might the therapist justify the positioning of the box?

Evidence Table 21-1 Best Evidence for Occupational Therapy Practice Regarding Strengthening, Stretching, and Endurance Training

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Resistive exercise program for muscle strengthening	Experimental groups received general conditioning, resistance training, and isokinetic exercise program.	52 healthy, inactive elderly persons were randomly assigned to groups (control, n = 10; isokinetic strengthening, n = 12; resistance training, n = 15; and general conditioning, n = 15).	45–55 minutes of exercise 3 times a week for 10 weeks.	Randomized controlled study. 1C1b	Yes. The resistance training group improved the most on the strength tests of the target muscles.	Concentric contractions of the knee extensors: $p < 0.05$, $r = 0.63$.	Malliou et al., 2003
Stretching to increase joint ROM	5 different groups of students received stretch of different lengths of time to the hamstrings.	35 healthy college students randomly assigned to 30-, 60-, 90-, or 120-second stretch treatment groups or a no-treatment control group.	One self-administered stretch daily for the prescribed period, 7 days a week, for 5 weeks.	Randomized controlled study. 1C1b	Yes. All stretching groups improved range; no differences between lengths of stretch.	Increase in knee extension range of motion: $p < 0.005$, $r = 0.24$.	Ford, Mazzone, & Taylor, 2005
Effect of occupationally embedded exercise for bilaterally assisted supination	Participants practiced assisted pronation under two conditions, one that was occupationally embedded and one that was rote.	28 stroke survivors were randomly assigned to 2 groups (mean age, 68.4 years; mean time since stroke, 53.5 days; ratio of left hemiplegia to right hemiplegia, 15:11).	20 trials of the activities in 1 day.	Randomized controlled study. 1C1a	Yes. Participants in the occupationally embedded condition had more bilaterally assisted supination than the control group.	Increased range of motion in bilaterally assisted supination: $p < 0.016$, $r = 0.40$.	Nelson et al., 1996

<p>Efficacy of the ROM Dance Program for adults with rheumatoid arthritis</p>	<p>ROM Dance Program is a 7-minute exercise and relaxation program.</p>	<p>34 adults with rheumatoid arthritis were assigned to the ROM Dance Program or control group.</p>	<p>8-week ROM Dance Program, followed by 1 month of self-administered ROM Dance Program, or control group that was not given any specific instructions for ROM or relaxation.</p>	<p>Randomized controlled study. 1C3a</p>	<p>Yes. ROM Dance Program participants had greater ROM in shoulder flexion, shoulder internal and external rotation, and total upper extremity ROM combined at 4-month follow-up.</p>	<p>Improvement in shoulder flexion, $p = 0.02$, $r = 0.21$; improvement in shoulder internal and external rotation, $p = 0.03$, $r = 0.21$; total upper extremity ROM combined, $p = 0.048$, $r = 0.16$.</p>	<p>Van Deusen & Hartlowe, 1987</p>
<p>Effect of Tai Chi exercise on physical function in inactive older persons</p>	<p>Tai Chi exercise group of 60 minutes.</p>	<p>94 inactive older adults were assigned to a Tai Chi exercise group or wait-list control group.</p>	<p>60 minute exercise sessions twice a week for 6 months.</p>	<p>Randomized controlled study. 1B2b</p>	<p>Yes. Tai Chi group improved in physical functioning.</p>	<p>Improvement in composite score of physical function of SF-20, $p = 0.008$, $r = 0.62$.</p>	<p>Li et al., 2001</p>

SUMMARY REVIEW QUESTIONS

1. What are the physiological aspects of muscle contraction?
2. Give an example of a third-class lever system in the body. What is the force arm (effort force)? What is the resistance arm (resistance force)?
3. Explain lifting a handled shopping bag in terms of torque.
4. Analyze the forces, stability, and motions required to put a can of soup on the shelf at nose height.
5. How should passive stretching treatment be modified if the patient acknowledges residual pain after treatment?
6. What parameters can be manipulated to alter stress on the muscle to increase strength?
7. What are the necessary characteristics of exercise or occupation required to increase muscle endurance?
8. Plan a therapeutic occupation program to strengthen a patient who has generalized poor (grade = 2) upper extremity musculature. Revise the program to accommodate changes in the patient's musculature from poor (grade = 2) to fair (grade = 3).
9. Differentiate between a therapeutic occupation program designed to strengthen muscles and one designed to increase muscle endurance.
10. Following replacement of the PIP joint of the ring finger, the patient's finger and hand are edematous. What treatment choices does the occupational therapist have?

ACKNOWLEDGEMENTS

CHAPTER 22

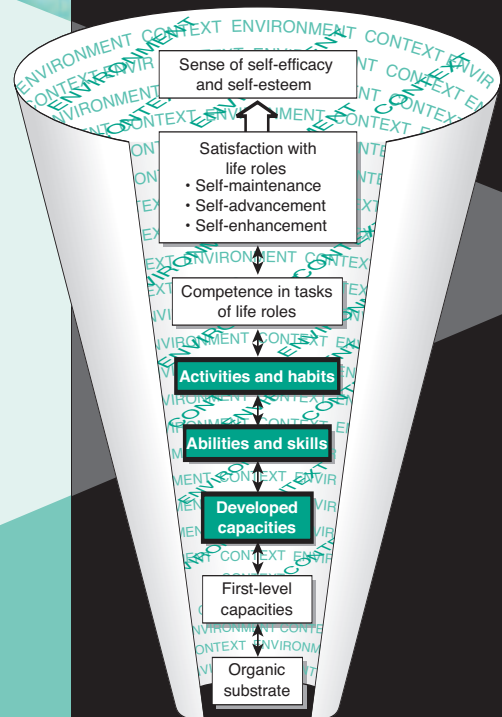

Optimizing Motor Behavior Using the Occupational Therapy Task-Oriented Approach

Julie Bass-Haugen, Virgil Mathiowetz, and Nancy Flinn

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Name the treatment principles of the Occupational Therapy (OT) Task-Oriented Approach.
2. Discuss personal and environmental factors that may be major influences on occupational performance.
3. Define the terms unique to the OT Task-Oriented Approach.
4. Explain the roles of the client and the therapist in the OT Task-Oriented Approach.

Glossary

Attractor—Preferred but not obligatory pattern of motor behavior that emerges from the interaction of a unique person with a particular task and environment.

Blocked practice—Practice that consists of drills and requires many repetitions of the same task in the same way (Schmidt, 1991).

Closed task—A task with stable environmental conditions and consistency from one trial to the next.

Collective variable—Fewest number of variables or dimensions that describe a unit of behavior quantitatively.

Continuous task—Repetitive task without a clear beginning or end.

Control parameter—Variable that shifts behavior from one preferred pattern to another and does not control the change but acts as agent for reorganization of behavior (Heriza, 1991).

Degrees of freedom—Elements that are free to vary.

Discrete task—Task involving movements with a recognizable beginning and end.

Motor learning—Acquisition of general strategies for solving movement problems in a variety of contexts.

Open task—Task in which some features of the environment are in motion or unstable and there is variation from one trial to the next.

Part learning—Practice of separate steps of a task.

Phase shift—Transition, often nonlinear, from one preferred qualitative coordinated pattern to another (Heriza, 1991).

Random practice—Practice of tasks that vary randomly within the session (Schmidt, 1991).

Serial tasks—Tasks with connected discrete movements.

Whole learning—Practice of a task in its entirety.

The OT Task-Oriented Approach emerges from a systems model of motor behavior and is influenced by recent developmental and motor learning (skill acquisition) theories. Two primary bodies of knowledge serve as the basis for the approach: task-oriented approaches that have been discussed in the physical therapy and exercise science literature (e.g., Davis & Burton, 1991; Horak, 1991) and OT models that are occupation based and client centered (Christiansen & Baum, 1997; Law et al., 1997; Trombly, 1995). In particular, the model of occupational functioning (Trombly, 1995) contributes to an emphasis on roles and tasks in the OT Task-Oriented Approach. The model of occupational functioning clearly influences the occupational therapy systems model of motor behavior depicted in Figure 6-2.

Before reading further, review the model, theories, assumptions, and basic evaluation ideas related to this approach in Chapter 6 and principles of learning in Chapter 14. This chapter examines specific treatment strategies related to the assumptions of this approach (Procedures for Practice 22-1).

Although many ideas (e.g., occupational performance, person, environment) presented as part of the OT Task-Oriented Approach are as old as occupational therapy itself, recent motor behavior literature provides a stronger theoretical basis for using purposeful and meaningful tasks as the primary treatment modality. The development of this approach is still evolving. The motor behavior, physical therapy, and adapted physical education literature is examined for identification of principles and key concepts related to task-oriented approaches. Similarly, the OT literature on client-centered, occupation-based models is

used to frame the task-oriented approach in an OT context. There is limited but growing empirical support for the assumptions and treatment principles of this approach. Further development of the OT Task-Oriented Approach and empirical research will provide direction for future practice.

This approach suggests that the client have active involvement in treatment and may have limited applications in acute settings and for clients with significant cognitive impairments. Some aspects of the OT Task-Oriented Approach (e.g., use of real objects and natural environments, focus on meaningful tasks and functional goals), however, are appropriate even in these situations.

PROCEDURES FOR PRACTICE 22-1

Assumptions for the OT Task-Oriented Approach

- Functional tasks help organize motor behavior.
- Occupational performance emerges from the interaction of multiple systems that constitute the unique characteristics of the person and environment.
- After central nervous system damage or other changes in personal or environmental systems, clients' behavioral changes reflect attempts to achieve functional goals.
- Practice and active experimentation with varied strategies and in varied contexts are needed to find the optimal solution for a motor problem and develop skill in performance.

TREATMENT PRINCIPLES AND PRACTICES

The treatment principles and general treatment goals are listed in Procedures for Practice 22-2 and are described next. Procedures for Practice 22-3 summarize general indicators used to determine when to discontinue treatment.

Client-Centered Focus

A client-centered focus is an integral aspect of the OT Task-Oriented Approach.

Adopt a Client-Centered Focus in Treatment

Many therapists refer to the art and science of OT. The art of the OT Task-Oriented Approach is the identification of interventions for the unique needs of each client, taking into account unique personal and environmental systems and roles that have importance and meaning for the individual. Thus, treatment planning cannot be prescriptive. This may seem overwhelming when trying to

process a lot of new information, but these challenges in practice can be the very things that make OT so exciting and rewarding.

In the OT Task-Oriented Approach, assessment and the planning of treatment should look different for each client. Although this may seem obvious, it has been shown that, in practice assessment, documentation and treatment activities often do not reflect the priorities and meaningful occupations identified by clients (Neistadt, 1995a, 1995b) and that perceptions of collaboration during goal setting differ for therapists and patients (McAndrew et al., 1999).

Elicit Active Participation of the Client During Treatment

Clients should have an active role in treatment. They should guide selection of tasks for treatment and contribute to finding solutions for occupational performance problems. Clients who are actively engaged in their treatment show achievement in self-identified goals (Trombly, Radomski, & Davis, 1998), greater participation in the rehabilitation process (Wressle et al., 2002), increased functional independence at discharge, and discharges to less restrictive environments (Gibson & Schkade, 1997).

PROCEDURES FOR PRACTICE 22-2

Treatment Principles of a Task-Oriented Approach

Client-Centered Focus

- Adopt a client-centered focus in treatment.
- Elicit active participation of the client during treatment.

Occupation-Based Focus

- Use functional tasks as the focus in treatment.
- Select tasks that are meaningful and important to the client's roles.
- Analyze the characteristics of the tasks selected for treatment.
- Describe the movements used for task performance.
- Determine whether the movement patterns are stable or in transition.
- Analyze the movement patterns and functional outcomes of task performance.

Person and Environment

- Identify the personal and environmental factors that serve as major influences on occupational performance.
- Anticipate that the personal and environmental variables influencing occupational performance will change.
- Address critical personal and environmental systems to cause change in occupational performance.

- Treat neural and non-neural factors of the sensorimotor system that interfere with optimal occupational performance.
- Adapt the task or broader environment to promote optimal occupational performance.
- Use natural objects and natural environments.

Practice and Feedback

- Structure practice of the task to promote motor learning.
- Design the practice session to fit the type of task and learning strategies.
- Provide feedback that facilitates motor learning and encourages experimentation with solutions to occupational performance problems.
- Optimize occupational performance given the constraints on the person and environment.

General Treatment Goals

- Discover the optimal movement patterns for task performance.
- Achieve flexibility, efficiency, and effectiveness in task performance.
- Develop problem-solving skills with clients so they can identify their own solutions to occupational performance problems in home and community environments.

PROCEDURES FOR PRACTICE 22-3

Discontinuing Treatment

The therapist looks for one or more of these indicators to assist in determining when it is appropriate to discontinue treatment:

- The client is satisfied with performance of occupations and related roles.
- The client spontaneously uses efficient and effective movements that are stable but flexible in functional tasks.
- The client has developed independent and effective skills for solving occupational performance problems in the home and community.
- The client uses movement patterns and demonstrates functional outcomes of task performance that are optimal given the constraints on the person and environment.
- The client easily reverts to long-standing obligatory or irregular movement patterns after an intervention is withdrawn.
- The client does not demonstrate more optimal movement patterns or improved task performance after critical personal or environmental systems have been systematically modified.

There are several ways to facilitate active participation in treatment. Provide user-friendly instructions on how to practice tasks outside of the therapy session and structure clients' environments to facilitate this practice (Ada, Canning, & Westwood, 1990). Create therapeutic environments that are conducive to active learning by attending to both organizational and physical structures of the setting. An environmental analysis can assist in determining whether the broader environment promotes passivity or active involvement in treatment. Characteristics of an active learning environment are summarized in Definition 22-1.

Teach clients the principles of task analysis (Higgins, 1991) and how to evaluate their own performance in terms of the outcomes of their efforts and the efficiency and effectiveness of their movement patterns. Involve clients in graphing their results and recording progress toward functional goals (Ada, Canning, & Westwood, 1990). A goal of therapy is to help clients understand the movement patterns and the performance contexts that contribute to optimal performance for given tasks (Burton & Davis, 1992). The therapist promotes understanding of personal capabilities and limitations and encourages exploration of modifiable environmental resources (Higgins, 1991). These strategies assist clients in developing skills needed for solving motor problems in their home and community.

Give skilled clients permission to solve their own motor problems and to use movement patterns that are the most functional for them, regardless of how these strategies are perceived by others (Burton & Davis, 1992; Latash & Anson, 1996). When clients become skilled in task analysis and solving motor problems, the therapist can celebrate their participation in various tasks and autonomy in learning (Higgins, 1991). This is true even when clients' solutions are not traditional or identical to the strategies therapists would recommend. For example, Mattson, a wheelchair racer with a C6-7 spinal cord lesion, found he could propel faster using a backhand stroke that maximized use of his remaining muscle groups (Burton & Davis, 1992). This technique was unconventional, but Mattson's performance dramatically improved, and soon afterward, many other wheelchair racers were using the same technique. Thus people may use unique movement patterns because they require the least amount of energy and are an efficient means of achieving a functional goal (Kamm, Thelen, & Jensen, 1990).

Occupation-Based Focus

The intervention plan for the OT Task-Oriented Approach is occupation based.

DEFINITION 22-1

Characteristics of an Active Learning Environment

- Create an environment that encompasses the common challenges of everyday life.
- Develop learning contracts that describe shared rehabilitation goals.
- Develop a cohesive team that is committed to active learning.
- Require clients to communicate their need for help in specific tasks to staff.
- Give clients control over when and where they are to be transported.
- Give able clients responsibility for routine housekeeping.
- Arrange chairs in small circles in reception and common areas.
- Provide opportunities for practice outside of therapy.
- Provide written instructions, audiotapes, videotapes, and diagrams for practice.
- Organize the environment to match the level of performance.
- Illustrate progress to clients.

Ada, L., Canning, C., & Westwood, P. (1990). The patient as active learner. In L. Ada & C. Canning (Eds.), *Key issues in neurological physiotherapy* (pp. 99–124). Boston: Butterworth Heinemann.

Use Functional Tasks as the Focus in Treatment

The goal of treatment for motor behavior problems is to enable clients to do the things they want to do now and in the future. Thus, at each point from the initial evaluation to recording progress to discharge to follow-up, the determination of the effectiveness of interventions is performance on functional tasks. The interventions themselves also emphasize the practice of real functional tasks.

There is renewed interest in functional tasks and goals in clinical and basic research. Neurological recovery from central nervous system (CNS) dysfunction supports task-related training and experiences (Dobkin, 1998, 2005), and functional disability is one of the most important predictors of discharge outcomes (Inouye et al., 2000). Thus, recently developed evaluations in OT emphasize measures of functional task performance. Treatment protocols for motor behavior problems emphasize using functional tasks (Burton & Davis, 1992; Carr & Shepherd, 1998) as both the means and ends in the treatment process (Gray, 1998; Trombly, 1995).

Many studies have examined the effect of functional goals on motor behavior. Thelen and Fisher (1983) studied kicking behavior in 3-month-old infants. They found that kicking increased when a mobile was tied to the leg by way of a control line. Adults with hemiplegia have demonstrated more repetitions of movement patterns when an occupation-based activity was used rather than rote exercise (Hsieh et al., 1996). Research is also beginning to support the idea that occupation-based interventions are more effective than other interventions in addressing impaired performance components such as coordination (Flinn, 1999; Neistadt, 1994; Trombly & Wu, 1998). Finally, performance efficiency improves when personal preferences and higher level functional goals are incorporated into treatment activities (Wu et al., 2001).

The results of these studies support the idea that therapists' interventions for motor behavior problems should revolve around meaningful occupations and functional goals. The functional goals of interest in OT are broad. Basic activities of daily living (ADLs) tasks are important. The functional goals, however, should also relate to other self-maintenance, self-advancement, and self-enhancement roles because the longer term reported limitations are often more significant for instrumental activities of daily living (IADLs) and community activities (Mayo et al., 2002).

Select Tasks That Are Meaningful and Important to the Client's Roles

The importance of many functional tasks is unique to the individual. What is important to one person may not be important to another. So how do therapists determine the key tasks for a given individual? They should consider a client's occupational roles and the meaning of these roles to the person (see Chapter 4). Life satisfaction is not

RESEARCH NOTE 22-1

Liepert, J., Bauder, H., Miltner, W. H. R., Taub, E., & Weiller, C. (2000). Treatment-induced cortical reorganization after stroke in humans. *Stroke*, 31, 1210–1216.

Abstract

The purpose of this study was to evaluate reorganization of the motor cortex in individuals with stroke who had received constraint-induced movement therapy. Thirteen subjects with stroke in the chronic stage participated in a 12-day period of constraint-induced movement therapy. They used the affected arm exclusively in a variety of tasks during the therapy period. Focal transcranial magnetic stimulation was used to map the cortical motor output area of a hand muscle on both sides before and after treatment. Results showed that before treatment, the affected hand muscle had a significantly smaller cortical representation area than the contralateral side. After treatment, the cortical representation of the affected hand muscle was significantly enlarged. There was also a corresponding improvement in motor performance of the affected limb. In follow-up studies to 6 months after treatment, motor performance remained improved, and the cortical area sizes in the two hemispheres became almost identical and close to the normal condition. This study supports a therapy-induced improvement in movement and long-term alteration in brain function after stroke.

Implications for Practice

- Individuals use whatever movements are possible and needed to achieve functional goals. In constraint-induced movement therapy, individuals use the affected arm for task performance when the unaffected arm is not available.
- The motor cortex demonstrates neuronal plasticity after stroke even in the chronic stage.
- Constraint-induced movement therapy programs that incorporate a variety of tasks may influence cortical reorganization after stroke and improve movements and performance.

determined by successful completion of a random set of functional tasks (e.g., changing a diaper and taking out the garbage). Satisfaction or reward comes from the feeling that roles are fulfilled (e.g., parent and homemaker). Roles are defined by the client in terms of the tasks and related activities that are interesting or important (Fisher & Short-DeGraff, 1993; Pollock, 1993; Trombly, 1993, 1995). For example, two clients may view the role of parent differently. One may identify washing a child's clothing as a key functional task, whereas another may view playing touch football as more important. These

two functional tasks vary greatly in their environments and in the motor behaviors required to achieve the functional goals.

The consideration of roles also helps the occupational therapist tap into the personal motivations of clients for performing particular tasks. When a client is motivated to change motor behaviors, it usually reflects an internal desire to perform, acquire, or accomplish something (Crutchfield & Barnes, 1993). This motivation may occur because the degree of skill in performance is not personally satisfactory (Higgins, 1991) or because of other intrinsic and extrinsic factors, including perceptions regarding the chance of success, importance of the goal, and the costs in terms of barriers and access as well as inclinations to continue current task performance (Phillips, Schneider, & Mercer, 2004). In summary, select tasks that are within the realm of capabilities, are goal oriented, have meaning for the clients, and motivate them.

Analyze the Characteristics of the Tasks Selected for Treatment

After a specific task has been selected for treatment, a task analysis is necessary because clients' capabilities vary and different tasks require different skills. Task analysis entails an examination of the task requirements and the personal capabilities to determine whether there is a match that permits task performance (see Chapter 13). If there is no match, the occupational therapist plans interventions that address the problems of the client or the characteristics of the environment or both. The outcome of a task analysis helps the therapist design appropriate **motor learning** experiences and select practice and feedback strategies that fit the nature of the task. Several classification schemes may be useful in task analysis (Davis & Burton, 1991; Gentile, 1987; Schmidt, 1988).

In Schmidt's (1988) classification, tasks and the required movements for tasks are described as discrete, serial, or continuous. Skilled performance in a **continuous task** is generally retained even when there are periods when practice is impossible (Crutchfield & Barnes, 1993). For example, most people learn to ride a bike when they are quite young. As an adult, they may go through long periods when there is no opportunity to practice this skill, but once they have learned to ride a bike, they easily remember it later after only brief practice. On the other end of the continuum are tasks requiring discrete movements. Many skilled movements used in sports with balls (e.g., hitting, slam dunking, and pitching) are discrete; they have a definite beginning and end. Frequent practice of the movements is required to maintain skill at a high level. Neither discrete nor continuous tasks are easily broken into steps, as **serial tasks** are.

Gentile (1987) proposed a taxonomy of tasks based on characteristics of the environment and a person's actions during task performance. The environment is described in

terms of its characteristics and variability in these characteristics from one performance to the next. The environment, which includes objects, supporting surfaces, and other people, may be stationary or in motion during a given task. In addition, there may be variation or consistency in these environmental characteristics from trial to trial. When the environment is stationary during performance and does not change from one trial to the next, the task is a **closed task**. Signing your name on a check at a desk is a closed task because the environment is generally stable and unchanging. In an **open task**, some features of the environment are in motion and vary from one performance to the next. These tasks are complex and place many demands on the person because the performance context is unstable and changes for different trials. Driving a car is an example of an open task (Poole, 1991) because the driver must process the motions of other cars, pedestrians, and the broader performance context (e.g., snow or rain). Furthermore, these features of the environment vary dramatically from one trip to another.

The function of a person's actions is the second dimension in Gentile's (1987) taxonomy. This dimension consists of the person's actions during task performance and includes body orientation and object manipulation. In a given task, body orientation might require stabilization or transport. For example, during a word processing task, the trunk and lower extremities primarily provide stability. In a tennis match, however, the trunk and lower extremities move or transport toward the ball. Actions are also analyzed in terms of whether the upper extremities provide stability or manipulate objects. For example, the upper extremities help maintain balance and are part of the postural support system when a person walks on a wet kitchen floor. In this situation, there is no object manipulation. In washing the floor, however, arms and hands are used for object manipulation (e.g., mop or sponge). The complete taxonomy proposed by Gentile combines the environmental context and the function of the action dimensions and results in 16 categories of tasks.

Describe the Movements Used for Task Performance

A description of the preferred movement patterns that emerge for a given task in a given context helps guide treatment. Preferred movement patterns, or **attractors**, are ordinarily stable and the optimal way to achieve a functional goal because they are efficient and effective (Kamm, Thelen, & Jensen, 1990). A preferred movement pattern can be illustrated by how a marble moves on different surfaces (Fig. 22-1). The wells in the figure depict the stability of the patterns (Thelen, 1989). The marble on a surface with a shallow well (Fig. 22-1A) illustrates optimal movement patterns used for everyday tasks. The movements tend to be stable, just as a marble would tend to fall into the same well. This well is shallow enough, however, that the marble can move out of it, signifying how a person can modify

Figure 22-1 Various attractor states. **A.** Shallow well, stable and flexible attractor state. **B.** No well, no attractor state. **C.** Deep well, stable and inflexible attractor state.

movements or use a new movement pattern if there is a change in the person or environment. For example, how would you describe movements used to write your name? One characteristic is that there is a fair amount of consistency in the way a person moves as he or she writes. These preferred movements are usually the best movements for a given situation (e.g., writing on paper with a pencil at a desk). There may be some variations in the ways people move in this situation, but the movements do not vary widely. There is also some flexibility in movements, however, so that if a need arises (e.g., one has a blister on a finger or wants to use a stick to write in the sand), a person can temporarily or permanently change the movements used to complete the task. Many clients with CNS damage show good motor recovery and resumption of movement patterns similar to this example. They resume stable but flexible performance of tasks in their daily lives (Fig. 22-1A).

Clients in the acute stage of recovery often use movement patterns that show little stability (Fig. 22-1B). Their performance is similar to the movement patterns represented by a marble on a flat or bumpy surface—very irregular and unpredictable. It may appear that there is no preferred movement pattern. Every time they do a task, they do it in a different way. As a result, task performance is not efficient or effective. This is similar to the movement patterns seen the first few times a new sport is tried.

Other clients seem obligated to perform a task in only one way (Fig. 22-1C). In this situation, the well is so deep that a large perturbation or disturbance would be needed to dislodge the marble or to change the preferred movement pattern. Performance is likely to revert to this pattern soon after treatment. This movement pattern may be effective for task performance in one context, but the person may be unable to achieve functional goals in varied contexts because there is no flexibility in movement patterns. For example, a client may use a flexor pattern for all tasks that require reaching. This pattern may be effective when the arm is only an assist in some bilateral

reaching tasks; most reaching tasks, however, require complex and varied motor skills. For these tasks, the client may be unable to adapt movements and thus be unable to achieve the functional goals. These obligatory patterns are often observed in people years after CNS damage.

Determine Whether the Movement Patterns Are Stable or in Transition

The next step is to determine whether the movement patterns are stable or in transition. This information is important because it helps the therapist identify the optimal times to provide treatment and the strategies necessary to produce a change in the preferred movement patterns (Kamm, Thelen, & Jensen, 1990; Scholz, 1990). The beginning of a transition period may coincide with aging, CNS damage, a new environment, or many other factors. Data on movement patterns are gathered by analyzing task performance and by constructing an individual developmental profile of previous changes in motor behavior (Thelen, 1989). The therapist observes performance of the same task several times in the same context and then in different contexts. Intervention is not needed if the preferred movement pattern is relatively efficient and effective for a given task and is stable but flexible so that it can be modified for different contexts. On the other hand, if there is no preferred movement pattern or if the pattern is fixed, the therapist may consider treatment to facilitate change in movement patterns and occupational performance.

If the movement patterns are in transition, there is increased variability in the movements used to complete a task and increased susceptibility to change or perturbation by the influence of some personal or environmental systems. In addition, movement patterns take longer to return to a stable state if perturbed (Heriza, 1991). These findings mark a potential transition period or **phase shift** and may be characterized as a marble on a smooth or bumpy surface (Fig. 22-1B). When the movement patterns are unstable or in transition, therapists are generally more likely to facilitate a change to different patterns—ones, it is hoped, that are more efficient and effective in achieving the task goal. Remediation of motor behavior problems should begin before the movement patterns fall into obligatory, stereotyped patterns (Kamm, Thelen, & Jensen, 1990).

If the movement patterns are stable in a particular performance context, it may be more difficult to produce a change in the way the task is performed in that context. In this scenario, change in movement patterns is less likely, and the person is apt to return easily to the preferred pattern, even if it is possible to produce a temporary change. This stability may be characterized as preferred but flexible (Fig. 22-1A) or obligatory (Fig. 22-1C). For example, neuromotor synergy patterns may represent the stable, obligatory movement patterns of a damaged system. If the movement patterns have been obligatory or

irregular for a long time, interventions may not effect a change to other movement patterns. In this case, perhaps only a trial period of therapy is warranted.

Analyze the Movement Patterns and Functional Outcomes of Task Performance

An analysis of movement patterns will help estimate stability and flexibility, understand changes, and prevent fixation of movement patterns (Kamm, Thelen, & Jensen, 1990; Scholz, 1990). Scholz used an example to illustrate two strategies for evaluating the stability of movement patterns. Consider the gait of a child with cerebral palsy. The preferred pattern for this child may be a bunny hop, and a goal of therapy may be to move toward a reciprocal pattern of walking. One quantitative measure of movement patterns may be the relative phase of the hip motions as measured by videography. That is, are the hip motions in the same phase (both in flexion) or in opposite phases (one in flexion and the other in extension)? The therapist analyzes the fluctuations in the relative phase when the child is using the preferred pattern, the bunny hop. Next, this pattern is perturbed by slowing the locomotion or by imposing a physical restraint on one lower extremity. The therapist learns the child's movement patterns for this task by analyzing how much slowing or restraint is needed to change to a reciprocal pattern and how long it takes to return to a bunny hop after the critical factors are removed.

The first strategy is to look at fluctuations in one or more quantitative measures of movement patterns during task performance. The second strategy is to determine what happens when the therapist tries to disturb or perturb the movement patterns by changing some critical personal or environmental factors. Therapists ask themselves how much change is necessary to disturb the pattern and how long it takes for the movement pattern to return to the previous state. The quantitative measures of movement patterns are **collective variables**, and the critical factors influencing behavior are **control parameters**.

One of the challenges in the OT Task-Oriented Approach is identification of collective variables, the measures of movement that can describe in simple terms all of the systems that cooperate to produce movements (Clark, 1997; Heriza, 1991; Thelen & Ulrich, 1991). These variables are a way of objectively measuring motor behavior and changes in motor behavior. Therapists continue to discover new ways to measure the outcomes of functional performance. Sometimes, however, OT interventions are not intended to result in a substantial change in the outcome. For example, a client may have achieved moderate independence in bathing but still not have optimal performance. The goal in OT may be to help change the movement patterns used for getting out of the tub so that performance is more safe and efficient. Thus, measures are needed to document progress in motor performance as well as levels of independence.

Motor behavior research may help to identify these potential measures of occupational performance. Slow reaction times, slow movement times, performance variable variance, movement trajectories with discontinuities, absolute error, and rate or speed limitations have been noted in disorders of movement (Campbell, 1991; Corcos, 1991; Reisman & Scholz, 2003). One measure that is easy to use in treatment is time (time to begin the task, time to complete the task, and time until movement patterns regress to previous patterns after being perturbed). As videography and movement analysis become more accessible in clinical settings, occupational therapists may measure the relative timing of one motion with respect to another (relative phase), the curvature or straightness of movements (trajectories), the distance and direction of movement (displacement), and the speed or constancy of speed (velocity, accelerations, and decelerations) (Corcos, 1991; Fetters, 1991; Heriza, 1991; Rice & Newell, 2004; Scholz, 1990).

Person and Environment

The interventions used in the OT Task-Oriented Approach address personal and environmental systems to enable optimal occupational functioning.

Identify the Personal and Environmental Factors that Serve as Major Influences on Occupational Performance

The therapist begins treatment planning by examining tasks that were difficult for the person to perform and describing the preferred movement patterns for these tasks. The therapist then identifies the personal and environmental systems that support optimal functional performance and those that contribute to ineffective performance (Letts et al., 1994). The interactions of these systems are also important (Shepherd, 1992) (see Chapter 6). Part of the OT process, then, is making systematic changes in personal characteristics (e.g., attention and positioning) and environmental context (e.g., size of object and stability of base of support) and observing the effect on occupational performance. This process can help identify one or several critical factors (control parameters) that can cause a shift in motor behavior.

A qualitative analysis (observation and description) also may be used to describe the interactions of person and environment on task performance. For example, VanSant (1991) identified the personal systems used for activities requiring righting (e.g., rising from a bed and getting up from a chair or the floor). She found that the preferred movement patterns for these activities are influenced by body dimensions (e.g., ratio of leg length to body length; size of body relative to bed or chair; height; weight; body build and topography), age, gender, and activity level. Thelen (1989) studied treadmill stepping in infants and

found that neurological and morphological maturation and the postures of the leg were the critical factors influencing the movements used. Velocity has been identified as a control parameter in the locomotion patterns used by people and animals (Scholz, 1990). If a horse is forced to increase its speed, changes in movements associated with a walk, trot, and gallop can be observed (Crutchfield & Barnes, 1993). Studies to determine control parameters of common motor behaviors are important to help occupational therapists identify the critical systems inherent in performing particular tasks.

Although it may seem impossible to identify only a couple of critical systems from the multiple systems and subsystems that influence motor performance, occupational therapists already do this, using quantitative and qualitative analysis. Consider the task of placing items on a shelf above shoulder level. Now imagine or, better yet, actually try placing various items on the shelf. Consider the different movement patterns used to lift an empty paint can and a full paint can to a high shelf. What is the critical factor that explains the change in movement patterns when lifting an empty can versus a full can? It is the weight of the can relative to arm strength. What is the critical factor that explains the change in movement patterns when lifting a tennis ball versus a beach ball in the same task (assuming weight is held constant)? In this situation, it is the size of the object relative to hand size. Both of the critical factors in these examples are performer-scaled variables (Davis & Burton, 1991), or parameters that link a characteristic of the person (e.g., strength or hand size) to a characteristic of the object that is used in the task (e.g., weight or size).

Thelen (1989) stated that it is also important to consider non-obvious and distantly related factors as possible critical factors. She described studies showing that the onset of crawling, a motor skill, is an influential factor in cognitive, affective, and social changes in children. The ability to move to another environment is a critical factor that can cause a dramatic change in the problem-solving, communication, and play behaviors of children.

One last clinical example suggests that other systems might serve as critical factors. In one long-term care setting, health care professionals were wondering why older men who had experienced cerebrovascular accidents were not achieving independence in dressing. One therapist hypothesized that it was loss of automatic reactions and postural control. Other therapists proposed that motor planning problems or general loss of strength and endurance explained the performance deficit. Although all of these systems did indeed influence motor behavior, a family member revealed that the critical factor for the motor behaviors related to dressing was the culture of the residents. That is, most residents in this setting were members of a culture that did not place value on independence in self-care for older adults,

especially men who had disease-related impairments. In fact, it was an expectation that women in the extended family would come to the residence every day to complete ADLs.

There are several purposes in relating these examples. One is to challenge therapists to use creativity and common sense in treatment. For given individuals with given tasks, the critical factors may be neural or non-neural sensorimotor components (e.g., soft tissue contracture, muscle weakness, and abnormal muscle tone). Occupational therapists, however, sometimes neglect important factors such as a different culture and look only at performance components that seem directly related to the motor behaviors. No system automatically deserves more attention than any other system unless research indicates otherwise.

Anticipate that the Personal and Environmental Variables Influencing Occupational Performance Will Change

The critical variables influencing motor behavior change over time. CNS damage affects each system differently relative to occupational performance. This idea is illustrated in Figures 22-2 and 22-3, which depict hypothetical changes in systems and subsystems over time for a unique person. The *y* axes represent the system's degree of positive or negative influence on occupational performance, and the *x* axes represent these changes over time from onset of CNS damage to the rehabilitation stage to discharge or home. Some systems are highly affected immediately after CNS damage, while other systems become more important later. For example, the physical environment in Figure 22-2 may become a more important variable when the person returns home. The home may or may not support performance of previous occupational roles and tasks. In rehabilitation settings, the physical environment is designed for persons with physical disabilities and thus may not be as important because the setting is so unlike the natural environment. Systems that influence occupational performance at one time may not be the critical systems at other times. Figure 22-3 shows the effects of neural and non-neural components of muscle tone at different points in time. Based on our clinical experience, neural factors (e.g., spasticity) are important immediately after the onset of CNS damage but have less of an effect on performance later. The influence of non-neural factors (e.g., soft tissue contracture), however, is almost the reverse.

A client's occupational performance at any one time reflects the interaction of all of these systems. The critical variables at a given time may vary greatly depending on the characteristics of the person and environment. What is effective for one client may not be effective for the next client with similar CNS dysfunction. In addition, systems that enhance performance at one time may interfere with

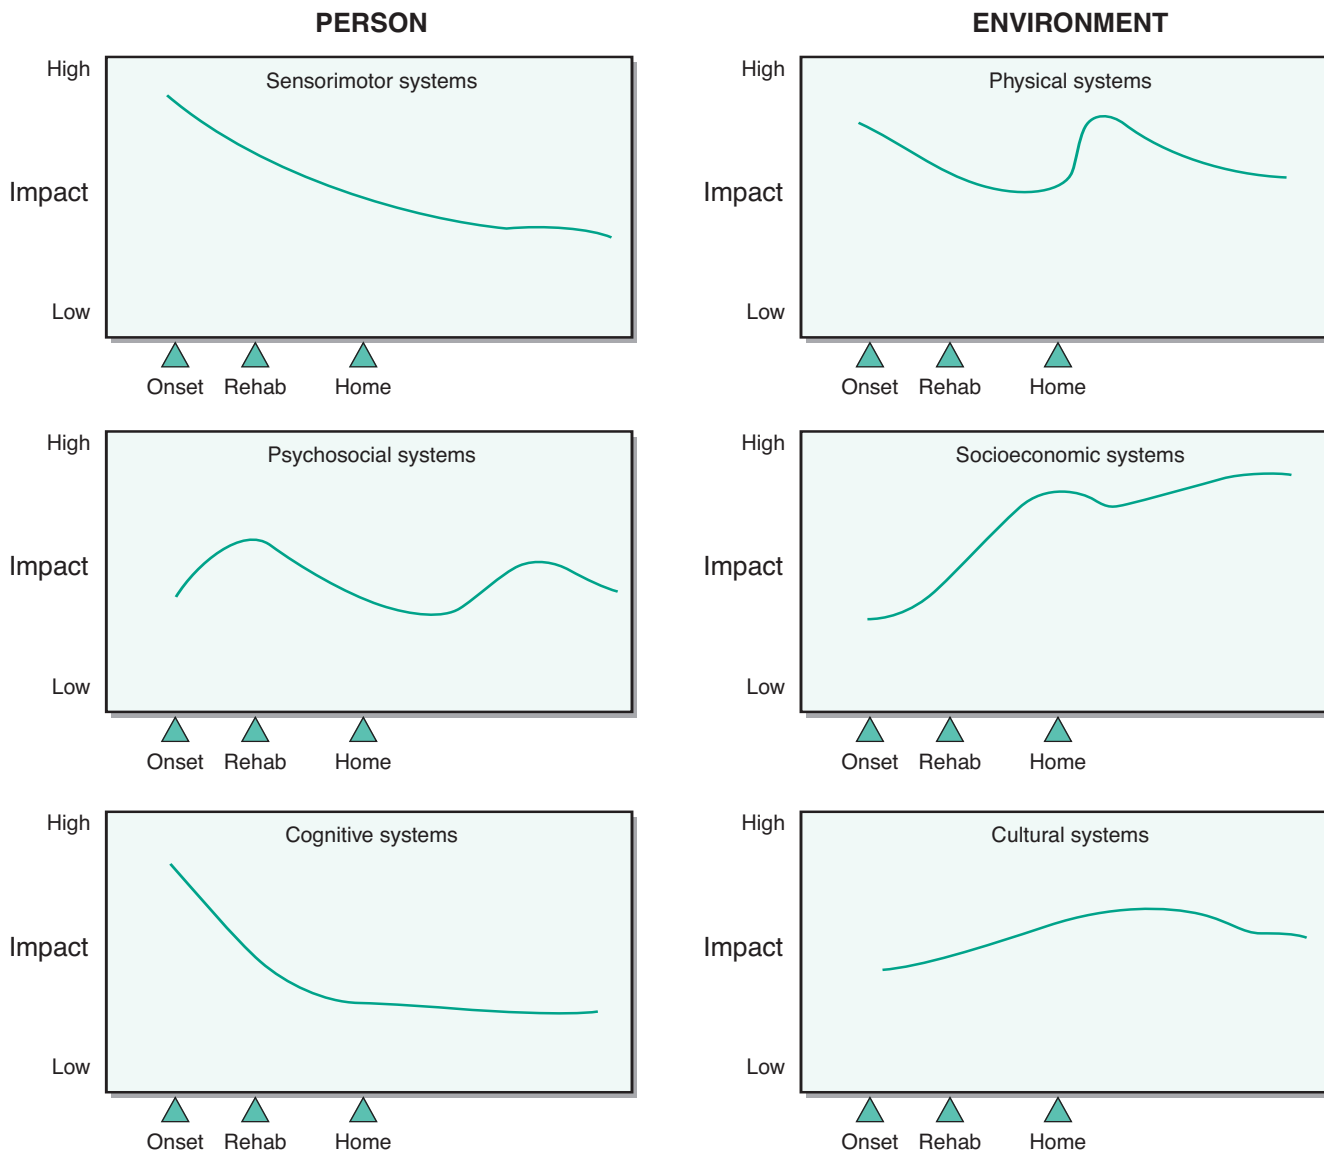

Figure 22-2 Hypothetical influences of personal and environmental systems on occupational performance for a unique person at different times (at onset, during rehabilitation, and at home).

it later (Kamm, Thelen, & Jensen, 1990). What is effective early in treatment may not be effective later. Therapists must identify the major influences on motor behavior at a specific time for a specific person and anticipate changes in the critical variables.

Address Critical Personal and Environmental Systems to Change Occupational Performance

After a critical personal or environmental factor is identified, the therapist alters this personal or environmental characteristic until a shift in motor behavior is observable.

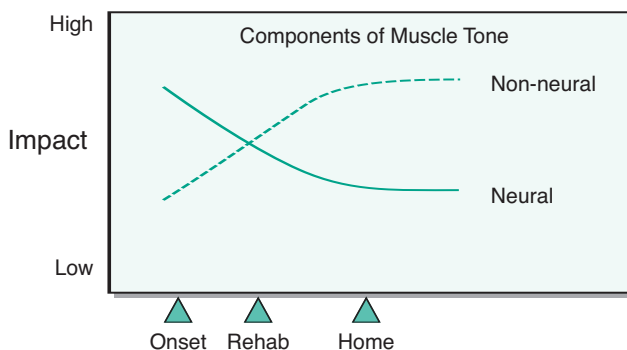

Figure 22-3 Hypothetical influences of neural and non-neural components of muscle tone on occupational performance at different points in time (at onset, during rehabilitation, and at home).

Relatively small changes in a critical personal or environmental system may produce large changes in the movement patterns used for a task (Thelen, 1989). For example, putting an infant in water (Thelen, 1989) or an adult on a treadmill with partial body weight support (Hesse, Konrad, & Uhlenbrock, 1999) dramatically affects walking. Forcing use of an affected arm by constraining the other arm (Morris, 1997; Miltner et al., 1999) or application of a splint to provide wrist support (Kamm, Thelen, & Jensen, 1990) may change the upper extremity movement patterns and thus change occupational performance. The goals of occupational therapy are to help individuals identify and use critical factors that support optimal performance and to determine the optimal value for producing the best performance outcome (Burton & Davis, 1992).

Treat Neural and Non-Neural Factors of the Sensorimotor System that Interfere with Optimal Occupational Performance

Studies show that many subsystems of the sensorimotor system, not just neural subsystems, may have a role in motor behavior after CNS damage. For example, muscle weakness and loss of dexterity are related to functional performance challenges in clients with hemiparesis (Canning, Ada, & O'Dwyer, 1999). Sabari (1991) described an inability to dissociate the scapula from the thorax or the pelvis from the lumbar spine, weakness of specific muscles, inability to counteract gravitational forces, abnormalities in muscle tone, and incorrect timing of components within a movement as possible sensorimotor factors constraining movement in a hemiplegic arm.

These sensorimotor factors offer alternative explanations for the movement patterns used by clients. For example, a client with hemiparesis may use a flexor pattern for reaching or lifting because of muscle weakness; a person without CNS damage, however, uses this pattern, too. Imagine lifting a very heavy object, for example, a television. Describe the positions of the arms. The arms are pulled in close to the body (a flexor pattern) because arm strength relative to the weight of the object requires use of a biomechanically efficient pattern (a short resistance arm). Clients may use this same pattern when lifting something as light as a feather. Their limited arm strength relative to the weight of the feather—and more important, the force of gravity on the arm—require an efficient pattern as they attempt to control the many **degrees of freedom** in movement of the arm (Flinn, 1995). Thus biomechanical and system factors, such as those described by Spaulding (1989) for prehension and those discussed in other chapters, are an important part of treatment approaches for clients with CNS dysfunction.

Adapt the Task or Broader Environment to Promote Optimal Occupational Performance

The performance context is as important as the personal characteristics in treatment (Dunn, Brown, & McGuigan, 1994; Fisher & Short-DeGraff, 1993). Consider the following examples. People with lower extremity motor impairments can scuba dive without special equipment and do so as well as any other person (Burton & Davis, 1992). On the other hand, walking can be difficult for even a person without physical impairments if the walking is attempted at an altitude of 15,000 feet. What factors influence motor behavior in these two examples? In both cases, the ability or inability to perform a task is context dependent.

There are various ways to alter the physical context of the task to promote optimal task performance (Davis & Burton, 1991; Gentile, 1987; Gillen, 2000; Sabari, 1991; Trombly, 1994). The slope and height of the support surface may be adjusted. The size, shape, and texture of the object used in a task may be varied to alter the movement patterns (Fuller & Trombly, 1996). Size, length, and weight of equipment or tools may be modified. The accuracy and speed requirements for a task as well as the task complexity can alter performance (Ma & Trombly, 2004). The information required or provided as part of task performance can be adjusted in terms of timing, precision, and abstractness of the response. These adaptations are similar to the compensatory strategies described in other occupational therapy approaches. In the OT Task-Oriented Approach, the therapist explores modifications of the physical performance context to promote optimal functional performance, not simply to compensate.

Systems other than the physical context must also be considered. Heriza (1991) and Thelen (1989) emphasized the importance of social influences on motor behavior. They reviewed studies that show that infants' locomotion changes and develops faster when there is social reinforcement of the behaviors. Therapists themselves are part of the broader environment affecting occupational performance (Newell, 1998). They coach clients to help them discover and adopt optimal patterns of task performance (Scholz, 1996). They structure the learning activities and provide feedback to help clients achieve reliable, stable, and efficient performance without prohibiting clients from identifying their own optimal movement patterns (Masters & Polman, 1996). A summary of the roles of the therapist is provided in Procedures for Practice 22-4. The role of environmental systems on motor behavior continues to be explored.

Use Natural Objects and Natural Environments

Use natural objects for practice of the task. Simulations and rote exercise do not produce the same movement

PROCEDURES FOR PRACTICE 22-4

Roles of Therapist

Many roles for the therapist are proposed in the literature (Burton & Davis, 1992; Gentile, 1992; Heriza, 1991; Higgins, 1991; Kamm, Thelen, & Jensen, 1990). All are important in helping the client to become autonomous in solving motor problems.

- Collaborate with the client in selecting a variety of tasks for practice.
- Modify the task initially so the learner can succeed.
- Teach task analysis, structure learning opportunities, provide feedback, and facilitate understanding of unique personal and environmental systems that promote optimal performance.
- Provide non-generalizable solutions that the client can memorize if the client cannot learn a more flexible approach.
- Coach the client during learning by directing the focus to the functional outcome, suggesting movements to try, recording progress, and assisting with decision making when new challenges arise.
- Alter the personal and environmental factors and identify optimal times to change movement.
- Provide manual guidance if necessary, but allow some elements to vary so that the client can experiment with movement patterns.
- Fade assistance provided through handling as soon as possible.

patterns as tasks using real objects. Studies of persons with stroke showed more efficient, direct, smooth, and planned movements in reaching tasks enriched with natural objects than in the condition without objects (Trombly & Wu, 1998; Wu et al., 1998, 2000). Other research supports the idea that the greater the number of real objects and the greater the symbolic information, the more performance is improved (Lin, Wu, & Trombly, 1998; Lin et al., 2001; Mathiowetz & Wade, 1995; Wu et al., 1998).

Use natural environments to help clients develop stable but flexible movement patterns for the tasks and contexts in their home and community (Burgess, 1989; Gillen & Wasserman, 2004). The rehabilitation unit should simulate the real-life setting as much as possible if interventions cannot be provided in the actual situation (Mulder, 1991; Poole, 1991). Therapeutic modules (Stahl, 1993) simulate community-based environments. Many rehabilitation units have apartments with ordinary home furniture. Other resources of the institution can also simulate community settings (e.g., gift shop, cafeteria, and chapel).

Practice and Feedback

The design of practice sessions and characteristics of feedback are important in interventions based on the OT Task-Oriented Approach.

Structure Practice of the Task to Promote Motor Learning

Until recently, motor learning, or the outcome of practice, was primarily measured in terms of observable changes in performance during or immediately after practice. Our goal for the outcome of practice, however, is that clients can perform better once they leave treatment. Research in motor learning (Schmidt, 1991) shows that measurement outcomes of the performance during practice are not the same as later performance. If the goal is to improve motor performance over the long term, the effectiveness of the practice must be evaluated in terms of later performance.

Blocked practice includes drills that require clients to perform many repetitions of the same task in the same way (Schmidt, 1991). For example, for dressing, the client is presented a series of steps that must be practiced again and again in the same manner. Some studies have examined the type of practice that is most beneficial for changing the capability for later performance. These studies (Hanlon, 1996; Schmidt, 1991) suggest that practice of tasks should vary randomly (**random practice**); that is, therapists should ask clients to try a variety of dressing tasks within one session. One thing to remember when adopting a random practice approach is that performance during the practice session may actually look worse than performance after blocked practice. This is acceptable because the goal is to enhance motor learning or the capability for later performance rather than change observable behaviors during a practice session.

Variation of the context within a task is also an important component of practice (Jarus, 1994; Keshner, 1991; Lee, Swanson, & Hall, 1991; Mulder, 1991; Sabari, 1991; VanSant, 1991). Manipulation of task dimensions such as support surfaces, objects, equipment, task demands, and required information are examples of strategies to vary the context (Davis & Burton, 1991). The contexts for mobility include distance, temporal characteristics, ambient conditions (light and weather conditions), terrain characteristics, physical load, attentional demands, postural transitions, and density (number of people and objects in immediate environment) (Shumway-Cook et al., 2003). Varied contexts promote development of preferred movement patterns for specific contexts and flexibility in movement patterns for different contexts (Heriza, 1991; Thelen, 1989). The client who practices only in a narrow context learns only a limited

number of solutions. The client who practices the task in many contexts, however, learns many solutions and can vary performance (Higgins, 1991). Bernstein (1967) summarized this principle by stating that people need repetition without repetition.

Design the Practice Session to Fit the Type of Task and Learning Strategies

Research shows that different types of tasks require different types of practice sessions to facilitate learning (Winstein, 1991). Practice may require the client to practice the task in its entirety (**whole learning**), in separate steps (**part learning**), or in some combination of whole and part learning. Winstein (1991) studied weight shifting with part learning to improve locomotion, a continuous task, in persons with hemiparesis. She found that persons in the treatment group using part learning did improve in the symmetry of standing posture but showed no significant improvement over a control group in actual locomotion. Ma and Trombly (2001) compared performance of elders on a signature task for part and whole task conditions. They found that the whole task condition produced movements that were more smooth, efficient, and forceful. Whole learning rather than part learning is generally recommended for both continuous and **discrete tasks** (Crutchfield & Barnes, 1993). Separate practice (i.e., part learning) of the discrete components of a serial task is beneficial. Kerr (1982) stated that the complexity of the task should also be taken into consideration. When the task is relatively simple, whole learning is recommended. Part learning is suggested for more complex tasks.

The stages of learning have been described as discovery (cognitive), mastery (associative), and generalization (autonomous) (Fitts & Posner, 1967; Higgins, 1991). Many clients are in the discovery stage as they develop an understanding of the task, identify the performance problems, and find a general solution for their new capabilities. This stage is characterized by slow performance, clumsiness, and self-imposed rigidity or freezing of body parts to control all degrees of freedom that are normally free to vary in high levels of skill. In this stage, clients attempt to exert control over some parts of the body to learn the influence of changes in their personal systems and relationships to the environment (Higgins, 1991). In later stages of learning, the client refines the solutions identified in the discovery stage and generalizes these solutions to other tasks. The behaviors in these later stages are more consistent, more accurate, faster, and better coordinated (see Chapter 14).

Therapists must also consider the type of learning that the practice session will elicit (Gentile, 1998). Explicit (declarative) learning requires conscious learning of the rules for task performance and is more generalizable because it is not very context dependent. Implicit (proce-

dural) learning requires learning how to do the task on an unconscious level. This type of learning is facilitated by structuring the environment and practice of the task. Chapter 14 provides additional detail on these aspects of learning.

Provide Feedback that Facilitates Motor Learning and Encourages Experimentation with Solutions to Occupational Performance Problems

If the goal is to have clients rely on intrinsic feedback for task performance in the future, careful planning of the extrinsic feedback during treatment is important. Lee, Swanson, and Hall (1991), Schmidt (1991), and Winstein (1991) reviewed results of studies on appropriate feedback strategies related to the knowledge of results or the outcome of performance. Studies of people without motor problems suggested that feedback should be less frequent, scheduled randomly or intermittently, faded over time, and given as summary information or when performance is outside a given error range. These feedback strategies resulted in better retention of motor skills over time than frequent, immediate, and consistent feedback. Preliminary studies indicate that reduced frequency of feedback may improve generalization when learning difficult tasks for elders (Rice, 2003) and performance consistency but not accuracy for individuals post stroke (Merians et al., 1995). Further research on feedback with subjects having motor problems is needed. Therapists should carefully analyze the effect of their feedback on an individual client's performance.

Optimize Occupational Performance Given the Constraints on the Person and Environment

“Optimization in the process of therapeutic intervention should be directed at a functional outcome rather than a peripheral motor pattern to promote learning in a functionally significant context so that adaptive solutions are developed and optimized by the CNS with respect to a certain activity” (Latash & Anson, 1996, p. 98).

After CNS damage, clients may have to learn strategies for task performance given personal limitations. When clients understand the idea of the task, their personal limitations and capabilities, environmental resources, and a basic solution to the problem, they may begin to practice the task. The inefficient and ineffective movements sometimes seen at this time are consistent with the limited understanding and control one has during the early stages of learning and at the lower levels of skill (Higgins, 1991). Perhaps the client simply needs further practice and time to develop skill. Therapists, however, must identify ineffective movement patterns that are hindering optimal task performance or contributing to future problems in personal and environmental systems. Mulder (1991) added one more caution regarding

the analysis of preferred patterns: The achievement of functional outcomes is probably more important to the client and family than the therapist's goal of "normal" movement patterns. Again, a client-centered approach focused on meaningful occupations and roles is important.

LIMITATIONS AND FUTURE DIRECTIONS

A consideration of limitations and future directions is important in the discussion of any occupational therapy approach.

Limitations

There are some limitations to the OT Task-Oriented Approach. It is not yet fully developed or refined, and efficacy studies are needed. It is also difficult to simulate natural environments or some work and leisure tasks in many clinical settings. As therapy clinics are remodeled and new clinics are designed, the potential exists to create more natural environments in the hospital. This limitation suggests that therapy interventions should ideally occur in clients' home, school, leisure, and work

settings whenever possible. The increased pressure to shorten hospital stays and the increased development of community-based treatment programs should support this trend. Another limitation of this approach relates to communication problems when using concepts that originate outside of occupational therapy and the testability of an approach based on abstract, complex ideas (Horak, 1991).

Future Directions

All treatment approaches evolve over time. Clinical practice and research will continue to test the assumptions and treatment principles of this approach. Some assumptions and principles will be supported and developed further. Others will not be supported and may be dropped or modified. The OT Task-Oriented Approach offers occupational therapists new ideas about the remediation of motor behavior problems. Basic and clinical research is needed. Development of evaluation tools and measures of change is critical. Identification of critical factors influencing occupational performance and measures of motor behavior will lead to more effective treatment strategies. Further testing of the assumptions and treatment principles with persons having CNS dysfunction and other motor behavior problems will provide additional support for its use in practice.

CASE EXAMPLE

Mr. B.: Application of the OT Task-Oriented Approach

Occupational Therapy Intervention Process

Patient Information

Mr. B., a 55-year-old man, had a left cerebral vascular accident with resultant right hemiparesis 6 months ago. He is on disability status from his job as an administrator at a junior college. His goal in outpatient rehabilitation is to participate in a trial of the student counseling aspect of his administrative job to determine whether he has potential to return to work. Mr. B.'s medical and social histories are further described in Chapter 6.

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist's Internal Dialogue

"I believe Mr. B.'s right hemiparesis is a significant barrier to his occupational functioning at the college. In addition, I assume his current job requires efficient and effective performance. I wonder about current features of the environment that support and limit current task performance. I think that Mr. B. has accurately identified critical tasks that are important in his role as worker."

Patient Information (cont'd)

Develop intervention hypotheses

“I hypothesize that targeted remediation interventions, compensation strategies, and modification of the physical and social contexts will assist Mr. B. in achieving optimal task performance.”

Select an intervention approach

“I will develop an intervention plan that emphasizes both compensation and remediation to improve task performance. I know from the evidence that he is at risk for learned non-use of his right upper extremity and that he may have muscle weakness that interferes with performance. I will provide Mr. B. with opportunities to practice the actual tasks important in his job and related tasks that may improve strength in targeted muscle groups. I will also want to examine the physical and social contexts to determine their influence on task performance.”

Reflect on competence

“I have a lot of ideas already about intervention strategies I want to explore with Mr. B. I realize I don't have very much information on expectations for performance in his job or the college's support for gradual resumption of his duties. I will also need more information on ADA policies and to refer Mr. B to his human resources department.”

Recommendations

The occupational therapist recommended three 1-hour treatment sessions at the college. The first session was to take place immediately. The second session would take place after supplies and furniture arrived, and the third session would take place about a week after the second session. (Separate recommendations were developed for other tasks related to his role as mediator.)

OT will work on tasks related to Mr. B.'s role as mediator in student issues. The following tasks were identified as important for success in this role: contact student to gather information and set up meeting; review documentation; meet the student in a conference room; discuss issue with student; document discussion; return to office; and write, copy, and send report on the outcome to student and others as needed.

It was agreed that documenting the discussion during the meeting was a critical component of the role and had to be addressed. During a simulation of a meeting, a number of problems related to performance of this task were evident: slow movement in bringing his chair close to the table; slow movement in bringing his arm to rest on top of the table; slow movement and limited endurance in grasping a regular pen; and decreased speed and accuracy and increased variation in cursive writing.

Critical factors impairing performance were the weight of the conference room furniture, decreased strength (power) in shoulder flexion, and decreased strength (power) and endurance in palmar pinch. Critical factors suggesting improved future performance were adequate budget for needed supplies and furniture, Americans with Disabilities Act support for return to work, desire to appear capable to handle the task, good cognitive skills, and supportive secretary.

Consider the patient's appraisal of performance

“I think that Mr. B. can make significant progress toward his goals within a short period of time. He seems highly motivated to improve task performance so he can go back to work. I have hope that occupational therapy will make it possible for Mr. B. to return to work at least on a part-time basis. At this point, the primary unknown is the level of performance that is necessary to meet expectations of the job.”

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

Summary of Short-Term Goals and Progress

The occupational therapist and Mr. B. established the following short-term goals. At the end of two sessions, Mr. B. will independently (1) adjust furniture in the conference room to prepare for task performance; (2) use a tape recorder to record the discussion; and (3) record notes during a 5-minute discussion with sufficient completeness and accuracy for development of a report.

During the first session, a conference room chair with adjustable height, wide armrests, and swivel seat was ordered. A tape recorder with voice activation, adjustable speed, and an internal microphone was requisitioned. Felt-tip pens with a textured grip were acquired. Several adapted pens and pen holders were lent to Mr. B. for a trial period. A practice session of writing using various pens and grasps was conducted. Mr. B. also helped design a home program of additional tasks that would strengthen targeted muscle groups in the right hand. The tasks included reaching for the spices needed for each meal, organizing cupboards, buttering bread, and writing down recipes.

During the second session, Mr. B. practiced a variety of ways to position himself for efficient writing. He learned to adjust the chair and use the swivel feature to position the chair close to the table before sitting. When moving from standing to sitting, Mr. B. could use his right arm as an assist by placing it on the table as he lowered himself. Mr. B. was instructed in and practiced operation of the tape recorder. Use of the left hand was better for manipulation of the small buttons on the recorder when efficiency in performance was needed. The occupational therapist observed Mr. B.'s right-handed writing using different devices and timed (1) bringing right arm from lap to table, (2) picking up pen, and (3) completing specified writing task. Summary feedback was provided after each performance. The home program was adjusted to promote practice of positioning self and operating the recorder and to increase the task demands related to targeted muscle groups. Finally, the occupational therapist worked with Mr. B. and the secretary to develop a template and some codes for recording discussions and reducing the writing requirements during the discussion.

During the third session, Mr. B. demonstrated all components of the task. He practiced variations in task performance. Mr. B. was instructed in strategies for analyzing his own performance. Increased speed in bringing the right arm from the lap to the table was noted. Movement time for picking up the pen was still slow. It was agreed that the left hand would pick up the pen and hold it vertical to allow an easier and quicker grasp by the right hand. The right palmar pinch had increased in strength and endurance sufficiently to enable completion of a 10-minute writing task with the felt-tip pen. The home program was adjusted to promote practice of use of codes in simulated discussions and to continue work on tasks related to targeted muscle groups.

Assess the patient's comprehension

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

"I think Mr. B. didn't fully realize the environmental supports that were available to improve his task performance. He had been frustrated with his speed of writing and didn't think he could adequately record information during a meeting. We talked about the combinations of strategies he could use to continue to work on improving his motor performance and, in the mean time, 'get the job done.' His interest in finding related tasks to perform at home made it easy to develop a home program."

"By the end of the second session, I could tell that Mr. B. was pleased to have smoother movements and successful strategies during a simulated meeting task. Mr. B. was also fortunate to have a supportive secretary who knew his responsibilities and communication style. They seemed eager to try working with the template and codes and had some of their own ideas on possible practice scenarios before a real meeting."

"I really felt that Mr. B. was more confident about resuming this important task of his job. The college was very supportive of Mr. B. working a few hours a day on selected tasks as a trial. Mr. B. seemed ready to resume responsibility for general student meetings that were routine in nature. I was glad he was taking it slow at work. I think that engaging in a variety of tasks will help Mr. B. discover his potential for movement in all his life roles."

Next Steps

Within 4 weeks, Mr. B. will independently record notes during a 15-minute discussion with sufficient completeness and accuracy for development of a final report.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. B. has learned some effective strategies for one of his tasks at work. More importantly, he is more engaged in learning about his own movement capabilities and performance as well as developing plans to improve performance in others tasks. I would like to meet with Mr. B. on a periodic basis to help him solve problems he encounters in different situations and reevaluate his motor performance.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Application of the OT Task-Oriented Approach

What information could you use to determine whether Mr. B.'s optimal performance of the writing task is with his left or right hand?

What other personal or environmental factors might influence Mr. B.'s performance in a discussion with a real student (see assessment of Mr. B. in Chapter 6)?

What might be some future changes in the personal or environmental factors influencing performance given what you know about Mr. B.?

How would you determine when performance is optimal and when to discontinue treatment for this particular goal?

SUMMARY REVIEW QUESTIONS

1. What are the treatment principles of the OT Task-Oriented Approach?
2. What does *attractor* mean? Describe the characteristics of the different movement patterns illustrated by Figure 22-1 in terms of attractor states. Give examples of these patterns that might be observed in clients who are attempting to achieve functional goals.
3. What are optimal and less than optimal times for producing a change in motor behavior?
4. What are some strategies for making the treatment process more client centered and unique to the characteristics of the person and environment?
5. What is the role of the client in the OT Task-Oriented Approach? What is the role of the therapist?
6. How is change in motor behavior measured?
7. What are some possible measures of performance, and how are they important in determining whether optimal performance is achieved?
8. What are critical variables (i.e., control parameters) or systems of the person and environment, and how should they be used in treatment to facilitate optimal performance?
9. What are the characteristics of skilled and optimal performance, and how can therapists facilitate development of these characteristics in their clients?
10. Describe feedback that facilitates development of skill in performance and an optimal solution to a motor problem.
11. Why are natural objects and environments important to use in finding the optimal solution for a motor problem and developing skill in performance?

Evidence Table 22-1 Best Evidence for Occupational Therapy Practice Regarding Aspects of the OT Task-Oriented Approach

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Use of real objects	Condition 1: reach to scoop coins off table; condition 2: reach forward without object present; setting: laboratory.	14 subjects with stroke: 8 with chronic LCVA, 5 with RCVA, 1 with other; 24 healthy subjects. Mean age was 61.8 years for stroke subjects and 63.2 years for healthy subjects.	10 trials/condition within 1 day.	IC1c	Yes. Better reaching movements when objects present on 4/5 kinematic variables ($p < 0.01$).	Mean effect over 5 variables: $r = 0.63$. Speed: $r = 0.70$; directness of movement: $r = 0.72$; smoothness: $r = 0.66$; pre-organization of movement: $r = 0.75$.	Wu et al., 2000
Use of natural objects with functional information	Condition 1: enriched affordance (reach to food chopper to chop mushroom); condition 2: impoverished affordance (reach to disguised food chopper and push handle down); setting: laboratory.	14 subjects with stroke: 8 with chronic LCVA, 5 with RCVA, 1 with other; 24 healthy subjects. Mean age was 61.8 years for stroke subjects and 63.2 years for healthy subjects.	10 trials/condition within 1 day.	IC1c	Yes. Better reaching movement for affordance on 3/5 kinematic variables ($p < 0.05$).	Mean effect over 5 variables: $r = 0.44$. Speed: $r = 0.54$; directness of movement: $r = 0.47$; smoothness: $r = 0.58$.	Wu et al., 1998
OT in natural environment	Experimental group: OT in home; patients practice between OT visits; leisure activities encouraged. Control group: Routine, existing services.	N = 185 acute, not hospitalized subjects (LCVA: 80; RCVA: 85; other: 20). Mean age = 74.3 years; attrition = 12%.	1–15 visits (mean = 5.8); 24–90 minutes per visit (mean = 52 minutes) for 5 months.	IA2b	Yes. Experimental group had better ADL and IADL ratings on 3 scales ($p < 0.01$) than the control group.	Nottingham EADL Scale: $\phi = 0.18$; Handicap scale: $\phi = 0.15$; Barthel Index: $\phi = 0.22$.	Walker et al., 1999

CHAPTER 23

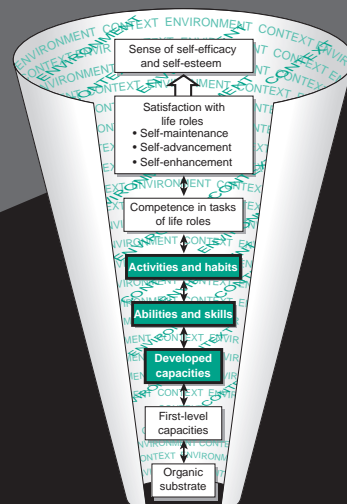

Optimizing Motor Skill Using Task-Related Training

Joyce Shapero Sabari

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Identify key concepts and principles from movement science that have influenced the use of task-related training, as described by Carr and Shepherd.
2. Describe the key factors that contribute to optimal movement and explain how therapeutic interventions can influence each of these key factors.
3. Interpret scores from the *Motor Assessment Scale* and practice using this tool to assess motor performance.
4. Analyze movement during functional task performance to determine occupational therapy treatment goals.
5. Develop individualized treatment plans to assist patients in reaching their optimal motor function in the areas of balance, walking, standing up and sitting down, and reach and manipulation.

Glossary

Glossary

Adaptive features—Physiological, mechanical, and functional changes that develop as a person’s neuromuscular system attempts to function within the constraints of negative features associated with CNS dysfunction.

Attractor state—Preferred pattern of organization within a system.

Control parameter—Variable that, when changed, will influence changes in a system’s pattern of organization. The term *regulatory condition* is used to describe control parameters within the task or environment.

Degrees of freedom—Number of elements that are free to vary within a system and hence must be controlled.

Kinematics—Description of movement in terms of direction, speed, and position of body segments.

Kinetics—Description of movement in terms of forces required.

Negative features—Losses in motor function directly attributable to CNS pathology.

Positive features—Exaggerations of normal phenomena after CNS pathology due to release of primitive centers from inhibitory hierarchical control.

Practice—Opportunity to develop skill through engagement in tasks that require problem solving and implementation of effective motor strategies.

Postural adjustments—Automatic, anticipatory, and ongoing muscle activation that enables individuals to maintain balance against gravity, optimal alignment between body parts, and optimal orientation of the head, trunk, and limbs in relation to the environment.

Skill—Goal-directed patterns of movement that efficiently address the spatiotemporal demands of a task.

Motor impairments are significant obstacles to the desired achievement of occupational and role performance in many individuals who have sustained disease or damage to the central nervous system (CNS). Occupational therapists provide intervention to assist these people in (1) optimizing their motor function and (2) integrating their improved motor skills into enhanced performance of functional activities that provide independence and meaning to their daily lives.

Research literature in neuroscience (Nudo, 2003; Pascual-Leone, 2001) and movement science (Schmidt & Lee, 2005; Shumway-Cook & Woollacott, 2000) provides consistent support for the efficacy of task-oriented **practice** in promoting motor skill and neural plasticity in humans with and without movement impairments due to CNS dysfunction. A core, historical assumption of occupational therapy practice, that engagement in specially designed therapeutic activities can improve motor function, is now embraced by every rehabilitation discipline. Carr and Shepherd, Australian physical therapists with doctoral degrees in movement science, have articulated and tested a coherent approach to task-related training in neurorehabilitation for the past 25 years (Carr & Shepherd, 1980, 1983, 1987, 1998, 2003). Their goal, along with others who advocate evidence-based rehabilitation, is to break away from the mid-20th century practice of offering a smorgasbord of treatment methods, from which therapists might choose the approach that personally appeals to them. Rather, Carr and Shepherd base their treatment model on published theoretical and outcomes evidence and present specific guidelines to direct patient treatment. Not all of Carr and Shepherd’s treatment suggestions are new. Rather, it is the coherent organization of their presentation and their ongoing modifications in response to theoretical and out-

comes research that make their published work so valuable to occupational therapy and physical therapy practitioners. Carr and Shepherd’s ideas are entirely compatible with the Occupational Functioning Model and the OT Task-Oriented Approach, presented in Chapter 22. A major difference is that Carr and Shepherd provide specific guidelines for assessing and treating deficits in motor performance but do not discuss guidelines for enhancing individuals’ participation in occupations or social roles.

Carr and Shepherd’s specific strategies for helping individuals reach optimal potential in motor control provide a foundation for a critical component of occupational therapy intervention. These strategies are particularly applicable to individuals who are coping with residual motor impairments after stroke (Carr & Shepherd, 2003) but may also be useful in interventions with clients who face challenges presented by traumatic brain injury, multiple sclerosis, or Parkinson’s disease (Carr & Shepherd, 1998).

Clients who demonstrate potential to improve motor control deserve the opportunity to learn to perform motor tasks with efficiency, fluidity, and versatility. Carr and Shepherd’s work provides occupational therapists with practical guidelines for the following:

- Assessment of motor function during task performance
- Analysis of motor performance to determine key limiting factors that are amenable to change through therapeutic intervention
- Prevention or reduction of these key limiting factors through direct intervention and client education
- Design of activities to be used as therapeutic challenges that stimulate development of effective movement strategies

- Adaptation of the physical environment to promote maximum function by each individual
- Assistance for individuals in developing strategies for approaching and mastering the motor challenges of new activities they may wish to perform in the future.

THEORETICAL FRAMEWORK

The framework for task-related training includes the dynamical systems theory of motor control, plasticity of the CNS, and the maladaptive biomechanical changes that occur after CNS injury. Principles of motor learning and biomechanics guide the therapist in structuring the therapeutic environment to maximize patients' recovery of motor function.

Dynamical Systems Theory and CNS Plasticity

A principle of dynamical systems theory, described in Chapter 6, is that organisms demonstrate an inherent tendency to self-organize throughout life (Perry, 1998). Plasticity (Boller, 2004) is a system's capacity to reorganize after disruption and to adapt to functional demands. Although damaged neural tissue does not structurally regenerate, plasticity in the mammalian CNS has been well documented (Ward, 2004). Neuroscience research (Calautti & Baron, 2003; Chen, Cohen, & Hallett, 2002) has shown that functional improvements after brain lesions are associated with changes in metabolic activity or patterns of neural connections in brain regions that were previously inactive during performance of the function under study. A critical factor common to all situations in which CNS plasticity has been observed is the presentation of environmental opportunities for animal or human research participants to attempt to perform functional tasks previously mediated by the impaired system (Briones, Klintsova, & Greenough, 2004; Johansson, 2003). Environmental challenges serve as the impetus for dynamic reorganization of an injured CNS.

Carr and Shepherd assume that therapeutic challenges have the potential to influence how a person's neuromuscular system will reorganize itself after injury to the CNS. Furthermore, they recognize that voluntary movements are initiated by functional task goals (Willingham, 1998) and influenced by the spatial and force characteristics of goal objects (Trombly & Wu, 1999; Wu et al., 2000). Therefore, functional task demands are used instead of exercise to provide graded motor challenges.

Dynamical Systems Theory: Attractor States and Control Parameters

Chapters 6 and 22 introduce the term **attractor state**, which refers to a preferred pattern. People develop preferred

movement patterns for various categories of motor performance. Attractor states for activities ranging from handwriting to a golf swing cast a unique and identifiable imprint on each individual's style of performance.

The flexibility of an attractor state is characterized, in a schematic presentation, by the depth of its well (see Fig. 22-1). Movement patterns with shallow wells are extremely unstable. They are inconsistent; they vary each time the task is performed. Movement patterns with deep wells are extremely stable. Deep well patterns make it difficult for the person to achieve versatility in task performance. Neither shallow nor deep attractor wells allow for optimal motor function. When one's neuromuscular system is functioning efficiently, the preferred patterns are characterized by attractor wells that are deep enough to allow for consistent performance but shallow enough to allow sufficient flexibility to deal with varying task and environmental demands.

Control parameters are variables that, when changed, influence changes in motor behavior (Perry, 1998). External control parameters, such as task requirements or features in the environment, frequently elicit variations in performance. In the case of efficient handwriting, the type of pen and the writing surface influence a person's motor strategies for executing the task. Internal control parameters, such as body alignment, muscle length, and muscle strength, also influence motor behavior. Postural asymmetry or mobility limitations impose constraints that limit a person's choices regarding motor performance. Although Carr and Shepherd do not typically use the terms *attractor states* and *control parameters*, Figure 22-1 illustrates how these concepts are critical to understanding and implementing their approach. Early in the intervention, internal control parameters for each individual are identified as obstacles to efficient movement. Interventions for preventing or reducing these obstacles to efficient movement are discussed later in this chapter.

Impairments of Interest to Rehabilitation Professionals

Typically, neuroscientists, physicians, and therapists have categorized the motor characteristics of CNS dysfunction as **positive features** or **negative features**. Positive features are exaggerations of normal phenomena due to release of spinal or brainstem reflexes from hierarchical inhibitory control. Positive features of stroke and brain injury include spasticity and hyperreflexia. In the latter decades of the 20th century, medical and therapy professions had considered positive features to be the major obstacle to improved clinical function, but no clinical or experimental evidence supports this view (Carr, Shepherd, & Ada, 1995). Furthermore, research findings are increasingly supporting the view that negative features of brain dysfunction are more important than positive features in causing motor disability. Negative features, which include weakness, fatigability, slowness, and impaired dexterity,

are due to impairments in recruitment and firing rate modulation of motor neurons (Ada et al., 1996).

Carr and Shepherd introduced a third category of features associated with upper motor neuron dysfunction. **Adaptive features** are physiological, mechanical, and functional changes in muscle and other soft tissues that develop in response to immobility, disuse, and attempts to move within the constraints of weakness. For occupational therapists, who typically use the term *adaptive* to connote behaviors that are effective in coping with environmental demands, Carr and Shepherd's term may seem misleading. *Secondary impairment*, which indicates areas of dysfunction that are not directly caused by the neurological pathology (Sabari, 2004), is synonymous with Carr and Shepherd's term *adaptive features*. When muscles are immobilized in their shortened position, physiological changes include the loss of sarcomeres and remodeling of connective tissue (Carr, Shepherd, & Ada, 1995; O'Dwyer, Ada, & Neilson, 1996). Subsequently, muscles undergo mechanical changes of shortening and stiffening. As illustrated in Figure 23-1, abnormal movement patterns are not necessarily manifestations of spasticity or reflex disinhibition. Rather, they can be explained as functional adaptations to movement demands in the presence of negative symptoms.

Carr and Shepherd advocate early therapeutic intervention after stroke or brain injury to prevent or minimize the adaptive features of CNS dysfunction. It is particularly essential to prevent muscle stiffness and shortening through early passive and active mobilization.

The Rehabilitation Environment

Above and beyond the actual therapeutic procedures that are employed, environmental factors play a critical role in determining the effectiveness of interventions. Carr and Shepherd suggest practical ways to structure the rehabilitation environment for enhanced efficacy in improving

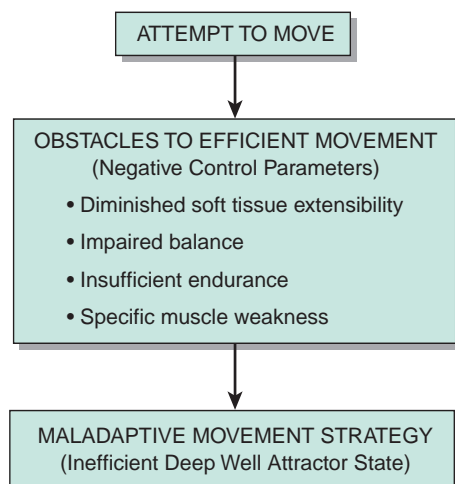

Figure 23-1 Development of maladaptive strategies.

motor skill. These factors include the therapeutic relationship between patient and therapist, the therapist's effectiveness at focusing a patient's attention on the most salient features of motor performance, and the type and amount of ongoing practice.

Therapist as Coach

The patient-therapist relationship in task-related training is an active, collaborative mentorship with regard to motor performance. Therapists must have extensive knowledge about the **kinetic** and **kinematic** features of movement, both as performed by individuals with intact neuromuscular systems and as frequently observed in people demonstrating specific motor dysfunction, such as hemiparesis or ataxia. Therapists apply this knowledge when assessing performance, setting goals, structuring practice sessions, and providing feedback and instruction. The therapist's critical goals as coach are (1) to encourage performance of the most important mechanical features within a given category of motor tasks and (2) to discourage behavioral adaptations that have limited effectiveness.

Focusing Attention

As coach, a therapist's goal is to structure the practice sessions so that the patient focuses attention on those features of the task that are most salient for learning. An early step in the process of learning a motor skill is to identify the key components of the action. At this stage, demonstration and instructions, which focus on one or two salient points, are important in directing the patient's efforts. Learning proceeds most smoothly when the patient has a clear idea of the motor goal and which strategies are appropriate or inappropriate for reaching that goal. Carr and Shepherd recommend that therapists routinely ask patients to describe or demonstrate, with another body segment if necessary, the specific movements required to achieve a task. This allows therapists to understand what patients think they are being asked to do. Instructions can then be modified to ensure that each patient and therapist is actually working toward the same goal.

Once an individual has internalized this "model" of an action, however, research indicates that the focus of attention shifts away from the details of the action to the external goals of the current activity (Fasoli et al., 2002; Wulf et al., 2000). At this stage, it may actually be detrimental to focus a patient's attention on the details of performance or to the way the movement "feels." Rather, reflecting a traditional occupational therapy tenet, Carr and Shepherd suggest that the task goal and control parameters inherent within the task objects be used to shape the intended kinematics of a movement sequence. This textbook provides many examples of applying this principle.

Addressing members of the physical therapy profession, Carr and Shepherd caution against an over-reliance on focusing patients' attention on abstract movements,

such as shifting weight or moving one's arm through a specific trajectory. Rather, consistent with occupational therapy practice and research (Hsieh et al., 1996; Ma et al., 1999; Nelson et al., 1996), they recommend the creative, individualized organization of control parameters within each task environment to focus a patient's practice of intended movement sequences. Similarly, Carr and Shepherd caution against excessive physical handling as a technique to teach patients the model of an action. Instead, they advocate the use of temporary adaptive aids designed to allow for practice with less need for physical support and manipulation by the therapist. Carr and Shepherd refer to this approach as "modifying the task or environment." Occupational therapists have long been familiar with this component of therapeutic intervention, which Trombly (see Chapter 1) terms "occupation-as-means." Occupational therapists must use, and report outcomes of, our skills in modifying the task and environment to elicit optimal practice opportunities for clients' emerging capacities and skills.

Practice

Theories about motor skill acquisition emphasize the active problem-solving aspects of learning (Schmidt & Lee, 2005). Correspondingly, Carr and Shepherd view the individual as an active participant whose major goal in rehabilitation is to relearn effective strategies for performing functional movement.

Instead of learning specific movements, participants in Carr and Shepherd's program learn general strategies for solving motor problems. Rather than performing exercises without functional goals, patients practice tasks that require mild variations in movement patterns during successive repetitions. Furthermore, limb movements and **postural adjustments** are always learned simultaneously and in the context of task performance. Whole task performance is emphasized, rather than practicing component parts of tasks.

Carr and Shepherd believe that practice is a critical component to motor skill development. Patients learn what they practice, so it is important that they not revert to compensatory movement strategies during daily activities outside of therapy. Carr and Shepherd emphasize that significant motor improvements are achieved only if patients practice movement according to the therapist's guidelines throughout each day. Therefore, the therapist structures a practice program for each patient to reinforce activities performed during therapy sessions. Friends and relatives learn effective ways to assist the patient in this program. The therapist provides clear written directions, photographs, drawings, and/or performance checklists to ensure that the additional practice is consistent with the motor strategies promoted during therapy. Group circuit training classes can be an effective way to increase the amount of training and practice, while also adding both competitive and cooperative components to the training

situation (McNevin, Wulf, & Carlson, 2000). Carr and Shepherd (2003) provide extensive guidelines and photographs from the outpatient circuit training classes for upper and lower limb rehabilitation they developed with colleagues at New South Wales Hospital in Australia.

Treatment is task specific and based directly on movement analysis of the patient's performance of that task. The therapist continues to reevaluate and analyze the patient's performance throughout each treatment session to make ongoing decisions about intervention. If performance does not improve, the therapist checks the original analysis of the patient's problems and considers whether the training approach should be modified. Finally, therapy includes opportunities for task analysis and motor problem solving through the introduction of novel activities that require application of a particular motor strategy the person has learned in a different context.

Self-care and leisure activities provide logical opportunities for task-based practice. Too often, occupational therapists prescribe universal methods for activities of daily living that contradict our goals for optimum motor performance. Unless balance and limb function are routinely challenged during daily activity performance, there are no environmental challenges to stimulate brain plasticity. Unless patients have opportunities for routine practice of motor skills required for balance and functional use of their affected limbs, time spent during therapy sessions will have little impact. Therefore, occupational therapists must design safe, individualized methods for *each* patient that continually include that person's emerging capacities into daily self-care and leisure performance.

INTERVENTION

The next section presents the general framework for intervention using task-related training and more specific information for treatment of four key areas of functional movement: standing up and sitting down, balance, walking, and reaching for and manipulating objects.

General Framework

An understanding of factors that contribute to optimal motor performance (Fig. 23-2) is key to applying Carr and Shepherd's framework to occupational therapy intervention. Implicit in their model is a recognition that positive and negative features of motor impairment may not be amenable to change through rehabilitation. Therapeutic challenges can certainly assist patients in learning to use their available muscle function, but no known interventions can facilitate muscle firing in the absence of required physiological substrates. Fortunately, therapists can play a critical role in preventing and reducing the adaptive features associated with CNS motor dysfunction. In addition,

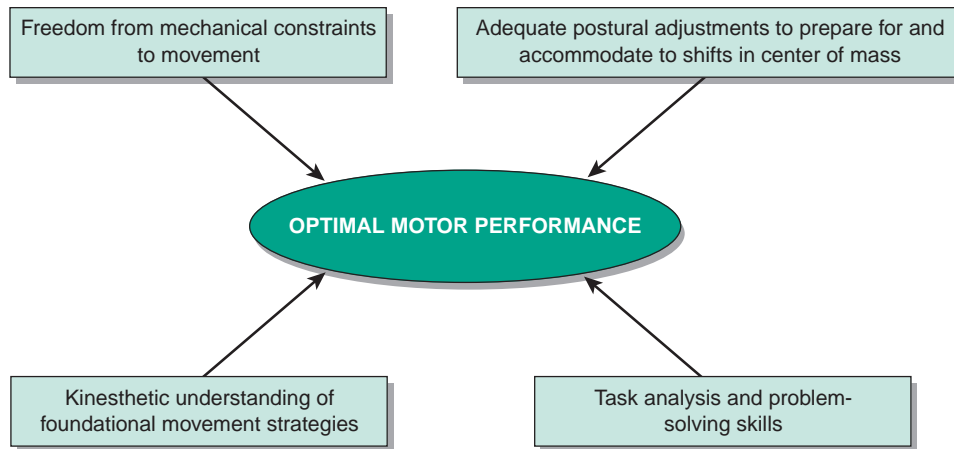

Figure 23-2 Contributing factors to optimal motor performance.

in our role as coaches, we can assist patients in developing cognitive skills that will enable them to optimize their available levels of motor control.

Carr and Shepherd (2003) present a framework for assessing and improving four general categories of motor performance: balance, walking, standing up and sitting down, and reaching and manipulation. For each of these areas, they provide these guidelines for therapists:

- Anticipate, prevent, and reduce mechanical constraints that are likely to interfere with performance.
- Understand the kinematics and kinetics that research has shown to accompany typical performance by individuals with intact musculoskeletal function.
- Understand how research has shown the kinematics and kinetics of performance to differ in individuals with CNS dysfunction.
- Understand how postural adjustments are integrated into efficient task performance.
- Structure activities to provide graded challenges to anticipatory and ongoing postural adjustments.
- Structure activities that help patients develop a kinesthetic understanding of fundamental movement strategies.
- Structure activities that help patients develop motor task analysis and problem-solving skills.

Evaluation and Treatment Planning

As with the OT Task-Oriented Approach, clinical evaluation is a detailed analysis of the patient's performance of selected tasks in each of the four categories of motor performance. Therapists observe patients as they perform functional activities and compare performance with critical kinematic features that are associated with these tasks (Procedures for Practice 23-1). This observation enables

therapists to develop individualized treatment plans that include the following:

- Stretching exercises to lengthen shortened muscles and enhance mobility at body segments where limitations were noted
- Environmental modifications or coaching to improve postural alignment
- Exercises and activities designed to strengthen muscles that are innervated but weak
- Verbal and kinesthetic instruction about key foundational strategies to improve performance
- Practice of key strategies in a variety of other tasks
- Practice of the observed task in varying conditions, incorporating newly acquired mobility, muscle strength, and foundational strategies

PROCEDURES FOR PRACTICE 23-1

Assessment

During task observation, the therapist assesses performance for the following:

- Evidence of mobility impairments at specific joints
- Missing or limited components (e.g., lack of anterior pelvic tilt, hip flexion, ankle dorsiflexion when rising to stand)
- Incorrect timing of components within a movement pattern (e.g., inappropriate interplay among extrinsic and intrinsic finger muscles during attempts at grasp)
- Evidence of weakness or paralysis of specific muscles (e.g., weakness in quadriceps on attempts to stand up)
- Compensatory motor behavior (e.g., elevation of the entire shoulder girdle on attempts to reach forward)

Patients are active participants in analyzing their own performance. This allows therapists to see how well each person can detect movement problems. In addition, this self-analysis encourages individuals to develop insight about their own movement, develop problem-solving skills, and understand the goals of the treatment program.

Although Carr and Shepherd recommend using a qualitative assessment style as a guide to treatment planning, they caution that the validity of these observations and subsequent analysis is dependent on a clinician's knowledge of normative biomechanics. With appropriate educational background, we *can* observe the kinematic characteristics of movement. We *cannot*, however, observe critical kinetic characteristics of movement, such as muscle forces or ground reaction force. Recognizing that kinetic assessments are not available in clinical environments, Carr and Shepherd developed a quantitative scale, based on kinematic observations. The *Motor Assessment Scale (MAS)* (Carr et al., 1985, revised: J. Carr & R. Shepherd, personal communication, 1994) consists of eight movements: supine to side-lying, supine to sitting on the edge of the bed, balanced sitting, sitting to standing, walking, upper arm function, hand movements, and advanced hand activities (Procedures for Practice 23-2). As indicated in Procedures for Practice 23-2 and discussed in Chapter 6, each motor activity is scored on a 7-point ordinal scale ranging from 0 to 6. A score of 6 indicates optimal behavior. The MAS has been successfully used as an outcome measure in published efficacy studies of clinical intervention (Ada & Westwood, 1992; Dean & Mackey, 1992; Monger, Carr, & Fowler, 2002; Nugent & Schurr, 1994; Thickbroom et al., 2004). Positive aspects of the tool include its ease of administration, high reliability (Poole & Whitney, 1988), high concurrent validity with selected items on the *Fugl-Meyer Assessment* (Poole & Whitney, 1988), and its emphasis on functional task performance. In addition, occupational therapists have found that use of the MAS, with its structured format of task observation, is helpful in focusing and sharpening their observational skills (Kieran, Lim, & Sabari, 1999). A study of the upper limb items, using Rasch analysis, provides support for the scoring criteria hierarchy on the upper arm item but indicates a need for revising the scoring criteria hierarchies for the two items of the MAS that assess hand function (Sabari et al., 2005).

Balance

Balance is the ability to maintain an upright posture against the dynamically changing effects of gravity on our body segments. Postural control mechanisms enable us to maintain balance by ensuring that our body's center of mass remains within the base of support. During daily activities, a person's center of mass can be displaced in three ways: (1) by an external force applied to the body, as occurs during contact sports; (2) by external movement of the support surface, as occurs when we sit or stand in a mov-

ing vehicle; and (3) during performance of activities requiring self-initiated movement of the head, limbs, or trunk (Carr & Shepherd, 2003).

Typically, for persons with motor impairments due to CNS dysfunction, balance challenges arising from self-initiated movement are more important to daily function than are balance challenges arising from external perturbations. Although traditional neurobehavioral approaches have focused on improving postural reactions to external perturbations, there is no evidence that these improvements have any positive effect on balance during self-initiated postural challenges.

Postural adjustments are both task and context specific. Studies have shown that muscle activation patterns for balance control vary according to (1) the position of the person, (2) the task being performed, (3) the context in which the activity occurs, and (4) the person's perception of which body part is in contact with the more stable base of support (Dean, Shepherd, & Adams, 1999a, 1999b; Nashner & McCollum, 1985). Therefore, Carr and Shepherd advocate that postural adjustments be learned only in the context of task performance. Furthermore, balance training in one position or during performance of one task is not likely to generalize to improved postural control in other contexts (Shepherd, 1992).

Essential Features of Performance

Effective balance requires adequate function in sensory and motor systems (Procedures for Practice 23-3). Sensory processing of visual, vestibular, tactile, and proprioceptive information allows a person to maintain continuous and dynamic awareness about the body's center of mass and alignment between body segments. Muscle contractions of appropriate amplitude and timing allow for predictive and ongoing force production to match the changing influence of gravity during motor performance. Sufficient joint mobility and muscle length allow the necessary movements to be generated through their full ranges of motion.

Individuals with impairments in these areas are likely to develop adaptive strategies that may seem effective in the short run but that have long-term maladaptive influence on balance and other motor function (Procedures for Practice 23-3). When people feel unable to maintain their balance in posturally threatening situations, one such strategy is to constrain movement at selected body parts and thus decrease the number of motor elements, or **degrees of freedom**, the CNS must control. Individuals with postural adjustment deficits as a result of CNS dysfunction may feel insecure about their ability to maintain balance, even in routine sitting or standing positions. The strategy of fixating one's pelvis on the lumbar spine or the scapula on the thorax has short-term benefits for enhancing the person's sense of postural security. A negative consequence is that these patterns lead to soft tissue shortening and difficulty disassociating the scapula and pelvis

PROCEDURES FOR PRACTICE 23-2

Abridged Criteria for Scoring MAS

The score assigned on each item is the highest criterion met on the best performance of three. A 0 score is assigned if the patient is unable to meet the criteria for a score of 1.

Supine to Side-Lying to Intact Side

1. Pulls self into side-lying with intact arm, moving affected leg with intact leg.
2. Moves leg across actively and lower half of body follows. Arm is left behind.
3. Lifts arm across body with other arm. Moves leg actively; body follows in a block.
4. Actively moves arm across body; rest of body follows in a block.
5. Rolls to side, moving arm and leg; overbalances. Shoulder protracts and arm flexes.
6. Rolls to side in 3 seconds. Must not use hands.

Supine to Sitting on Edge of Bed

1. After being assisted to side-lying, lifts head sideways; cannot sit up.
2. Side-lying to sitting on edge of bed with therapist assisting movement.
3. Side-lying to sitting on edge of bed with standby help assisting legs over side of bed.
4. Side-lying to sitting on edge of bed with no standby help.
5. Supine to sitting on edge of bed with no standby help.
6. Supine to sitting on edge of bed within 10 seconds with no standby help.

Balanced Sitting

1. Sits only with support after therapist assists.
2. Sits unsupported for 10 seconds.
3. Sits unsupported with weight well forward and evenly distributed.
4. Sits unsupported with hands resting on thighs; turns head and trunk to look behind.
5. Reaches forward to touch floor 4 inches in front of feet and returns to starting position.
6. Sitting on stool, reaches sideways to touch floor and returns to starting position.

Sitting to Standing

1. Gets to standing with help (any method).
2. Gets to standing with standby help.
3. Gets to standing with weight evenly distributed and with no help from hands.
4. Gets to standing; stands for 5 seconds, weight evenly distributed, hips and knees extended.
5. Stands up and sits down with no help; even weight distribution; full hip and knee extension.
6. Stands up and sits down with no help 3 times in 10 seconds; even weight distribution.

Walking

1. Stands on affected leg with hip extended; steps forward with other leg (standby help).

2. Walks with standby help from one person.
3. Walks 10 feet alone. Uses any walking aid but no standby help.
4. Walks 16 feet with no aid in 15 seconds.
5. Walks 33 feet, picks up small sandbag from floor, turns around, walks back in 25 seconds.
6. Walks up and down four steps with or without an aid three times in 35 seconds. May not hold rail.

Upper Arm Function

1. Supine, protracts shoulder girdle. Tester places arm in 90° flexion and supports elbow.
2. Supine, holds shoulder in 90° flexion for 2 seconds. (Maintains 45° external rotation and 20° elbow extension.)
3. From position in level 2, flexes and extends elbow to move palm to forehead and back.
4. Sitting, holds arm in 90° shoulder flexion with elbow extended, thumb pointing up, for 2 seconds. No excess shoulder elevation.
5. Achieves position in level 4; holds for 10 seconds; lowers arm. No pronation allowed.
6. Standing, arm abducted 90°, with palm flat against wall. Maintains hand position while turning body toward wall.

Hand Movements

1. Sitting, lifts cylindrical object off table by extending wrist. No elbow flexion allowed.
2. Sitting, forearm in midposition. Lifts hand off table by radially deviating wrist. No elbow flexion or forearm pronation allowed.
3. Sitting, elbow into side, pronates and supinates forearm through three quarters of range.
4. Sitting, reaches forward to pick up 5-inch ball with both hands and puts ball down. Ball placement requires elbow extension. Palms stay in contact with ball.
5. Sitting, picks up plastic foam cup from table and puts it on table across other side of body.
6. Sitting, continuous opposition of thumb and each finger more than 14 times in 10 seconds.

Advanced Hand Activities

1. Reaches forward arm's length; picks up pen top; releases it on table close to body.
2. Picks up a jellybean from teacup with eight jellybeans and places it in another cup. Cups are at arm's length.
3. Draws horizontal lines to stop at a vertical line 10 times in 20 seconds.
4. Makes rapid consecutive dots with a pen on a sheet of paper. (Picks up and holds pen without assistance; at least 2 dots per second for 5 seconds; dots, not dashes).
5. Takes a dessert spoon of liquid to the mouth, without spilling. (Head cannot lower toward spoon).
6. Holds a comb and combs hair at back of head. (Shoulder is externally rotated, abducted at least 90°; head is erect.)

PROCEDURES FOR PRACTICE 23-3

Impairments Underlying Balance Dysfunction

Negative Features Affecting Balance Dysfunction

- Impairments in muscular force and timing
- Impairments in sensory processing (visual, tactile, proprioceptive, vestibular)

Adaptive Features Affecting Balance Dysfunction

- Avoiding all shifts in center of mass
- Shifting weight away from a paretic limb
- Using hands for support
- Stiffening the body
- Soft tissue shortening

from adjacent proximal structures. This lack of sufficient mobility at the limb girdles subsequently limits the normal kinematics of upper and lower extremity movement. Figure 23-3 illustrates how immobility and muscle shortening interact in a self-perpetuating cycle.

The strategies of shifting weight away from a paretic leg, unnecessarily widening the base of support, or using one's hands excessively for support present further obstacles to using and improving available muscle strength and sensory processing skills. In addition, they contribute to additional problems in gait and in using the upper limbs to their maximum potential. Task-related training seeks to prevent the development of these maladaptive strategies through the early introduction of techniques to enhance balance and postural security.

Assessment and Treatment

Balance is assessed through observational analysis as the person performs self-initiated movements in sitting and standing. These include the following:

- Looking in a variety of directions (e.g., up at the ceiling, behind oneself)
- Reaching forward, sideways, and down to the floor to pick up objects
- Walking in various conditions

Figure 23-3 Cycle of immobility and soft tissue shortening.

PROCEDURES FOR PRACTICE 23-4

Graded Task Demands to Improve Balance

Position of the Person

- Size and shape of base of support (foot placement, seating or standing surface)
- Initial alignment of body segments

Object Placement

- Position determines direction of weight shift; moving laterally more difficult than moving forward
- Distance

Object Characteristics

- Weight
- Size; greater challenge to balance when both hands must be used

Temporal Demands

- Stationary object—increasing demands on speed of performance
- Moving object—increasing the speed at which the object moves

Balance training overlaps with each of Carr and Shepherd's three other areas of functional performance. Patients are presented with activities that offer graded challenges to their ability to shift their center of mass over the base of support. Prior to activity engagement, the therapist ensures that joint mobility and postural alignment are maximized. Procedures for Practice 23-4 lists the critical activity elements that therapists manipulate in structuring activity-based balance training. These general guidelines provide occupational therapists with limitless possibilities for creative activity synthesis based on each patient's interests, goals, and level of function. The outcomes study (Dean & Shepherd, 1997) highlighted in this chapter's Research Note provides support for the clinical efficacy of these interventions.

Walking

Walking, a critical component of daily task engagement, is a reasonable expectation for many individuals with CNS dysfunction. Occupational therapists work with patients who wish to improve their performance in kitchen and bathroom activities and in leisure or work pursuits. In each of these contexts, the occupational therapist must help patients reach their optimal walking potential.

Essential Features of Performance

Successful walking requires production of a basic locomotor rhythm, support and propulsion of the body in the desired direction, dynamic balance control of the moving

RESEARCH NOTE 23-1

Abstract: Dean, C. M., & Shepherd, R. B. (1997). Task-related training improves performance of seated reaching tasks after stroke: A randomized controlled trial. *Stroke*, 28, 722–728.

After a stroke, the ability to balance in sitting is critical to independence. Although impairments in sitting balance are common, little is known about the effectiveness of rehabilitation strategies designed to improve it. The purpose of this randomized placebo-controlled study was to evaluate the effect of a 2-week task-related training program aimed at increasing reaching distance and the contribution of the affected lower leg to support and balance.

Twenty subjects, at least 1 year after stroke, were randomized to an experimental or control group. The experimental group participated in a standard training program involving practice of reaching beyond arm's length. The control group received sham training, which involved completion of cognitive-manipulative tasks within arm's length. Reach while sitting was measured before and after training using electromyography, videotaping, and two force plates. Variables tested were movement time, distance reached, vertical ground reaction forces through the feet, and muscle activity. Subjects were also tested on sit-to-stand, walking, and cognitive tasks. Nineteen subjects completed the study.

After training, experimental subjects could reach significantly faster and farther, significantly increase load through the affected foot, and increase activation of the affected leg muscles compared with the control group ($p < 0.01$). The experimental group also improved in sit-to-stand. The control group did not improve in reaching or sit-to-stand. Neither group improved in walking. This study provides strong evidence of the efficacy of task-related motor training to improve the ability to balance during seated reaching activities after stroke.

Implications for Practice

- After a stroke, sitting balance can be improved through opportunities to practice reaching to grasp objects with the unaffected hand under variable conditions.
- Providing patients with task-related challenges to use self-initiated balance adjustments is an effective method for improving sitting balance and performance in rising to stand.
- When self-initiated balance adjustments are not challenged, patients do not improve sitting balance or sit-to-stand.
- Individuals recovering from stroke need opportunities to sit without external supports and to challenge self-initiated balance adjustments by reaching to grasp objects, with variations in object location and weight, seat height, movement speed, and extent of thigh support on the seat.

body, and the ability to adapt movement to changing environmental demands and goals (Carr & Shepherd, 1998, 2003).

Research on individuals with no musculoskeletal impairments has revealed remarkable consistency among people in the kinematic aspects of gait. Patterns of muscle use, however, vary widely. Besides differing between subjects, the kinetics of gait may vary within a single subject, depending on walking speed and fatigue. Furthermore, a natural redundancy in the motor system for walking readily allows for compensation by stronger muscles when specific muscles are weak.

Walking forward in a uniform direction is achieved through repetitive performance of sequential gait cycles. Each cycle begins when the heel of one foot makes contact with the ground. As that leg supports the body weight, it rocks forward until its only ground contact is at the toes. Simultaneously, the other leg swings forward until its heel makes contact with the ground. Double support is the brief period when both feet are on the ground. Immediately after double support, the first leg swings forward while the second leg supports the body weight. One gait cycle is completed when the heel of the first foot touches the ground once again.

For purposes of description, the gait cycle for each leg is divided into a stance phase and a swing phase. Definition 23-1 shows the subdivision of these phases of the gait cycle. Basic knowledge about the motor requirements during each phase of the gait cycle guides therapists in their interventions for patients with CNS dysfunction.

The essential components of motor activity during the stance phase include extensor muscle activity at the hip, knee, and ankle; smooth alternation of eccentric and concentric muscular activity in knee and ankle muscles; muscle activity in the gluteus medius at midstance to prevent excessive downward tilt of the pelvis on the side of the swing-

DEFINITION 23-1

The Gait Cycle

Stance Phase

- Weight-load acceptance: from heel contact to foot flat on ground
- Midstance: from foot flat on ground to heel off of ground
- Push-off: weight moving forward onto toes and foot preparing to leave ground

Swing Phase

- Ltoff (early swing): leg swings forward with foot clearing the ground.
- Reach (late swing): leg decelerates and prepares for heel contact.

ing leg; and ongoing postural adjustments to balance the body mass over a dynamically changing base of support.

Since the goals of the swing phase are (1) to clear the foot from contacting the ground as the leg swings forward and (2) to prepare the leg to assume a stance position as it reaches the end of its swing forward in space, the essential components of motor activity during the swing phase are fluid pelvic mobility, including lateral pelvic tilt as weight is shifted from the current leg onto the other leg and pelvic rotation to allow the swinging leg to advance forward; sufficient hip, knee, and ankle (dorsi) flexion to shorten the leg for foot clearance as the leg swings forward; and knee extension and ankle dorsiflexion just prior to heel contact to ensure that the heel, rather than the flat foot or the toes, will strike the ground to initiate the stance phase.

Assessment and Treatment

Gait problems in stroke patients and others with neurological diagnoses are caused by impairments associated with the lesion as well as by secondary cardiovascular and musculoskeletal consequences of disuse, physical inactivity, and aging. Physical therapists determine initial walking goals based on observation and comparison of each patient's performance against the critical kinematic features of walking that have been determined through descriptive research. Although observational analysis cannot provide information about the kinetics of a person's gait, spatiotemporal and kinematic variables provide clues about the underlying kinetic dynamics.

Treatment goals are to prevent soft tissue shortening; improve muscle strength and control for support, propulsion, balance, and toe clearance; and improve rhythm and coordination during functional walking. Treatment methods include soft tissue stretching; active exercises to lengthen shortened muscles; strength training to improve force generation and speed of muscle contraction; step-up, step-down, and side-stepping exercises; and actual walking practice. Carr and Shepherd advocate early walking training using treadmills and, when necessary, harnesses providing partial body weight support (Carr & Shepherd, 2003; Shepherd & Carr, 1999). Treadmill training provides opportunities for practice at walking velocities that foster more efficient gait parameters than walking at slow speeds (Hesse et al., 2003; Visintin et al., 1998).

Consistent with their emphasis on training in a variety of environmental contexts, Carr and Shepherd advocate walking and stair climbing practice on a variety of surfaces, slopes, and naturalistic settings. Occupational therapists play a critical role in maximizing walking **skill** during our interventions that require the simultaneous performance of walking with carrying or pushing, as is inherent in naturalistic activities within home, work, and leisure environments. In addition, we can incorporate sideways, forward, and backward walking, as well as step-up and step-down practice into task-based training activities designed to challenge upper limb and balance skills.

Standing Up and Sitting Down

Carr and Shepherd argue that the stand pivot transfer is typically overemphasized in neurorehabilitation. For patients who demonstrate potential to walk, learning how to stand up and sit down has greater functional implications and is more natural to learn than traditional transfer techniques.

Treatment to enhance a patient's ability to stand up and sit down improves that person's sitting posture, sitting and standing balance, functional reach, and gait. Each of these aspects of motor performance demands ability to appreciate how one's own body alignment and dynamic movement affect one's center of mass. In addition, each of these categories of functional activity demands a balance of mobility and stability in the pelvis, trunk, and limbs.

Essential Features of Performance

There are two phases to the normal kinematics of standing up. During the pre-extension phase, or forward phase, the hips flex to move the center of mass forward (Shepherd & Gentile, 1994). The extension phase, or upward phase, begins at "thighs off" (TO). During this phase, the hips and knees extend to move the center of mass upward to final standing alignment. Each phase is characterized by kinematic and kinetic requirements. Force requirements are most important during the extension phase. These are met via contractions in the extensors of the ankle, knee, and hip. The kinetic requirements of standing up are similar to those of the stance phase during gait. To ensure that the limb does not collapse, a decrease in force at one joint can be compensated for by an increase at the other joints.

Several kinematic features during the pre-extension phase influence the amount of force needed during the extension phase. Forward foot placement has been found to interfere with both phases of standing up (Khemlani, Carr, & Crosbie, 1999; Shepherd & Koh, 1996). Therefore, Carr and Shepherd recommend that people with CNS movement dysfunction prepare for standing by placing their feet behind an imaginary perpendicular line drawn down from the knees, with the ankles at approximately 75° of dorsiflexion (Carr & Shepherd, 1998, 2003). Trunk position during pre-extension, determined by flexion at the hips, significantly affects the kinematics and kinetics of the extension phase. In subjects with normal movement, failure to flex forward at the hips lengthens the extension phase, increases muscle force requirements during the extension phase, and changes the order of movement during the extension phase from knee-hip-ankle to hip-knee-ankle (Shepherd & Gentile, 1994). Therefore, forward flexion at the hips is emphasized in treatment as a key element to standing up and sitting down.

Arm movement and speed of performance also affect the mechanics of rising to stand. Active arm flexion naturally accompanies the onset of leg extension and contributes to maximizing available extensor force in the

lower limb (Carr & Gentile, 1994). Forward motion of the arms and upper body assists in establishing momentum prior to the extension phase. This momentum decreases the amount of lower limb force required to lift the body up against gravity to the erect standing posture. Research evidence (Carr, Ow, & Shepherd, 2002) indicates that slower speed of performance, as measured by hip flexion velocity, decreases the potential effect of this momentum. To capitalize on this momentum, Carr and Shepherd recommend that patients learn to complete the task of standing up with no pause between the pre-extension and extension phases. Therefore, unless there are safety considerations, they advise that patients practice the task in its entirety.

Finally, Carr and Shepherd caution against using the common strategy of teaching patients to push down with their arms to assist themselves in standing up. Although this may be useful in the short run as a compensatory technique to reduce force requirements at the hip, knee, and ankle, it denies patients the opportunity to improve their muscle strength. Instead, Carr and Shepherd recommend raising seat height for individuals with weak hip and knee extensors to practice standing up and sitting down. As strength increases, lowering the seat height will provide progressive strength training to lower limb extensors (Carr & Shepherd, 2003).

Assessment and Treatment

Procedures for Practice 23-5 provides the essential factors of Carr and Shepherd's program for developing the ability to stand up. Passive muscle lengthening may be necessary if patients demonstrate mobility limitations in ankle dorsiflexion, knee flexion or extension, hip flexion or extension, or sagittal-plane pelvic motion. Whole-task practice

is important to assist patients in developing necessary sequencing and timing during functional performance.

Sitting down from standing has several similarities to standing up but is a different activity that must be practiced as well. No momentum to reduce force requirements is present, so additional muscle strength (particularly in knee extensors) is needed just before the body mass is lowered onto the seat. Carr and Shepherd recommend that, when learning to stand, patients should be instructed to stop the movement and reverse their direction for a few degrees. This will help them develop control over changing from concentric to eccentric muscle activity.

Reach and Manipulation

The arm and hand function as a single unit in reach and manipulation, with the hand beginning to open for grasp at the start of a reaching action (Hoff & Arbib, 1993). In many activities, the upper body, or even the entire body, is an integral component of this single coordinated unit. Clearly, reach and grasp are not exclusively upper limb activities. All reaching actions from sitting or standing are preceded and accompanied by postural adjustments. When objects are beyond the arm's reach, shifts in total body alignment contribute to functional performance.

Essential Features of Performance

Forward reach in sitting entails (1) anterior movement of the pelvis, (2) flexion of the trunk at the hips, and (3) active use of the legs to aid in balancing by creating an active base of support. Reaching sideways while sitting is more challenging than reaching forward, since the base of support is smaller. Reaching while standing requires (1) establishment of an appropriate base of support with one's feet and (2) shifting body weight and center of mass toward the direction of the goal object.

Therapeutic interventions for individuals with CNS dysfunction must inherently combine evaluation and treatment of balance with assessment and training of reach and manipulation. Carr and Shepherd caution against waiting until patients achieve a certain level of balance before introducing therapeutic tasks to improve reach and manipulation. Similarly, they caution against waiting until patients demonstrate a specified level of shoulder function before assessing for and providing treatment to improve hand skills.

Current Perspective for Conceptualizing Therapeutic Intervention

Traditionally, upper limb function after serious stroke or traumatic brain injury has been associated with poor outcomes (Nakayama et al., 1994). Carr and Shepherd suggest that several factors, in addition to the direct extent of neural pathology, have limited the effect of rehabilitation inter-

PROCEDURES FOR PRACTICE 23-5

Sit-to-Stand

Strategic Movement Components

- Initial foot placement (knee and ankle $<90^\circ$)
- Forward motion of upper body (requires sufficient ankle dorsiflexion and hip flexion; trunk remains erect)
- Sequential extension at the knee, hip, and ankle
- Relatively equal contributions by both lower limbs

Environmental Modifications

- Raise seat to decrease lower limb force requirements.
- Grade seat to lower heights as strength in leg extensors improves.
- Use chair without arms if patient shows over-reliance on using hands for push-off.
- Select chair that allows for placing the feet back (knee and ankle flexed to less than 90°).

ventions on functional recovery of reach and grasp. They agree with Taub and Wolf (1997) that, during the flaccid period immediately after brain injury, patients learn to rely exclusively on the unaffected arm for performing one-handed activities. This “learned nonuse” (Taub et al., 1993), combined with inappropriate therapeutic intervention for the upper limb, results in insufficient practice opportunities for the paretic arm. In addition, the effects of immobilization on soft tissue extensibility limit active motor function even further. Finally, Carr and Shepherd debunk some common beliefs that prevail among rehabilitation professionals. They recommend that therapists shed unsubstantiated beliefs about recovery of motor control after brain injury and replace them with the following guidelines:

1. Recovery does not necessarily proceed in a proximal to distal sequence. Rather, therapists and patients should consistently monitor emerging muscle strength in all segments of the upper limb.
2. There is no reason to wait until patients demonstrate shoulder stability and control before presenting therapeutic challenges to hand function. Rather, the presentation of activities requiring limited grasp may provide valuable therapeutic challenges that can help organize emerging shoulder function.
3. Therapeutic challenges to active limb use need not be postponed until spasticity is inhibited. In fact, evidence indicates that the hypertonus, or resistance to passive movement, that many clinicians associate with spasticity is, in most patients, typically due to muscle shortening and increased stiffness (Carr, Shepherd, & Ada, 1995). Therefore, Carr and Shepherd do not advocate the use of any procedures aside from those that preserve or enhance soft tissue extensibility for reducing spasticity as a means to enhancing active, functional use of the upper limb.
4. There are no universal patterns of muscle linkages associated with recovery of motor function after brain injury. Rather, research has shown that abnormal patterns of motor performance are related to each patient’s distribution of muscle weakness combined with the mechanical demands of each task (Trombly, 1992, 1993). For example, the pattern of shoulder elevation combined with retraction of the shoulder girdle, which is often seen when individuals attempt to flex or abduct a hemiparetic shoulder, is not directly linked to the neural pathology. Rather, it is an adaptive use of available muscle strength against gravitational force. Thus, interventions to improve motor patterns are based on individualized analyses of each patient’s abilities, and activities are presented as graded challenges to provide opportunities for developing motor skills.
5. Conventional slings and splints that immobilize the affected shoulder or hand contribute to the development of learned non-use. The current approach is to provide

shoulder supports (Shepherd & Carr, 1998) and splints that provide necessary stabilization and to use these devices to promote active use of the upper limb during task-based training. Occupational therapists are developing these functional orthoses for clinical practice, but, to date, have rarely reported them in the published literature.

6. Traditional rehabilitation efforts at improving upper limb function have previously focused on those patients with the most severe paralysis of arm and hand muscles. Aside from providing preventive intervention to minimize secondary impairments of muscle shortening and postural misalignment, restorative treatments are most applicable to those stroke survivors with mild to moderate impairment levels (Duncan et al., 1998).

The Degrees of Freedom Problem

Of the four categories of motor performance addressed by Carr and Shepherd’s approach, reach and manipulation are characterized by the greatest number of degrees of freedom. This provides us with exceptional flexibility in tailoring reach and manipulation to the contextual demands of different tasks and environments. At the same time, this freedom of choice increases the complexity of motor demands during upper limb activities (Latash & Latash, 1994). Many people with stroke or head injury demonstrate a capacity to perform singular motions of a paretic upper limb when assisted by a therapist. Their inability to control multiple degrees of freedom, however, results in an inability to use the arm for functional reach or grasp.

One effective strategy observed in people who move with ease is to reduce the degrees of freedom by linking some elements together in synergistic combinations. The kinesiology of normal movement is characterized by several synergistic combinations in the upper limb and trunk (Levangie & Norkin, 2005). Some examples are:

- Combined action of rotator cuff muscles to assist the deltoid during glenohumeral (GH) flexion and abduction
- Upward rotation of the scapula that accompanies GH flexion and abduction (scapulohumeral rhythm)
- Shifts in body weight and pelvic orientation that accompany reaching motions of the upper limb
- Synergistic combinations between GH and forearm rotators for efficient positioning of the hand in space
- Synergistic contraction of the wrist extensors during grasp patterns requiring forceful finger flexion

After stroke or head injury, many persons lose their ability to implement these synergistic linkages automatically. The critical goals of intervention to improve reach and manipulation skills are:

- Minimize movement obstacles presented by weakness and immobility.

- Teach foundational movement combinations that underlie efficient reach and grasp.
- Provide graded opportunities to practice controlling an increasing number of degrees of freedom during exercise and activity performance.

Assessment and Treatment

Like other evaluations in Carr and Shepherd's approach, clinical assessment of reach and manipulation is achieved through detailed observation of each patient's attempts to perform selected functional tasks. Therapists use their knowledge about the kinetics and kinematics of upper limb function to develop hypotheses as to which deficits may be serving as control parameters in limiting the versatility or efficiency of motor strategies. Most motor dysfunction can be attributed to specific muscle weakness, muscle stiffness and length changes, and/or adaptive strategies developed to compensate for these impairments. Shoulder pain may also be a significant control parameter to efficient reach. (Safety Note 23-1 lists ways to prevent secondary impairments at the shoulder.) Therapists test their hypotheses through direct assessment of muscle strength and length and through patients' responses to interventions designed to modify adaptive strategies.

Training is individualized and based on the hypotheses developed during observation of functional task performance. Early control of weak muscles is facilitated by finding an optimal length for muscle contraction, by providing early opportunities for eccentric exercise, and by positioning the limb so that gravity assists rather than resists the muscle. An example also used in the neurodevelopmental treatment (NDT) approach is to elicit early contraction of the deltoid with the person lying supine with the shoulder flexed to 90°. In this position, gravity provides a stabilizing force on the shoulder. Therefore, activation of fewer motor

units is required for the individual to hold the arm and move it slightly from this position. Shortened muscles are lengthened by slow, passive stretch by the therapist, family members, or patients themselves. Therapists make patients aware of inefficient adaptive strategies and provide them with opportunities to perform a variety of reach and grasp activities using alternative movement strategies. Definition 23-2 summarizes the motor components essential to reach and manipulation. Therapists consider these components when synthesizing and grading therapeutic tasks.

Carr and Shepherd recognize that many patients with hemiparesis may rely excessively on one-handed perform-

DEFINITION 23-2 *definition*

Essential Components to Functional Arm Use

Reaching (Forward, Diagonally, Upward, Sideways, Backward)

- Appropriate scapular motion (upward rotation and abduction for forward, sideways, and upward reach; downward rotation and adduction for backward and downward reach)
- Elbow extension and varying amount of shoulder external rotation
- Opening of hand aperture between thumb and fingers
- Extension of wrist
- Pronation and supination appropriate to object orientation

Grasping

Preparation to grasp:

- Extension of wrist and fingers
- Abduction and opposition at thumb carpometacarpal joint
- Finger abduction for large objects

Grasp: Closure of thumb and fingers around object

Holding

- Flexion and extension of wrist while holding object
- Lifting, placing, and rotating objects of various sizes, shapes, and weights

Manipulating

- Flexion and extension of fingers
- Flexion and opposition at carpometacarpal joints of thumb and fifth finger
- Independent finger flexion and extension (e.g., keyboard depression)

SAFETY NOTE 23-1

Preventing Secondary Impairments at the Shoulder

- Prevent muscle shortening of adductor and internal rotator muscles; provide stretch through positioning or passive motion.
- Minimize downward gravitational force on soft tissue around glenohumeral joint.
- Avoid passive humeral flexion or abduction without appropriate concomitant scapular motion.
- Avoid any passive movement of the arm by individuals unfamiliar with scapulohumeral interactions.

Shepherd & Carr, 1998.

ance of daily tasks, even when they demonstrate potential to use their affected arm and hand. They support the use of constraint-induced movement therapy (Mark & Taub, 2004; Wolf et al., 2002) when appropriate. In addition, they recognize that bimanual tasks provide a natural framework for encouraging active use of available hand function.

Actual training in grasp and manipulation is achieved through varied task-related practice of both unilateral and bilateral activities. Sensory training is provided naturalistically through opportunities to manipulate objects with various shapes, sizes, and textures in the context of task performance. Carr and Shepherd suggest a variety of interventions to augment training, including specialized feedback, functional electrical stimulation, mental practice, and the use of functional orthoses. Intensity of practice can be increased through constraint-induced movement therapy (Mark & Taub, 2004), access to computer-driven games, and teaching friends and family to serve as training coaches. Dean and Mackey’s (1992) study provides research support for the efficacy of Carr and Shepherd’s approach in improving upper limb and hand function.

Occupational therapists are particularly qualified to synthesize activities designed to provide graded challenges to reach and manipulation. In addition, occupational

therapists excel at designing individualized orthotic and environmental adaptations to facilitate task performance while providing opportunities to develop functional skill to each person’s maximal potential. In their most recent textbook about stroke rehabilitation, Carr and Shepherd (2003) acknowledge this in their references to studies conducted by occupational therapists.

SUMMARY

Carr and Shepherd’s approach to optimizing motor control is well suited for use and adaptation in occupational therapy. Occupational therapists who apply these ideas use their skills in analyzing the kinematic and kinetic requirements of specific activity performance to develop individualized goals and treatment. In addition, occupational therapists structure tasks and environments to assist patients in developing efficient motor strategies and motor problem-solving skills. Finally, occupational therapists provide meaningful practice that enables individuals to use their available motor function to its fullest potential in daily activity performance.

CASE

EXAMPLE

Mr. M.: Optimizing Motor Skill Using Task-Related Training According to Carr and Shepard Guidelines

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information Mr. M. is a 70-year-old man who sustained an infarct to his left middle cerebral artery 4 weeks before his referral for home-based occupational therapy. After hospitalization and inpatient rehabilitation, he returned home to his apartment in a building with an elevator. After occupational therapy assessment in his home, the following problems were identified:</p> <ul style="list-style-type: none"> Mild difficulties with bed mobility and sitting balance because of limitations in thoracolumbar dissociation and pelvic mobility. Need for contact guard and occasional minimal assist in rising to stand from sitting because of limitations cited above. Insecure balance in standing. 	<p>Appreciate the context</p> <p>Develop intervention hypotheses</p> <p>Select an intervention approach</p>	<p>“Enhancing thoracolumbar and pelvic mobility will enable Mr. M. to use more effective movement kinematics during functional task performance.”</p> <p>“Enhancing Mr. M.’s knowledge of movement kinematics and his ability to monitor his own performance will contribute to improving his motor skills.”</p> <p>“Opportunities for practice of available movements, with increasing number of degrees of freedom, will help Mr. M. develop enhanced arm motor skill.”</p> <p>“I will implement task-related training, with specific guidelines suggested by Carr and Shepherd.”</p>

- Inability to use his dominant right arm for any task. Testing revealed intact proprioceptive and tactile sensation and ability to perform all active movements of the shoulder, elbow, forearm, and wrist with therapist support and positioning. All individual movements required great effort, however, and he could not combine movements at multiple arm segments to meet the demands of functional tasks. Although he could perform finger flexion and extension, he was unable to achieve functional grasp and could not oppose his thumb to his other fingers.

- Inability to independently perform self-care activities requiring advanced skills in sitting or standing balance, standing up or sitting down, or use of both arms. He relied on assistance from a home health attendant to perform toileting activities in sitting or standing, get on to and off a tub seat, dress himself, cut meat, shave himself to his own high expectations, and prepare any food.

Reflect on competence

“I have sufficient knowledge of kinesiology and skill in analyzing control parameters when observing Mr. M.’s movement patterns during functional task performance.”

“I am knowledgeable about the findings of research literature describing efficient kinematics during performance of a variety of tasks.”

“I am knowledgeable about findings of research studies identifying common control parameters of inefficient movement patterns demonstrated by stroke survivors.”

Initial MAS scores are indicated in Figure 23-4.

Motor Assessment Scale		
Patient's Name: <u>Mr. M.</u>		
	Pre-treatment Score	Re-evaluation Score
1. Supine to side lying	4	6
2. Supine to sitting over side of bed	5	6
3. Balanced sitting	4	6
4. Sitting to standing	3	5
5. Walking	3	5
6. Upper arm function	1	6
7. Hand movements	3	5
8. Advanced hand activities	0	3

Figure 23-4 Mr. M.’s MAS scores.

Recommendations

The occupational therapist recommended two treatment sessions each week for 6 weeks and, in collaboration with Mr. M., established the following long-term treatment goals: (1) Mr. M. will safely and independently stand up and sit down from a variety of seating surfaces and will perform functional tasks while standing. (2) Mr. M. will use his right arm and hand during task performance. (3) Mr. M. will safely and independently perform all activities in which he engaged prior to the stroke and will have sufficient motor and task analysis skills to attempt performing new activities.

Consider the patient’s appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient’s endorsement of plan

“Mr. M.’s motor, cognitive, and perceptual skills are sufficient for his success with task-related training. He follows directions well and shows the ability to participate as an active collaborator in the treatment process. He shows potential to apply his improvements in motor flexibility to improved functional performance. He has expressed willingness to follow the therapist’s recommendations for practice outside of therapy sessions.”

Summary of Short-Term Goals and Progress

Mr. M. will achieve full, fluid, active motion at the right scapula, the thoracic and lumbar spine, and the pelvis.

Treatment focused on teaching Mr. M. exercises in lying supine and sitting that provided soft tissue stretch to improve mobility in scapular protraction and upward rotation, thoracolumbar dissociation, and pelvic mobility. The OT taught Mr. M. to appreciate which planes of motion should be available in his scapulae, trunk, and pelvis and encouraged Mr. M. to design activities that would elicit movements at each body segment in all available planes of motion. Mr. M. also learned to determine optimal alignment of body segments for various body postures and functional tasks. Achievement of this goal enabled Mr. M. to attain full independence in bed mobility and facilitated his performance in tasks requiring sitting balance, standing balance, sit-to-stand, and right upper arm control.

Mr. M. will maintain sitting balance during activities requiring self-initiated movements of his head, limbs, and trunk and will independently stand up and sit down from a variety of seating surfaces.

Mr. M. improved his balance by using his improved mobility at the trunk and pelvis and practicing unilateral and bilateral reach and grasp in sitting and standing. He improved his ability to stand up and sit down from a variety of seating surfaces in his home after the OT identified the major control parameters influencing his initial performance (Figs. 23-5 and 23-6) and helped him improve his performance strategy (Figs. 23-7 and 23-8).

Mr. M. will use his right arm and hand as an assist to his left during a variety of functional tasks. He will achieve this by improving his control over increasing numbers of degrees of freedom at the right shoulder, elbow, forearm, and hand.

Mr. M. began by practicing holding his shoulder at 90° flexion while supine, with decreasing external support from the therapist. As soon as he demonstrated ability to hold his shoulder in this position, the therapist added one new movement demand at a time, while Mr. M. maintained his shoulder in this position. Examples of new movement demands included scapular motions, elbow motion, wrist motion, lateral pinch to grasp a tissue, and rotational movements at the GH (glenohumeral) joint. Mr. M. practiced varying movement combinations as homework, and he progressed to controlling these combined motions while sitting, a position with greater gravitational demands. Mr. M. accomplished his earliest hand activities while resting his right hand in his lap and reaching down and forward or down and to the side. He practiced a variety of bimanual tasks, such as ripping paper, operating a vacuum cleaner (Fig. 23-9A), buckling a belt, and holding his face in position while shaving. Unilateral tasks included grasping tissues (Fig. 23-9B), operating a television remote control, applying lotion to his left forearm, and using cylindrical grasp to pick up a variety of items in his home. On reevaluation, he could achieve lateral pinch and pad-to-pad pinch. He developed active control of thumb flexion and began to demonstrate thumb opposition.

Assess the patient's comprehension

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Mr. M. showed full understanding of his own body's potential for optimal alignment and full flexibility of his scapula, spinal column, and pelvis. He understood the therapist's rationale for the exercises and task-related practice opportunities. Mr. M.'s part-time attendant is available to help him during practice after therapy sessions to ensure safety.”

Figure 23-5 Early pre-extension phase of standing up: Mr. M.'s initial evaluation.

Figure 23-6 Extension phase of standing up: Mr. M.'s initial evaluation.

Figure 23-7 Pre-extension phase of standing up: Mr. M.'s reevaluation.

Figure 23-8 Extension phase of standing up: Mr. M.'s reevaluation.

Figure 23-9 Functional task practice during occupational therapy sessions: **A.** Standing. **B.** Seated.

Next Steps

Mr. M. will be able to perform activities requiring right thumb opposition and individual finger movements. He will be able to perform all hand activities, regardless of what shoulder position is required for a given task.

Mr. M. will be able to perform activities requiring the integration of standing balance, bilateral use of his upper limbs, and unilateral use of his right arm and hand while holding a cane in his left hand.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. M. understands that continued practice is essential to maintain the new motor skills he has developed. Occupational therapy sessions will be discontinued. Ideally, Mr. M. should have access to periodic reevaluations by an occupational therapist who is trained in implementing a task-related training approach. During these reevaluations, the therapist would assess Mr. M.’s safety, movement kinematics, and addition of new activities to his performance repertoire. The therapist would collaborate with Mr. M. to update his daily exercise and activity routine to reflect practice needs determined by changes in his motor, cognitive, and/or perceptual status. In Mr. M.’s case, Medicare would not provide reimbursement for such reevaluations.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Assessing Sit to Stand

Analyze Mr. M.’s performance in Figures 23-5 and 23-6 to determine which factors contributed to his difficulty in rising to stand. What interventions would you use to assist him in improving his ability to rise to standing to the level of function illustrated in Figures 23-7 and 23-8?

Evidence Table 23-1 Best Evidence for Efficacy of Task-Related Training in Improving Motor Skill in Patients with CNS Dysfunction

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-related training	Treatment group: home-based program of reaching tasks while seated; control group: no motor intervention.	9 stroke survivors >1 year post stroke, randomized to group.	10 sessions over a 2-week period	IC1b	Yes. This treatment resulted in increased distance reached. Ipsilateral reach: Treatment group (TG) gained an average of 80 mm; control group (CG) lost 20 mm. Forward reach: TG gained 90 mm; CG lost 30 mm. Across reach: TG gained 120 mm; CG lost 30 mm. And a significant increase in load through affected foot when reaching forward. Peak vertical ground reaction force (by % of body weight) improved by 5.9% for TG; in CG, it decreased by 1.9%.	Ipsilateral reach, $p = 0.042$, $r = 0.39$. Forward reach: $p = 0.005$, $r = 0.59$. Across reach: $p = 0.028$, $r = 0.44$. Increase in load through affected foot: $p = 0.004$, $r = 0.61$.	Dean & Shepherd, 1997

continued

Evidence Table 23-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-related circuit training	Treatment group: exercise class to strengthen the affected lower limb and to practice functional tasks involving the affected limb; control group: practice of upper limb tasks.	9 stroke survivors > 3 months post stroke; able to walk 10 m with or without assistive device. Randomized to group (treatment group, n = 5; control group, n = 4)	1-hour class 3×/week for 3 weeks.	IC2c	Yes. The treatment resulted in immediate and retained (2-month follow-up) improvement in walking distance, walking speed without assistive devices, and standing balance. No significant changes in upper limb (unpracticed) strength or dexterity.	Statistical results were not reported; the change scores on which the statistical analyses were done were also not reported; therefore, effect size could not be calculated.	Dean, Richards, & Malouin, 2000
Task-related training (TRT) vs. progressive resistive exercise (PRE)	TRT = reaching to contact or grasp objects placed across work space. PRE = whole arm pulling against resistive therapeutic tubing in planes and distances similar to that in TRT. Home-based training (testing in laboratory).	12 stroke survivors > 5 months after rehabilitation, randomly assigned to 1 of 2 treatment conditions and subsequently categorized at high or low functional level based on speed of reach movement.	4 weeks; 12 sessions.	IC2c	Yes. TRT was significantly more effective in improving straightness of hand path (better coordination of elbow-shoulder motion) for the more impaired group but not for the less impaired group whose hand paths were already relatively straight. However, PRE was more effective in decreasing compensatory use of the trunk during reach in the less impaired group, although it had no effect on the more impaired group.	Hand path: $F_{(1,8)} = 5.60$, $p < 0.05$, $\eta^2 = 0.41$. Rivermead Stroke Assessment (arm section): $F_{(2,16)} = 6.8$, $p < 0.03$, $\eta^2 = 0.46$. MAS: not significant. Arm motion (without trunk motion): $F_{(2,16)} = 5.40$, $p < 0.02$, $\eta^2 = .40$.	Thielman, Dean, & Gentile, 2004

Task-related training	Home-based program to improve sit-to-stand (STS). Exercise protocol consisted of 10 repetitions of sit-stand-sit (using graded chair heights) and two exercises in standing (step-ups and calf-stretches).	6 stroke survivors >1 year post stroke evaluated before and after treatment.	3×/week for 3 weeks.	IIIc1c	Yes. This treatment resulted in increase in MAS score for STS; a significant improvement in timing of thigh-off, which approximated that seen in able-bodied subjects; and an increase in walking speed (mean change of 0.24 m/sec).	MAS score: $p = 0.04$, $r = 0.71$. Timing of thigh-off: $p = 0.01$, $r = 0.95$. Increase in walking speed: $p = 0.03$, $r = 0.77$.	Monger, Carr, & Fowler, 2002
Occupationally embedded exercise to improve active forearm supination	Treatment group: adapted dice game requiring bilaterally assisted supination of hemiparetic forearm; control group: repeated performance of bilaterally assisted supination of the hemiparetic forearm.	6 stroke survivors with pronator spasticity, full PROM in supination after brief stretching, and no active supination. Randomized to group.	2 sets of 10 repetitions; 1 treatment session.	IC2c	Yes. Treatment resulted in significantly more bilaterally assisted forearm supination (as measured by degrees of rotation of the measurement handle). Treatment mean = 95.3°; control mean = 81.9°.	$t_{(24)} = 2.28$, $p < 0.05$ (one tailed), $r = 0.42$.	Nelson et al., 1996
Occupationally embedded exercise to improve forward arm reach	Treatment group: engagement in Simon, a computer-controlled game, positioned to promote forward arm reach; control group: repeated exercise in forward reach, with no embedded task. Counterbalanced design: each subject experienced each condition 1 week apart.	20 young adults after traumatic brain injury with mild to moderate upper limb spasticity.	Single session with 10 movement repetitions for each condition.	IIC2c	Yes. The occupationally embedded condition resulted in significantly greater arm reach (based on video analysis of distance from hip to wrist). Treatment mean = 71.6 cm; control mean = 59.4 cm.	$t_{(19)} = 5.77$, $p < 0.001$, $r = 0.80$.	Sietsema et al., 1993

SUMMARY REVIEW QUESTIONS

1. What are the relationships between control parameters, adaptive features of CNS dysfunction, and attractor states?
2. How are the principles of activity analysis and synthesis applied when implementing task-related training?
3. Why do Carr and Shepherd lay greater emphasis on assessing and intervening to improve postural adjustments than postural reactions?
4. What are the essential components of the stance phase and swing phase of the gait cycle? How can occupational therapists structure interventions to assist patients in walking to their optimal potential?
5. Which kinematic features of the pre-extension phase of standing up influence the ease with which a person will perform the extension phase?
6. How can occupational therapists structure interventions to assist patients in controlling increasing numbers of degrees of freedom when performing reach and manipulation tasks?
7. What specific mechanical constraints are likely to affect a person's ability to maintain balance during activity performance? To stand up and sit down? To walk during activity performance? To perform activities requiring reach, grasp, and manipulation?
8. What foundational movement strategies are likely to assist a person's ability to maintain balance during activity performance? To stand up and sit down? To walk during activity performance? To perform activities requiring reach, grasp, and manipulation?
9. Provide specific examples of postural adjustments that are likely to assist a person's ability to stand up and sit down, to maintain balance during activity performance, to walk during activity performance, and to perform activities requiring reach, grasp, and manipulation.
10. How can occupational therapists assist patients in developing their task analysis and problem-solving skills in the context of functional movement?

CHAPTER 24

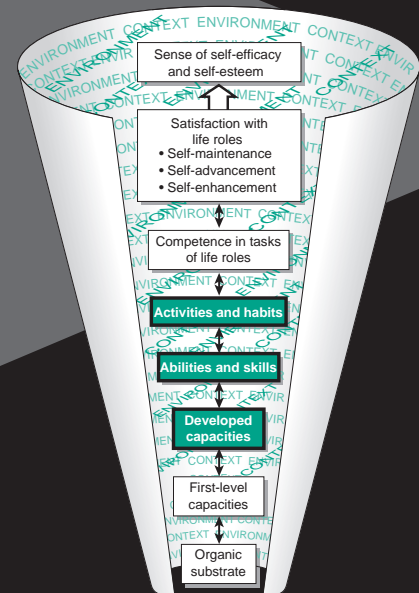

Optimizing Motor Behavior Using the Bobath Approach

Kathryn Levit

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Identify the major problems that result from stroke according to Bobath and Bobath.
2. Describe the major principles underlying the Neuro-Developmental Treatment (NDT)/Bobath approach to stroke rehabilitation.
3. Discuss the role of muscle tone and postural control in the production of normal movement, and describe how problems in these areas contribute to impaired occupational functioning.
4. Integrate NDT/Bobath concepts and techniques with the occupational functioning model.
5. Develop an OT treatment plan for a patient with acute stroke using NDT/Bobath principles and techniques.

Glossary

Abnormal coordination—Patterns of muscle activation, timing, and sequencing that deviate from normal, resulting in inefficient, stereotyped movement patterns.

Abnormal tone—Muscle tone that is higher or lower than normal.

Associated reactions—Involuntary and non-functional changes in limb position and muscle tone associated with difficult or stressful activities.

Facilitation—Manual techniques and other processes including tactile and verbal feedback used to help the patient achieve a more normal quality of movement.

Flaccidity—Muscle tone that is lower than normal. Also known as hypotonicity.

Handling—Manual techniques designed to change muscle tone and normalize movement. Handling includes inhibition and facilitation.

Inhibition—Manual techniques and positions used to decrease or eliminate the effects of spasticity and abnormal coordination.

Key points of control—Hand placements used to influence the quality of posture and movement.

Loss of postural control—Inability to use automatic patterns of muscle activation to maintain the body within a stable base of support at rest and during movement.

Placing response—Part of the normal system of postural adjustments to changes in position, characterized by automatically maintaining a position when support is removed.

Reflex-inhibiting pattern (RIP)—A position that is used to inhibit spasticity by lengthening shortened muscles.

Spasticity—Muscle tone that is higher than normal and resists passive stretching; also known as hypertonicity.

K Bobath and B. Bobath developed a treatment approach designed to increase normal movement patterns in children with cerebral palsy and adults with acquired hemiplegia. Their treatment is known as the Bobath approach or Neuro-Developmental Treatment (NDT). NDT/Bobath treatment focuses on eliminating abnormal movements and restoring normal movements. The occupational functioning model usually describes this type of treatment as preparatory because it is directed toward establishing sensorimotor performance components that are prerequisites for function while minimizing the impairments that interfere with functional behavior. This chapter introduces the NDT/Bobath approach to the treatment of adults with hemiplegia. A complete description of the treatment approach and its techniques can be found in Bobath (1990) and Davies (1985). Eggers (1984) provides information on using the approach to improve occupational functioning. Current theoretical foundations and principles of clinical practice are described in Howle (2002).

INTRODUCTION

NDT is one of the classic neurophysiological treatment approaches that were developed to address the impairments associated with damage to the central nervous system. This section briefly reviews the history of the NDT approach and provides an overview of principles of treatment and methods for integrating this treatment into occupational therapy for individuals with stroke and brain injury.

History and Principles

Bobath and Bobath began to develop their treatment approach in England in the 1940s. B. Bobath, trained in Germany as a gymnast and remedial movement specialist, went to England to avoid persecution and found work as a physical therapist. When treating adults with hemiplegia, she noted the abnormal stiffness in their affected extremities, their asymmetrical body postures, and the non-functional stereotyped patterns of movement in their involved side. B. Bobath tried to help her patients regain functional use of their hemiplegic side. She assumed that the abnormal patterns of muscle tone and motor control were the major impairments interfering with normal motor control of the trunk, arm, and leg. Through trial and error, B. Bobath developed techniques for decreasing abnormal reflex activity and muscle tone and for increasing control of normal patterns of movement on the hemiplegic side of the body. These techniques were based on her knowledge of normal kinesiology, not the developmental sequence.

B. Bobath discovered that she could help her patients with hemiplegia move more freely and function with less compensation by decreasing the abnormal tone in their affected side. She also found that, when spasticity decreased, her patients could acquire improved control of posture and movement on their affected side and could use these new patterns for function. Based on these clinical findings, B. Bobath developed a new model for treating adults with hemiplegia. Her approach involved the use of manual techniques to eliminate abnormal tone and dysfunctional movement and to retrain normal patterns of coordination in the affected trunk, arm, and leg.

Since her goal was to restore normal movement and function on the affected side, she specifically rejected compensatory approaches that neglected the potential for function in the hemiplegic side and other neurophysiological approaches that encouraged abnormal movement and reflex activity.

As B. Bobath developed the treatment techniques, neurologist K. Bobath reviewed research in neurology and neurophysiology to develop a scientific basis for his wife's treatment. B. Bobath's claims that her treatment could change spasticity and restore normal movement responses were controversial, and K. Bobath used research findings to support her discoveries. Since the clinical techniques developed first, K. Bobath presented his scientific rationale in hypothetical terms, describing it as an explanation for, not the basis of, intervention.

Bobath and Bobath called their treatment approach a living concept because they expected it to change and develop over time. They made many changes to the treatment over the years to make it more active and functional. They also made an effort to update their theory by adding new scientific explanations for certain aspects of their treatment. Although controversial when first introduced, many of the assumptions of Bobath and Bobath are now an accepted part of stroke rehabilitation, and the approach is widely used throughout the world (Rast, 1999). The theoretical models that K. Bobath proposed as a basis for treatment are now out of date, however, and the NDT/Bobath approach has been the target of criticism (Howle, 2002; Gordon, 1987). For the past 15 years, the Neuro-Developmental Treatment Association (NDTA) in the United States and similar groups in other countries have been working to update the theoretical basis for NDT/Bobath treatment (Definition 24-1). The NDTA Theory Committee has recently published an updated account of theoretical foundations and principles of treatment as they apply to adults with hemiplegia and children with cerebral palsy (Howle, 2002).

Definitions of Terms and Constructs

Bobath and Bobath developed their approach to address the motor problems associated with **hemiplegia**, or loss of muscular control on one side of the body. They believed that hemiplegia is associated with two categories of motor problems: the loss of normal movement responses and the development of abnormal tone and movement. B. Bobath hypothesized that these two problems cause the abnormal patterns of coordination and functional limitations common following stroke. She also believed that treatment that addressed these problems would improve movement control on the hemiplegic side and, hence, increase the possibilities for occupational performance. These assumptions are discussed separately in the sections that follow.

DEFINITION 24-1

NDT Philosophy

The NDTA website (www.ndta.org) contains the following statement about Neuro-Developmental Treatment:

“The Neuro-Developmental Treatment (NDT)/Bobath approach was developed by Berta and Karel Bobath as a ‘living concept.’ The approach is intended to grow and develop over time as new information is gained from clinical experience and scientific research. NDT is used for the treatment and management of individuals with movement dysfunction resulting from central nervous system (CNS) pathophysiology. The individual's strengths and impairments are identified through an in-depth analytical process and addressed in relation to functional abilities and limitations. NDT is an interactive process which includes individuals, caregivers and members of the interdisciplinary team in assessment, treatment planning and application.

The overall goal of treatment and management is to enhance the individual's capacity to function, minimize impairments, and prevent disabilities. To achieve this goal, the therapist addresses the quality of movement utilizing principles of movement science. Intervention involves direct handling including facilitation, and inhibition to optimize function. The application of NDT contributes to the individual's increased independence and an enhancement of the quality of life.”

Movement Control Problems after Stroke

Bobath and Bobath described the loss of normal movement responses as the first type of motor impairment associated with hemiplegia. Patients with hemiplegia may demonstrate **loss of postural control**, or inability to activate muscles automatically to maintain the body in balance at rest and during movement, and **loss of selective movement control** of the muscles controlling movement of the hemiplegic arm and leg. Loss of postural control is associated with difficulty shifting weight, maintaining a stable body position against gravity, and activating equilibrium responses when balance is challenged. These problems interfere with the performance of life roles and lead patients to rely on adaptive equipment to substitute for poor balance (Fig. 24-1). Loss of selective movement control prevents patients from using the hemiplegic arm, resulting in reliance on one-handed techniques for task performance. B. Bobath suggested that patients who adopt these asymmetrical compensations learn to neglect the potential for functional performance on the hemiplegic side even when the necessary sensory-motor components are present.

Bobath and Bobath identified **abnormal tone** as the second major problem interfering with movement control and function in hemiplegia. Abnormal tone refers to alterations in muscle tension and resistance to passive stretch. After a stroke, muscle tone on the hemiplegic side may be

Figure 24-1 Patient showing poor postural control while walking with a cane.

higher or lower than normal. Patients demonstrate **flaccidity**, or hypotonia, when muscle tone is lower than normal. Flaccidity is generally present immediately after the stroke. **Spasticity**, or hypertonia, develops gradually in selected muscles of the affected trunk, arm, and leg and is characterized by excessive muscle stiffness and slow effortful movements. Spasticity is often accompanied by **associated reactions**, which are involuntary, nonfunctional changes in limb position associated with the performance of difficult or stressful activities. For example, the hemiplegic arm may assume a flexed position when the patient walks (Fig. 24-2). According to Bobath and Bobath, spasticity interferes with selective muscle activity on the hemiplegic side, contributing to abnormal patterns of coordination and loss of functional use.

Bobath and Bobath believed that these two categories of motor impairment result in the stereotyped non-functional movement patterns and functional limitations associated with hemiplegia. In their writings, the Bobaths also emphasized that sensory disturbances may contribute to abnormal coordination and decreased motor control. They hypothesized that patients with hemiplegia have forgotten how to move in normal patterns of coordination and suggested that this sensory disturbance may result in loss of normal movement responses, even when muscles are sufficiently strong to support movement. The loss of the sensory memory for movement may also contribute to abnormal patterns of coordination by causing patients to initiate and sequence muscle activity inappropriately. Thus, although

Figure 24-2 Patient showing associated reaction in the hemiparetic arm while walking.

their treatment approach was designed to address problems with tone and movement, Bobath and Bobath recognized that sensation was necessary for motor coordination and motor learning, and their treatment techniques use sensory information as part of the process of reeducating normal movement.

Neuro-Developmental Treatment of Patients with Stroke

NDT/Bobath treatment uses manual techniques to address the problems of tone and movement control and to provide sensory messages about how movement is organized and executed. These techniques have the goals of preventing or eliminating abnormal tone and coordination, retraining normal movement responses, and increasing functional use of the hemiplegic side (Definition 24-2). B. Bobath used her hands on the patient's body to produce therapeutic changes in tone and movement. She called this treatment **handling** to reflect the hands-on quality of her treatment. Initially, handling was relatively static, requiring the use of reflexes and passive positioning to produce changes in muscle tone.

DEFINITION 24-2 *fin·i·tion*

NDT/Bobath Principles of Treatment

- The goal of treatment is to retrain normal movement responses on the patient's hemiplegic side.
- The therapist should avoid activities and exercises that increase abnormal tone or strengthen abnormal movement responses and should use treatment techniques to suppress or eliminate these patterns.
- The therapist should use treatment activities and exercises that encourage or strengthen normal movement patterns in the patient's trunk and extremities.
- The therapist should help the patient use existing motor control on the hemiplegic side for occupational performance.
- When the patient lacks adequate strength and control of the affected arm and leg for normal occupational performance, the therapist should develop compensations and adaptations that encourage use of the affected side and decrease the development of abnormal movements and asymmetrical postures.

As the approach evolved, handling became a more dynamic process used to activate movement responses to decrease abnormal tone and coordination and reeducate normal movements.

The NDT therapist uses handling to provide specific tactile, proprioceptive, and kinesthetic messages that help organize the quality of the patient's movement and influence the status of relevant impairments, such as spasticity and flaccidity. Although B. Bobath did not specifically identify impairments such as subluxation and contracture as contributing to abnormal coordination, these secondary impairments may present mechanical blocks to normal movement and are also addressed through handling (Howle, 2002). B. Bobath found that certain hand placements, which she called **key points of control**, are most effective for controlling the patient's movement. During treatment, the therapist selects key points that give maximal control over the patient's problems and the movement pattern the therapist wishes to influence. Proximal key points are used to influence posture and movement of the trunk, shoulder girdle, and hip, and distal key points are used to control the position of the distal extremities (Fig. 24-3).

Handling incorporates two types of techniques: inhibition and facilitation (Procedures for Practice 24-1). **Inhibition techniques** are used for problems of abnormal tone and abnormal coordination. The NDT therapist uses inhibition to decrease spasticity and block or eliminate abnormal patterns of movement. B. Bobath believed that therapists should not attempt to retrain normal move-

Figure 24-3 Therapist's hands showing key points of control on the trunk.

PROCEDURES FOR PRACTICE 24-1

NDT Handling Techniques

Inhibition techniques are used to:

- Decrease abnormal muscle tone that interferes with passive and active movement.
- Restore normal alignment in the trunk and extremities by lengthening spastic muscles.
- Stop unwanted movements and associated reactions from occurring.
- Teach methods for decreasing the abnormal posturing of the arm and leg during task performance.

Facilitation techniques are used to:

- Provide the sensation of normal movement on the hemiplegic side.
- Provide a system for relearning normal movements of the trunk, arm, and leg.
- Stimulate muscles directly to contract isometrically, eccentrically, or isotonicly.
- Allow practicing movements while the therapist maintains some constraints.
- Teach ways to incorporate the involved side into functional tasks and occupations.

ment responses until spasticity is minimized through inhibition because spasticity blocks the patterns of reciprocal muscle activation needed for optimal motor and functional performance. For this reason, treatment often begins with the use of inhibition techniques to reduce spasticity. Inhibition techniques often use **reflex-inhibiting patterns (RIPs)**, a term for patterns that counteract the pull of tight or spastic muscles. Spasticity may also be inhibited by using weight bearing and trunk rotation to lengthen shortened muscles.

When muscle tone is normalized through inhibition or when spasticity is not a major impairment, the NDT therapist uses **facilitation techniques** to train normal movement patterns. Facilitation techniques are used to activate automatic postural responses and trunk control and to reeducate weight-bearing and non-weight-bearing movements in the arm and leg. The assumption is that facilitation will minimize the learning of abnormal movements by allowing the patient to practice normal patterns of movement and coordination from the earliest days of rehabilitation. Occupational therapists may also use facilitation techniques to introduce and practice new strategies for performing functional activities in occupation-as-means or occupation-as-end. During facilitation, the therapist establishes light contact with appropriate key points of control and manually assists the patient's movement patterns. The therapist initially controls the quality and characteristics of the movement, while the patient follows these manual cues and moves with assistance. As the patient learns to perform the desired movements, the therapist gradually decreases the amount of assistance provided until the patient moves without input from the therapist.

Relationship to Occupational Functioning

Bobath and Bobath assumed that most of the disability associated with hemiplegia is related to impairments in posture and movement (Bobath, 1990; Howle, 2002). Thus, they believed that treatment directed toward improving the status of sensorimotor performance components would result in improved occupational performance. They noted that, when patients learn new movements, they often spontaneously use these movements functionally without further treatment. For example, when NDT facilitation techniques are used to increase postural control in sitting, patients may spontaneously use their improved trunk control to lean forward to adjust the foot pedals on the wheelchair or to stay erect while putting on a shirt. Since remediation of lower level functional prerequisites may not, however, automatically result in improved occupational performance (Dijkers, 1999; Trombly, 1995), NDT therapists must also use aspects of occupation-as-means and occupation-as-end to ensure that improvements in tonal state and movement control are incorporated into occupational functioning.

In occupation-as-end, the patient is directly engaged in learning an activity or task. After a stroke, occupational therapists use occupation-as-end to teach self-care skills, such as dressing and bathing, or mobility activities, such as rolling, transfers, and wheelchair propulsion. NDT therapists have developed compensatory occupation-as-end techniques for activities such as dressing, grooming, and bed mobility. These techniques are designed to maintain symmetry and bilaterality and to encourage patients to activate their trunk muscles and incorporate their involved extremities into task performance. The NDT/Bobath approach rejects the use of one-sided compensations, emphasizing instead that patients should perform tasks in ways that use the hemiplegic side. Examples of the use of NDT/Bobath techniques in occupation-as-end are discussed later in the chapter.

In occupation-as-means, the therapist uses activities therapeutically to influence impairments and provide opportunities for motor learning and practice. The NDT therapist frequently uses actual tasks or parts of tasks in occupation-as-means treatment to increase postural control or improve strength and coordination in the hemiplegic arm. For example, in the sitting position, the therapist may use activities that require weight shifts over the body's base of support to increase control of the postural muscles of the trunk and the lower extremity (Fig. 24-4). Similarly, the therapist may structure cooking or grooming tasks to practice weight support in the hemiplegic arm or to train the use of the hemiplegic arm in bilateral grasp. Occupation-as-means should incorporate movement patterns that the patient can perform independently without asymmetry or excessive use of the uninvolved side. Activities that are too difficult or that result in increased tone or compensation should be avoided, although the NDT therapist may use facilitation to help the patient practice an activity that cannot be performed independently. Some examples of NDT occupation-as-means activities are in-

Figure 24-4 Patient swinging a tennis racquet to increase control of trunk.

cluded in the treatment section of this chapter. Eggers (1984) provided a complete description for using occupation-as-means within an NDT framework.

EVALUATION AND TREATMENT PLANNING

The NDT/Bobath approach uses assessment to gather information about the patient's movement control and functional status, the problems interfering with functional use of the hemiplegic side, and the patient's response to handling (Procedures for Practice 24-2). This information is used to set treatment goals and plan treatment activities. This section reviews the important components of this system of evaluation and treatment planning.

Assessment in the NDT/Bobath Approach

The NDT therapist gathers assessment information through a variety of procedures. During the initial contact with the patient, the therapist observes the patient's behavior to gather information about typical posture, preferred movement patterns, and spontaneous use of the hemiplegic side. The therapist also observes how the patient performs activities of daily living (ADL), transfers, and bed mobility and notes whether the patient spontaneously uses the affected side or relies on compensations that reflect asymmetry and neglect. The therapist also watches to see whether the patient demonstrates abnormal tone and coordination on the hemiplegic side. Although these initial observations yield important information, the most important aspect of the NDT assessment is the evaluation of motor patterns and the patient's response to being moved. These tests are described briefly next. A more detailed description of the tests can be found in Bobath (1990).

The NDT therapist uses handling to identify the normal patterns of movement that are present on the hemiplegic side and the abnormal patterns that are contributing to the patient's movement problems and functional limitations. To assess movement control, the therapist moves the patient into postures and movement sequences that are important for occupational performance. For example, the therapist tests postural control by facilitating trunk movements, equilibrium reactions, and protective responses (Fig. 24-5) with the patient sitting and standing. The therapist also uses handling to test selective control of arm and leg movements by moving proximal and distal limb segments in varying combinations of joint movement. The therapist uses information about the patient's balance and spontaneous movements gained in the observational stage of assessment and the goals of treatment identified by the patient to select the movement patterns to be assessed via handling.

During assessment, handling provides the therapist with specific sensory information about the quality and strength of the patient's movements. When movement control is present on the hemiplegic side, the patient actively assists with the movement, and the movement seems effortless and flowing. If the therapist stops the movement briefly and lightens manual support, the patient will briefly hold the position. B. Bobath referred to this as the **placing response** (Fig. 24-6). Facilitation is easy and placing is possible when muscle tone is in the normal range and muscle strength is available to support movement. Facilitation and placing are not possible, however, when muscle tone on the hemiplegic side is too high or too low. When the therapist facilitates movements that require spastic muscles to lengthen, the therapist feels resistance while movements that go in the direction of

PROCEDURES FOR PRACTICE 24-2

NDT/Bobath Evaluation and Treatment Planning

1. Identify abilities and functional capabilities. Include movements of both the arm and leg, postural patterns of the trunk, and functional independence in life skills. How does the patient accomplish these functions?
2. Identify functional limitations, including functions that the patient cannot perform that are necessary for improved independence and quality of life.
3. Determine what problems interfere with movement control and functional performance, such as:
 - Abnormal tone
 - Abnormal coordination
 - Loss of postural control
 - Loss of selective movement control
 - Loss of or changes in sensation
4. Establish functional goals and treatment goals.
 - Identify the functions that the patient will be able to learn to perform within an established time frame. Indicate whether performance will involve compensation or use of the involved side with normal coordination.
 - Identify the impairments that you will need to address to meet the functional goal.
5. Based on the patient's response to handling, determine where to begin treatment. What techniques of inhibition and facilitation will be used?

spastic activity are performed with excessive assistance. Similar problems with facilitation arise when muscle tone is hypotonic. Patients with flaccidity do not assist movements or show the placing response. Their limbs feel heavy and floppy during handling.

Figure 24-6 Therapist using placing to assess control of the hemiparetic arm.

Treatment Goals for the Stages of Recovery

The NDT/Bobath therapist uses the information about muscle tone and movement control gathered in the evaluation to establish treatment goals. NDT therapists establish several types of goals. The therapist sets functional goals to be achieved through practice of occupation-as-means or occupation-as-end. These goals address limitations in ADL and IADL. The therapist also establishes treatment goals for impairments in basic abilities and capacities in the trunk and arm and identifies problems that may benefit from inhibition and facilitation. These treatment goals depend on the patient's problems, level of functional independence, movement control, and reasons for seeking treatment. Treatment goals will also vary according to where the person is in the process of recovery and his or her prognosis.

In acute-care or inpatient rehabilitation settings, most patients have impairments such as weakness, low tone, and loss of muscle control and are dependent in most self-care activities. NDT goals focus on increasing independence in self-maintenance roles, preventing the development of abnormal tone and abnormal movements, and increasing motor control on the hemiplegic side. To accomplish functional goals, the NDT/Bobath therapist introduces and practices adapted techniques for ADL, bed mobility, transfers, and wheelchair management designed to increase occupational performance and level of independence while preventing learned neglect, postural asymmetry, and associated reactions. For example, the therapist may train the patient to sit up in bed from lying on the hemiplegic side to introduce weight bearing on the hemiplegic arm and leg (Fig. 24-7). The therapist also uses positioning and inhibitory treatment techniques, such as supine scapula mobilization and weight bearing on the hemiplegic arm, to maintain muscle length and prevent spasticity. Facilitation is used to increase muscle control in postural adjustments and selective movements of the arm as preparation for skilled use.

As patients recover from strokes, a new set of treatment goals is necessary. Although some patients remain flaccid on their hemiplegic side or recover motor control without developing abnormal tone, many develop spasticity in some muscles of the affected side. Spasticity first appears as an associated reaction in conjunction with patients' efforts to become more independent in self-care activities and walking. Over time, the spastic muscles develop increased resistance to passive stretch. The hemiplegic side of the trunk may appear shortened or rotated posteriorly, and the arm assumes a flexed position during movement and at rest. Patients with spasticity typically use compensatory patterns for gross motor patterns like rolling and sitting up and for ADL activities. Although they are usually able to sit and stand without loss of balance and walk with a brace and cane, their

Figure 24-7 Patient practicing sitting up using the hemiparetic arm for support.

trunk posture is often asymmetrical, with less weight taken on the hemiplegic leg and a flexed arm posture during most activities. The patient with spasticity may also have regained sufficient muscle control in the hemiplegic arm to move it, but abnormal coordination and excessive stiffness prevent skilled functional use (Fig. 24-8).

NDT treatment goals for the patient with spasticity include inhibiting abnormal tone and movement, increasing normal movement responses, and improving occupational performance by incorporating the hemiplegic side into task performance. The therapist uses inhibition techniques to address problems with abnormal tone, abnormal coordination, and associated reactions, followed by facilitation to increase postural control in sitting and standing and to develop selective movement control in the hemiplegic arm and hand. Patients at this stage of recovery are functionally independent in many tasks, thus, functional goals may include training of new tasks, decreasing compensations in tasks that are performed independently, and increasing functional use of the hemiplegic arm and hand. For example, to increase functional independence for a patient who shaves with his uninvolved hand while sitting, the therapist may either teach him to perform this task while standing or train him to use the hemiplegic hand to apply shaving cream.

Many patients with hemiplegia do not progress beyond the problems associated with spasticity and fail to develop normal movement control in their hemiplegic side, some patients never develop spasticity in the involved side, and

Figure 24-8 Patient moving arm that demonstrates abnormal pattern of coordination.

other patients recover movement control. These higher level patients walk well without postural asymmetry because they have better trunk control and are able to support weight on their hemiplegic leg. They also show improvements in motor control of the hemiplegic arm and may be able to use the arm for weight support and to hold objects that are placed in the hand. Despite the good motor recovery, problems opening the hand to initiate grasp and release and maintaining good elbow extension during reaching may persist. These patients may also complain of problems with the accuracy and speed of movement that make it difficult to use the arm for function. NDT goals for higher level patients focus on improving coordination of the hemiplegic arm and hand, especially in the patterns necessary for reach, grasp, and manipulation; increasing functional use of the arm and hand; and decreasing compensation in life tasks. The therapist may use facilitation, occupation-as-means, and occupation-as-end to achieve these goals.

TREATMENT TECHNIQUES: INTEGRATING NDT/BOBATH INTO OCCUPATIONAL THERAPY PRACTICE

The NDT/Bobath approach is most effective when nurses; physical, occupational, and speech therapists; and family members all use a similar approach to management. Occupational therapists can have a significant effect on tone and movement, however, by integrating NDT principles and techniques into OT practice, even when other professionals use different treatment approaches. The next section describes ways to integrate NDT concepts and techniques into rehabilitation of the hemiplegic arm and into ADL. The Neuro-Developmental Treatment Association (NDTA) offers postgraduate training courses for physical and occupational therapists interested in learning more about this approach to treatment (Resource 24-1).

Treatment of the Hemiplegic Arm

The NDT/Bobath approach to treatment of the hemiplegic arm is designed to address impairments, such as abnormal tone, pain, subluxation, and the loss of movement control, that are related to deficits in capabilities and occupational performance. Specific impairments are treated using inhibition techniques such as reflex-inhibiting patterns, scapula mobilization, trunk rotation, and weight bearing. NDT therapists also use facilitation to reeducate selective arm movements, to teach the patient to use the arm for weight bearing, and to increase skilled use of the hand. Although inhibition of abnormal responses is generally done before facilitation of normal movements, the line between inhibition and facilitation is often indistinct because techniques such as weight bearing can be used for both inhibition and facilitation. The amount of treatment time devoted to inhibition versus facilitation varies according to severity of problems and treatment goals, but both techniques are generally used in every treatment session so that changes in tone and muscle length are immediately translated into motor and functional performance.

Use of Inhibition

Inhibition is an important part of the NDT approach to movement reeducation because normal movements cannot be facilitated in the presence of abnormal tone and reflex activity. NDT therapists use inhibition with patients who have spasticity to decrease the amount of tension in the muscle, restore normal resting lengths to muscles that are habitually shortened, and stop excessive or unwanted muscle contraction. B. Bobath described inhibition of spasticity as the process of “normalizing tone” because, after treatment, the spastic arm feels flexible and light rather than stiff and heavy. This reduction in spasticity allows the patient to follow guided movement more easily and to initiate arm movements outside of synergy.

Reflex-inhibiting patterns (RIPs) are one of the main techniques for inhibiting spasticity in the hemiplegic arm. Since flexor spasticity in the arm is concentrated in shoulder elevators and internal rotators and elbow, wrist, and finger flexors, the tension in these muscle groups can be systematically decreased or “inhibited” by gradually moving the arm into a position that includes shoulder girdle depression and shoulder external rotation, elbow and wrist extension, and an open hand (Fig. 24-9). Spastic muscles resist lengthening, and the therapist must use handling to gradually lengthen the affected muscles and bring the arm into the full RIP (Procedures for Practice 24-3). Rather than passively stretching the spastic muscles into the RIP, B. Bobath (1990) described the use of trunk rotation and shoulder mobilization in the supine position and weight bearing to inhibit flexor spasticity in the hemiplegic arm. Once spasticity in the arm has decreased, the therapist immediately begins to retrain selective movements using facilitation, as the purpose of decreasing muscle tone is always to allow the patient to experience normal movement. The process of facilitation, including using weight bearing to increase muscle contraction in the arm, is described in the next section.

Figure 24-9 Therapist using a reflex-inhibiting pattern (RIP) to inhibit flexor spasticity.

PROCEDURES FOR PRACTICE 24-3

Inhibition of Spasticity in the Hemiplegic Arm using RIP

1. Position patient in sitting.
2. Place hands on the hemiplegic arm using proximal and distal key points of control. Patient's arm will be in a flexed, adducted position.
3. Correct adduction of the humerus first, leaving the elbow in flexion.
4. Maintain the humerus in neutral rotation by the side of the body and use pressure on top of the forearm to extend the elbow gradually. If the forearm is supinated, pronate it first.
5. When the tension in the biceps has decreased, slide your hand from the top of the forearm to the wrist and hand. Extend the wrist to neutral first, leaving the fingers flexed.
6. When tension in the wrist flexors has decreased, open the fingers, keeping the wrist in a neutral position.
7. Maintain the arm in an extended position and proceed to weight bearing or guided movement.

In acute rehabilitation, most patients exhibit low tone and weakness rather than spasticity. In this setting, inhibition techniques are used to maintain muscle length and normal joint mechanics in the arm and to prevent the development of spasticity and abnormal coordination as the patient learns to function more independently. For example, the therapist may maintain the affected arm in an extended position while the patient practices moving from sitting to standing to prevent an associated reaction in the arm during this difficult movement. If the hemiplegic arm has little or no flexor spasticity, it does not resist movements into extension, so the therapist must be careful not to overstretch the elbow, wrist, and hand while using this technique (Safety 24-1).

Positioning is another way to prevent the development of spasticity during the times the patient is in the wheelchair or in bed. The therapist and nurse should help the patient position the flaccid arm in patterns that maintain muscle length in elbow extension and shoulder girdle abduction and external rotation to counteract the development of flexor spasticity. For example, when the patient lies supine in bed, the hemiplegic arm should be positioned with the elbow in extension, the shoulder and forearm in neutral rotation, and the hand and wrist supported so that they do not fall into flexion (Fig. 24-10). This position is preferable to allowing the patient to rest the arm in flexion across the chest since this flexed position may increase muscle tone. While the patient is in the wheelchair, lap boards or pillows should support the hemiplegic arm. These wheelchair aids help prevent both shoulder

SAFETY NOTE 24-1

Avoiding Overstretch of the Flaccid Hand and Wrist

The therapist must be careful to avoid overstretching the flaccid muscles of the hand and wrist during inhibition, facilitation, and upper extremity weight bearing. Precautions include:

- Avoid positioning the wrist in maximal extension or flattening the palm of the hand.
- Do not pull the hemiplegic thumb into hyperextension or hyperextend the metacarpal joints of the fingers because this may result in hypermobility of these small joints.
- Use a distal grip that maintains the wrist joint in neutral or slight extension and supports the transverse arches of the palm. The therapist may let the patient's fingers flex when the palm and wrist are supported.

subluxation and spasticity. Positioning techniques are used less frequently as the patient is more active or recovers motor control in the hemiplegic arm.

Facilitation in Arm Treatment

Facilitation techniques are designed to restore normal movement responses. In treating the arm, facilitation includes teaching the patient to support weight on the hemiplegic arm, teaching the patient to perform selective movements of the hemiplegic arm and hand, and providing opportunities to practice functional use of the arm in occupation-as-means. Facilitation in occupation-as-end is discussed separately in the next section.

Facilitation of Weight Bearing

Weight bearing is one of the most important aspects of treating the hemiplegic arm because it can be used to maintain muscle length, normalize tone, and increase activity in the muscles of the trunk and arm (Ryerson & Levit, 1997b). In the NDT/Bobath approach, weight bear-

Figure 24-10 Hemiplegic arm correctly positioned for sleeping.

ing is a dynamic process. Rather than statically propping on a rigid arm, the patient is taught to activate muscles in the trunk by moving body weight over the stable arm. The movements of the trunk cause muscles in the arm and hand to lengthen and shorten and contract to maintain the arm on the support surface. Since use of the arm for weight support does not require fine motor control, even patients with severe weakness and loss of motor control can learn to use their hemiplegic arms to support body weight. Thus, weight bearing is used both to facilitate muscle activity in the hemiplegic arm and to increase functional use of that arm.

The NDT therapist generally begins by teaching the patient to accept weight on the hemiplegic arm with forearms on a table (Ryerson & Levit, 1997a). This pat-

Figure 24-11 Patient using hemiparetic arm to support weight and provide stability while writing.

tern is important for activities that are commonly performed at a table, such as eating, reading, and writing (Fig. 24-11). Weight bearing on an extended arm is more difficult for the patient because it requires control of the elbow and wrist joints as well as control of the trunk and shoulder girdle. It is used with patients who have more selective control of the arm. NDT therapists often train extended-arm weight bearing with the hemiplegic arm by the side of the body when the patient is sitting. As the patient improves balance control in standing, the therapist may also train extended-arm weight bearing in standing, so that the patient learns to use the hemiplegic arm for support while working in the kitchen or bathroom.

Facilitation of Arm Movement

Facilitation of arm movements is another important part of arm treatment (Procedures for Practice 24-4). The NDT therapist uses this aspect of facilitation to give the patient the sensation of normal movement, teach normal patterns of initiation and sequencing, and reeducate and strengthen normal movements to be used for function (Ryerson & Levit, 1997a). Facilitation is really a system of guided movement or active-assistive exercise. The therapist uses proximal and distal key points to establish normal alignment in the arm and maintains this control while moving the patient's arm in patterns that are important for functional use. This handling provides sensory messages about how movements are sequenced. The patient is encouraged to assist with the movement when possible. As the patient begins to participate, the therapist decreases the assistance, giving the patient partial control of arm movement. The NDT therapist uses

PROCEDURES FOR PRACTICE 24-4

The Process of Facilitation

1. Restore alignment of the segments to be moved using key points of control.
2. Assist the desired movement using light hands.
3. Proceed slowly and feel for the patient's response. The arm will feel lighter and movement easier when the patient is assisting.
4. Repeat movements until patient can actively assist and you feel the patient is active.
5. Lighten messages of your hands so that the patient moves with less assistance. Give verbal feedback during this phase.
6. Gradually withdraw control. The patient's movement control may decline but should not produce an abnormal response.
7. Provide practice opportunities through use of activities (occupation-as-means) or home exercises.

sensory information from handling to decide where and when to let go, so that the quality of movement stays relatively consistent when the therapist withdraws control. The active-assistive quality of facilitation also helps to decrease the excessive effort that many hemiplegic patients use to initiate movements of their involved side.

Facilitation is used to reeducate or strengthen movements that are difficult for the patient to perform without assistance. The movements of shoulder flexion or shoulder abduction with elbow extension are usually the most difficult because they go against the pattern of muscle return. The therapist facilitates extended arm movements to establish this difficult pattern of coordination and to prevent the patient from learning to use flexor spasticity to move the arm. To use the arm for function, however, the patient must initiate arm movements with different combinations of shoulder and elbow movements. To do this, the therapist uses facilitation of elbow flexion and extension so that the patient gains control of elbow movements outside the pattern of mass flexion.

During facilitation of arm movements, the therapist must make sure that the humerus is correctly positioned in the glenoid fossa and the scapula can rotate on the thorax. Patients feel pain in the hemiplegic shoulder during facilitation when the humerus is not seated in the fossa or when normal scapulohumeral rhythm is not available. Therefore, the therapist must correct shoulder joint alignment and maintain normal joint mechanics while facilitating arm movements in any position to avoid traumatizing the shoulder joint. This is described further in Procedures for Practice 24-5. As the muscles of the shoulder girdle become more active, the therapist may decrease control of joint alignment and mechanics.

Arm Treatment in Supine

The NDT therapist often begins to inhibit abnormal tone and facilitate normal patterns of arm movement with the patient lying supine. Supine is the easiest position for patients with loss of postural control and weakness to practice moving their arms because the bed or mat provides postural stability. The stable position of the patient's trunk also makes it easier for the therapist to maintain normal scapulohumeral rhythm while lifting the hemiplegic arm into flexion and abduction. To facilitate arm movements in supine, the therapist uses proximal and distal key points on the arm to extend the hemiplegic elbow and bring the patient's shoulder into flexion (Fig. 24-12). The therapist should make sure that the scapula rotates easily before elevating the arm above 60° of shoulder flexion. If spasticity or muscle tightness is blocking scapula movement, it is important to use inhibition to restore normal joint mechanics before bringing the arm into elevation.

PROCEDURES FOR PRACTICE 24-5

Restoring Normal Joint Mechanics to the Subluxed Shoulder

The therapist must reposition the subluxed shoulder joint before active or passive movements of the arm are attempted. Correcting the subluxation entails moving the scapula into neutral or slight upward rotation and lifting the humerus so that it rests in the glenoid fossa. The therapist should maintain the shoulder joint in this corrected position during treatment of the arm. To restore normal joint mechanics, the therapist should follow these steps:

1. Place one hand under the axilla to support the inferior portion of the shoulder joint and the other hand on the patient's scapula. The therapist uses this hand placement to correct the position of the upper trunk and to rotate the scapula upward.
2. Hold the corrected shoulder position with one hand, and move the other hand to the distal humerus. Gently lift the humerus up into the glenoid fossa.
3. If the humerus is internally rotated, move the humerus into neutral or slight external rotation.
4. Check that the scapula can rotate on the thorax before moving the arm above 60° of forward flexion or abduction. If the scapula cannot rotate freely, scapular mobility should be restored before moving the humerus into elevation.
5. Maintain correct scapulohumeral rhythm during active and passive arm movements.

When the hemiplegic arm can be moved without pain or resistance, the therapist begins to use facilitation to increase muscle activity. The extended arm is moved slowly through small ranges. As the therapist feels the patient begin to assist or follow her movements, she asks the patient to try to hold the arm in position. B. Bobath called this technique “place and hold” because it is based on the normal placing response. Place and hold can be practiced with the shoulder and elbow in varying positions so that the patient develops control of proximal and distal arm movements (Fig. 24-13). As the patient develops the ability to place the arm and to move in small ranges without loss of control, handling is lightened or removed to allow opportunities for independent practice.

Arm Movement in Sitting

As soon as the patient begins to assist with facilitated movements in supine, the therapist should begin to practice guided movements of the arm with the patient in sitting. Subluxation of the glenohumeral joint is more common in sitting than supine because the muscles of the

Figure 24-12 Therapist corrects position of hemiparetic arm prior to facilitating arm movements.

Figure 24-13 Placing and holding for the hemiparetic arm.

hemiplegic arm are too weak to hold the scapula in the correct position on the trunk and because the loss of trunk control also affects scapula alignment (Ryerson & Levit, 1997a, 1997b). The therapist must reduce the subluxation before beginning facilitation and maintain this corrected position during arm treatment. (Figs. 24-14 to 24-16). Initially, the therapist controls the position of the shoulder girdle during guided movements of the arm to strengthen normal patterns of coordination and prevent pain. As strength and control increase in the hemiplegic arm, the therapist gradually withdraws this control, and the patient attempts to move the arm in the same patterns and ranges.

Using Occupation-As-Means in Arm Treatment

The NDT therapist uses occupation-as-means activities to practice and strengthen movement control in the hemiplegic arm. The therapist uses handling to introduce these activities but should withdraw this control as quickly as possible, letting the patient practice without assistance. Occupation-as-means activities can be set up with the hemiplegic arm in weight bearing. For example, the patient may play checkers on the treatment mat while weight bearing on the hemiplegic arm or rinse dishes in the sink

Figure 24-14 Close-up of shoulder showing glenohumeral subluxation.

Figure 24-15 Therapist correcting subluxation.

Figure 24-16 Therapist controlling subluxation while facilitating arm movement.

with the unaffected hand while maintaining the hemiplegic arm on the counter (Fig. 24-17). These activities help the patient learn to use the hemiplegic arm to provide support and assist balance. The patient may also practice using weight bearing to inhibit associated reactions during dressing (Fig. 24-18).

Occupation-as-means also provides opportunities for practice moving the hemiplegic arm or coordinating use of both hands in bilateral patterns of coordination. For example, the patient may strengthen reaching patterns of the hemiplegic arm by practicing wiping the table or washing a window. To practice control of elbow movements, the therapist may facilitate arm movements while the patient holds an object in the hemiplegic hand and practices bringing it to the body or face (Fig. 24-19). Bilateral coordination is reinforced by tasks such as carrying a tray or pushing a vacuum cleaner. The therapist selects tasks for occupation-as-means according to the movement components embedded in them. The practice of these meaningful activities is expected to generalize to

increased functional use of the hemiplegic arm in other tasks that use similar components.

Occupation-As-End Treatment

Occupational therapists incorporate NDT/Bobath principles into occupation-as-end training of ADL and other tasks by using specific compensations that support the goals of handling. These compensations are designed to incorporate the involved arm into task performance and to prevent spasticity and abnormal coordination in the hemiplegic arm. The therapist selects the occupations to be trained according to the patient's level of functioning and the goals for independence. Early treatment may focus on retraining basic ADLs, such as bathing, dressing, and toileting, and tasks such as rolling in bed and transfers. As patients regain their independence in these tasks, therapists may incorporate NDT principles into occupation-as-end training of vocational tasks, such as using a computer mouse, or leisure activities, such as golf or swimming.

Figure 24-17 Therapist helps maintain the hemiparetic arm in weight bearing while the patient rinses the dishes at the sink.

Figure 24-18 Patient uses hemiparetic arm in weight bearing while dressing.

Figure 24-19 Therapist facilitates elbow flexion while the patient grasps the cup with both hands and brings it to the mouth.

Gross motor activities, such as rolling in bed, sitting up, and standing up, are important functional tasks that are introduced in acute treatment. When the patient cannot move the hemiplegic arm, the NDT therapist trains specific compensations designed to promote symmetry, prevent neglect of the hemiplegic arm, and inhibit abnormal tone and movement. For example, the patient may be taught to interlace the fingers of both hands, keeping palms together and thumbs facing up, when it is necessary to move the arm. This clasped-hand grip helps patients to maintain the hemiplegic forearm in an extended position during self-range of motion and during movements such as rolling and standing up. The therapist may teach rolling to the uninvolved side by having the patient clasp the hands, reach both hands toward the ceiling with extended elbows, and then initiate rolling by turning the head and reaching both arms across the body (Fig. 24-20, A & B). This technique ensures that the hemiplegic arm does not get left behind the body and that the patient will actively use her trunk muscles to initiate rolling rather than turning in bed by pulling on the bed rails. Similarly, having the

Figure 24-20 A. Patient lifts hemiplegic arm. B. Patient turns the arms and upper trunk to roll to the uninvolved side.

patient clasp hands before coming to standing prevents an associated reaction in the hemiplegic arm, maintains symmetry in the trunk and lower body, and prevents the patient from pushing up with the unaffected arm.

The NDT therapist also uses compensatory techniques to incorporate the hemiplegic arm into activities such as dressing and grooming. Flexor posturing of the arm during task performance is a major problem for some patients, particularly when the patient is struggling or using excessive effort. After the task is complete, the arm may remain in this flexed position. The NDT therapist introduces compensations during life tasks to maintain symmetry in the trunk and maintain the hemiplegic arm in extension. For example, to prevent posturing of the hemiplegic arm while the patient puts on a shirt, the patient may be taught to flex the trunk forward and reach the hemiplegic arm to the floor before putting it into the shirt sleeve (Fig. 24-21) (Davis, 1990). This technique passively maintains extension in the arm during this difficult movement. As control of the arm improves, the patient may learn to place the hemiplegic arm in a position of extended weight bearing on the bed during tasks such as buttoning

Figure 24-21 Patient using compensation to put the hemiplegic arm in the sleeve.

a shirt, when the arm is most likely to posture in a pattern of flexor spasticity.

Although functional training is designed to promote independent task performance, the NDT therapist initially uses handling in combination with verbal instructions and demonstrations to teach the patient what is expected. The NDT therapist uses handling to structure the task, so that the patient has only to control the movement of one body segment during task practice. Handling is a particularly important part of occupation-as-end training in the acute phase, since patients at this stage of recovery have problems controlling both trunk and arm position (Van Dyck, 1999).

For patients with poor sitting balance, the NDT therapist may assist the movement of the trunk during task practice. For example, the therapist may use his or her hands on the patient's trunk to provide stability and maintain weight on the hemiplegic hip while the patient leans forward to don shoes (Fig. 24-22). Or the therapist may assist the upper extremity in task performance while the patient performs the necessary trunk movements independently. For example, the therapist may facilitate the

Figure 24-22 Therapist using handling techniques to provide trunk stability while the patient fastens his shoes.

correct shoulder and elbow movements while the patient holds the deodorant stick in the hemiplegic hand and applies it to the uninvolved side. As the patient's movement control increases and task performance becomes more automatic, the therapist withdraws physical assistance. At this point, verbal feedback may be offered to help improve the patient's performance.

Contributions to Psychosocial Adjustment

The emphasis that the NDT/Bobath approach places on functional recovery in the hemiplegic side has potential psychosocial as well as physical benefits to patients who have had strokes. In traditional rehabilitation approaches, the emphasis is on compensatory use of the uninvolved side. This may suggest that the hemiplegic side will not recover. In contrast, the NDT/Bobath approach, with its emphasis on treating the hemiplegic side, offers stroke patients a very different message. From the early days of rehabilitation, NDT therapists help

stroke patients relearn functional tasks in ways that make use of the existing motor patterns in the trunk, arm, and leg. They also use treatment to increase control of movement in the affected side and to minimize or eliminate secondary impairments that affect quality of life. These treatment activities give the patient realistic hopes of functional recovery in the affected side of the body and may contribute to a more positive attitude toward the disability and a sense of self-efficacy.

EFFICACY AND OUTCOMES RESEARCH

Since NDT/Bobath treatment is widely used in many countries, research documenting the efficacy of this approach is an extremely important component of evidence-based practice. A literature search identified a small number of recent studies examining the efficacy of the NDT/Bobath approach in stroke rehabilitation. The majority of these studies compare treatment outcomes of patients receiving the Bobath approach to the outcomes of patients receiving other therapeutic interventions with the goal of determining which approach is most effective for remediating impairment and improving general functional outcomes. Although this literature suggests that the NDT/Bobath approach is effective for improving physical and functional outcomes, no strong evidence supports the superiority of NDT/Bobath over other treatment approaches following stroke. Methodological limitations and inadequate outcome measures, however, may limit the conclusions that can be drawn from these research studies (Luke, 2004; Paci, 2003), and the nature of this approach may make it difficult to devise standardized treatment interventions for research study.

Systematic literature review and meta-analysis provide the highest level of scientific evidence. Two recent studies used systematic literature search to investigate the clinical effectiveness of NDT/Bobath in the treatment of stroke. Paci (2003) reviewed the literature in English, French, and Italian and identified 15 studies where Bobath treatment was used in either experimental or control groups. Outcome measures included effectiveness of general treatment, effectiveness of treatment of lower extremity and gait, and effectiveness of treatment of the arm. Although the groups receiving NDT/Bobath treatment showed an improvement in some or all measures in most studies, the majority of studies found no significant differences between treatment groups. Luke (2004) performed a similar literature search and identified eight articles that compared the effectiveness of Bobath treatment in upper limb disability with similar findings. Like Paci, Luke concluded that NDT/Bobath is not superior to other treatment approaches at improving tone and movement in the upper limb,

addressing activity limitation, or increasing participation in life roles. Since Hiraoka (2001) and Hafsteinsdottir (1996) reported similar results after reviewing a slightly older group of studies, it seems safe to conclude that the bulk of existing research does not demonstrate any advantage for NDT as a clinical intervention over other methods of neurological rehabilitation.

The evidence from recent randomized, controlled studies is more ambiguous. Langhammer and Stanghelle (2000) performed a randomized, controlled study of 61 acute stroke patients, half of whom were treated with NDT/Bobath and half of whom received treatment based on Motor Relearning Program (MRP). During the acute phase of rehabilitation, patients treated with MRP had shorter hospital stays and showed significantly greater improvements on two tests of motor function. The authors concluded that these results demonstrate that MRP is preferable to Bobath in the rehabilitation of acute stroke. When the same patients were reassessed at 1 and 4 years post stroke (Langhammer & Stanghelle, 2003), however, both groups showed a large decrease in function, and no significant differences were present between the two groups on measures of arm function and ADL independence. In other words, the type of treatment patients received in the acute phase did not have a differential effect on long-term recovery because the patients treated with NDT did not have significantly lower functioning than those who had been treated with MRP.

A second series of studies presents evidence of positive benefits associated with NDT treatment for the hemiplegic arm. Feys et al. (1998) performed a single-blind, randomized, controlled study in which 100 stroke patients were assigned to a control group that received standard rehabilitation or an experimental group that received 6 weeks of sensorimotor treatment based on NDT/Bobath concepts to the arm in addition to standard rehabilitation. The experimental treatment involved 30 minutes of active or active-assisted exercise with the hemiplegic arm positioned in an RIP in an air splint. Feys et al. found that, although both groups improved significantly over time and there were no group differences on the *Barthel Index*, the experimental group showed a greater improvement in the hemiplegic arm as measured by the *Brunnstrom-Fugl-Meyer Motor Assessment* at the 6- and 12-month follow-ups. In addition, when subjects were re-assessed 5 years later (Feys et al., 2004), patients in the experimental group scored significantly higher on the *Brunnstrom-Fugl-Meyer Motor Assessment* and *Action Research Arm Test*. As in the earlier study, the groups did not differ significantly on the *Barthel Index*. These studies suggest that the sensorimotor stimulation provided by the supplemental NDT/Bobath intervention was highly effective in improving arm function in the acute phase and that the benefits of this intervention were long lasting.

In considering the evidence, it is important to note that several problems with the existing research may limit the

conclusions that can be drawn about the efficacy of NDT/Bobath treatment. Paci (2003), Luke (2004), and Hafsteinsdottir (1996) all cite methodological problems with the research studies included in their reviews. These concerns include the lack of availability of valid outcome measures sensitive to the changes in movement control, postural responses, and muscle tone that may result from NDT/Bobath treatment; heterogeneous samples with few controls on age, location, and severity of the stroke; and differences in the duration and dosage of treatment. In many studies, small sample size also resulted in low power to detect treatment effects. These problems have also been noted in relation to outcome research on NDT/Bobath for children with cerebral palsy (Butler & Darrach, 2001). Existing research on the effectiveness of NDT/Bobath has also focused almost exclusively on intervention for acute hemiplegia. As the studies of Langhammer and Stanghelle indicate, this focus may not adequately reflect the long-term benefits of a given intervention.

A second problem with the existing research is related to the nature of NDT/Bobath treatment and the problems inherent in standardizing and measuring motor interventions for a treatment intervention that is evolving and individualized. NDT/Bobath treatment principles and techniques have changed over time and are taught mainly through post-graduate continuing-education courses. For this reason, the Bobath text (1990), cited in many of the studies as the source of the techniques used, does not adequately reflect the current practice of NDT. The NDT approach is individualized, so that NDT therapists may use very different strategies for individual patients depending on the problems identified during assessment. Since the procedures and techniques used in research must be standardized, the NDT delivered in the treatment protocol may not reflect the true benefits of the technique. Finally, the effectiveness of NDT and other motor interventions depends largely on the experience and skill of the therapist and specific goals of the treatment session (Butler & Darrach, 2001). Although the skill level of the therapists delivering the treatment is rarely mentioned and is difficult to quantify, it is clear that most research studies do not use therapists with expertise in the NDT/Bobath approach. This suggests that the research outcomes may underestimate the true efficacy of the approach. Given these problems, research studies in which operationally defined and current NDT/Bobath treatment is delivered by experienced therapists with clinical education in this approach will be needed to accurately evaluate the efficacy of this approach in the future.

Barriers to Effectiveness

The NDT approach and NDT handling has been criticized by motor learning theorists as too passive and lacking in opportunities for independent practice (Gordon, 1987). This criticism may be valid. Although B. Bobath

stressed that handling should involve active participation by the patient, she also stressed that the therapist should prevent abnormal tone and movement. Her emphasis on movement quality has resulted in a perception among NDT therapists that patients should not move independently until they are able to use normal patterns of muscle activation. Research on motor learning suggests that this restriction may limit the patient's functional recovery and affect both functional performance and use of the involved arm (Langhammer & Stanghelle, 2000). For example, Langhammer and Stanghelle (2000) performed a randomized double-blind study comparing motor

function and functional level of patients treated with Bobath with motor function and functional level of patients receiving the Motor Relearning Program (MRP), which is a treatment stressing independent practice. They found that motor function in the arm was significantly better in the MRP group at discharge, although this did not remain true at 5-year follow-up. NDT therapists and clinical instructors are aware of this problem and are changing the practice of handling to incorporate opportunities for independent practice (Ryerson & Levit, 1997a; see Howle, 2002 for a complete discussion of this problem).

CASE EXAMPLE

Mr. R.: Optimizing Motor Behavior Using the Bobath Approach

Occupational Therapy Intervention Process

Patient Information

Mr. R., a 64-year-old retired economist 2 months post stroke, was referred to outpatient occupational therapy after treatment in a rehabilitation center and at home. Mr. R. had a severe stroke that resulted in flaccidity in the muscles of the left trunk, arm, and leg and loss of balance in sitting and standing. At the time of the evaluation, the patient and his wife were living with a daughter and her family because of the demands associated with his care. The occupational therapy assessment identified the following problems: (1) dependence in ADLs and IADLs due to loss of postural control; (2) severe pain in left shoulder and edema of the left hand; (3) failure to attend to the left side of the body or to position the left arm for safety or comfort; (4) non-functional left arm and hand due to flaccidity and weakness; and (5) mild depression.

Clinical Reasoning Process

Objectives

Appreciate the context

Develop intervention hypotheses

Examples of Therapist's Internal Dialogue

"Mr. R was an active person with a challenging and important job before his stroke. He was forced to retire because of his physical limitations, and he and his wife have left their own home to live with their daughter because he is too much for his wife to manage independently. These dual losses must be hard on this proud man and disruptive to his sense of self-efficacy. His depression seems appropriate to these changes in life roles. He is also discouraged because he remains so dependent after 2 months of intensive rehabilitation and home therapy. It is clear that he has begun to doubt that he will ever get better."

"I believe that Mr. R.'s poor trunk control and his shoulder pain are the two major causes of his inability to care for himself. He seems afraid to touch or move his left arm because it may hurt, and he knows he is likely to fall over when he tries to dress himself or transfer to the wheelchair. Sleeping at night is also difficult because of arm and hand pain, and he cannot find a comfortable position or turn easily. Therefore, reducing his pain and making him safer during daily activities are important priorities. Improvements here should give him hope."

Summary of Short-Term Goals and Progress

Goal 1: Mr. R. will be able to sit unsupported on a firm chair and initiate trunk weight shifts in anteroposterior, lateral, and rotational planes without loss of balance.

The therapist determined that Mr. R. lacked sufficient control of trunk movements in sitting to dress safely. During treatment, she worked to increase control of trunk movements in the patterns necessary for upper and lower body dressing and grooming. She also used upper extremity weight bearing at a table to increase trunk control so that Mr. R. would learn to support weight on his affected left arm and activate muscles in his trunk and shoulder girdle. The therapist taught Mr. R. and his daughter how to practice these trunk movements at home. She also changed the way the daughter helped Mr. R. transfer to increase weight bearing on the left leg and appropriate activity in trunk extensor muscles. As trunk control improved, Mr. R. could use his uninvolved right arm to put on his shirt while sitting without loss of balance. He also could independently manage his wheelchair locks and foot pedals. Visual neglect of the left side decreased, as he was able to turn his head to the left without loss of balance.

Goal 2: Mr. R. will wear the prescribed shoulder support and hand splint while he is out of bed and perform edema massage and shoulder exercises three times a day.

The therapist removed the elevated arm trough from the patient's wheelchair because it increased shoulder pain. She showed the patient's daughter how to use a pillow to position the arm in the wheelchair. Mr. R. was fitted with a commercial shoulder brace for use during walking. This brace supported the subluxation but did not position the elbow in flexion. The therapist also fabricated a wrist splint that supported the wrist in neutral. The patient and daughter were instructed to stop all exercises that caused pain. They were taught how to massage the hand to decrease edema. In addition, the therapist taught Mr. R. how to move his arm in small ranges, supporting the left hand in the right using the modified clasped hand grasp and how to position the arm in bed.

The treatment was successful. Hand edema began to decrease immediately, and the hand was no longer painful to the touch after three treatments. The therapist also could passively move the arm below 60° of shoulder elevation without pain in supine when supporting the shoulder joint. The therapist changed the massage and passive exercise program to reflect these improvements. She also introduced transfers and rolling using the clasped-hand technique to incorporate the left arm into the activity.

Goal 3: Mr. R. will actively assist with dressing.

Mr. R.'s daughter dressed her father while he lay in bed. The therapist recommended that they start dressing with Mr. R. seated in a straight chair with arms. One treatment session was devoted to teaching Mr. R.'s daughter how to assist dressing while encouraging her father to be active and assist the task. The daughter initially supported the left arm and assisted trunk weight shifts. As her father grew more confident, she provided less physical assistance but continued to give verbal cues. The therapist introduced occupation-as-end dressing when Mr. R. had sufficient trunk control to perform necessary weight shifts without loss of balance and when pain no longer limited passive movements of the left arm. The slow approach gave Mr. R. time to learn and fostered confidence in his own abilities.

Assess the patient's comprehension

"Mr. R. is able to follow directions in therapy and to repeat the directions and goals on command. I think his cognitive abilities will be a strength—he has more difficulty with execution because his body doesn't always behave the way he wants. He is able to get set up for his home exercises independently but needs some physical assistance from his daughter to get his sling and splint on correctly."

Understand what he is doing

"The daughter reports that he is motivated to do things the way we practiced in therapy. Transfers are easier, as are ADLs. Both are pleased with the program."

Compare actual to expected performance

"Mr. R is starting to come into each therapy session with a list of questions or problems. He is able to see a difference in the edema in his hand and has been using the positioning techniques in the wheelchair and in bed. He reports that he is able to fall asleep more easily now that he knows where to put his arm, but he still wakes up with shoulder pain, which shows that we are making progress but have more work to do."

Know the person

Appreciate the context

"Daughter is extremely concerned and follows through well. His success with his home exercises is due to her. She is a real asset to him."

Select an intervention approach	“I will develop a treatment plan based on NDT principles and techniques to treat his trunk control and attempt to change the pain and increase function in the left arm. I believe that improving his trunk control and restoring pain-free shoulder movements in the left arm will make it possible for Mr. R. to dress and bathe himself. I know that there is no evidence that NDT is more effective than compensatory training, but Mr. R. has already had 2 months of compensatory training without results, and focusing on his motor impairments will represent a new approach to his loss of independence. I will also work with his daughter to develop more consistent ways to perform ADLs, transfers, and arm exercise.”
Reflect on competence	“Mr. R. is very similar to other stroke survivors that I have worked with, and I believe he will respond well to my treatment plan. I expect that we can decrease his pain fairly quickly, which should make therapy/home exercises less stressful. I also believe that his depression will lighten when he starts to see progress, but if not, he may require a medical evaluation and medication.”

Recommendations

The occupational therapist recommended 2 therapy sessions per week for 8 weeks. Mr. R.’s insurance company authorized 16 30-minute sessions. In consultation with Mr. R. and his daughter, the occupational therapist established the following treatment goals, which were motivated by the patient’s desire to return to his own home: (1) Mr. R. will bathe his upper and lower body and dress himself with assistance and verbal cues using compensations that increase the use of the left side; (2) Mr. R.’s daughter will be able to move his left arm through 120° of shoulder elevation without pain; (3) Mr. R. will transfer with contact guarding to and from wheelchair to bed and toilet; (4) Mr. R. will position his left arm on the table during meals and speech therapy and shift weight over this arm; (5) the left arm will be properly positioned in wheelchair with hand splint on 75% of the time; and (6) hand edema will be eliminated.

Consider the patient’s appraisal of performance	“I think that continued therapy is warranted despite the lack of improvement in previous treatment programs. Mr. R. is anxious to be more independent so that he can move back to his own home and participate in more of his former life roles. His cognitive abilities do not seem to be affected, and he has a realistic sense of what he can do now and what is needed to return to his own home with his wife. He seems afraid to be too optimistic for fear of failure, but I expect that if he can see progress he will want to keep going.”
Consider what will occur in therapy, how often, and for how long	
Ascertain the patient’s endorsement of the plan	“Mr. R. is extremely happy with the goals we have set and our new methods. His daughter is rather protective but interested in helping her father with his therapy and pleased with our goals. Because of her physical limitations, Mrs. R. is not likely to assume much of a role in direct care. But she is supportive of her husband and watches each therapy session.”

Next Steps

Revised Short-Term Goals (after 16 treatments)

- Mr. R. will perform upper body and lower body dressing activities independently while sitting in a straight chair.
- Mr. R. will attend to the position of his left arm at all times and will position the arm appropriately without verbal reminders.
- Mr. R. will support weight on the left forearm while sitting at a table and use this pattern functionally in activities such as eating, reading, and writing.
- Mr. R. will transfer independently from the wheel chair using the clasped-hands technique.

Anticipate present and future patient concerns

Analyze the patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. R. has made good progress on all our goals but still requires assistance for most life roles. He is beginning to realize that, while he may achieve his goals, therapy is likely to last several more months. He has been talking with his wife and daughter about moving back to their own house with a live-in aide to assist with his care and exercises. I think this is probably a good solution but encouraged him to continue to work on the program we have set up to see if we can accomplish our new goals. He agrees that continuing treatment is important no matter where he is living.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Effects of Physical Impairments on ADL Performance**

At the time of his evaluation, Mr. R. could not dress himself and his daughter was dressing him. The occupational therapist wanted to start dressing training immediately because independent self-care was a major long-term goal. Her plan was to develop a system for Mr. R. and his daughter to use at home. The daughter would provide support and assistance initially and gradually withdraw her assistance as Mr. R. developed better control of the movement components necessary for independence.

What impairments contributed to Mr. R.'s loss of functional performance? What types of support and assistance are most important during the first dressing sessions? How do you teach Mr. R.'s daughter to assist upper body dressing during the early phase of treatment? How could she position the hemiplegic arm during lower extremity dressing?

Evidence Table 24-1 Best Evidence for Occupational Therapy Practice Regarding NDT/Bobath

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
NDT for stroke survivors	Effectiveness of NDT in 3 areas: general treatment, upper limb recovery, and lower limb and gait.	726 acute stroke survivors; age range, 15–95 years; mean age cannot be calculated.	Ranged from 2–15 weeks.	Systematic review of 15 trials: 6 randomized controlled trials, 6 non-randomized controlled trials, and 3 case studies.	Of general effectiveness studies (n = 6), 1 found more improvement in NDT group, and 5 found no difference or more gains in alternate group; 1 of 3 studies of upper extremity effectiveness found greater benefit with NDT.	$p < 0.001$ set as statistical significance level for all studies included. Effect sizes were not reported.	Paci, 2003
NDT for upper limb post stroke	Effectiveness of NDT in improving impairment (tone, strength, pain), activity limitation, and participation.	374 stroke survivors 6 weeks to 2 years post cerebrovascular accident; age range, 35–95 years; mean age cannot be calculated.	Ranged from 1 session to 20 weeks of daily 45-minute sessions.	Systematic review of 8 studies: 5 randomized controlled trials, 1 single-group crossover design trial, and 2 single case studies.	NDT more effective than proprioceptive neuromuscular facilitation but not more than general rehab at reducing muscle tone. No significant effects of NDT on motor control, upper extremity function, or participation.	Improvement in upper extremity tone using RIPs, $d = 0.46$.	Luke, 2004

SUMMARY REVIEW QUESTIONS

1. What do Bobath and Bobath say are the major problems after stroke?
2. Define the following terms: facilitation, inhibition, and handling. How are these procedures used to treat adult hemiplegia?
3. How do Bobath and Bobath define postural control, and what problems are associated with loss of postural control?
4. Explain why abnormal tone is a major problem requiring occupational therapy treatment.
5. List several ways to control spasticity.
6. What is the overall goal of NDT/Bobath treatment for stroke patients? How does this goal relate to the practice of occupational therapy?
7. Describe several ways occupational therapists may incorporate NDT/Bobath concepts into ADL training.
8. How do the goals of treatment differ for patients with low tone and patients with spasticity?
9. Why is weight bearing on the arm important for function? List several ways to use upper extremity weight bearing in treatment.
10. Describe a treatment program to increase movement and function in the hemiplegic arm if the patient has flexor spasticity.

CHAPTER 25

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. State the assumptions that underlie the Brunnstrom Movement Therapy approach.
2. List the six stages of recovery for the upper extremity and for the hand.
3. State the treatment principles of this approach.
4. Describe the treatment procedures to facilitate movement control in the trunk and upper extremity of hemiparetic patients using this approach.
5. Suggest functional activities suitable to encourage practice of movement behavior at various stages of recovery.

Optimizing Motor Behavior Using the Brunnstrom Movement Therapy Approach

Catherine A. Trombly Latham

Glossary

Associated reaction—Involuntary movement or patterned, reflexive increase in muscle tone and limb position on the hemiplegic side that occurs in stressful situations. An associated reaction is commonly seen when movement is resisted, when the patient exerts effort, or when the patient fears loss of balance.

Assumption—Supposition that something is true, although not proved; component of a theory.

Extensor synergy—For the upper extremity: scapular protraction, shoulder horizontal adduction and internal rotation, elbow extension, and forearm pronation. For the lower extremity: hip extension, adduction, and internal rotation; knee extension; plantar flexion and inversion of the ankle; and plantar flexion of the toes.

Facilitate—To make easier.

Facilitation—State of readying neurons to depolarize and propagate an impulse or to make contraction of a muscle or a reflex response more likely.

Facilitation techniques—Manual treatment techniques and hand placements used to increase muscle tone and to produce movement responses.

Flaccidity—State of lacking tone; limb feels limp and falls into place when not supported.

Flexor synergy—For the upper extremity: scapular elevation and retraction, shoulder abduction and external rota-

tion, elbow flexion, and forearm supination. For the lower extremity: hip flexion, abduction, and external rotation; knee flexion; ankle dorsiflexion and inversion; and dorsiflexion of the toes.

Inhibit—To restrain; to make more difficult.

Inhibition—State of hyperpolarization of neural cell membranes decreasing the likelihood of propagating an impulse or to make contraction of a muscle or a reflex response less likely.

Inhibition technique—Manual treatment techniques and movement patterns used to decrease spasticity and stop abnormal movement patterns.

Practice—Repetition with the intent to improve.

Rasch analysis—A mathematical procedure that compares how an individual with a specific ability responds to assessment items of various difficulties. Rasch analysis produces tables and graphs that place “person ability” and “item difficulty” on the same continuum (Woodbury & Velozo, 2005).

Spasticity—State of excess tone and hyperactive response to stretch. If moderately to severely spastic, the limb feels tight and is difficult to move into position.

Synergy—Patterned movements of the entire affected limb in response to a stimulus or to voluntary effort.

Brunnstrom, a physical therapist, was particularly concerned with remediation of impaired motor control following stroke to enable everyday activities. Her method of developing this treatment approach gives therapists insight into the behaviors of a master clinician. Brunnstrom created movement therapy procedures after reading studies on recovery of motor control in animals and humans and observing the natural recovery of her patients post stroke. She experimented with trial-and-error application of these procedures and observed the patients’ responses. She paid careful attention to the patients’ motor and verbal reactions to each procedure, interpreted those reactions in light of her knowledge of motor control and development, and adjusted the procedure accordingly. Successful procedures were replicated patient to patient, until an integrated treatment approach was created. Brunnstrom’s Movement Therapy is an example of augmented maturation treatment because it facilitates the recovery of abilities from first-level or developed capacities and organic substrate.

The principles of movement therapy and the evaluation and treatment procedures presented here are summarized and adapted from Brunnstrom (1970). This publication describes her approach in detail. No further development of the approach has occurred since then.

ASSUMPTIONS AND PRINCIPLES OF BRUNNSTROM MOVEMENT THERAPY

The **assumptions** that underlie the Brunnstrom Movement Therapy approach are as follows:

- In normal motor development, spinal cord and brainstem reflexes become modified and their components become rearranged into purposeful movement through the influence of higher centers.
- Because reflexes and whole-limb movement patterns are normal stages of development and because stroke appears to result in “development in reverse,” reflexes and primitive movement patterns should be used to **facilitate** the recovery of voluntary movement post stroke. Brunnstrom (1956) believed that no reasonable training method should be left untried. She stated, “It may well be that a subcortical motion synergy which can be elicited on a reflex basis may serve as a wedge by means of which a limited amount of willed movement may be learned” (p. 225).
- Proprioceptive and exteroceptive stimuli can be used to evoke desired motion or tonal changes.

PROCEDURES FOR PRACTICE 25-1

Principles of the Brunnstrom Movement Therapy Approach

- Treatment progresses developmentally from evocation of reflex responses to willed control of voluntary movement to automatic functional motor behavior.
- When no motion exists, facilitate it using reflexes, associated reactions, proprioceptive facilitation, and/or exteroceptive facilitation to develop muscle tension in preparation for voluntary movement.
- Elicit reflex responses and associated reactions in combination with the patient's voluntary effort to move, which produces semi-voluntary movement; this allows the patient to feel the sensory feedback associated with movement and the satisfaction of having moved to some degree voluntarily.
- Proprioceptive and exteroceptive stimuli also assist in eliciting movement. Resistance, a proprioceptive stimulus, promotes a spread of impulses to other muscles to produce a patterned response (associated reaction), whereas tactile stimulation (exteroceptive) and muscle or tendon tapping (proprioceptive) facilitate only the muscles related to the stimulated area.
- When voluntary effort produces a response, ask the patient to hold (isometric) the contraction. If successful, ask for an eccentric (controlled lengthening) contraction and finally a concentric (shortening) contraction.
- Even when only partial movement is possible, stress reversal of movement from flexion to extension in each treatment session.
- Reduce or drop out facilitation as quickly as the patient shows evidence of volitional control. Drop out facilitation procedures in order of their stimulus-response binding. Reflexes, in which the response is stereotypically bound to a certain stimulus, are the most primitive and are dropped out of treatment first. Responses to exteroceptive stimulation are least stereotyped, and therefore, tactile stimulation is eliminated last. No primitive reflexes, including associated reactions, are used beyond stage III.
- Place emphasis on willed movement to overcome the linkages between parts of the synergies. Willed movement means that the patient is trying to accomplish it. Patients may be more successful if you ask them to do familiar movements involving a goal object (Trombly & Wu, 1999; Wu et al., 2000).
- Have the patient repeat correct movement, once elicited, to learn it. Practice should involve functional activities to increase the willed aspect and to relate the sensations to goal-directed movement.
- Recovery of voluntary movement post stroke proceeds in sequence from mass stereotyped flexor or extensor movement patterns to movements that combine features of the two patterns and, finally, to discrete movements of each joint at will. The stereotyped movement patterns are called limb synergies. **Synergy** in this sense refers to patterned movements of the entire limb in response to a stimulus or to voluntary effort.
- Newly produced correct motions must be practiced to be learned.
- **Practice** within the context of daily activities enhances the learning process.

The principles of this approach derive from these premises and are listed in Procedures for Practice 25-1.

EVALUATION

Evaluation using the Brunnstrom Movement Therapy approach is appropriate for persons who have had a stroke and who have occupational dysfunction secondary to sensorimotor impairments. If the occupational therapist determines that the patient cannot carry out activities and tasks that are important to the roles that the patient wants,

needs, or is expected to do, the therapist observes the patient's attempts and, if it is indicated, assesses the patient's sensorimotor status (Procedures for Practice 25-2).

Sensation

The sensory evaluation precedes the motor evaluation. The patient's ability to recognize movements of the affected arm and to localize touch in the hand without looking are especially noted because they are associated with better eventual recovery of voluntary movement of the arm and hand, respectively. See Chapter 7 for evaluation procedures. The results of the sensory evaluation guide the therapist's choice of **facilitation** modalities to improve movement or alert the therapist to encourage the patient to substitute visual feedback for lost movement or position senses.

Tonic Reflexes

Tonic reflexes are assessed to determine whether they can be used in early treatment to initiate movement when none exists. The primitive tonic brainstem reflexes that may be present include the symmetrical and asymmetrical tonic neck reflexes, tonic labyrinthine reflexes, and tonic

PROCEDURES FOR PRACTICE 25-2
Evaluation in the Brunnstrom Movement Therapy Approach

Determine the following:

1. Proprioceptive and exteroceptive sensory status
2. Effect of tonic reflexes on the patient's movement
3. Effect of associated reactions on the patient's movement
4. Level of recovery of voluntary motor control

lumbar reflexes. The evaluation of these reflexes is described in Procedures for Practice 25-3. The complete reflex response may not be manifest; however, a change in tone does occur if the patient's movement is under reflex control. A change in tone is gauged by comparing the amount of resistance to passive stretch in the test condition to that in a neutral condition.

Associated Reactions

Associated reactions are involuntary movements or patterned, reflexive increases of tone in muscles that would be expected to contract to cause the movement. Associated reactions are triggered by effortful voluntary movement (Boissy et al., 1997). They are seen in the involved extremities of stroke patients when other parts of the body are resisted during movement or when the patient makes an effort to move. Associated reactions are

evaluated to determine which can be used to facilitate movement when no voluntary movement exists.

Basic Limb Synergies

Limb synergies are instances of associated reactions. They may occur reflexively or as early stages of voluntary control when **spasticity** is present. When the patient initiates a movement of one joint, all muscles that are linked in synergy with that movement automatically contract, causing a stereotyped movement pattern.

In the upper extremity, the **flexor synergy** is composed of scapular retraction and/or elevation, shoulder abduction and external rotation, elbow flexion, and forearm supination (Fig. 25-1; see Fig. 24-8). Position of the wrist and fingers is variable. Elbow flexion is the strongest component of the flexor synergy and the first motion to appear or to be facilitated. Shoulder abduction and external rotation are weak components. Shoulder hyperextension may be seen when abduction and external rotation are weak, although it is not considered part of the flexor synergy. Flexor synergy can be evoked when no movement exists by applying resistance to shoulder elevation or elbow flexion of the uninvolved upper extremity.

The **extensor synergy** of the upper extremity is composed of scapular protraction, shoulder horizontal adduction and internal rotation, elbow extension, forearm pronation, and variable wrist and finger motion, although wrist extension and finger flexion may be seen (Fig. 25-2). The pectoralis major is the strongest component of the extension synergy; consequently, shoulder horizontal adduction and internal rotation are the first motions to appear or to be facilitated. Pronation is the next strongest component. Elbow extension is a weak

PROCEDURES FOR PRACTICE 25-3
Evaluation of Brainstem Reflexes

Reflex or Reaction	Stimulus	Response
ATNR	Turn head 90° to one side; repeat to the other side.	Increase in extensor tone of limbs on the face side and flexor tone on the skull side.
STNR	1. Flexion of the head 2. Extension of the head	1. Flexion of arms and extension of legs. 2. Extension of arms and flexion of legs.
TLR	1. Prone position 2. Supine position	1. Increased flexor tone in arms and legs. 2. Increased extensor tone in arms and legs.
Tonic lumbar	Rotate upper trunk in relation to the pelvis	Increased flexor tone in the upper extremity and increased extensor tone in the lower extremity on the side toward which the trunk is turned. Tone increases in the opposite way on the side opposite to the direction of rotation.

ATNR, asymmetrical tonic neck; STNR, symmetrical tonic neck; TLR, tonic labyrinthine.

Figure 25-1. Flexor synergy. This patient lacks the supination component of the flexor synergy.

component. Extensor synergy can be evoked when no movement exists by applying resistance to horizontal adduction of the uninvolved upper extremity.

Upper extremity flexor synergy usually develops before extensor synergy. When both synergies are developing and spasticity is marked, the strongest components of the flexion and extension synergies sometimes combine to produce the typical upper extremity posture in hemiplegia: the arm is adducted and internally rotated, with the elbow flexed, forearm pronated, and the wrist and fingers flexed.

The lower extremity flexor synergy is composed of hip flexion, abduction, and external rotation; knee flexion; dorsiflexion and inversion of the ankle; and dorsiflexion of the toes. In this synergy, hip flexion is the strongest component; hip abduction and external rotation are weak components. The lower extremity extensor synergy is composed of hip extension, adduction, and internal rotation; knee extension; plantar flexion and inversion of the ankle; and plantar flexion of the toes. Hip adduction, knee extension, and plantar flexion of the ankle with inversion are all strong components. Weak components of this

synergy are hip extension, hip internal rotation, and plantar flexion of the toes. Ankle inversion occurs in both lower extremity synergies.

The lower extremity extensor synergy is dominant when the person is standing because of the strength of this synergy combined with the influences of the positive supporting reaction and stretch forces against the sole of the foot that elicit plantar flexion.

Other Associated Reactions Identified by Brunnstrom

The brainstem reflexes listed in Procedures for Practice 25-3 are associated reactions that Brunnstrom used to evoke some movement when no movement existed but spasticity was present in hemiparetic limbs. In addition to these brainstem reflexes and to the basic limb synergies, Brunnstrom identified other associated reactions that she used in the early stages of treatment:

- Resistance to flexion of the uninvolved leg causes extension of the involved extremity, and resistance to extension of the uninvolved leg causes flexion of the involved extremity. This has been verified electromyographically (Fujiwara, Hara, & Chino, 1999).

Figure 25-2. Extensor synergy.

- Resisted grasp by the uninvolved hand causes a grasp reaction in the involved hand. This is an example of mirror synkinesis.
- Attempt to flex the involved leg or resistance to leg flexion causes a flexor response in the involved arm. This reaction is called homolateral synkinesis.
- Actively or passively raising the affected arm above the horizontal causes the fingers to extend and abduct. This is Souque's phenomenon.
- Resistance to abduction or adduction of the unaffected lower limb results in a similar response in the opposite affected leg. This is Raimiste's phenomenon.

Level of Recovery of Voluntary Movement

The level of motor recovery is evaluated using an instrument that sequences motor performance after stroke from reflex to full voluntary control. In preparation for evaluation, the patient is made physically and psychologically comfortable. Each motion is demonstrated to the patient, who does it with the unaffected extremity before attempting to do it with the affected one. That allows the therapist to be certain that the person understands the request. Instructions should be given in functional terms. For example, to test the flexor synergy of the upper extremity, say "Touch your ear" and, for the extensor synergy, say "Reach out to touch your [opposite] knee" (Brunnstrom, 1966). No facilitation is used during the evaluation.

The Brunnstrom Stages

Definition 25-1 lists the six stages of recovery of the proximal upper extremity and the hand that Brunnstrom (1970) identified. Although, on average, stroke patients proceed through these stages, recovery of a particular patient may stop at any stage. To date, there are no reliable ways to predict which patients will recover voluntary movement.

Brunnstrom stages I to VI are useful to designate summarily the status of voluntary control. The patient is reported to be in the stage at which he or she can accomplish all motions specified for that stage (Definition 25-1). Because progress is gradual, sometimes the patient is in transition between stages. If the patient has completed one stage but is just beginning to be able to do the motions of the next stage, many therapists report the level as II going on III, III going on IV, and so on. The upper and lower extremities and the hand may all be in different stages of recovery at a given time.

The stages were quantified in Brunnstrom's original evaluation, the *Hemiplegia Classification and Progress Record* (Brunnstrom, 1966). That instrument was valid in that it reflected both observations made by Twitchell (1951) of

DEFINITION 25-1

Stages of Recovery of the Upper Extremity

Arm

- I. Flaccidity: no voluntary movement or stretch reflexes
- II. Synergies can be elicited reflexively; flexion develops before extension; spasticity developing
- III. Beginning voluntary movement, but only in synergy; increased spasticity, which may become marked
- IV. Some movements deviating from synergy:
 - a. Hand behind back
 - b. Arm to forward horizontal position
 - c. Pronation and supination with the elbow flexed to 90°; spasticity decreasing
- V. Independence from basic synergies
 - a. Arm to side horizontal position
 - b. Arm forward and overhead
 - c. Pronation and supination with elbow fully extended; spasticity waning
- VI. Isolated joint movements freely performed with near normal coordination; spasticity minimal

Hand

- I. Flaccidity
- II. Little or no active finger flexion
- III. Mass grasp or hook grasp; no voluntary finger extension or release
- IV. Semi-voluntary finger extension in a small range of motion; lateral prehension with release by thumb movement
- V. Palmar prehension
 - a. Cylindrical and spherical grasp (awkward)
 - b. Voluntary mass finger extension (variable range of motion)
- VI. All types of prehension (improved skill).
 - a. Voluntary finger extension (full range of motion).
 - b. Individual finger movements

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Planning Treatment According to the Brunnstrom Stages of Recovery

It is useful for therapists to think ahead of need about what occupations could and could not be used to reinforce particular levels of recovery. To that end, list home-making activities that a patient in stage IV of upper limb recovery and stage V of hand recovery can be expected to do. What are some activities the patient won't be able to do?

the recovery process of 118 patients with acute and chronic strokes and Brunnstrom's (1970) own observations of 100 patients. However, a preliminary cross-sectional study in which **Rasch analysis** was applied to the scores of the upper extremity subtest of 100 subjects calls into question the underlying sequence proposed by Brunnstrom on which the *Fugl-Meyer Motor Assessment* is based (Woodbury & Velozo, 2005). More extensive analysis and longitudinal study of recovery sequence are needed. No data exist concerning the reliability of the *Hemiplegia Classification and Progress Record*, but it can be assumed to be low because the rating scales were not operationally defined.

The Fugl-Meyer Assessment of Motor Function

The *Fugl-Meyer Motor Function Assessment (FMA)* (Fugl-Meyer et al., 1975), sometimes called the *Brunnstrom-Fugl-Meyer Motor Function Assessment*, is a widely used adaptation of Brunnstrom's *Hemiplegia Classification and Progress Record*. This assessment is used by researchers as well as clinicians, even when Brunnstrom's approach to therapy is not used.

Fugl-Meyer et al. (1975) defined 50 details of movement across Brunnstrom's six levels of recovery. The patient's ability to do the requested movement is scored according to the degree of completion. The *FMA* uses an ordinal-level scoring system in which each detail is rated 0, cannot be performed; 1, can be partly performed; or 2, can be performed faultlessly. For example, when asked for a flexor synergy response, if the patient can bring the hand only as far as the mouth rather than to the ear, the score is 1. When the patient's response is incomplete, as in this example, it is necessary to observe the patient's repeated attempts to determine the specific weak areas of the synergy or movement pattern.

Total score ranges from 0, flaccidity, to 100, normal motor function, for the upper and lower extremities. The subtests may be used independently; Table 25-1 shows the upper extremity subtest. The total score for the upper extremity is 66. The score can also be recorded as percentage of recovery (score obtained \div total score \times 100%) (Duncan et al., 1994).

Both intra-rater and inter-rater reliability of the upper extremity subtest of the *FMA* (33 items) were determined to be strong ($r = 0.96$) (Duncan, Probst, & Nelson, 1983; Sanford et al., 1993). The *FMA* is more discriminative than the [*Carr & Shepherd*] *Motor Assessment Scale* (Malouin et al., 1994). The *FMA* correlates strongly ($r = 0.97$) with the *Arm Function Test*, which uses tasks for evaluation; however, the *FMA* is more responsive because it does not exhibit the ceiling and floor effects that the *Arm Function Test* does (Berglund & Fugl-Meyer, 1986). A preliminary study that applied **Rasch analysis** to the *Upper Extremity Subtest* of the *FMA* indicates that the underlying sequence may not be as Brunnstrom and Fugl-Meyer described (Woodbury & Velozo, 2005); more extensive analysis is needed.

TREATMENT

Rehabilitation of trunk control precedes treatment of the limbs.

Rehabilitating Trunk Control

Some patients with hemiplegia have poor trunk control and require training to enable them to bend over to retrieve an object from the floor or to dress their lower extremities. To elicit balance responses, the patient is gently pushed forward, backward, and side to side. Reaching for objects in various locations while seated demands dynamic trunk balance responses (Dean & Shepherd, 1997) and seems to be a better, more natural approach to improve balance than simply pushing the patient. Brunnstrom, had she known about the newer research that documents the importance of goal and context on the organization of movement (Ma, Trombly, & Robinson-Podolski, 1999; Trombly & Wu, 1999; Wu et al., 2000), in all likelihood would have incorporated task-oriented movement into her approach.

Brunnstrom emphasized promoting contraction of trunk muscles on the uninvolved side first by pushing the patient off balance toward the involved side (today we would place an object to be touched or grasped on the involved side), while guarding in case of poor response. Then, once it is determined that the person has that skill, recovery from a push toward or reach toward the uninvolved side is sought. This requires contraction of the trunk muscles on the involved side. The patient is pushed or asked to reach only to the point at which he or she can hold the position and regain upright posture. **The patient is guarded throughout.** Training then progresses to promote trunk flexion, extension, and rotation.

Practice in forward flexion of the trunk is assisted. The patient crosses the arms with the uninvolved hand under the involved elbow and the uninvolved forearm supporting the involved forearm. The therapist, sitting facing the patient, supports the patient under the elbows and assists in trunk flexion forward, avoiding any pull on the shoulders (Fig. 25-3). Some pain-free shoulder flexion is accomplished during this forward movement. While the patient is concentrating on trunk control, shoulder movement occurs without conscious awareness.

Return from trunk flexion is performed actively by the patient. Then, while sitting without back support and with the involved arm supported as described, the patient is pushed backward and encouraged to regain upright posture actively. Forward flexion in oblique directions is done next, not only to promote regaining balance but also to incorporate more scapular motion with the shoulder flexion already achieved.

NOTE: The scores pertain to the person described in the case example.

NT, not tested. Because recovery is sequential, more advanced movements are not tested if the patient fails the movements in the earlier stage.

Figure 25-3 Therapist supporting the patient's arms to assist forward flexion of the trunk. The shoulders become more flexed as the patient leans forward.

Next, trunk rotation is practiced with the patient supporting the involved arm and the therapist guiding trunk motion. Trunk rotation can be combined with head movements in the opposite direction of the trunk rotation, so that the tonic neck and tonic lumbar reflexes can be used to begin to elicit the shoulder components of the upper extremity synergies. The arms and trunk move in one direction, and the head turns in the opposite direction (Fig. 25-4). Head and trunk movements are combined with increasing ranges of movement of the shoulder, enabling pain-free shoulder and scapular abduction and adduction during trunk rotation.

Retraining Proximal Upper Extremity Control

The focus of treatment is the recapitulation of normal movement developmentally from its reflexive base to voluntary control of individual motions that can be used functionally. The general format for treatment is listed in Procedures for Practice 25-4. Because recovery proceeds sequentially, once the stage of recovery is identified, the short-term goal is the next step in the sequence.

Stages I to III

The goal of treatment is to promote voluntary control of the synergies and to encourage their use in functional activities. In these stages, all movements occur in synergy patterns but with increasing voluntary initiation and control of these patterns.

To move the patient from stage I (**flaccidity**) to stage II (beginning synergy), the basic limb synergies are elicited at a reflex level, using as many reflexes, associated reactions, and facilitation procedures as are necessary to elicit a response. The effects of these procedures are additive and combine to produce a stronger response. The patient tries

to move (willed movement) as these facilitation techniques are used.

The flexor synergy is the first to develop. Elbow flexion, the strongest component of that synergy, is the first motion to be elicited. Once the elbow flexes, the therapist turns concentration from elbow flexion to the proximal components of the synergy with the goal of enabling the patient to “capture the synergy,” that is, bring it under voluntary control (stage III). Efforts to achieve voluntary control of the flexor synergy begin with scapular elevation. Lateral flexion of the neck toward the involved side can be used to initiate scapular elevation because the upper trapezius does both motions, although it may have “forgotten” how to elevate the scapula. With the patient's arm supported on a table in shoulder abduction with elbow flexion, the therapist simultaneously gives resistance to the head and shoulder while the patient is asked to hold the head and not let it move away from the shoulder. When the trapezius is felt to respond, both the patient's effort and the therapist's resistance emphasize shoulder elevation when lateral flexion of the neck is repeated. Once elevation begins, active contraction may be promoted by an

Figure 25-4 Through manual guidance, the therapist helps direct the patient to carry out trunk rotation while keeping the head forward or looking in the opposite direction.

PROCEDURES FOR PRACTICE 25-4

General Treatment Sequence to Achieve Movement Control Within Brunnstrom's Movement Therapy Approach

1. Gain some movement through sensory facilitation and reflexes, including associated reactions.
2. Resist the movement and ask for a holding (isometric) contraction.
3. If the patient can produce an isometric contraction, ask for a lengthening (eccentric) contraction.
4. If the patient can produce a controlled lengthening contraction, ask for a shortening (isotonic) contraction.
5. Once the patient can voluntarily move the limb to some degree, ask the patient to reverse the movement repeatedly.
6. Provide opportunities for use of the targeted movement and the reversing movement functionally.
7. Provide suggestions of functional situations that would allow practice of the newly acquired movements in daily life.

associated reaction. For example, as the patient attempts bilateral scapular elevation, resistance is given to the uninvolved scapula. If the involved scapula elevates as an associated reaction, resistance is added on the involved side as the patient is asked to hold.

Unilateral scapular elevation of the involved arm is attempted next; it may be achieved as a result of the previous procedures. If the patient cannot do the motion, the therapist supports the patient's arm and assists the patient to elevate the scapula. Percussion or stroking over the upper trapezius facilitates muscle contraction. The therapist tells the patient to hold and "Don't let me push your shoulder down." After repeated holding with some resistance added, the patient does an eccentric contraction, that is, lets the shoulder down slowly. Then a concentric, or shortening, contraction is attempted when the person is told, "Pull your shoulder up toward your ear."

Active scapular elevation evokes other flexor components and tends to **inhibit** the pectoralis major. The patient repeats scapular elevation and relaxation as the therapist gently abducts the shoulder in increasing increments. Because many patients with hemiplegia have shoulder pain and/or shoulder subluxation, the shoulder is given special care, and the correct scapulohumeral orientation is maintained. Once shoulder elevation and some active abduction have been achieved, external rota-

PROCEDURES FOR PRACTICE 25-5

Procedures to Develop Elbow Extension

"Rowing"

1. Sit facing the patient.
2. Cross your arms so that your right hand grasps the patient's right hand and your left hand grasps the patient's left hand.
3. Resist as the pronated, uninvolved extremity moves toward the involved knee (Fig. 25-5). This elicits elbow extension in the involved arm through an associated reaction.
4. At the same time, assist the involved arm into extension toward the uninvolved knee.
5. Still holding the patient's hands, guide movements into flexion combined with supination (Fig. 25-6).
6. Repeat steps 3 to 5 until you feel the affected limb actively extending.
7. Then, offer resistance bilaterally.
8. Then, reinforce voluntary effort of the involved extremity by asking the patient to hold against resistance to that limb only.
9. Facilitate the extensors by lightly and repeatedly pushing the involved arm back toward elbow flexion, which causes quick stretches to the triceps.

Weight Bearing

When the extensor synergy is seen to come under some active control, it is further developed through use of bilateral weight bearing.

1. Have the patient lean forward onto extended arms supported by a low stool or cushions placed in front (Fig. 25-7). To make it comfortable for the patient, place a sandbag, pillow, or towel on the stool.
2. Stroke the skin over the triceps vigorously or tap over the triceps tendon while the patient attempts to bear weight on both outstretched arms (Fig. 25-8).
3. Once this is successful, have the patient shift weight so that the involved extremity bears more of the weight of the upper trunk.
4. Again, tap the tendon and apply tactile stimulation to the triceps.
5. In the unilateral weight-bearing position, have the patient do functional tasks such as holding down objects with the affected arm while working on them with the other hand, such as holding a piece of wood while sawing, hammering, or painting it; holding a package steady while opening it, addressing it, or fastening it; or supporting body weight while polishing or washing large surfaces with the uninvolved arm.

Figure 25-5 “Rowing.” The therapist resists the pronated uninvolved (left) extremity while guiding the involved (right) extremity into extensor synergy.

tion and forearm supination are included in the movement. Reversal of movements to the opposite direction is done from the start, and this begins to develop some components of the extensor synergy.

The extensor synergy tends to follow the flexor synergy but may have to be assisted in its initiation. Contraction of the pectoralis major, a strong component of the extensor synergy, can be elicited by the associated reaction in which the therapist supports the patient’s arms in a position between horizontal abduction and adduction, instructs the patient to bring his arms together, and resists the uninvolved arm just proximal to the elbow. As bilateral contraction occurs, the patient is instructed, “Don’t let me pull your arms apart.” Then the patient attempts to bring the arms together voluntarily.

Because of the predominance of excess tone in the elbow flexors and relative weakness of elbow extensors, elbow extension is usually more difficult to obtain, but it can be assisted by the methods in Procedures for Practice 25-5. Other means that may be used to facilitate extension movement include use of supine position (tonic labyrinthine reflex); having the patient watch the extremity, which requires head turning and pulls in the asymmetrical tonic neck reflex; working with the forearm pronated, which is a strong component of the extensor synergy; and rotating the trunk toward the uninvolved side to facilitate extension of the involved arm via the tonic lumbar reflex.

After the patient achieves elbow extension in weight bearing, the goal is to encourage active elbow extension free of weight bearing. Unilateral manual resistance is offered to the patient’s attempts to move into an extension synergy pattern. Resistance gives direction to the patient’s effort and facilitates a stronger contraction.

As the synergies come under voluntary control, they should be used in functional activities. The extensor synergy can be used to stabilize an object to be worked on by the other arm, to push the arm into the sleeve of a

Figure 25-6 “Rowing.” The therapist guides the patient into the reverse motion of flexion and supination.

Figure 25-7 Developing arm extension through bilateral weight bearing.

Figure 25-8 The therapist taps on the skin over the triceps to encourage greater muscle contraction and better arm extension while the patient is bearing weight on the outstretched arm.

garment (Fig. 25-9; see also Fig. 24-21), to smooth out a sheet on the bed, or to sponge off the kitchen counter. The flexor synergy can be used functionally to assist in carrying items (such as a coat, handbag, or briefcase); feeding oneself; putting on glasses; and combing the hair. Bilateral pushing and pulling reinforce both synergies. Bilateral identical movements performed independently (i.e., no ball or stick connecting the two limbs) were observed to improve movement of the hemiplegic arm when that arm was tested unilaterally. The improvement was limited to the practiced movement patterns but was maintained over time (Mudie & Matyas, 2000). Sanding, weaving, ironing, and polishing (Fig. 25-10) use the flexor and extensor synergies alternately and repeatedly.

Stages IV to VI

To promote movement deviating from synergy, motions that begin to combine components of synergies in small increments are encouraged as a transition from stage III to stage IV. For example, as the patient begins to extend the

Figure 25-9 The patient practices extensor synergy functionally when putting his arm through the sleeve of garments.

Figure 25-10 Polishing the car window functionally alternates between flexion and extension. The adapted polisher assists the patient who lacks grasp. This photograph was taken at Independence Square inside of Sister Kenny Institute in Minneapolis; the patient was not polishing the car in the street at a stop sign!

arm consistently in response to the unilateral manual resistance that the therapist provides, the therapist guides the direction of movement away from the extensor synergy pattern and toward greater shoulder abduction in conjunction with elbow extension. This breaks up the synergistic relationships of shoulder adduction with elbow extension and shoulder abduction with elbow flexion. The therapist directs the patient to push the hand into the therapist's hand and moves the hand in small increments away from the patient's midline. When the triceps and pectoralis major are disassociated, the synergies no longer dominate.

In stages IV and V, the goal of treatment is to “condition the synergies,” that is, to promote voluntary movement combining components of the two synergies into increasingly varied combinations of movements that deviate from synergy. Proprioceptive and exteroceptive stimuli are still used in this phase of training, but tonic reflexes and associated reactions, appropriate in the earlier stages when reflex behavior was desirable, are no longer used. Willed movement with isolated control of muscle groups is the desired goal.

The first out-of-synergy motion of stage IV is hand behind the body (see Definition 25-1), which combines relative shoulder abduction (flexor synergy) with elbow extension and forearm pronation or internal rotation (extensor synergy). This motion requires that the strongest components of each synergy be subdued. A swinging motion of the arm combined with trunk rotation helps to get the hand behind the body. If balance is good, this can be done more easily when standing. As the hand reaches the back of the patient, the patient strokes the dorsum of the hand against the body to complete the sensory awareness of the movement. Stroking the dorsum of the hand on the back is thought to give direction to the attempted voluntary movement. If the patient cannot do the full motion actively, the therapist passively moves the patient's arm into final position and strokes the dorsum of the patient's hand against the sacrum. The patient, while attempting to do the movement independently, is assisted into and out of the pattern, which gradually becomes voluntary with practice. Practice, using functional tasks as much as possible, continues until the motion can be freely accomplished. Examples of functional tasks include putting a belt on when the patient is standing, swimming using the crawl stroke, and tucking a shirt into trousers (Fig. 25-11).

The second out-of-synergy motion is shoulder flexion to a forward horizontal position with the elbow extended. If the patient cannot flex the shoulder forward actively, even with the therapist providing local facilitation and guidance of movement, the arm is brought passively into position. While tapping over the anterior and middle deltoid muscles, the therapist asks the patient to hold the position. If the patient can hold after positioning, active motion in small increments is sought, starting with lowering of the arm fol-

Figure 25-11 The patient attempting to tuck his shirt into his trousers uses arm-behind-the-back motion functionally.

lowed by active shoulder flexion. This continues until the full forward flexion motion can be done. Stroking and rubbing of the triceps are used to help the patient keep the elbow straight as the arm is raised. Repetitive non-resistive activities are used to motivate this action. Raising the arm to forward horizontal is involved in any vertically mounted game, such as tic-tac-toe or checkers (using Velcro tabs to secure the pieces), or in reaching for objects in a cupboard (Fig. 25-12), for example.

The third motion sought in stage IV is pronation and supination with the elbow flexed to 90°. Supination would not be expected to be a problem unless the pronators retained some spasticity. The problem would be to combine pronation of the extensor synergy with elbow flexion of the flexor synergy. Initially, pronation can be resisted with the elbow extended, and gradually, the elbow can be brought into flexion as the resistance to pronation is repeated. Block printing is an activity to consider when resistance to pronation is wanted. It can be positioned to resist pronation, with gradual changes in the amount of elbow flexion. This motion has been achieved when resistance is no longer required and the patient can supinate and pronate with the elbow near the trunk. Practice should include activities that require turning objects,

Figure 25-12 Attempting to reach for objects in the cupboard offers opportunities to practice forward (and overhead) reach.

such as a knob, a screwdriver, or a dial, to reinforce it. Some games, such as skittles, are knob operated and require rotary motions, as do card games that require turning the cards over and the adapted dice game described by Nelson et al. (1996).

Once the patient is confident of these stage IV movements and performance is fairly consistent, stage V training commences. Movement in stage V entails active attempts by the patient to move in patterns increasingly away from synergy. Excess effort is avoided, however, so that the limbs will not revert to stereotyped movements. The attempts are bolstered by use of quick stretch and tactile stimulation. Each new motion is incorporated into functional activities. Although it is Brunnstrom's approach to regain motion through exercise and then introduce functional activities to practice the motion, recent research indicates that goal is a powerful organizer of movement, including that of stroke patients (Ma, Trombly, & Robinson-Podolski, 1999; Trombly & Wu, 1999; Wu et al., 2000); therefore, functional activities should be introduced earlier in treatment.

The first motion sought in stage V is arm raised to side horizontal, which combines full shoulder abduction with

Figure 25-13 By arranging the dish drainer on the patient's hemiparetic side, he practices arm to the side motion when putting the clean dishes into the drainer.

elbow extension. When this can be accomplished, disassociation of components of the synergies has occurred. No longer will the arm drift toward horizontal adduction when the elbow is extended or the elbow flex when the shoulder is abducted, as they would when the muscles are still under the influence of the synergies. Again, practice with functional tasks assists learning. Activities that have game pieces or materials that can be placed on a high table to the side of the patient to encourage side horizontal movement to play the game or do the project are useful in encouraging this motion. The table can be gradually moved to require more and more horizontal abduction and elbow extension. Other activities that could be used to encourage this motion include weaving on a floor loom, table tennis, driving golf balls, hitting a baseball, and washing dishes (Fig. 25-13).

The second motion of stage V is arm overhead. To achieve it, the scapula must upwardly rotate. The serratus anterior must be specifically retrained to do this. If the scapula is bound by spastic retractor muscles, passive mobilization may be necessary before seeking an active protraction response. Passive mobilization of the scapula is done by grasping the vertebral border and repeatedly and *slowly* rotating it as the arm is passively moved into an overhead position. Once the scapula is mobilized, the serratus is activated in its alternative duty of scapula protraction by placing the arm in the forward horizontal position and asking and assisting the patient to reach forward. **Do not put traction on the patient's glenohumeral joint.** It is helpful to rehearse this motion with the patient using the uninvolved extremity. Apply quick stretches by pushing backward into scapular retraction to activate the serratus. Once the serratus is activated, seek a holding contraction of the serratus. These procedures continue, with the therapist

moving the arm incrementally overhead. Once the movement has been achieved, practice with functional activities reinforces it. Sanding on an inclined plane is an example of an activity requiring a forward push with an increasing range of movement in scapular protraction and rotation and shoulder flexion. Bilateral sanding will allow the stronger uninjured arm to help the weaker one. Table tennis would still be useful, as would shooting baskets and putting on overhead garments every day. Washing a wall or painting it with a roller requires repeated reversal of movement up overhead and down.

The third motion sought in stage V is supination and pronation (external and internal rotation) with the elbow extended. To improve supination, the elbow is at first kept close to the trunk and gradually extended. Brunnstrom had no special treatment recommendations to assist in developing disassociation of supination and elbow flexion. The best way to achieve control of supination and pronation with the elbow extended is to have the patient use both hands in activities of interest that entail supination and pronation in various arm positions. One such activity is grasping a beach ball with the arms outstretched and rotating it so the affected arm is on top (pronated) and the unaffected arm is on the bottom (supinated) and vice versa. The patient can graduate to handling a smaller ball, such as a basketball. Adapted games, such as an adapted dice game, that capture the patient's attention and interest have been found to be more effective than exercise (Nelson et al., 1996).

Patients who recover comparatively rapidly after a stroke may spontaneously achieve stage VI; however, many patients do not achieve full recovery after stroke. Twitchell (1951) stated that patients who reached stages III and IV within 10 days after stroke recovered completely; however, this observation has never been verified in the literature. In Twitchell's sample, patients who failed to respond to proprioceptive facilitation did not recover willed movement at all. He observed, and it is generally accepted, that the longer the flaccid stage lasts, the less likely recovery will occur. Duncan et al. (1994) verified that patients with a severely impaired upper extremity did not regain full voluntary use of that extremity.

Retraining Hand and Wrist Control

Training techniques for return of function in the hand are presented separately from the rest of the upper extremity because the hand may be at a different stage of recovery from that of the arm. If the patient cannot initiate active finger flexion (hand stage I) or mass grasp (hand stage II), the traction response in which stretch of the scapular adductors produces reflex finger flexion or an associated reaction of resisted grasp by the unaffected hand may be used in combination with voluntary effort.

In hemiplegia, wrist flexion usually accompanies grasp initially, so stability of the wrist in extension must be developed. It is easier for the patient to stabilize the wrist in extension when the elbow is extended; therefore, training starts with the elbow extended and the wrist supported by the therapist. The wrist extensor muscles are facilitated, and the therapist directs the patient to do a forceful grasp by saying, "Squeeze!" That grasp should promote normal synergistic contraction of the facilitated wrist extensors. This is repeated until the wrist extensors are felt to respond, allowing the therapist to remove support from the wrist with the command, "Hold." Tapping on the wrist extensor muscles facilitates holding. Once wrist extension and grasp with the elbow extended are possible, the process of positioning, percussion, and hold is repeated in increasing amounts of elbow flexion. Emphasis in this stage of training is on wrist stability, although wrist flexion, extension, and circumduction may also be practiced.

To move from hand stage III (flexion) to hand stage IV (semi-voluntary mass extension) spasticity of the finger flexors must be relaxed using a series of manipulations listed in Procedures for Practice 25-6. The second motion sought at hand stage IV is lateral prehension and release. The patient attempts to move the thumb away from the index finger to gain release of lateral prehension while the therapist percusses or strokes over the extensor pollicis longus and abductor pollicis longus tendons to facilitate this motion. Once the patient has some active release, functional use of lateral prehension is encouraged. Activities include holding a book while reading, holding or dealing cards, using a key, and dressing.

Once the patient can extend the fingers voluntarily to release objects, advanced prehensile patterns (hand stage V) are encouraged through activities. As the patient progresses, activities are chosen to reinforce particular prehensions at more precise levels. Holding a pencil or paintbrush encourages palmar prehension. Spherical grasp is used to pick up or hold round objects such as containers (Fig. 25-15) or an orange. Cylindrical grasp is used to hold the handles of tools.

Individual finger movements (hand stage VI) may be regained in rare instances. The patient should be given a home program of activities to encourage more and more individual finger use and to increase speed and accuracy of finger movements but should also be cautioned about expecting full recovery. One stroke survivor published a workbook of his exercises for hand recovery that may be incorporated into the home program of a patient with determination to recover hand function (Smits & Smits-Boone, 2000). It advocates many repetitions of simple activities. Intensive repetitive movement has been shown to improve the particular movements practiced (Barreca et al., 2003; Butefisch et al., 1995; Kawahira et al., 2004).

Brunnstrom also described gait patterns, principles used in preparation for walking, and training to walk.

PROCEDURES FOR PRACTICE 25-6

Procedures to Develop Finger Extension

1. Release the patient's grasp by holding the thumb into extension and abduction.
2. Still holding the thumb, *slowly* and rhythmically supinate and pronate the forearm.
3. Apply cutaneous stimulation over the dorsum of the hand while the forearm is supinated.
4. With the forearm still supinated, apply rapid, repeated stretch to the extensors of the fingers by repeatedly rolling them toward the palm (Fig. 25-14).
5. Continue these manipulations until flexion relaxes.
6. Slowly pronate the forearm and elevate the arm above horizontal to evoke a finger extensor response (Souque's phenomenon).
7. Stroke over the dorsum of the fingers and forearm as the patient attempts extension. To avoid a buildup of flexor tension, do not allow the patient to exert more than minimal effort. Imitation synkinesis, in which the normal side performs a motion that is difficult for the involved side (Boissy et al., 1997), may be observed when the patient attempts finger extension.
8. After the fingers can be voluntarily extended with the arm raised, gradually lower the arm.
9. If there is a decreased range in extension, repeat all above manipulations to again inhibit flexion and facilitate extension.
10. Provide opportunities for the patient to reach and pick up large, lightweight objects and to release them. Putting bagels, apples, or oranges into a basket is one example of an activity to practice finger extension. The larger the object, the greater the extension required. Other extensor-type activities require the hand to be used flat, such as smoothing out a garment while ironing or a sheet while making the bed.

These procedures are the primary responsibility of the physical therapist.

EFFECTIVENESS

The only study of the effectiveness of this approach compared the relative effectiveness of Brunnstrom's movement therapy to Bobath's neurodevelopment treatment (Wagenaar et al., 1990). Seven selected post-stroke patients were randomly assigned to one treatment for 5 weeks and then to the other for 5 more weeks; this was repeated using a B-C-B-C design. Functional recovery of activities of daily living (ADLs), upper limb function, and

Figure 25-14 The therapist applies rapid repeated stretches to the extensors of the fingers by rolling the fingers toward the palm.

Figure 25-15 Holding a round container demands spherical grasp.

Evidence Table 25-1 Best Evidence Regarding the Brunnstrom Movement Therapy Approach

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Movement Therapy Approach vs. Bobath NDT therapy	One treatment (randomly assigned) applied during the 5-week B phases and other treatment applied during the alternate 5-week C phases. Treatments adhered to published principles and were applied by specially trained therapists.	7 persons 5–9 days post stroke. Age 40–77 years. Ischemic stroke in area of MCA; 5 patients with right cerebrovascular accidents; 2 with left cerebrovascular accidents. No severe memory or understanding deficits. No medical complications.	30 minutes per weekday while inpatient; 30 minutes 3–4 times per week after discharge for a total of 20 weeks (10 weeks each treatment).	Single-subject experimental design (BCBC) across subjects. Level IV. (Lacked control for many threats, especially spontaneous recovery and the design of alternating two opposing treatments.)	No, neither treatment was better than the other. All patients improved, but that may be due to spontaneous recovery. No difference in ADL function (<i>Action Research Arm Test</i>); or gait quality. One patient improved significantly in gait speed during the Brunnstrom weeks compared with the Bobath weeks.	Not reported.	Wägenaar et al., 1990

MCA, middle cerebral artery.

CASE

EXAMPLE

Mrs. G.: Moving from Brunnstrom’s Stage III to Stage IV

Occupational Therapy Intervention Process	Clinical Reasoning Process	
Objectives	Examples of Therapist’s Internal Dialogue	
<p>Patient Information Mrs. G. is a 38-year-old right-hand dominant woman who was employed as a clerk in a local department store prior to June 2005, when she suffered an embolytic stroke of the left middle cerebral artery. She was an accomplished amateur artist who did oil portraiture. She lives with her husband, a plumber, and 16-year-old son in a ranch-style house. This young woman identified several roles important to her: self-maintenance roles of independent person, mother, and homemaker; self-advancement role of worker, and self-enhancement role of artist.</p>	Appreciate the context	<p>“Gosh, she is young; she’s only 10 years older than I am. I wonder how I would react if this had happened to me? I think I will discuss my feelings of vulnerability and vicarious anger with my supervisor so that I can offer Mrs. G. the best therapy I can.”</p> <p>“Mrs. G. will be returning to good, enabling physical and social environments.”</p> <p>“She is making rapid recovery. Restoration of some useful motor control in the upper extremity seems feasible.”</p>
<p>At admission to inpatient rehabilitation, she had no voluntary movement of the right upper extremity and impaired kinesthesia of that limb. She was wheelchair dependent. She was discharged to outpatient rehabilitation after 15 days, independent in ambulation and in self-care ADL using the unaffected arm.</p>		
<p>At admission to outpatient occupational therapy, Mrs. G. is dependent in her valued roles of homemaker and artist because of weakness and poor motor control of the dominant upper extremity. However, she did score 24 (36%) on the <i>Fugl-Meyer Motor Assessment</i> (see Table 25–1).</p>		
<p>The problem list concerning upper limb motor control includes:</p> <ul style="list-style-type: none"> • Unable to do extensor synergy movement, although the strongest components are active (stage III). • Able to maintain wrist extension in any elbow position but cannot take resistance. • Able to hold a playing card put between her thumb and index finger but not against resistance (stage IV). • Unable to do other types of grasp, other than mass grasp, or to extend the fingers, other than release of mass grasp (stage III). 	Develop intervention hypotheses	<p>“Spontaneous recovery can be enhanced through neurodevelopmental therapies such as Brunnstrom’s Movement Therapy. Repetitive practice of motor activities with the unaffected upper extremity will enhance occupational performance. This approach does not contradict Brunnstrom’s Movement Therapy.”</p>

Recommendations

The patient's long-term goals are to use both upper extremities to recover IADL related to self-care, preparation of meals, and other household tasks and to resume oil painting. Therefore Mrs. G. agrees to the three focuses of therapy:

1. Brunnstrom's Movement Therapy
2. Compensatory methods of accomplishing IADL
3. Practice to improve motor skill of the unaffected limb

Select an intervention approach

"Although there is no published evidence of the effectiveness of Brunnstrom's Movement Therapy, I will use that approach because I have had success with other patients similar to Mrs. G. in age, diagnosis, and pace of recovery. Concurrently, I will teach compensatory methods for meal preparation and other household tasks important to her so she can resume that role more quickly than if we wait for restoration of motor control. I will also engage her in occupations to improve dexterity of the unaffected non-dominant upper extremity."

Reflect on competence

"I have used these approaches numerous times before. I am competent to administer these therapies."

Consider the patient's appraisal of performance

"Mrs. G. has decided to take an extended leave of absence from her job because of the continuing excessive effort required for all tasks. This is a sensible decision to allow for concentration on the work of rehabilitation."

Consider what will occur in therapy, how often, and for how long

"Constrained by limited insurance coverage, I recommend treatment 3 times weekly for 6 weeks with intensive home practice between therapy visits. Then, there is enough insurance coverage for an additional 6 visits if warranted. Mrs. G. agrees and is eager to begin the work of therapy."

Ascertain the patient's endorsement of the plan

Summary of Short-Term Goals and Progress

1. Increase dexterity of the left, unaffected hand to accelerate engagement in instrumental self-care and homemaking activities. Dexterity of the unaffected hand increased through Mrs. G.'s efforts to accomplish tasks of her self-maintenance roles that naturally demanded dexterous responses. She is now able to apply make-up, crack and separate eggs, and write shopping lists.
2. Develop elbow extension (stage III). Voluntary control of the extensor synergy was achieved using rowing and weight-bearing maneuvers listed in Procedures for Practice 25-5. Between therapy appointments, Mrs. G. practiced using whatever extensor movement she had to do activities like sponging off the table and kitchen counters after meals, putting her arms into the sleeves of sweaters and jackets, and vacuuming with a self-propelled vacuum cleaner. She interspersed these activities with weight bearing on the affected arm with the elbow extended while working with the other hand.
3. Develop the first motion of stage IV: hand behind back. After repeated attempts in therapy to swing the hand behind the back, with tactile facilitation of the latissimus dorsi, posterior deltoid, and triceps, Mrs. G. was successful in bringing her hand past the anterior superior iliac spine. Encouraged, she continued to practice at home and to use the motion functionally in pulling on her underpants and slacks.

Track progress

"Mrs. G. is progressing nicely. She is particularly pleased that we have related each improvement to important functional activities."

4. Improve wrist stability against mild and moderate resistance. Wrist stability was encouraged during mass grasp and lift of increasingly heavy objects by tapping the wrist extensors during the lift. At home, she practiced lifting weighted shopping bags.
5. Strengthen lateral pinch (stage IV) and develop release to enable primitive use of paintbrushes, paint tubes, and other artist tools. Therapy to develop release of lateral pinch consisted of tapping of the extensor pollicis longus and the abductor pollicis longus tendons. Once release was enabled, resistance to pinch was gradually increased and alternated with active release. The patient was given a home program of activities to encourage lateral prehension. She resumed painting with the canvas on the table and used lateral pinch to squeeze the paint tubes and hold the brushes.
6. Develop palmar pinch (stage V) to enable more normal use of a paintbrush and other artist tools. In the process of using various brushes, Mrs. G. redeveloped palmar prehension without specific treatment.

Anticipate present and future patient concerns

“Although Mrs. G. is making good progress in recovering use of her affected arm and hand, I must be sure that she understands that recovery can stop at any time and that it is unlikely that she will regain 100% normal use of her limb. I must keep a balance between encouraging her to work for greater improvement and having realistic expectations.”

Next Steps

Revised Short-Term Goals (6 weeks)

1. Develop arm forward flexion (second motion of stage IV) to enable painting on an easel.
2. Develop cylindrical grasp (stage V) to enable use of a toothbrush, broom, mop, large spoons, etc.

Decide if the patient should continue or discontinue therapy and/or return in the future

“Based on the progress made after 6 weeks of therapy (refer to the column labeled 8/10/2005 in Table 25-1) and her faithful practice at home, Mrs. G. and I formulated new goals for 6 more weeks of once-a-week therapy.”

walking ability were assessed weekly. The treatment program included occupational therapy, physical therapy, and nursing. All members of the treatment team adhered strictly to the written protocol for each treatment developed from primary sources. The only significantly different outcome was greater improvement of gait speed by one patient in the Brunnstrom condition compared with the Bobath condition. The lack of difference detected in other subjects and for other assessments may be the result of alternating short periods of each treatment for each subject; that is, no subject received a full treatment program that followed one method. This is an important limitation because these methods have opposite views concerning the use of associated reactions. The recovery graphs for each patient showed steady recovery regardless of treatment, indicating that either (1) both methods were effective or (2) the subjects were recovering spontaneously. The actual interpretation cannot be made, however, because the study did not include a control condition (i.e., a

period when no treatment was given) to determine the effects of spontaneous recovery alone. In a critical review of studies of interventions aimed at improving the paretic upper limb of stroke survivors, no significant difference was found among various “sensorimotor” treatment approaches, although these did not include the Brunnstrom approach, *per se* (Barreca et al., 2003).

SUMMARY REVIEW QUESTIONS

1. What are the assumptions of the Brunnstrom Movement Therapy approach?
2. What is an associated reaction and how is it elicited?
3. Describe the flexor synergy of the upper extremity and state which component or components are strongest.

4. Describe the extensor synergy of the upper extremity and state which component or components are strongest.
5. List in order the six recovery stages of the proximal upper extremity.
6. List in order the six stages of hand recovery.
7. Name the treatment principles of the Brunnstrom Movement Therapy approach.
8. How is the flexor synergy initiated in the upper extremity when the patient is flaccid?
9. How is elbow extension developed?
10. How is finger extension developed?

CHAPTER 26

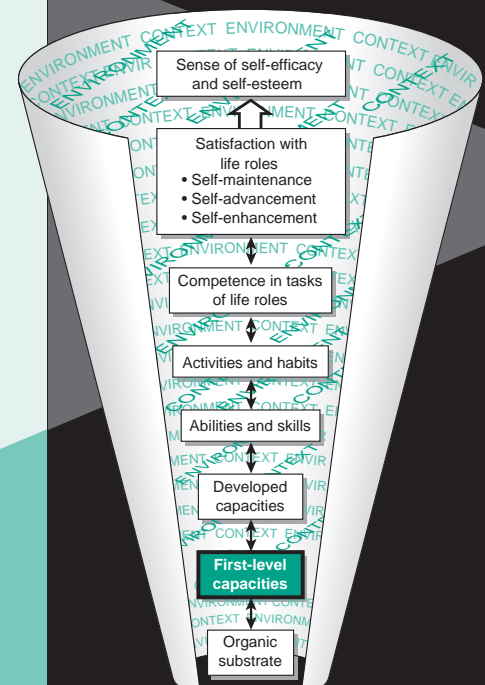

Managing Deficit of First-Level Motor Control Capacities Using Rood and Proprioceptive Neuromuscular Facilitation Techniques

Kathy Longenecker Rust

LEARNING OBJECTIVES

After studying this chapter the reader will be able to:

1. Use knowledge of controlled sensory input for making treatment choices to reduce first-order motor impairments and prepare patients with orthopedic and central nervous system conditions for successful participation in occupational performance.
2. Delineate treatment strategies for improving mobility and stability.
3. Analyze the diagonal components of functional activities and use this knowledge to utilize optimal movement patterns and positions in treatment.
4. Perform the proprioceptive neuromuscular facilitation diagonal patterns of the head, neck, trunk, and upper extremities.

Glossary

Balance of antagonists—Normal mobility and strength of both agonist and antagonist muscles to allow successful motor function for activity to occur.

Chopping—Bilateral asymmetrical D1 extension. One arm performs the chop and the other hand is placed on the lateral-extensor surface of the distal forearm. The reversal of this pattern is the reverse of the chop.

Contracture—Fixed posture secondary to shortening or loss of elasticity of ligaments, joint capsule, tendons, and muscles (Preston & Hecht, 1999).

Controlled sensory stimulation—Concept that the neural component of tone can be affected by sensory stimuli applied in a specific manner to increase or reduce the electrical charge of interneurons or motor neurons, making them more or less likely to fire when they receive additional goal-specific stimulation from supraspinal centers.

Controlled mobility—The ability to perform fluid reversing motions necessary to perform skilled activity.

D1 extension—The final position of D1 extension is shoulder extension, abduction, and internal rotation; elbow extension; and pronation so that the hand passes the hip on the same side of the body. The wrist, fingers, and thumb extend, and fingers and thumb abduct. During range of motion exercises, D1 extension is combined with its reciprocal, D1 flexion.

D1 flexion—The final position of D1 flexion is shoulder flexion, adduction, and external rotation; elbow flexion; and supination so that the hand passes close to the ear on the opposite side of the head. Wrist, fingers, and thumb flex, and fingers and thumb adduct.

D2 extension—The final position of D2 extension is shoulder extension, adduction, and internal rotation; elbow extension; and pronation so that the hand moves past the opposite hip. Wrist flexes; fingers flex and adduct; and thumb opposes. During range of motion exercises, D2 extension is combined with its reciprocal, D2 flexion.

D2 flexion—The final position of D2 flexion is shoulder flexion, abduction, and external rotation; and supination so that the hand comes close to the ear on the same side of the head. Wrist extends, and fingers and thumb extend and abduct.

Lifting—Bilateral asymmetrical D2 flexion. One arm performs the lift, while the other arm maintains contact on the lateral flexor side of the forearm. The opposite of this pattern is called reverse of lift.

Normalization of tone—Process of changing excessive tone (hypertonia) or insufficient tone (hypotonia) to a state of normal tone needed for normal motor responses.

Overflow—The neuromuscular response to increasing resistance where the electrical activity of the interneuronal pool continues to rise with more and more motor units recruited to fire. Muscles are recruited in a predictable manner.

Reciprocal inhibition—The mechanism whereby contraction of an agonist muscle produces inhibition of its antagonist.

Vital functions—Respiration, facial motions, tongue motions, swallowing, and bowel and bladder control.

Without movement, occupational functioning is jeopardized. The organic substrate that supports movement includes the skeleton, muscles, sensory and motor nerves, heart, lungs, and skin. Therapists who developed the neurophysiological treatment approaches in the 1950s and 1960s presented clinical solutions to improve motor function for individuals who had impairments of these structures. In a seminal publication of the *American Journal of Physical Medicine* (1967), the proceedings of a 4-week conference on therapeutic exercise were detailed. One objective of the conference was to explore the thesis that an understanding of normal motor behavior is essential to the use of therapeutic exercise as a rehabilitative procedure and that exercise is bound to motor learning (Wood, 1967). Another important objective was to identify common denominators among the various approaches to treatment. Both of these objectives were met, and today there is a growing body of scientific evidence that supports many of the assumptions of the presenters. Chapters 24

and 25 describe the history and evolution of two of the approaches from this conference, the Bobath and Brunnstrom approaches. This chapter presents the methods of two additional approaches that have directed our understanding of how neuromuscular function affects occupational functioning. Both the Rood and proprioceptive neuromuscular facilitation (PNF) approaches share the commonality of using reflex arcs to elicit particular types of motor responses by supplying sensory stimulation in a controlled way. Another interesting similarity is that both of these approaches address **vital functions**. Understanding these mechanisms and using the techniques provide the occupational therapist with skills to affect first-level motor control capacities for patients with both orthopedic and neurological problems and for patients with muscle weakness secondary to primary illness or disuse. Facilitation and inhibition of muscle function along with the concepts of **stability** and **mobility** are basic to the application of **controlled sensory stimulation** used in both approaches.

DEVELOPED CAPACITIES OF STABILITY AND MOBILITY THAT SUPPORT MOVEMENT

When planning treatment and considering the goal of an activity, technique, or exercise to improve motor function, the first question that needs to be answered is whether the patient's limitation is due to a stability problem or a mobility problem. If both problems exist, then it is usually best to start with reestablishing stability. Stability is both dynamic and static. An individual must be able to maintain a posture and, when disturbed from a position, be able to recover the posture.

Mobility has two components. First of all, an individual needs adequate functional range of motion to engage in activity. The second aspect of mobility is the ability to initiate and sustain active range of motion (AROM) in activity. Patients with central nervous system (CNS) damage may lack this ability due to abnormal tone such as spasticity with concomitant weakness of the antagonist, flaccidity, loss of sensory input, and loss of voluntary control as is seen in conditions such as Parkinson's disease. Non-CNS conditions also exhibit muscle weakness.

The Rood approach addresses these components of motor function in Margaret Rood's classification of light-work or heavy-work muscles, her sequence for development of motor control, her ontogenic skeletal muscle sequence, and the techniques she identified for muscle facilitation and inhibition (Trombly, 1995). The PNF approach employs a similar model that addresses the progressive stages of movement control and also relies heavily on techniques for facilitation and inhibition of movement. The PNF approach, however, applies a broader scope of techniques, using additional applications of vision, sound, and normal reflex activity.

ABNORMAL TONE FOLLOWING CNS INJURY

After CNS injury, the basic first-level capacity of movement, muscle tone, changes (see Definition Box 6-2). Tone is a constant state of mild tension in the muscle. It is the characteristic of muscle that resists passive elongation or stretching (Gilman & Newman, 1992). Movement is superimposed on normal postural muscle tone (Carpenter, 1996; Gilman & Newman, 1992) and is difficult or impossible when tone is low or excessive. For persons with abnormal tone, the goal is **normalization of tone** to enable the patient to engage in and benefit from therapies and to accomplish the activities and tasks of daily life.

Hypertonicity, or high tone, is more than normal resistance to passive elongation. An arm that displays high tone requires effort from the therapist to move it in the direction opposite to the high tone, yet in its most frequent manifestation, it moves easily into the other direction. It was once believed that it was necessary to reduce excessive tone before voluntary movement could develop. Although current research indicates that that is not so (Ada et al., 1998; Malouin et al., 1997; O'Dwyer, Ada, & Neilson, 1996; Teixeira-Salmela et al., 1999), it is still important to decrease excessive tone. With abnormally high tone, malalignment of trunk and limbs occurs quickly because of shortening of spastic muscles on one side of a joint. If prolonged malaligned positioning is allowed, the outcome is a **contracture** with subsequent deformity and/or interference with basic activities of daily living (BADL) and increased caregiver burden. For example, an individual with end-stage multiple sclerosis may be confined to bed. Washing under the arm or the palm of the hand may be very difficult for the caregiver if the areas have high tone. These sequelae of hypertonicity should be prevented with daily stretching (Braddom, 1996).

Hypotonicity (low tone, or flaccidity) is less than normal resistance to passive elongation of the muscle. When a flaccid arm is moved, it feels heavy, and the muscles feel soft. If dropped, the arm falls because it cannot hold the position against gravity. For persons with low tone, the goal is to increase muscle response through sensory input and to blend this with the effort to move to accomplish goal-directed actions (Fig. 26-1). Even if movement is not achieved, it is important to increase tone to counteract joint subluxation, overstretching of muscles, edema, pain, and contracture. Normalization of muscle action is facilitated within the context of attempted goal-directed movement or maintained posture (Huss, 1971; Voss, 1967). Application of facilitation techniques alone is inadequate therapy. Even though the patient may not be able to do any activity, the effort to accomplish a simple goal is powerful and should be an integral part of every therapy session. Because attempting to accomplish a goal enhances neurological integration, facilitation is always done within an occupational context.

FACILITATION AND INHIBITION TECHNIQUES DEVELOPED PRIMARILY BY ROOD (1954, 1956, 1962)

Facilitation Techniques

Techniques to facilitate muscle activation include application of tactile, thermal, and proprioceptive stimuli, and stimuli to the special senses. These various techniques may be combined to produce a greater response.

Figure 26-1 Patient's arm is supported on a therapeutic skate, a rectangular board supported by easily movable ball-bearing casters at the corners. With the slightest effort, the patient can move the arm at the shoulder and elbow on a smooth surface. The patient should concentrate on an activity goal rather than the movement per se. (Photo by Robert Littlefield, Scientific and Technical Photography, Dorchester, MA.)

Tactile Stimuli

Tactile stimulation is done using light touch (A-brushing) or fast brushing (C-brushing).

Light Touch

Light touch or stroking of the skin activates the low threshold A-size sensory fibers to activate a reflex action of the superficial phasic or mobilizing muscles (Rood, 1956, 1962; Stockmeyer, 1967). Light stroking of the dorsum of the webs of the fingers or toes, or of the palms of the hands or the soles of the feet elicits a fast, short-lived withdrawal motion of the stimulated limb (Rood, 1962). The stroking is done at a rate of twice per second for approximately 10 seconds (Rood, 1956). After a rest period, this procedure can be repeated 3–5 more times. When the reflex response occurs, resistance to the movement in activity is usually given to reinforce it and to help develop voluntary control over it (Stockmeyer, 1967).

Brushing

Fast brushing involves brushing the hairs or the skin over a muscle with a soft camel hair paintbrush that has been substituted for the stirrer of a hand-held battery-powered cocktail mixer to produce a high-frequency, high-intensity stimulus (Harris, 1969; Rood, 1962; Stockmeyer, 1967). The revolving brush, which is held sideways to avoid catching and pulling the hair, is applied on each skin area to be stimulated (Rood, 1956, 1962). Fast brushing is thought to stimulate the C-size sensory fibers, which discharge into polysynaptic pathways that influence the background activity of muscles involved in the maintenance of posture (Harris, 1969; Matyas & Spicer, 1980; Rood, 1962). Spindles so biased respond more readily to added external or internal stretch (Rood, 1962).

Rood (1962) proposed that the effect of fast brushing was non-specific, had a latency of 30 seconds, and reached its maximum facilitative state 30–40 minutes after stimulation because of the enhancement of the reticular activating system into which the C fibers feed. In controlled studies of fast brushing applied to normal and poststroke individuals, however, it was demonstrated that, although fast brushing produced a significant immediate facilitatory effect, the effect lasted only 30–45 seconds (Mason, 1985; Matyas & Spicer, 1980; Spicer & Matyas, 1980). Moreover, in normal subjects, the facilitatory effect was seen only in the lower extremity and not in the upper extremity.

Precautions necessary for controlled and appropriate fast brushing are listed in Safety Note 26-1.

Thermal Stimuli

Icing is thought to have similar effects as stroking and brushing through the same neural mechanisms (Harris, 1969; Rood, 1962). Icing, however, has been found to be significantly less effective than fast brushing for recruitment of motor units in hemiplegic patients (Matyas & Spicer, 1980). Two types of icing, A and C (referring to the size of the sensory fibers), are used.

A-Icing

A-icing is the application of three quick swipes of an ice cube to evoke a reflex withdrawal, similar to the response to light touch, when the stimulus is applied to the palms or soles or the dorsal webs of the hands or feet (Rood, 1962). The water is blotted up after every swipe. A-icing of the upper right quadrant of the abdomen in the dermatomal representation for T7-9 (along the rib cage) stimulates the diaphragm and inspiration. Touching the lips with ice opens the mouth (a withdrawal response). But ice applied to the tongue and inside the lips closes the mouth (Rood, 1962). Swiping the ice upward over the skin of the sternal notch promotes swallowing.

SAFETY NOTE 26-1

Precautions Necessary for Appropriate Application of Afferent Stimuli

- Fast brushing of the pinna of the ear stimulates the vagal parasympathetic fibers, which influence cardiorespiratory functions (Rood, 1962). Activation of these fibers slows the heart, constricts the smooth muscles of the bronchial tree, and increases bronchial secretions (Gilman & Newman, 1992). Fast brushing or scratching of the skin over the back at the level of S2-4 may cause bladder emptying (Gilman & Newman, 1992).
- In the application of C-icing, the distribution of the posterior primary rami along the back is avoided because it may cause a sympathetic nervous system fight or flight protective response (Rood, 1962; Huss, 1971).
- Icing of the pinna causes vagal responses, including cardiovascular reactions such as low blood pressure (Umphred, 1995). Ice to the back at the level of S2-4 may cause voiding (Rood, 1962).
- Prolonged icing is contraindicated for patients with Raynaud's phenomenon or circulatory disorders, including hypertension.
- Vibration applied on tendons can be conducted to adjacent muscles via the bone, and this possibility must be attended to and prevented (Dobkin, 1996; Preston & Hecht, 1999).
- Vibration should not be maintained longer than 1–2 minutes in any one place because of the heat that develops from the friction and potential for tearing thin skin. Vibration over areas previously immobilized can dislodge a blood clot and cause an embolism (Umphred, 1995).
- Scapulohumeral rhythm must be adhered to during all upper extremity range of motion (UE ROM) movements to prevent damage to the shoulder muscles and development of pain syndromes.
- Isometric contractions may produce the Valsalva maneuver, resulting in tachycardia and increased blood pressure, followed by reflexive bradycardia. Patients with cardiac conditions must be closely monitored.
- Application of quick stretch (QS) in diagonal patterns must be carefully applied. If a muscle is very near its full anatomical range (see D2 flexion example), application of too great a stretch may damage the muscle. Neck muscles are also close to their full anatomical range at the beginning of patterns.

C-Icing

C-icing is a high-threshold stimulus used to stimulate postural tonic responses via the C-size sensory fibers (Rood, 1962). Icing to activate the C fibers is done by holding the

ice cube in place for 3–5 seconds, then wiping away the water. The skin areas to be stimulated are the same as for fast brushing, with one exception. *The distribution of the posterior primary rami along the back is avoided because it may cause a sympathetic nervous system fight or flight protective response (Rood, 1962; Huss, 1971).* Other precautions about icing are similar to those for brushing, see Safety Note 26-1.

Proprioceptive Stimuli

Quick Stretch

Quick, light stretch of a muscle is a low-threshold stimulus that activates an immediate phasic stretch reflex of the stretched muscle and inhibits its antagonist (Rood, 1962). Stretch is applied in the form of quick movement of the limb or tapping over the muscle or tendon. The therapist uses fingertips to vigorously tap the skin over a muscle or tendon while the patient is attempting to contract the muscle (see Fig. 25-8). This provides intermittent mechanical stretch to the muscle to evoke a stronger response. Evocation of the stretch reflex without a conjoint attempt to move or hold a position is not therapeutic.

Vibration

High-frequency (100–300 Hz, with 100–125 Hz preferred) vibration, delivered by an electric vibrator that has an excursion of 1–2 mm, to the belly or tendon of the slightly stretched muscle is an additional form of stretch (Umphred, 1995) (Fig. 26-2). The action of the vibrator pro-

Figure 26-2 An electrical vibrator is applied to the triceps tendon to elicit a sustained elbow extensor response while the patient is weight bearing in quadruped.

vides a rapidly repeated mechanical stretch to the muscle, which increases the number of motor units recruited. This is the tonic vibratory reflex (TVR). Tension within the muscle increases over 30–60 seconds and is sustained for the duration of the application of the vibrator (Umphred, 1995). The stronger response is obtained from application over the tendon. Vibration evokes a tonic holding contraction and adds to the strength of an already weakly contracting muscle.

Stretch to Finger Intrinsic

Stretch to the intrinsic muscles of the hand is used to facilitate co-contraction of the muscles around the shoulder joint (Ayres, 1974; Stockmeyer, 1967). Forcefully grasping handles of tools obtains this response, especially if the handles have been modified to be spherical or conical, with the widest part of the cone at the ulnar border of the hand, both of which increase intermetacarpal stretch. This treatment is used for patients who have distal movement but proximal weakness.

Heavy Joint Compression

Heavy joint compression facilitates co-contraction of muscles around a joint, thereby facilitating the stability component of movement in activity. Heavy compression refers to resistance greater than body weight that is applied so that the force is through the longitudinal axes of the bones whose articular surfaces approximate each other (Ayres, 1974; Rood, 1962). Resistance greater than body weight is resistance that is more than the weight of the body parts usually supported by the joint. One method by which heavy joint compression can be achieved during activity is to have the patient, who is in a weight-bearing position, lift one limb off the supporting surface. The arm still in contact with the surface now has more than the usual weight. Other methods include compression delivered by the therapist or the addition of weights, for example, having the client wear a weighted cap.

Resistance

Resistance to an ongoing movement or maintained posture is a form of stretch in which many or all of the spindles of a muscle are stimulated (Umphred, 1995). The muscle spindle, of course, cannot know whether the discrepancy between itself and the extrafusal muscle fibers is due to stretching by a moving force or by resistance that is preventing extrafusal muscle fibers from shortening as the spindle continues to shorten as programmed. The discrepancy causes the spindle to fire. The electrical activity of the interneuronal pool is consequently high, and more and more motor units are more easily recruited to fire; this phenomenon is called **overflow**.

Inhibition Techniques

Hypertonicity is treated with general inhibition techniques or by applying tactile, thermal, or proprioceptive stimulation either to the muscle itself or to the antagonists of the spastic muscle in the context of goal-directed activity. It is hypothesized that, when stimulation is applied to the antagonist, the relaxation effect in the agonist spastic muscle occurs through **reciprocal inhibition**. The reciprocal inhibition mechanism of persons post stroke, however, has been found to be disturbed and may result in unexpected outcomes (Okuma & Lee, 1996). Therefore, application of these techniques in this population must be monitored carefully.

Some of the following methods are aimed at the neural component of hypertonicity, and others, such as prolonged stretching, address the viscoelastic component. The therapist determines which component needs treatment and chooses appropriate techniques.

Tactile Stimuli

Slow stroking over the distribution of the posterior primary rami produces general relaxation. It involves rhythmical moving touch instead of maintained touch. The person lies prone or sits unsupported in a quiet environment with his or her back exposed. The therapist uses the palm or extended fingers of one hand to apply firm pressure along the vertebral musculature from occiput to coccyx, at which time the therapist's other hand starts at the occiput and progresses likewise to the coccyx. One hand is always in contact with the patient. This slow, rhythmical stroking using alternating hands is done until the patient relaxes or for about 3–5 minutes (Rood, 1956; Farber, 1982).

Thermal Stimuli

Both warming and cooling can be inhibitory.

Neutral Warmth

Neutral warmth refers to maintaining body heat by wrapping the specific area to be inhibited or the area served by the posterior primary rami for a general effect. A cotton flannel or fleece blanket or a down comforter is used for 10–20 minutes (Ayres, 1974; Huss, 1971). Neutral heat, rather than heat greater than body temperature, is used to avoid a rebound effect in 2–3 hours. The rebound effect manifests as facilitated or even superfacilitated muscles (Rood, 1962). Elastic bandages and air splints (see Fig. 16-75) can be used also. They not only maintain neutral warmth but also offer sustained pressure, both of which are inhibitory (Preston & Hecht, 1999).

Prolonged Cooling

Sustained cooling of the skin to 50°F (10°C) decreases the monosynaptic stretch reflex excitability (Preston & Hecht, 1999). A cold pack applied for 20 minutes achieves this effect (Braddom, 1996).

Proprioceptive Stimuli

Several proprioceptive techniques to inhibit one or both components of hypertonicity are described next.

Prolonged Stretch

Prolonged manual stretch is used to inhibit a specific spastic muscle so that the patient may move more easily (Carey, 1990). The limb is held so that the muscle is *steadily* kept at its greatest length for more than 20 seconds, until letting go is felt as the muscle adjusts to the longer length. As a special case of this inhibitory procedure, prolonged holding of the thumb in abduction and extension may relax a tight grasp.

Prolonged stretch by splinting or positioning the limb so that the hypertonic muscles are maintained in stretch over several hours to several weeks allows growth of additional sarcomeres and makes the muscle less sensitive to stretch during movement (O'Dwyer, Ada, & Neilson, 1996). The mechanical lengthening also changes the viscoelastic configuration of muscle by disrupting cross-bridges between myosin and actin filaments and/or by reducing the stiffness of periarticular connective tissue (Carey, 1990). See serial casting in Chapter 16.

Joint Approximation

Light joint compression, also called joint approximation, can be used to inhibit specific spastic muscles. This procedure is commonly used to relieve shoulder pain due to spastic muscles in hemiplegic patients. The method is to grasp the patient's elbow and, while holding the humerus abducted to about 35–45°, gently move the head of the humerus into the glenoid fossa and hold it there (Fig. 26-3) until the spastic muscles relax (Ayres, 1963, 1974).

Tendon Pressure

Pressure on the tendinous insertion of a muscle inhibits that muscle (Ayres, 1974; Huss, 1971; Stockmeyer, 1967). The extrinsic flexors of the hand may be inhibited by applying constant pressure over the length of the long tendons (Stockmeyer, 1967) through grasp of enlarged, hard handles of tools or utensils or via splints.

Vestibular Stimuli

Slow, rhythmical movement is inhibiting (Huss, 1971). Slow rolling is done by the therapist holding the patient at the hip and shoulder and slowly rolling him or her

Figure 26-3 Light joint compression, or joint approximation, is used to inhibit spastic muscles and to allow range of motion.

from supine to side-lying (Fig. 26-4). The patient should be lying comfortably, with a pillow under the head and between the knees if necessary for comfort. A decrease in hypertonicity should be seen within minutes.

Stimuli for the Special Senses

Rood (1962) used stimulation to the special senses to facilitate or inhibit the skeletal musculature generally. Auditory and visual stimuli can be used deliberately.

Figure 26-4 Slow rolling inhibits spastic or tense muscles. The therapist holds the patient at the hip and shoulder and *slowly* rolls him from supine to side-lying and back again. (Photo by Robert Littlefield, Scientific and Technical Photography, Dorchester, MA.)

However, auditory and visual stimuli also occur incidental to treatment, a fact of which the therapist needs to be aware. Music with a definite beat is facilitatory. A noisy, raucous clinic is stimulating and may affect the performance of the patient with CNS dysfunction. A colorful, bright multistimulus environment has a general facilitatory effect. The therapist's voice and manner of speech (fast and staccato vs. slow and calming) may also affect the patient's performance. A loud, sharp command yields a quick response and recruits more motor units (Voss, 1967).

Olfactory and gustatory stimuli are facilitating or inhibiting through their influence on the autonomic nervous system. Unpleasant or dangerous stimuli (like ammonia smell) elicit a sympathetic fight or flight reaction, and pleasant stimuli (like vanilla) evoke a parasympathetic response that inhibits the sympathetic response (Rood, 1962). These stimuli, especially olfactory, produce an emotional response as well as a motor response.

Moving from Muscle Contraction to Movement

As noted earlier, facilitation and inhibition techniques are used in conjunction with attempts at goal-directed action for the purpose of enabling development of movement-related capacities and abilities. Rood (1962) identified a sequence regarding the development of movement that is useful in guiding activity choices. She stated that movement first appears as phasic, reciprocal shortening and lengthening contractions of the muscles that cause movement subserving a protective function. Such movements might be facilitated using A-brushing or A-icing. In these phasic movements, muscles contract to cause movement through range, which produces reciprocal inhibition of the antagonists (Ayres, 1974; Rood, 1962). The movement of an infant waving his or her extremities back and forth when shown a desired object typifies phasic movement. Movement to touch an object or bat away a lightweight object, such as a balloon or bubble, is the first voluntary movement to aim for in patients beginning to develop tone and movement.

After phasic movements begin, tonic holding contractions are next to develop, according to Rood. Stability is obtained through co-contraction, such as occurs during heavy joint compression (Ayres, 1974; Stockmeyer, 1967). A goal-directed action, such as leaning on the desk with the affected arm while writing with the unaffected hand, is again sought.

PNF APPROACH AS TAUGHT BY VOSS

Proprioceptive neuromuscular facilitation (PNF) has been defined as “a method of promoting or hastening the

response of the neuromuscular mechanism through stimulation of the proprioceptors” (Voss, Ionta, & Myers, 1985, p. xvii). To take the name of the approach literally, however, is to do disservice to the comprehensive theory proposed by the originators of the approach. As we see with the techniques outlined in the Rood approach, clinical reasoning considering the beneficial aspects of the application of controlled sensory input leads to the application of multisensory afferent input. The PNF approach uses these sensory tools additively after evaluating the functional problem and identifying the necessary diagonal patterns of movement in the appropriate positions. Also, the clinical reasoning to enhance first-level motor control capacities considers the patient's breathing, pain, and general arousal level congruent with motor performance. Treatment sessions start with attention to therapeutic applications for breathing. Controlled sensory input and the effects of reflex activity are superimposed on movement patterns to provide as many favorable influences as possible to affect motor function that is the basis for skills and abilities. Baum et al. (1998) published a case study that demonstrates some of these multiple applications in an exercise protocol for a patient with acute C5 quadriplegia. The approach as described in this chapter presents basic knowledge and techniques directed toward the entry-level occupational therapist.

The Rotational Requirement for Developed Movement Capacities

The PNF approach is based on patterns of motion identified in 1951 by Kabat, a neurophysiologist and physician, while working with the other developers of the approach, Maggie Knott and Dorothy Voss, physical therapists (Myers, 1995). All parts of the body, head and neck, trunk, limbs, and even facial muscles have two diagonal patterns based on normal motor activity, and the motor pattern itself is a method of facilitation. The stronger muscles in the diagonal patterns influence weaker ones, which is in keeping with the axiom that the brain knows nothing of individual muscle action but knows only of movement (Voss, Ionta, & Myers, 1985). The skeletal, ligamentous, and muscular systems of the body support these patterns. Muscle alignment is spiral and diagonal. Shimura and Kasai (2002) investigated the effect of starting a movement pattern from a neutral position of the wrist versus starting with the wrist in the PNF-prescribed position. The initiation of voluntary wrist movement was operationalized in terms of the electromyographic reaction time (EMG-RT) and the excitability of the motor cortex as measured by motor-evoked potentials (MEPs). The PNF group performed significantly better. The authors concluded that the

amount of sensory input coming from the periphery was greater in the PNF position. Also, the PNF position improved movement efficiency by inducing changes in the sequence in which the muscles were activated.

The PNF diagonal patterns are combinations of the cardinal plane movements of flexion or extension, abduction or adduction, and internal or external rotation. The inclusion of a rotary component in all movement patterns is the unique aspect of the approach. Therapeutic applications, as we see in analysis of normal human movement, are not performed in cardinal planes of movement. In this approach, all movement patterns are reversing. If you reach up to install a light bulb, you need to be able to bring your arm back down. To perform these functional reversing patterns of the diagonal movements, a **balance of antagonists** is required. If a patient does not have this balance, treatment must start with techniques that focus on the agonist.

A significant body of literature from the disciplines of exercise physiology, sports medicine, athletic training, and physical education purports to investigate many of the PNF stretching techniques. Most of these studies, however, implement exercise in only one plane of motion. PNF patterns are performed in all three planes of movement (sagittal, frontal, and horizontal) simultaneously. Although the research generally substantiates the hypotheses that the techniques tested achieve increased ROM, two major problems preclude any generalization of findings to the clinical practice of PNF. The first major problem with the studies that focus on hamstring tightness to demonstrate effectiveness of PNF stretching (Bonnar, Deivert, & Gould, 2004; Carter et al., 2000; Feland & Marin, 2004; Feland, Myrer, & Merrill, 2001; Ferber, Osternig, & Gravelle, 2002; Funk et al., 2003; Rowlands, Marginson, & Lee, 2002; Spernoga et al., 2001; Stopka et al., 2002) is that passive range of motion (PROM) and isometric and isotonic contractions are used with only the hamstrings and their antagonists applied in the position of a straight leg raise from the hip. Movement occurs only in the sagittal plane, and not in the diagonal patterns of a PNF approach. Similarly, a study testing the effects of contract-relax (CR) on the soleus muscle involved only sagittal plane movement (Etnyre & Abraham, 1986). Without rotation, these are not PNF techniques.

The second major problem with “PNF” research from the athletic sciences is the manner in which these studies define and apply their techniques. The use of hold-relax (HR) and CR are very common in athletic training. Unfortunately, they are not using the techniques as they were originally developed. For example, Young and Elliott (2001) described their CR procedure as a maximal isometric contraction against resistance, relaxation, and passive stretch by the examiner “where the participant held the stretch for 15 s [seconds]” (p. 275). Compare this to the definition in Procedures for Practice 26-1, which summa-

rizes the PNF relaxation techniques as developed by Knott and Voss.

The Two Diagonal Patterns of Movement for Each Body Part

Note that vision is always combined with diagonal patterns.

Head and Neck, Trunk

- Flexion [of head and neck, or head, neck, and trunk] with rotation [of head and neck, or head, neck, and trunk] to the right (reversing, extension with rotation to the left)
- Flexion [of head and neck, or head, neck, and trunk] with rotation [of head and neck, or head, neck, and trunk] to the left (reversing, extension with rotation to the right)

Head and neck patterns may be performed specifically, but they are generally combined with the patterns of the trunk and extremities. Beazell (1998) published a case study of the use of the head and neck patterns for a patient who incurred two incidents of cervical trauma. Trunk patterns will naturally include the head and neck patterns when the patient is upright.

Upper Extremity

- Diagonal one (D1): **D1 flexion** combines flexion + adduction + external rotation at the shoulder (Fig. 26-5). It reverses as **D1 extension**, which combines the shoulder movements of extension + abduction + internal rotation (Fig. 26-6).
- D1 extension, when performed in a bilateral asymmetrical pattern, is called **chopping**, and D1 flexion is called **reverse of chop**.
- Diagonal two (D2): **D2 flexion** combines flexion + abduction + external rotation at the shoulder (Fig. 26-7). It reverses as **D2 extension**, combining extension + adduction + internal rotation of the shoulder (Fig. 26-8).
- D2 flexion, when performed in a bilateral asymmetrical pattern is called **lifting**, and D2 extension is called **reverse of lift**.

The upper extremity patterns are named by the direction of movement at the shoulder joint. A flexion pattern occurs when the patient moves his or her arm upward to retrieve an object from a high shelf. As the arm moves in a downward direction, as it does when we put on socks, this is an extension pattern. Again, patients are always directed to look at their hand while they move. In this manner, the movements of the head, neck, and trunk reinforce limb movements. The movements of the forearm and hand are delineated in the Glossary. It is important to note that some joints do not

PROCEDURES FOR PRACTICE 26-1

PNF Relaxation Techniques

Understand before you start:

- The techniques are based on reciprocal inhibition.
- “Any technique which demands or makes possible a gain in range of motion in one pattern has achieved relaxation of its antagonist” (Knott & Voss, 1968, p. 98).
- Contract = isotonic contraction.
- Hold = isometric contraction.
- The agonist is the pattern that has limited motion.
- The antagonist is the muscle or muscles that are shortened, limiting the range of the agonist pattern.

Technique	Method
Contract–Relax (CR) Indication: When agonist is weak	1. Passive or active-assisted movement in the agonist pattern until limit is felt 2. Isotonic contraction of antagonist pattern (“Turn and pull” or “Turn and push”) and resist 3. Relaxation 4. Passively move through new available range; repeat
Hold–Relax (HR) Indication: Muscle spasm with pain	1. An isometric contraction of the antagonist 2. Relaxation 3. Active movement of the agonist by the patient
Slow Reversal–Hold–Relax (SRHR) Indication: When the patient has the ability to move the agonist	1. Isotonic contraction of the agonist 2. Isometric contraction of the antagonist 3. Relaxation 4. Active movement of the agonist
Rhythmic rotation (Rro) Indication: Hypertonicity	1. Perform PROM until resistance is met 2. Slowly and gently repeat and reverse rotation of all limb segments 3. Continue PROM and repeat

These principles have been derived from the writings of Myers (1995).

Figure 26-5 D1 flexion. Starting position is represented by the darkest drawing of the therapist. Manual contacts: The therapist’s left hand is in patient’s palm (thumb to thumb), and her right arm wraps under to contact the flexor tendons of the forearm. Patient’s head is drawn to demonstrate how the head and neck turn while the patient watches his or her hand during the movement. Note the therapist’s movement as the pattern progresses (progressively lighter drawings). Note: Figures 26-5, 6, 7, and 8 are used with permission from: Voss, D.E., Ionta, M.K., & Myers, B.J. (1985). *Proprioceptive Neuromuscular Facilitation: Patterns & Techniques* (3rd ed.). New York: Harper & Row.

Figure 26-6 D1 extension. Starting position is represented by the darkest drawing of the therapist. Manual contacts: Therapist’s right hand is over the dorsum of the patient’s hand, while the therapist’s left hand cradles the triceps.

Figure 26-7 D2 flexion. Starting position is represented by the darkest drawing of the therapist. Manual contacts: Therapist's right hand is over the dorsum of the patient's hand, and her left hand is over the triceps.

move through their full anatomical ranges in diagonal patterns. The PNF patterns represent functional range of motion.

Another attribute of the diagonal patterns is that each upper extremity muscle is a prime mover in one of the patterns. Sullivan and Portney (1980) demonstrated this in a study that electromyographically recorded muscle activity during diagonal patterns of shoulder musculature in 29 healthy adults. Therefore, the therapist selects the optimum pattern for particular muscles (see example of radial nerve injury, below).

As the arm starts in a pattern, all of the muscles are in their lengthened range. As the pattern continues, the muscles of the pattern contract, and when the movement is completed, the muscles are now in their shortened range. This distinction between shortened range and lengthened range is important because the muscles respond differ-

Figure 26-8 D2 extension. Starting position is represented by the darkest drawing of the therapist. Manual contacts: The therapist's left hand is in the palm of the patient's left hand, and her right hand is over the finger and wrist flexors in the forearm.

ently in the application of quick stretch (QS) based on their length.

It is easiest to learn the upper extremity patterns as unilateral or bilateral symmetrical patterns. In treatment though, for the majority of applications, attention is always given to how to use the upper extremities in contact, that is, when one hand contacts the opposite forearm and wrist with the patient facilitating their own flexion or extension pattern with manual contact (see below) over the muscle that is acting in the pattern. These patterns are technically bilateral asymmetrical patterns but are most commonly called *chopping* and *lifting*. Keeping both upper extremities in contact is referred to as self-touch, and Voss, Ionta, and Myers (1985) described the spontaneous appearance of self-touch during development, during daily activity, and in the patient in pain. The facilitatory effect of self-touch is frequently described as “closing the sensory loop.”

The PNF approach also uses two other upper extremity patterns called thrusting patterns, but they are not included in this chapter because they add an additional level of complexity when learning the basic D1 and D2 movements.

Lower Extremity

There are two diagonal patterns in the lower extremities as well, but they will not be discussed here. The advanced occupational therapy PNF practitioner may use these patterns to facilitate functional ambulation or to retrain bowel and bladder control (Voss, Ionta, & Myers, 1985). Yigiter et al. (2002) compared traditional prosthetic training versus PNF resisted gait training in patients with transfemoral amputations. Although both groups improved significantly on all measures ($p < 0.05$), the group who received intervention based on the PNF approach had more improvement.

Emphasis on Breathing and Other Vital and Related Functioning

Vital and related functions include respiration, facial motions, tongue motions, swallowing, and bowel and bladder control. Respiration is addressed in all PNF treatment. The other functions are considered advanced practice and will not be addressed here. Stimulation of the intrinsic muscles of respiration and increased AROM of the chest and diaphragm is achieved by directing facilitory techniques toward motions of the lateral chest walls, upper chest, sternum, and diaphragm (Voss, Ionta, & Myers, 1985). Nitz and Burke (2002) performed a randomized double-blind study of PNF breathing techniques and found that the combined techniques of PNF were the main contributor to improvement in arterial oxygen saturation for subjects

Figure 26-9 Bilateral symmetrical D2 flexion, shortened range; bilateral symmetrical D2 extension, lengthened range. Shoulders flex, abduct, externally rotate; elbows extend (as the intermediate joint, the elbow, may flex or extend); forearms supinate; wrists extend toward radial side; fingers extend and abduct; and thumbs extend and adduct.

with myotonic dystrophy. Two methods to facilitate breathing are as follows.

Bilateral Symmetrical (BS) D2 Pattern of the Upper Extremities Combined with Trunk Movements

To facilitate breathing, patients are placed in upright positions or in supine. Both arms do the D2 pattern, combined with trunk flexion and extension. Quick stretch (QS, described below) is added by the therapist, along with an appropriate tone of voice and manual contacts (MC) in the direction of trunk flexion, shoulder extension, or both. The bilateral symmetrical D2 flexion pattern of the extremities facilitates trunk extension and expands the chest (Fig. 26-9). If a patient lacks upper extremity strength or ROM to complete the full D2 pattern, the therapist may actively assist the patient or the patient may move only through partial ROM or perform the pattern with elbows bent. Bending the elbow reduces the resistance of the arm, which reduces the effort necessary to perform the movement.

Facilitation of the Chest Wall Muscles in Side-Lying or Supine

In side-lying or supine positions, the therapist applies manual contacts on the chest walls using quick stretch (QS) at the end of exhalation to enhance the inspiratory response. The muscles of the chest attach so that

their placement relative to the ribs is diagonal. MCs are applied directly over the muscles of the chest wall considering their diagonal orientation. This method is used with patients in acute care who cannot be moved from supine.

Positions and Movement between Postures

Treatment planning considers the best position for the patient and the need to move between postures. These postures are combinations of the patterns of the head, neck, trunk, and extremities, as necessary, to accomplish the motor aspects of occupational performance. Positions include side-lying, prone on elbows, hands-knees, plantigrade, kneeling, half-kneeling, long sitting, short sitting (knees flexed from long sitting position), tailor sitting (sitting with knees bent and legs crossed), heel sitting, side-sitting, and chair sitting (Myers, 1981). Modified plantigrade is a frequently used position where the client is standing or sitting with both arms in contact with a surface such as a table. Having clients bear weight on their elbows can further modify this. Consider the balance requirement of each position. Are there different demands for the head and neck; for the trunk; for the upper extremity; or for the lower extremity?

Several factors influence the choice of postures in therapy. For more involved patients, treatment is started in the position in which the client is most stable. Frequently this is side-lying, although patients in acute care may need to start supine in bed. The progression toward the use of the arm and hand in activities considers basic mobility (adequate ROM), stability, **controlled mobility**, and finally skill. Stability is comprised of two sequential skills: tonic holding, where muscles can perform an isometric contraction in their shortened range; and co-contraction, where muscles are able to maintain isometric contractions in their midrange. Controlled mobility is the ability to use a limb in a smooth and regulated movement against gravity. Once a patient demonstrates stability in a bilateral weight-bearing position and demonstrates the ability to perform isometric contractions in the midrange, tasks are presented where one arm leaves the contact surface to engage in activity (Fig. 26-10). As controlled mobility improves, patients will be able to move their arm through greater arcs of active range of motion (AROM). When one arm is stationary and the other arm is moving, PNF terms this position simultaneous static dynamic (SSD).

Another consideration when choosing postures is the activity of the client. If the activity that the client is performing is difficult, then the postural demand is lowered. Conversely, if the activity is not challenging, then the postural demand may be increased. For example, a patient who has the goal of signing his or her

Figure 26-10 Bilateral reciprocal D1 in a palmar prehension activity. Note the simultaneous static and dynamic position, with the left arm weight bearing (static) in D1 extension and the right arm moving (dynamic) in D1 flexion.

name (difficult activity) may work on writing activities in prone on elbows (lowered postural demand). If a patient is performing a surface contact activity like washing a counter (easy), standing may be the posture of choice (high demand).

Finally, movement between postures is an essential skill. Patients may start a treatment session in side-lying, progress to side-sitting and then to kneeling, and then return to a less demanding posture such as heel sitting as they fatigue. A progression beginning with bilateral weight bearing, moving to an activity performed in a simultaneous static dynamic (SSD) position, and then moving back again to weight bearing demonstrates an upper extremity–based progression between postures. In these sequences, by asking patients to look at their hands or in the direction of the activity, reflex support (see below) reduces conscious effort (Voss, 1967).

The Influence of Reflex Activity

A basic tenet of the PNF approach is that the reflex mechanisms underlying normal movements are potent forces for influencing movement and posture (Voss, Ionta, & Myers, 1985). The tonic neck reflexes and righting reflexes (see Chapter 6) are used to influence movement. For example, in assisting a patient who is lying supine in bed to roll to side-lying, a very important functional movement, the facilitatory effects of the asymmetric tonic neck reflex (ATNR) and optical righting reflex are used as

the therapist simultaneously slaps the surface of the bed and uses a sharp tone of voice in the command “Look over here” while using his or her other arm at the scapula or hip to actively assist rolling. Looking at where the therapist indicated activates the ATNR by neck rotation and the optical righting reflex by change in position of the head.

Application of Controlled Sensory Input

As was described in the Rood approach, tactile, proprioceptive, and auditory systems are used in treatment. The PNF approach expands proprioceptive input to include inner ear receptors (in reflex support) and also includes an essential emphasis on visual input. The procedures that follow are basic to the approach and part of the treatment of every patient.

Proprioceptive Stimuli

The proprioceptive input as applied in PNF has many similarities to the manner in which it is used in the Rood approach. For example, the physiology that supports the use of quick stretch (QS) is the same; however, in the PNF approach, the therapist administers QS with his or her manual contacts to muscles in their lengthened range.

Traction and Approximation

Traction, or separation of joint surfaces, promotes mobility by stimulating the joint receptors that are sensitive to stretch (Knott & Voss, 1968). Approximation, or compression of the joint surfaces, promotes joint stability.

Quick Stretch (QS)

Muscles respond with greater force after stretch, particularly when they are in their lengthened positions. Stretch increases feedback from muscle and joint receptors and enhances the response. Specific to PNF, however, is the precept that QS is always applied to all three components of the diagonal pattern with an emphasis on the rotational components (Voss, Ionta, & Myers, 1985). As mentioned earlier, the PNF diagonal patterns do not require full anatomical range of motion. The difference between the PNF position and full anatomical range allows for the safe application of stretch to a muscle. For example, if you want to facilitate the D2 flexion pattern for an overhead reaching activity, the patient’s arm begins in the lengthened range of D2 flexion (shortened range of D2 extension), and the therapist places manual contacts to the back of the hand and to the dorsal surface of the scapula. Then, the therapist quickly leans a slight bit more into the D2 extension pattern and administers QS at the same time giving the

verbal command for movement. *Avoid excessive stretch to the wrist extensors. In this starting position, the wrist extensors are close to their end range anatomical position.* In the PNF approach, the therapist's entire body is involved in the application of QS, not just his or his hands and arms. This is a much smoother and safer application. Study the beginning position in Figure 26-7. To facilitate the movement with QS, the therapist moves very slightly but quickly into the D2 extension pattern and commands the patient to execute the movement. Immediately, the patient responds and performs the D2 flexion pattern.

Resistance

Resistance is used to improve muscle contraction. Padua et al. (2004) used a PNF intervention as one of three shoulder exercise protocols on 57 physically active college-age men and women. Although all three exercise protocols resulted in significant improvement ($p < 0.05$) on measures of strength, active angle reproduction, and single arm balance, only the PNF group demonstrated significant improvement in functional performance (throwing). The PNF group actively performed D1 and D2 patterns against maximal resistance offered manually by the investigator. From a PNF perspective, we resist the patient's effort while, at the same time, we are part of the movement. The therapist moves at the same time as the patient. If the therapist does not move, the pattern will be blocked. As was described for QS, graded resistance is applied by the therapist using whole-body movements. Although pulleys or weights may provide resistance as the client works independently, manual resistance through manual contacts (MCs) and the therapist's use of his or her body is integral to the approach. Resistance can be provided in many different ways depending on the goal, such as only at the end of ROM in a pattern; intermittently as the patient moves through the pattern (this is called repeated contractions, or RC); or continuously throughout the range. Figures 26-6 and 26-8 demonstrate how the therapist applies resistance with one choice of placement for manual contacts in the extension patterns. Understanding how resistance is applied in these patterns is important because the muscles of the extension patterns will not be fully activated without resistance. In most positions, the effect of gravity will cause the muscles of the flexion pattern to work in an eccentric contraction. Certainly there are instances where working on the ability to perform eccentric contractions is the goal, but if your goal is to activate the muscles of the extensor patterns, you must consider the effects of gravity.

"Maximal resistance" is the term that has historically been used to describe the application of resistance in PNF. This is misleading, however, because resistance is always graded in relation to the patient's capabilities. Although the term appears in older textbooks, the current

thinking is to drop the word "maximal." The amount of resistance you would use to facilitate movement in a healthy young adult is very different from what you would use with a 55-year-old patient with Guillain-Barré syndrome who is still in acute care. With isotonic contractions, the appropriate amount of resistance is the amount that can be applied allowing full AROM to occur. For isometric contractions, it is the amount of resistance that the patient can manage in a stable position. Resistance is never used to "break" the effort of the patient. The goal is to cause irradiation to other muscles, which increases as resistance increases. Irradiation causes muscle groups other than the ones originally excited to take part in the response. This spread of facilitation is not haphazard but occurs in synergistic muscles. This effect is also referred to as overflow. As applied in PNF, resisting stronger movements to facilitate weaker muscle groups is termed reinforcement. Research supports the use of resistance to one extremity to increase the response in the opposite extremity for orthopedic patients with unilateral lower extremity impairment (Arai et al., 2001) and in healthy women at the shoulder (Pink, 1981) and elbow (Kamplain, 1986).

Tactile Stimuli

The therapist's manual contacts and the patient's use of self-touch are the two primary methods of providing tactile afferent input. Temporal and spatial discriminations occur with MCs and help patients understand the direction of the anticipated movement (Knott & Voss, 1968). Cold or vibration, as described in the Rood approach, may be used adjunctively (Myers, 1995).

The therapist places his or her hands on the skin overlying the muscles or tendons responsible for the pattern. There are no absolutes as to which segments of the body are to be facilitated with MCs. You can vary MCs, shifting the emphasis. For example, with an upper extremity pattern you may choose contacts at the wrist and upper arm or at the scapula and forearm. When facilitating rhythmic stabilization (RS) of the trunk, you may place MCs on one shoulder and the opposite hip, or on both shoulders, or on both hips. For a patient with significant weakness or pain, however, the therapist must support the limb and is not able to use MCs over the muscles in the patterns. As mentioned earlier, it is crucial that therapists place themselves in the diagonal pattern and move with the patient for successful completion of the range of the pattern. When the goal is stability, the therapist must be in a stable position for techniques to be successful.

Auditory Stimuli

Auditory input takes two primary forms. Tone of voice is the first. Sharp commands are used for maximum stimu-

lation. Moderate tone of voice is used when the patient is responding with their best effort. A soft tone of voice is used when a patient has pain or when they are in an aroused state.

Commands are the second. Commands both prepare the patient for what is going to happen and are timed to provide maximum stimulation. For example to achieve D1 flexion you may first explain, “You are going to close your hand, turn it, and pull up and across your face.” Then, with appropriate manual contacts, you simultaneously apply the quick stretch and say, “Squeeze, turn, pull up and across [your face]!”

Visual Stimuli

Visual input is used to facilitate movement. In diagonal patterns, the clients are always instructed to look at their hand (or object in their hand) when performing the unilateral or bilateral upper extremity patterns or to look at a specific place (e.g., “Look at the corner of the room” or “Look back at me”) when working specifically on head and neck patterns or trunk patterns. In moving between postures, the optical righting reflexes are harnessed by directing the patient’s gaze in the direction of movement, which is timed congruently with other facilitory stimuli at the initiation of movement.

Basic Techniques

Slow Reversal (SR)

The diagonal patterns were described earlier. The reversing nature of the diagonal pattern reflects how we all move in activity. In treatment, whether the direction of the pattern is named agonist or antagonist will vary. For example, if you are working with a client following a radial nerve repair and your objective is to strengthen the extensor carpi radialis longus (ECRL), the extensor carpi radialis brevis (ECRB), and the supinator, the focus would be on these muscles, and they would be designated the agonist muscles. All three of these muscles are prime movers in the D2 flexion pattern, so it would be considered the agonist pattern. D1 extension becomes the antagonist pattern.

In addition to irradiation, described earlier, two additional physiological principles are active during slow reversal (SR). Reciprocal inhibition is one principle. As explained in the Rood approach, when voluntary or reflexive contraction of a muscle occurs, the antagonist simultaneously relaxes. Successive induction is the second principle. According to this principle, the stronger antagonist becomes a source of proprioceptive facilitation for the weaker agonist. One action lowers the threshold for the opposite action. Successive induction causes a greater motor response because of the increased synaptic activity (Knott & Voss, 1968). Therefore, it is not uncommon to

perform the antagonist pattern first to use the facilitating mechanism of successive induction.

Rhythmic Initiation (RI)

Rhythmic initiation (RI) is a technique used with patients who have trouble initiating movements, such as is seen in patients with Parkinson’s disease. It involves a sequence of voluntary relaxation followed by therapist-assisted isotonic contraction and then unassisted movement by the patient. Tone of voice is slow, soothing, and repetitive. The therapist starts the movement, “Relax and let me move you” (PROM). The therapist repeats the movement with reversal several times. Then the patient is instructed, “Now do it with me” (active-assisted range of motion). Finally, the therapist removes his or her manual contacts while saying, “Now you do it,” and the patient then performs the motion in activity (AROM). Components of feeding, washing, and dressing are examples of some of the activities that this technique facilitates. Wang (1994) studied the effects of RI on the gait patterns of patients with both long- and short-duration hemiplegia and found that the cumulative effects (treatment over time) were more beneficial than the immediate effects (at initial treatment session) and that patients with hemiplegia of short duration respond to training sooner than those with hemiplegia of long duration, although the cumulative effect for both groups was similar.

Rhythmic Stabilization

Rhythmic stabilization (RS) is a primary method for developing stability. This technique involves a midrange isometric contraction of the agonist that is followed by an isometric contraction of the antagonist with no movement occurring (co-contraction). It may be used in all positions. Joint approximation may be added and is administered on the “1, 2, 3” command. Establishing trunk stability is practiced with the therapist using manual contacts at both shoulders, both hips, or at the contralateral hip and shoulder. There will be no movement of the patient or therapist involved in this technique, but both are working to maintain stability (Fig. 26-11). Commands are the same regardless of position or contacts. Preparation involves the instruction, “On the count of three, I am going to push you from side to side. Don’t let me move you.” The action commands are, “1, 2, 3, hold! [sharp]. And hold [moderate, drawn out], and hold [same], and relax.” The use of “hold” in PNF always means an isometric contraction. See Case Example #2, which elucidates this process.

RS involves only three reversals to avoid the potential for the patient to hold their breath. It is not infrequent to have to provide reminders to the patient to maintain a normal breathing pattern. Especially for patients with

Figure 26-11 Lifting to the left. The therapist approximates at the pelvis. Before fatigue is evident, the patient would place both hands on the countertop, and both the patient and the therapist would perform rhythmic stabilization.

cardiac precautions, the relationship between isometric contractions and the Valsalva maneuver must be monitored (see Safety Note 26-1).

RS is also used with patients experiencing pain. Pain typically causes muscles in the area to be tightly contracted, a protective mechanism. Breathing, rhythmic stabilization, and reciprocal reversing movements of other body parts are what PNF refers to as indirect approaches to reduce muscle guarding and reestablish the balance of antagonists necessary for functional movement. For example, RS is performed on a part of the body that is not compromised by pain. Irradiation, or overflow, starts to

break up the protective muscle contractions in the painful area. For patients with upper extremity pain, this is frequently performed with the patient lying supine with knees bent (hook-lying) with the therapist sitting along side of the patient. The therapist encircles the patient's legs with both arms and uses body weight to provide resistance in one direction and then the other. Again, if you are observing this procedure, you will not see any movement but the patient and therapist are working very hard. This is an instance where diagonal movement is not used.

If the patient is unable to perform rhythmic stabilization, it is necessary to develop the precursor muscle contractions by facilitating shortened-range isometric contractions.

Recuperative Motion

PNF takes a novel approach to fatigue. At the earliest sign that the patient is beginning to tire, rather than resting, the patient is guided into the use of a new combination of movements to reduce or circumvent fatigue produced by repetitive activity against resistance. In treatment focusing on improving upper extremity function, this may mean activity in the other diagonal. When working with patients on trunk stability, this may mean reducing the postural demand by changing the position that the client is working in. Temporarily stopping the activity and engaging in RS may also reduce the fatigue. For example, working with a client on morning ADLs (activities of daily living), activity may start with the patient sitting to apply toothpaste to a brush (skill) and then standing to brush the teeth. Brushing would be performed using the chopping pattern or in a simultaneous static dynamic (SSD) position. If standing for this part of the activity appears to be getting more difficult for the patient, a modified plantigrade position may be used while the patient rinses his or her mouth and the therapist performs RS. Alternatively, the patient would sit to finish the activity.

CASE

EXAMPLE # 1

K.S.: PNF Treatment of Limitations of Occupational Functioning Because of Pain and Limited Shoulder Range of Motion

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

K.S. is a 46-year-old married mother of two who works full time as an operating room technician. She presents with a diagnosis of adhesive capsulitis of her left (L) dominant shoulder. An outpatient occupational therapy assessment identified the following problems: (1) decreased ability to perform ADL and BADL activities taking place above shoulder level secondary to PROM limitations, muscle spasms, and pain with active movement and decreased muscular endurance; (2) decreased overall systemic endurance, and (3) increased irritability in work and home situations secondary to pain disturbing sleep.

Appreciate the context

“K.S. has a multitude of occupational roles. All of them are affected by the problems she is currently experiencing with her shoulder.”

Develop intervention hypotheses

“Frustration with her inability to use her dominant arm in her very busy lifestyle is wearing on this client. We need to develop some compensatory strategies and pain control measures that she can manage independently right away while we work to gain PROM and then concurrent strength and endurance of her dominant arm in activities.”

Select an intervention approach

“A PNF approach should work well for her pain. In addition to starting with breathing techniques, teaching the use of the unaffected arm in diagonal patterns with left arm in contact as able will lay the foundation for reestablishing normal motor function on her dominant side.”

Reflect on competence

“I can adapt many of the bilateral asymmetrical arm patterns to help her move within her pain-free range. She can use her unaffected arm to provide support to the affected one when she needs to perform skilled activities.”

Recommendations

The occupational therapist recommended two treatment sessions per week for 6 weeks. In collaboration with the patient, the following long-term goals were developed: client will return to competent pre-morbid occupational task performance, family, and job roles using strategies to prevent recurrence of pain and ROM limitations.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

“I feel we have a very good chance of remediating symptoms and regaining occupational functioning objectives without the client undergoing an invasive orthopedic procedure. She appears motivated and agrees with the plan. There do not appear to be any cognitive issues precluding her participation in a home program. Her employer is willing to allow her to reduce her work days by 40%, and the family has discussed the ramifications of this temporary decrease in her salary.”

Summary of Short-Term Goals and Progress

1. For relaxation and/or pain control during daily activities, K.S. will demonstrate performance of breathing technique: bilateral D2 trunk and arm pattern in sitting, elbows flexed initially.

K.S. learned the pattern during her first outpatient session. The therapist used quick stretch, soothing tone of voice, and active assist strategies until the pattern was learned. K.S. said it was a little more difficult to perform this pattern by herself at home.

2. K.S. will demonstrate performance of non-painful, weight-bearing, modified plantigrade postures to perform occupational tasks, alternating arms as able. Diagonal patterns superimposed on this posture will initially support laundry activities, loading and unloading the dishwasher, and placement and retrieval of items in drawers.

K.S. participated in many modified plantigrade postures during initial therapy sessions. She was quick to learn how to use these movement patterns around home and work.

3. K.S. will demonstrate active-assisted use of affected arm in bilateral asymmetrical diagonal patterns in skilled activities.

In therapy, K.S. learned unilateral D1 and D2 with her right upper extremity (RUE) in activity. Chopping and lifting were demonstrated by the therapist, and then she learned modified chopping and lifting performed with the left arm, modifying the placement of the right hand to provide active-assisted movement to use her dominant hand in activities without increasing shoulder pain.

4. K.S. will gain left shoulder PROM, AAROM (active-assisted range of motion) and AROM in flexion, abduction, and external rotation by participation in therapy sessions and home exercise program.

Rhythmic stabilization in various supportive postures will follow breathing techniques.

After manual techniques by the therapist, K.S. participated in AAROM activities, which she continued in her home program. She kept an active log given to her by her therapist, and the two of them discussed her comments and reactions to the program, usually while they were doing icing.

Assess the patient's comprehension

Compare actual to expected performance

Know the person

Appreciate the context

“One of K.S.’s strongest habits was ‘pushing through’ to complete activities, no matter what. She felt that she needed to do this to complete all tasks of her many life roles. I had to do a lot of patient education about that. Many of the therapeutic techniques during treatment gave us time to talk. Rhythmic stabilization in hook lying position helped break up muscle spasms. As she was experiencing less pain and starting to sleep better, she was more willing to accept my suggestions for at least slowing down and taking breathing breaks. Learning the active-assisted diagonal patterns helped her immensely when she had to perform fine motor tasks with her dominant hand. K.S. told me that she had never had anyone explain the use of breathing patterns for this kind of problem. Sure, she had done it during labor, but, ‘that was a different story.’”

Next Steps

Initial short-term goals were modified throughout the 6-week period by increasing the movement demands. Initially, diagonal patterns were performed with the elbow flexed as she lifted her arm against gravity and with her elbow extending on the reversals. Gradually, gentle manual resistance was added to the eccentric contractions. She maintained gains in range of motion between treatment sessions by using diagonal movements in activity and exercise. As strength returned, K.S. continued to increase repetitions, improve muscular endurance, and avoid potential reinjury during activities requiring eccentric contractions of shoulder muscles.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“At the end of 6 weeks, K.S. ‘graduated’ from OT. The protective techniques that she learned throughout her therapy interventions and that she incorporated into her daily habits served her well. By the end of treatment, she was a real ‘pro’ at knowing when she might be overdoing it with her arm, but more importantly, she knew how to change the task before overdoing became a problem.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Modified Upper Extremity Diagonal Patterns

With pain and limited active range of motion, movement through the full range of either diagonal pattern was not possible for K.S.

1. Why would you instruct the client to do diagonal plane movements when she cannot complete the patterns instead of instructing her in one-plane shoulder exercises?
2. How is the client’s use of self-touch different than what is typically done in chopping and lifting?
3. What else would you teach her to do while working in the patterns?

CASE

EXAMPLE # 2

M.G.: PNF Treatment to Develop Postural Control

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist’s Internal Dialogue

Patient Information

M.G. is a 24-year-old male, former Marine, who is 20 months post closed-head injury and right (dominant) humeral fracture with subsequent peripheral nerve damage following a motor vehicle injury while on active duty in Iraq. He was in a coma for nearly 2 months. He has gone through extensive inpatient rehabilitation. He received an honorable discharge from the military. Four months ago, surgeons performed a triple tendon transfer to restore hand function, replacing muscle function that was lost because peripheral nerve regeneration was not occurring. Subsequently, he received extensive hand therapy at a VA hospital near his home. Currently, he is returning to college to complete his final year of studies and is referred as an outpatient to this local VA hospital in the city where he will be studying. The objective is to complete rehabilitation following tendon transfers while he is in school. He participated in an occupational therapy assessment, and in addition to RUE impairments with resulting functional deficits, he has an ataxic gait. Upon further evaluation, problems related to the ataxia included: (1) inability to maintain midrange isometric contractions of the right shoulder girdle in seated position; and (2) limited control of trunk midrange isometric contractions in side-lying secondary to abdominal muscle weakness.

Appreciate the context

“M.G. presents in an upbeat manner. He acknowledges the important role his parents have played in his rehabilitation process but appears to be glad to be out from ‘under their wings.’ He talks in an animated manner about the therapists he worked with and identifies things he liked about rehab and things that he did not like. His frustration with not being able to use his right hand appears appropriate; however, he does not demonstrate a lot of affect when talking about his initial injury.”

Develop intervention hypotheses

“M.G. needs significant work to reestablish postural muscle control and strength, not only at the shoulder, but also the trunk.”

Select an intervention approach	“We will be using PNF diagonals and thrusting patterns extensively to meet objectives for restoring RUE control. The approach also offers techniques to effect trunk stability.”
Reflect on competence	“Despite his enthusiastic manner (or perhaps because of it), M.G. is going to be a challenge. I will need to restrain myself from getting into a “parent” role. He accomplished so much so quickly in rehab so far that I am going to have to gradually inform him that this stage of his rehab is not going to move as quickly.”

Recommendations

The client’s physician referral was for “upper extremity/hand rehabilitation, 2 times per week.” Following assessment, the therapist contacted the physician to increase frequency of therapy to 3 times per week. Sessions were scheduled for 30–45 minutes, with potential use of modalities being the consideration for increasing the time of some visits. Therapy was approved until maximum benefit was achieved.

M.G.’s identified long-term goal was to be able to throw a baseball. In addition to the long-term hand function goals related to this task, the long-term goals related to his ataxia were identified as: (1) M.G. will demonstrate postural control adequate to pitch slow-pitch softball; (2) M.G. will demonstrate postural control adequate to support throwing a ball from second base to home plate.

Consider the patient’s appraisal of performance	“M.G. is back on campus, but all of his former friends have graduated. He is very personable and motivated; however, he states that he is pretty bored and doesn’t know how much this will change once school starts in 10 days. Due to the poor fine motor skills in his dominant hand, he is taking a reduced load of 9 credits each semester, then 6 credits the following summer, at the end of which he will graduate. Because of his long rehabilitation, he is familiar with therapies and has seen improvement. He states, ‘I always liked OT.’ Due to the scope of issues related to his return to college with the extent of his rehab needs, 3 times per week seemed the appropriate frequency of treatment, and M.G. agreed. We also agreed that we could be flexible with this scheduling if school tasks were more demanding than he anticipated. He also agreed to use a tape recorder in lieu of note taking at the beginning of the fall semester.”
Consider what will occur in therapy, how often, and for how long	
Ascertain the patient’s endorsement of plan	

Summary of Short-Term Goals and Progress (Specific to Ataxia)

1. M.G. will perform midrange isometric contractions of trunk muscles in side-lying, as evidenced by successful rhythmic stabilization (RS) side-lying right and side-lying left.

Following breathing exercises, therapy started with hold-relax active motion (HRAM) in side-lying and was eventually graded to slow reversal-hold (SR-H) in side-lying. When RS was successful in side-lying, we started a progression of movements from side-sitting to kneeling, to half-kneeling, to standing, moving back and forth between the positions, decreasing the skill requirement during the most challenging postures and increasing the skill of hand and arm activities in the less demanding postures. RS was performed multiple times in all positions, and the less demanding positions and activities were performed at initial signs of fatigue.

2. M.G. will demonstrate strengthened abdominal muscles by performing 10 sets of sit-ups, arms across chest, in a sequence of left diagonal sit-up, straight sit-up, and right diagonal sit-up (1 set).

This is an ex-Marine. When the weakness of his abdominal muscles became apparent, he appeared to be fairly devastated by this. We had to work at this very carefully because this was one area where he was prone to overdo it. The progression of sit-ups was performed until he could do 15. Then the number decreased as we made the task harder by moving his arms behind his head (increasing the lever arm). Lower abdominal exercises were gradually introduced and graded as well.

Assess the patient’s comprehension	“When the patient is unable to perform isometric contractions, the patient must be taught to ‘hold.’ One approach is to have him perform slow reversal-hold (SR-H) through decreasing ranges of motion until no motion occurs (Voss, Ionta, & Myers, 1985). Another approach is hold-relax active motion (HRAM). This is probably the approach we need to start with because it is more appropriate when there is an imbalance of antagonists. We will try both to see which is easier to begin with.”
Understand what he is doing	
Compare actual to expected performance	“It was interesting that, despite all of the limitations he has endured and overcome, the weakness of his abdominal muscles affects him so deeply. However, this was his first real-time experience of being out of the military. He is exhibiting no other signs that might be indicative of post-traumatic stress syndrome (PTSS); however, this strong reaction led to the discussion of many of his feelings about being injured so early in his tour of duty. His father was a retired military man (served in Vietnam), and while his dad was available for him during his extensive rehab, he said that they never talked about combat experiences.”
Know the person	
Appreciate the context	
	“He worked diligently at all of his home program activities and exercises. Frequency of therapy was reduced to two times per week after normal gait was reestablished.”

3. M.G. will perform midrange isometric contractions of right shoulder girdle in reversal of both D1 and D2 patterns as demonstrated by successful rhythmic stabilization (RS) efforts in these patterns both from sitting and side-lying on left side.

Work toward this goal started with SR-H in sitting and side-lying, monitoring arm position for biomechanical load and modifying as appropriate. As he was able to perform RS at the shoulder, he began spending a lot of time in prone on elbows while practicing fine motor abilities and skills. He took a liking to the fine felt-tipped marker drawing kits of relatively small and complex designs and initially did these in prone on elbows. Eventually, we would tape these to the wall, and he would work on them from a standing position with his elbows in contact with the wall.

Next Steps

M.G.'s improvement in gait foreshadowed his improvements with hand function and provided the necessary support for skilled movement of his affected arm. M.G. was performing a controlled underhand and overhand throw with a nerf ball before hand strength was adequate to advance to a heavier ball.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"M.G. made excellent progress and eventually internalized the need to take things at a rate a bit slower than he really thought he could perform at. He was discontinued from OT at the point when he was able to perform his own note taking during lectures. The following spring, he invited the OT staff to his first slow-pitch baseball game. It appeared that he was developing some good friendships in this activity."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Facilitating Trunk Control in Side-Lying

M.G. is unable to perform rhythmic stabilization (RS), so you must build the ability to perform isometric contractions of the muscles in their shortened range.

1. How should you start the session?
2. What should the therapist be doing?
3. For stability techniques in side-lying, where are your manual contacts?
4. When and how do you use resistance?
5. Describe how you use quick stretch (QS) and resistance.
6. What tone of voice do you use?
7. What else must you do?

Evidence Table 26-1 Best Evidence for Occupational Therapy Practice Regarding Restoration of First-Level Motor Control Capacities

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Soft tissue mobilization plus PNF in patients with musculoskeletal disorders	PNF group vs. control group	20 persons, aged 21–83 years with orthopedic shoulder pathology of 1 year or less. (No significant difference in age between groups).	10 minutes, one-time treatment.	Randomized controlled study. IB1a	Yes, soft tissue mobilization combined with PNF intervention was found to be effective both in gaining external rotation at the shoulder and in overhead reach as compared with no treatment.	Significant gain in external rotation ($p < 0.0005$; $r = 0.74$). Significant gain in overhead reach ($p < 0.009$; $r = 0.53$)	Godges et al., 2003
Prosthetic training for individuals receiving first prostheses following unilateral trans-femoral amputation	PNF group vs. traditional prosthetic training group.	50 persons with unilateral trans-femoral amputations, 20–40 years old.	30 minutes daily for 10 treatments.	Randomized controlled study. IA1a	Yes. PNF intervention was an effective way to achieve balance, symmetrical weight acceptance, and gait in this population.	Weight acceptance and gait parameters, $p < 0.05$.	Yigiter et al., 2002
Effects of 3 shoulder exercise protocols	PNF vs. closed kinetic chain vs. open kinetic chain vs. control.	54 college-aged persons with no history of upper extremity injury.	3 times per week for 5 weeks.	Randomized controlled study. IC1a	Yes. Shoulder strength, proprioception, and neuromuscular control improved; however, only the PNF group improved in functional performance.	All three groups significantly improved on all 3 measures ($p < 0.05$). <i>Functional Throwing Performance Index</i> was significantly greater for the PNF group compared with the other groups ($p < 0.05$).	Padua et al., 2004

SUMMARY REVIEW QUESTIONS

1. What specific parameters must be considered in the application of appropriate sensory stimulation to enhance motor performance?
2. Describe how general hypertonicity, such as seen in some patients after traumatic brain injury, may be inhibited.
3. How does abnormal tone affect occupational functioning?
4. How does flaccidity contribute to contracture development? How does spasticity contribute?
5. What are the unique characteristics of the PNF approach that distinguish it from other approaches to therapeutic exercise?

ACKNOWLEDGEMENT

The author wishes to thank Beverly Myers, OT, and Sharon Mukayama, OT, PT, for their enthusiasm, patience, and knowledge as PNF instructors.

CHAPTER 27

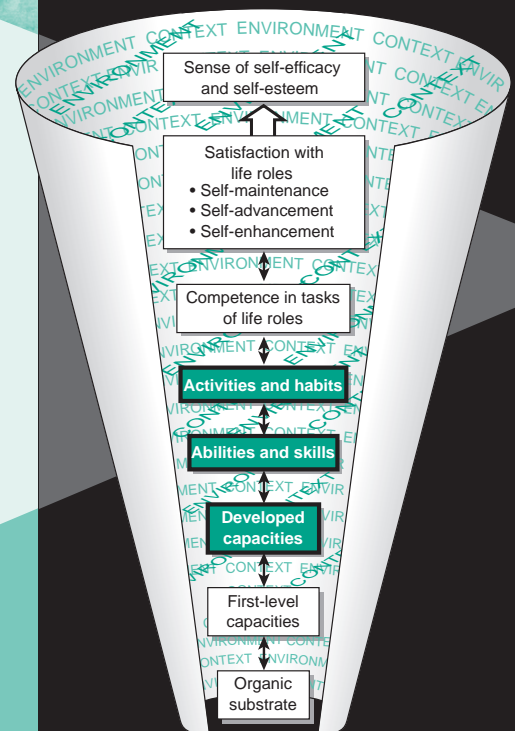

Optimizing Sensory Abilities and Capacities

Karen Bentzel

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Select appropriate sensory treatment for a patient or description of a patient.
2. Explain the rationale for sensory reeducation and desensitization.
3. Demonstrate a variety of sensory reeducation and desensitization strategies for patients following peripheral nerve injury and stroke.
4. Name several mechanisms of damage to areas of skin with diminished protective sensation and describe related compensatory strategies to prevent injury.

Glossary

Allodynia—Condition in which non-painful stimuli produce painful sensations.

Decubitus ulcer—Open sore caused by pressure, friction, and moisture. These factors lead to reduced blood flow to the area and consequent tissue death. The most common sites for decubitus ulcers are over bony prominences.

Hyperesthesia—Condition in which there is increased sensitivity to somatosensory stimuli

Hypersensitivity—Condition in which ordinary stimuli produce an exaggerated or unpleasant sensation.

Learned non-use—Loss of capacity in an impaired extremity because of a tendency to avoid using that extremity and to use other body parts instead.

Protective sensation—Painful sensation evoked by potentially damaging sensory stimuli, such as excessive temperature, pressure, or tissue stress.

Graphesthesia—The ability to identify numbers or letters traced on the skin.

Tactile sensation is considered by many people to be less important than visual and auditory sensations (Manske, 1999). Most would be surprised to find the extent and number of difficulties resulting from loss of tactile and proprioceptive information. The story of Ian Waterman, who lost all tactile and proprioceptive sensations from the neck down as a result of a rare neurological illness, was introduced in Chapter 7. As Waterman tried to explain to others what was wrong with him, he found that they could not begin to understand the severe difficulties he faced as a result of his sensory loss. His family and friends failed to find the connection between his sensory loss and his inability to move and complete activities of daily living. Even those in the medical community did not comprehend the extent of his difficulties. A detailed account of Waterman's struggle to compensate for his lost sensation is provided in Cole's book (1991), *Pride and a Daily Marathon*.

Touch is a developed capacity that supports abilities and skills such as grasping and releasing objects. These abilities and skills are necessary for competence in self-maintenance, self-enhancement, and self-advancement. Biologist Geerat Vermeij (1999), who is blind, states that, in general, people neglect the role of the hand as a source of information about the world around us. Handling and manipulating objects enhances learning and helps human beings appreciate the world. Touch is also a means of communication and a source of pleasure.

Without sensation in the hand, there is a greater risk of injury to the hand and decreased ability to manipulate small objects. There is also a tendency not to use the hand in functional activities, which adds to the phenomenon of **learned non-use**, loss of function that results from not using the hand (Carr & Shepherd, 1998). Because of the role of tactile sensation in learning, exploring, and communicating and because loss of hand sensation is particularly disabling, occupational therapists should provide treatment or education in compensatory strategies for patients with lost or diminished sensation.

CHOOSING AN INTERVENTION STRATEGY

Chapter 7 addresses assessment of sensation and describes types of sensory losses. The choice of interventions for sensation is based on the diagnosis, prognosis, and evaluation findings. Diminished or lost **protective sensation**, the inability to feel pain in response to stimuli that are potentially damaging, suggests a need for teaching the patient and/or caregiver compensatory strategies to prevent injury. Findings of discomfort associated with touch (hypersensitivity) suggest a need for desensitization. Sensory reeducation is provided for patients who have some sensation and potential for better sensation or better interpretation of sensory information.

All of the sensory interventions described in this chapter are learning experiences for the patient. Strategies of learning (see Chapter 14) should be applied. Dellon (1997) describes sensory retraining strategies based on learning principles. Each patient should practice within the natural context of activities. Tailor training and training materials to the interest and ability of the patient. Grade the activity so that the patient can meet the expectations for improved performance. The patient must attend to the stimuli and information provided and perceive them as important and relevant.

COMPENSATION FOR IMPAIRED OR ABSENT PROTECTIVE SENSATION

Protective sensations are sensations of pain and temperature extremes that signal the threat of tissue damage. When the brain receives this message, the normal response is to move the body part away from the source of the stimulus. Without this message, tissue damage can quickly occur. The goal of treatment for the patient with diminished or

absent protective sensation is to avoid injury. Treatment consists of teaching the patient and/or the caregiver precautions necessary to prevent injury to any body part with compromised protective sensations. The loss of sensation could be due to diagnoses such as stroke, head injury, spinal cord injury, or peripheral nerve injury.

Rationale for Compensation

In a classic 1969 article in the *American Journal of Occupational Therapy*, Helen Wood described the role of the occupational therapist in preventing injury and deformity in hands that lacked sensitivity. She stated that, when hands are used in activities without protective sensory feedback, there is a high frequency of burns, cuts, lacerations, and bruises. Damage or injury to an insensitive limb is the result of external forces that are normally avoided by people who are able to feel pain, which acts as a warning mechanism. Sensations of pain warn us when we are gripping an item too tightly or sitting in one position for too long. Therefore, pain has been considered the most valuable sensation that humans have (Brand, 1979).

Brand (1979) described five mechanisms of damage to insensitive limbs: continuous low pressure, concentrated high pressure, excessive heat or cold, repetitive mechanical stress, and pressure on infected tissue (Definition 27-1). Prevention principles evolve from an understanding of these mechanisms of damage.

DEFINITION 27-1

Mechanisms of Damage Secondary to Loss of Protective Sensation

- Continuous low pressure: With sustained pressure as light as 1 pound per square inch, capillary flow is blocked; this can cause tissue necrosis, leading to pressure sores (**decubitus ulcers**).
- Concentrated high pressure: Sudden high force that is accidental and/or a high force applied over a very small area, so that the force is inadequately distributed. This may result in tearing of skin and/or soft tissue or tissue necrosis as a result of insufficient blood supply.
- Excessive heat or cold: Temperature extremes that lead to burn or frostbite injuries.
- Repetitive mechanical stress: Repetitive motions or shearing of skin against clothing or objects that causes inflammation of the tendons or skin. Blistering of skin can also occur.
- Pressure on infected tissue: Continued use and pressure on infected tissue can hinder or prevent the natural healing process.

Adapted from Brand, P. (1979). Management of the insensitive limb. *Physical Therapy*, 59, 8–12.

Compensation Techniques

Brand et al. (1999), Skirven and Callahan (2002), and Eggers (1984) recommend the following content for patient education sessions, based on the five mechanisms of damage to insensitive skin. Skin areas over bony prominences are particularly prone to pressure ulcers because the cutaneous tissue is trapped between the unyielding bone and the external pressure. Frequent position changes are necessary for patients with decreased or absent protective sensation to avoid damage due to continuous low pressure. Cushions for seating and shoe insoles help to distribute forces over larger areas.

Instruct patients to avoid concentrated high pressure by careful handling of sharp tools and by using enlarged handles on suitcases, drawers, and keys. Patients may need to become consciously aware to use only as much force as necessary to grasp objects. Excessive pressure can also result from splint straps that are too narrow and splints that are too tight; therefore, therapists must carefully construct splints to prevent injury.

Teach patients to increase their awareness of potential sources of extreme heat or cold and to protect themselves from contact with them. Insulated coffee mugs are recommended. Oven mitts or quality pot holders are necessary for cooking. Utensils with wooden or plastic handles are better than metal ones. Patients using wheelchairs should insulate exposed hot water pipes under sinks. In cold weather, gloves or mittens are necessary protection for insensate hands.

Instruct patients to avoid repetitive motions and excessive friction between skin and objects. Decrease repetitions by working for shorter periods, resting, using a variety of tools, or alternating hands or type of grip. Methods to reduce friction include wearing gloves and using enlarged or padded handles on tools.

Educate patients who have lost protective sensation regarding special care for blisters, cuts, and bruises necessary to avoid infection. If infection occurs, the infected part should be completely rested to keep it free from pressure and overuse, allowing healing to occur.

Additional techniques of compensating for absent sensation incorporate reliance on other senses. For example, vision may be used to prevent contact with sharp objects. Using a body part with intact sensation to test water temperature before immersion of any body part without sensation is recommended. Auditory cues may also help to prevent injury. For instance, a person with paraplegia might hear the rubbing of the wheelchair caster against the foot if it slips from its proper position on the leg rest.

Finally, patients should be instructed in good skin care. Applying lotion or oil daily enhances skin hydration. Well-hydrated skin is more elastic and pliant and less prone to injury. Skin needs to be visually inspected daily. A warm or reddened area indicates a possible site of tissue breakdown, which will lead to a decubitus ulcer, and extreme

care must be taken to relieve pressure totally from this area until the color returns to normal. *If the time for the skin to recover its normal color exceeds 20 minutes, it is absolutely essential to discover the cause of the skin irritation and correct it. Modification of position, schedule, procedure, equipment, or orthotics is necessary.* If the patient cannot inspect and care for the skin properly, instruct a care provider to perform these tasks every day.

Effectiveness of Compensatory Techniques

A review of the literature reveals no research studies that confirm the effectiveness of instructing patients to avoid injury. These compensatory techniques have face validity in that they evolved out of evidence that patients lacking protective sensation had incurred injuries, many of which could have been prevented. Anecdotal evidence of effectiveness includes Wood's (1969) description of a patient who had a series of hand injuries prior to occupational therapy and none following instruction and fitting of gloves to be worn in his electronics repair work.

Widespread acceptance of compensatory techniques is further evidence of reliance on their assumed effectiveness. The American Diabetes Association (2004) recommends sensory testing of the feet of all people with diabetes so that foot ulcers and amputations can be prevented in those with sensory loss. Techniques of testing and education for patients with diabetes appear in the nursing and physical therapy literature (Sloan & Abel, 1998; Thompson, Medley, & Motts, 2002).

DESENSITIZATION

Desensitization is chosen when the sensory evaluation reveals an area of **hypersensitivity**, in which ordinary stimuli produce exaggerated or unpleasant sensations (Yerxa et al., 1983). The term hypersensitivity includes **allodynia**, which is the perception of pain as a result of a non-painful stimulus, and **hyperesthesia**, which is a heightened sensitivity to tactile stimuli (Venes, Thomas, & Taber, 2001). Desensitization is an intervention designed to decrease the discomfort associated with touch in the hypersensitive area. A program of desensitization generally includes repetitive stimulation of the hypersensitive skin with items that provide a variety of sensory experiences, such as textures ranging from soft to coarse.

Rationale for Desensitization

Hypersensitivity is observed in some but not all patients following nerve trauma, soft tissue injuries, burns, and amputation (Waylett-Rendall, 1995; Yerxa et al., 1983).

Patients with hypersensitivity tend to avoid using the affected part in functional activities (Waylett-Rendall, 1995) and typically hold the affected part protectively (Hardy, Moran, & Merritt, 1982). Hypersensitivity can lead to disability through non-use of the involved body part (Robinson & McPhee, 1986).

Desensitization is based on the idea that progressive stimulation will allow progressive tolerance. The origin of the concept of desensitization is unknown. Civil War veterans with amputations were known to tap silver spoons on their residual limbs to improve their tolerance of artificial limbs, which, in those days, were constructed from wood (Hardy, Moran, & Merritt, 1982). Dellon (1997) considers desensitization a form of sensory retraining during which the patient learns accurate, less painful perception of sensory input. The desensitization program should use principles that enhance learning, such as structured practice within the context of functional activities.

Desensitization Techniques

Initially, a patient may have to compensate for hypersensitivity by wearing a splint or padding over the affected area. The patient must be weaned gradually from the protective device as improvement occurs (Anthony, 1998). In the treatment program, the patient develops progressive tolerance to a hierarchy of sensory stimuli, although several different hierarchies of desensitization materials exist.

The hierarchy described by Hardy, Moran, and Merritt (1982) includes five levels:

- Level 1. Tuning fork, paraffin, massage
- Level 2. Battery-operated vibrator (Fig. 27-1), deep massage, touch pressure with pencil eraser
- Level 3. Electric vibrator, texture identification
- Level 4. Electric vibrator, object identification
- Level 5. Work and daily activities

Patients advance to the next level after they demonstrate tolerance of the current level without signs of irritation. Work simulation is believed to be extremely important to ensure that the patient is using the painful site. Activities must be tailored to the patient's interest and occupation.

Table 27-1 shows the Downey Hand Center hierarchy of textures and vibration (Barber, 1990; Yerxa et al., 1983). Commercial dowel and immersion textures (Resources 27-1) are similar to this hierarchy. Patients arrange the dowel textures and immersion textures (Fig. 27-2) according to their own perception, in the order of least to most irritating. They select the dowel texture, immersion texture, and vibration level that are uncomfortable but tolerable for 10 minutes three or four times daily. Advancing to the next level of treatment depends on tolerance of lower levels. Documentation includes the patient's initial

Figure 27-1. The small head of this battery-powered vibrator is useful for desensitization of specific areas of the hand.

hierarchy and progress for each of the three modalities (Waylett-Rendall, 1995).

Other clinical activities thought to decrease hypersensitivity include weight-bearing pressure, massage, transcutaneous electrical stimulation, fluidotherapy, and therapy putty. Use of the affected body part in leisure, work, and daily occupations is believed to facilitate desensitization. Typing, hair washing, macramé, and assembling leather link belts are examples of activities used to decrease hypersensitivity in the hand or fingers (Anthony, 1998; Dellon, 1997; Waylett-Rendall, 1995).

Effectiveness of Desensitization

Evidence of the effectiveness of desensitization techniques in therapy is limited to a small number of studies. Barber (1990), using descriptive statistics, reported effectiveness following a chart review of intervention. Additional evidence of the success of desensitization includes a narrative single-case study (Robinson & McPhee, 1986) and a small-sample, non-randomized trial (Hardy, Moran, & Merritt, 1982).

Despite the lack of evidence, desensitization techniques are generally accepted as effective in clinical practice. Experts in the field of hand therapy describe patient improvement and promote use of desensitization techniques (Skirven & Callahan, 2002; Walyett-Rendall, 1995). In a

Adapted from Barber, L. (1990). Desensitization of the traumatized hand. In J. Hunter, L. Schneider, E. Mackin, & A. Callahan (Eds.), *Rehabilitation of the hand* (3rd ed., pp. 721–730). St. Louis: Mosby.

Figure 27-2. Immersion of the hand into a container filled with popcorn kernels and pinto beans facilitates desensitization. Patients use touch to find objects hidden in the immersion particles.

large study of hand therapy practice, all of the therapists surveyed used desensitization techniques on at least some of their patients, and more than half of the therapists elected to use the techniques for 26–50% of their patient caseload (Muenzen et al., 2002).

SENSORY REEDUCATION

Sensory reeducation is a combination of techniques that helps the patient with a sensory impairment learn to reinterpret sensation (Dellon, 1997). Dellon (1988), a hand surgeon, related his experience in 1970 with nerve-injured patients who could feel fingertip stroking, pinprick, and pressure but could not correctly identify a nickel and a quarter using only touch sensation. These patients could feel a difference between the coins, but they could not identify them, and the coins did not feel the same as before the injury.

Dellon concluded that the sensibility was recovered but that there was a mismatch of the new sensory profile with past profiles in the association cortex. Within a few minutes, he could train patients to tell the difference between the two coins. With the patient's vision shielded, he placed a nickel in the hand, said what it was, and explained that it did not feel the way a nickel used to feel but that what the patient was feeling should thereafter be called a nickel.

After repeating the process with a quarter, the patient could correctly identify both coins. The sensation had been reeducated.

In daily activities, cutaneous information from the fingers, palm, and toes is most important because it is generally these skin surfaces that interact with the external environment (Dannenbaum & Dykes, 1988). The focus of sensory reeducation is usually to regain the use of sensation of the hand. Ninety-nine percent of hand therapists surveyed reported using sensory reeducation techniques (Muenzen et al., 2002). Sensory reeducation is an appropriate and commonly used treatment for patients with a variety of peripheral nerve injuries, including nerve lacerations and neural compressions and injuries resulting in replantation, toe-to-thumb grafting, and skin grafting (Dellon, 1997).

Sensory reeducation is also sometimes used for patients who have had cerebral vascular accidents (CVA). In a study of occupational therapists treating patients with CVA, Neistadt and Seymour (1995) asked the therapists to rank 10 categories of treatment activities according to frequency of use. Sensory reeducation was ranked ninth, indicating that sensory retraining following CVA has low priority in many clinical settings. Despite evidence that recovery of motor function depends on sensation, the focus of treatment following CVA seems to be motor rather than sensory deficits (Dannenbaum & Jones, 1993).

Rationale for Sensory Reeducation after Peripheral Nerve Injury

Cortical maps have been found to change as a result of peripheral nerve injuries. Loss of sensory input from the peripheral nerve causes the associated areas of the sensory cortex to begin to serve sensory inputs from adjacent areas. After nerve repair, when the peripheral nerve regrowth leads to reinnervation of sensory receptors, the corresponding area of the somatosensory cortex reorganizes to allow interpretation of incoming stimuli from the affected area (Dellon, 1997; Merzenich & Jenkins, 1993). In children, this reorganization is sufficient for return of normal sensory interpretation without sensory retraining. In adults, the neural reorganization may be facilitated by sensory reeducation (Rosen et al., 1994).

The return of sensation following hand injury is an extremely complex event. Recovery is not just a process of altering the cortical representation; it also depends on reinnervation. Following nerve laceration and surgical repair, some sensory fibers, given sufficient time, regenerate and reinnervate the tactile receptors. Return of sensation is limited by scar tissue that blocks sensory fiber regrowth and atrophy of sensory receptors prior to reinnervation. Sensory return is also limited by malalignment of axonal sheaths that allows misdirection of regrowing

fibers, meaning that fibers do not usually regrow to innervate the same sensory receptors that they innervated before the injury (Callahan, 1995).

As a result of scar tissue, atrophy of sensory receptors, and the misdirection of fibers, there is an inevitable change in the profile of neural impulses reaching the sensory cortex. A previously well-known stimulus initiates a different set of neural impulses from that elicited by the same stimulus before the injury. When this altered profile reaches the sensory cortex, the patient cannot match it with patterns previously encountered and remembered (Callahan, 1995; Dellon, 1997) and, hence, cannot identify or recognize the stimulus (Fig. 27-3). The purpose of sensory reeducation in patients with peripheral injuries is to help them learn to recognize the distorted cortical impression (Skirven & Callahan, 2002).

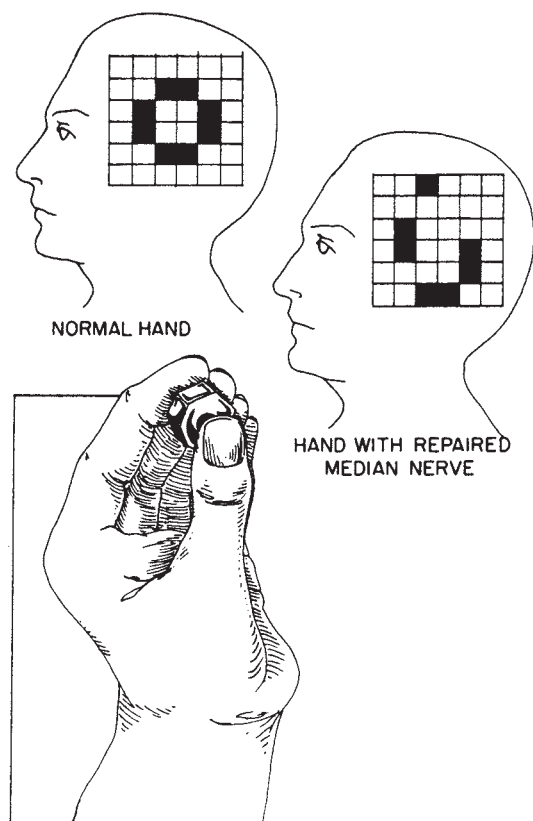

Figure 27-3. In the normal hand, a stimulus, such as this gripped bolt, elicits a profile of neural impulses that reaches the sensory cortex and ultimately is perceived, as represented by the checkerboard pattern. After a nerve repair, the same stimulus elicits an altered profile of impulses that reaches the sensory cortex. The new perception, the altered checkerboard pattern, may be so different from the previous one that object recognition is at first impossible. (Reprinted with permission from Dellon, A. [1988]. *Evaluation of sensibility and re-education of sensation in the hand*. Baltimore: Lucas.)

Sensory Reeducation Techniques after Peripheral Nerve Injury

After peripheral nerve injury, axonal regeneration and reinnervation are necessary for improvement in sensation. Dellon (1997) cautions that implementation of sensory reeducation before adequate axonal regeneration has no benefit and causes frustration. Because of varying rates of axonal sprouting and growth, sensory receptors are reinnervated over time. Sensory reeducation can begin when the patient first can appreciate deep, moving touch. In the early phase of intervention, the patient concentrates on learning to match the sensory perception of stimuli with the visual perception. After time, when reinnervation allows for perception of light non-moving touch with good touch localization, the focus of intervention changes to more functional tasks, such as object identification through touch (Fig. 27-4) (Dellon, 1988).

Sensory reeducation protocols differ among facilities, even those treating patients with similar diagnoses. Dellon (1997) shares protocols for sensory reeducation after peripheral injury from five institutions. A summary of the protocol he presents from the Raymond M. Curtis Hand Center of Union Memorial Hospital, which is based on Dellon's earlier work, is given in Procedures for Practice 27-1.

Skirven and Callahan (2002) describe similar procedures. They begin each moving and constant touch sequence with eyes closed, followed by eyes open, and concluding with eyes closed. They recommend using a smaller and lighter stimulus as the patient improves, with a goal of localization of a touch that is near the light-touch threshold. Touch localization continues throughout the sensory reeducation process, and more tasks are added to the training program. Discrimination of similar and different textures using sandpaper, fabrics, and edges of

Figure 27-4. Late-phase sensory reeducation after peripheral nerve injury includes identification of various objects by touch.

PROCEDURES FOR PRACTICE 27-1

Sensory Reeducation Principles

- Choose a quiet environment that will maximize concentration.
- Sessions should be brief, approximately 5–15 minutes.
- Three or four practice or homework sessions per day are recommended.
- Instruct the patient and/or family in techniques to be used during practice.
- Monitor patient's home program and progress during therapy sessions.

Prerequisites for Early-Phase Sensory Reeducation

- Patient must be able to perceive 30 cycles per second vibration and moving touch in the area.
- Patient must be motivated and able to follow through with the program.

Techniques for Early-Phase Sensory Reeducation

- Use the eraser end of a pencil.
- Apply moving strokes to the area.
- Use enough pressure for the patient to perceive the stimulus but not so much that it causes pain.
- Ask the patient to observe what is happening first and then to close the eyes and concentrate on what is being felt.
- Instruct the patient to put into words (silently) what is being felt.

- Instruct the patient to observe the stimulus again to confirm the sensory experience with the perception.
- When perception of constant touch returns to the area, use a similar process for constant touch stimuli.
- Test the patient by requiring localization of moving and constant touch without seeing the stimulus.

Prerequisites for Late-Phase Sensory Reeducation

- Patient must be able to perceive constant and moving touch at the fingertips.
- Patient must demonstrate good localization of touch.

Techniques for Late-Phase Sensory Reeducation

- Use a collection of common objects that differ in size and shape.
- Instruct the patient to grasp and manipulate each item with eyes open, then with eyes closed, and then with eyes open for reinforcement.
- The patient should concentrate on the tactile perception.
- Test the patient by timing correct identification of each object without vision.
- Grade the practice by introducing objects of similar size but different texture and then small objects that vary in size and shape but are similar in texture.

Adapted from Dellon, A. L. (1997). *Somatosensory testing and rehabilitation*. Bethesda, MD: American Occupational Therapy Association.

coins are introduced early. Patients practice identification of shape or letter blocks and **graphesthesia**, which is the ability to identify a letter or number drawn on the skin. In the later stages of training, patients pick objects from containers filled with sand or rice and practice identification of common objects. Finally, patients practice daily living activities with vision occluded. Skirven and Callahan state that a variety of activities, including games or puzzles, are more engaging and therefore more beneficial than simply practicing with various objects.

Nakada and Uchida (1997) described a five-stage sensory reeducation program that was useful for a patient with very limited sensation in her left hand as a result of peripheral neuropathy secondary to leprosy. She also had total impairment of vision, so that sensory feedback was critical to occupational performance. Following reeducation, the patient regained hand function for activities of daily living such as drying dishes, putting on socks, and holding dentures while brushing them. The reeducation program included the following five stages:

- Stage 1. Object recognition using feature detection strategies. Objects that varied greatly in shape, material,

and weight were used. The patient was encouraged to handle each object and identify the object characteristics.

- Stage 2. Prehension of various objects with refinement of prehension patterns. In this stage, grasping objects that varied in size and shape was emphasized. The patient needed to maximize the contact between the object and the hand to develop the ability of the hand to closely contour to objects, which is seen in normal grasp.
- Stage 3. Control of prehension force while holding objects. Feedback regarding excessive force that was used to maintain grasp was provided through the use of a strain gauge and therapy putty.
- Stage 4. Maintenance of prehension force during transport of objects. While holding an object, the patient moved the shoulder, elbow, and wrist into varying positions of flexion and extension.
- Stage 5. Object manipulation. The patient practiced grasp and release of objects and moved objects in the hand into various positions.

Appropriate grading of sensory reeducation activities is important to optimize patient motivation and progress.

Choose activities that provide a challenge but allow for success. During stimulus localization tasks, progress from firm pressure to lighter pressure. When working with objects, progress from larger items to smaller items and from dissimilar items to more similar items. Progress from differentiation of a few objects to selecting, sequencing, or organizing many objects (Skirven & Callahan, 2002).

As daily training is necessary for successful sensory reeducation, teach patients techniques appropriate for a home program. Patients can be involved in assembling their own collection of objects for use in their program. Include objects with varying size, shape, texture, weight, and temperature (Fess, 2002).

Effectiveness of Sensory Reeducation after Peripheral Nerve Injury

Dellon (1997) reviewed a large number of studies of the effectiveness of sensory reeducation following peripheral nerve injury, replantation, and innervated skin graft. Study designs included: (1) comparison of patients who today routinely receive sensory reeducation with those in the past before widespread acceptance of the technique, and (2) assessment of the results of sensory reeducation provided long after spontaneous recovery is likely. Dellon concluded that sensory reeducation clearly improves sensory and functional recovery in a shorter period than without training and indicates that the techniques have been globally accepted as necessary following peripheral nerve injury.

The best evidence in the therapy literature for the effectiveness of sensory reeducation is the study by Cheng et al. (2001) described in Evidence Table 27-1. Sensory reeducation effectiveness following digital replantation and revascularization has also been demonstrated in a small, randomized control trial (Shieh et al., 1995).

Rationale for Sensory Reeducation after CVA

Sensory reeducation after CVA is based on the concept of neural plasticity. Carr and Shepherd (1998), in their review of the scientific evidence for the ability of the brain to reorganize following brain lesions, stated that reorganization seems to be related to frequency of use. They suggested that enlargement of sensory receptive areas within the cortex is a result of increased participation of the body part in activities requiring tactile sensations. Therapists may alter the cortical map by directing the sensory experiences of the patient. Therefore, the goal of sensory reeducation after CVA is to gain a larger cortical representation for the areas of skin from which sensory feedback is crucial to performance of daily tasks.

The rationale for sensory reeducation following CVA is also based on the premise that functional use of a body part with reduced sensation is possible but that spontaneous use is limited. Without training, there is a tendency

not to use the extremity, and learned non-use leads to further loss of sensory and motor abilities (Dannenbaum & Dykes, 1988). Sensory reeducation has the potential to facilitate increased functional use of the hand and prevent loss of function due to learned nonuse.

Sensory Reeducation Techniques after CVA

Sensory reeducation after CVA is less well defined than the protocols described for peripheral injuries. Carr and Shepherd, in their book, *A Motor Relearning Programme for Stroke* (1982), and in their more recent work (1998), emphasize the need for sensory learning concurrent with motor learning. They advocate the use of meaningful and relevant sensory and motor experiences very early in rehabilitation. Use of the more involved hand in bimanual tasks such as opening jars and using eating utensils is advocated. They suggest that the patient can be cued to attend to the tactile aspects of the task and that practice of object identification without vision may be helpful.

Dannenbaum and Jones (1993) give detailed goals and proposed methodology for sensory intervention following CVA. They believe that appreciation of some form of tactile stimulation and some basic motor skills are prerequisite to success in sensory reeducation. To establish that a patient with severe sensory loss can perceive some stimuli, they recommend testing and early training using 100-Hz electrical stimulation. Patients identify which finger was stimulated, first with vision and then with eyes closed. Patients with better sensation perform a similar task, first with textured moving stimuli followed by non-moving stimuli.

In addition, Dannenbaum and Jones suggest early incorporation of the hand into functional activities and prevention of abnormal patterns of grasp and movement. Add textures to handle surfaces to increase the friction and support weak grasping ability. Enlarge or modify handles to facilitate both tactile contact and tactile feedback. Patients should practice modulation of grip forces in response to the objects and maintenance of appropriate grip force during forearm movements.

Yuketiel and Guttman's (1993) research protocol included the following sensory reeducation activities:

- Identification of the number of touches
- Graphesthesia tests
- "Find your thumb" without looking
- Identification of shape, weight, and texture
- Passive drawing and writing; the patient identifies a letter, number, or drawing made by the therapist passively moving the patient's hand while it holds a pencil

These sensory treatment activities are just a few examples of a wide variety of techniques that can be used in clinical treatment for patients after CVA. Therapists working with this population use creativity, patients' interests, and

Evidence Table 27-1 Best Evidence for Occupational Therapy Practice Regarding Sensory Reeducation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Early tactile stimulation for digital nerve injuries	In-clinic stimulation of digital sensation by pressing injured finger against rotating disc with raised and lowered segments. Home program of rubbing finger over rows of raised staples on a plastic card.	49 subjects with a total of 65 digital nerve injuries following surgical repair.	Clinical program required 20 minutes twice weekly; home program completed daily, as much as patient desired. Clinic program averaged 11 weeks in duration; home program averaged 16 weeks.	Randomized control trial, using ordinal measures and nonparametric statistics. IB2a	More participants in the experimental group recovered touch threshold; $p = 0.0023$, $r = 0.48$ for static two-point discrimination; and $p = 0.0144$, $r = 0.36$ for moving two-point discrimination.	$p = 0.097$, $r = 0.22$ for touch threshold; $p = 0.0023$, $r = 0.48$ for static two-point discrimination; and $p = 0.0144$, $r = 0.36$ for moving two-point discrimination.	Cheng et al., 2001; Cheng, 2000
Training of somatosensory discrimination after stroke	Training in discrimination of textures and joint motion, using training principles of high intensity, repetition, graded progression, intermittent feedback, and comparison with visual feedback or contralateral hand.	10 subjects with a diagnosis of stroke and tactile or proprioceptive discrimination impairment	Ten treatment sessions, scheduled three times per week, lasting 40-60 minutes each.	Single case, multiple baseline experiments with meta-analysis of intervention effects. IC2b	Yes. Discrimination of textures and joint position improved from baseline following initiation of training.	Meta-analysis $p < .001$. Average effect size 0.52	Carey & Matyas, 2005

theoretical understanding to develop programs of sensory intervention since no one protocol has been widely accepted or thoroughly researched.

Effectiveness of Sensory Reeducation after CVA

The number of research studies of the effectiveness of sensory retraining after CVA is limited, and the results of these studies have not been strong enough for the technique to be recommended in the *Clinical Practice Guideline: Post-Stroke Rehabilitation* (United States Department of Health and Human Services, 1995) or in the Veterans Affairs/Department of Defense Clinical Practice Guidelines (Bates et al., 2005).

Improved proprioception, touch localization, two-point discrimination, and tactile discrimination following training have been demonstrated in several small, non-randomized studies (Carey, Matyas, & Oke, 1993; Dannenbaum & Dykes, 1988; Yekutieli & Guttman, 1993).

Increased cerebral blood flow and changed cerebral activation in the somatosensory cortex following proprioceptive input has been demonstrated experimentally (Nelles et al., 1999). Additional sensory input was associated with improved grip-force modulation in one small non-randomized controlled trial (Aruin, 2005). The best evidence of effectiveness of sensory reeducation following cortical injury is the study by Carey and Matyas described in Evidence Table 27-1, which showed good learning of texture discrimination and joint position with a systematic program that heavily incorporated principles of learning.

Teasell and Kalra (2004) described six emerging trends in stroke rehabilitation, two of which relate to sensory reeducation. There is increasing use of robotic-assisted sensorimotor training, in which repetitive passive or active-assistive motion provides proprioceptive stimulation and leads to improved motor recovery. Another trend is the increased understanding of the importance of sensory stimulation in facilitating stroke recovery. Both of these trends are likely to increase research in treatment of somatosensory dysfunction after cortical injury.

CASE EXAMPLE

Mr. T.: Sensory Remediation after Median Nerve Laceration

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
Patient Information Mr. T., a 25-year-old appliance repairman with a laceration of the median nerve, was reassessed approximately 6 weeks after his injury. The outpatient occupational therapy reassessment identified the following sensory problems: <ul style="list-style-type: none"> • Absent and decreased protective sensation in the thumb, index and middle fingers, and radial palm • Mislocalization of touch sensations in the radial portion of the palm • Hypersensitivity in the area of the scar • Decreased ability to pick up and manipulate objects • Decreased use of the right hand in functional activities 	Appreciate the context	(See Chapter 7 for description of the assessment process and patient's background.)
	Develop intervention hypotheses	"While a good bit of time in therapy will be spent on Mr. T.'s motor deficits, I know that good sensation is needed for hand coordination and for return to full function at work."
	Select an intervention approach	"Because Mr. T. has multiple sensory issues, he will need multiple approaches. A compensatory approach will be needed for lost protective sensation and a remedial approach is needed to decrease hypersensitivity and relearn touch localization and object identification."
	Reflect on competence	"As I work with Mr. T., I may need to discuss ideas with a colleague, particularly for creative sensory retraining strategies to increase the variety of activities."

Recommendations

At the time of the reassessment, the occupational therapist recommended outpatient occupational therapy twice a week for 6 additional weeks and then reassessment, with reduction to one session per week likely at that time. Mr T. has demonstrated quick learning of therapy instructions and will be responsible for an intensive home program. Because recovery of the ability to differentiate small objects at the fingertips will probably not occur until 10–12 months after the nerve repair, therapy would ideally continue for that length of time. In collaboration with Mr T., the occupational therapist established the following long-term goals for sensory intervention: (1) Mr. T. will correctly interpret sensory stimuli throughout the right hand, as demonstrated by correct tactile identification of objects; and (2) Mr. T. will demonstrate good use of the right hand in work simulation activities that rely on touch sensation.

Consider the patient's appraisal of performance

"Mr. T. has demonstrated quick learning of therapy instructions so far. He doesn't seem to fully understand the connection between sensation exercises and his eventual hand function, so I may need to give him more examples of how he uses sensory feedback in his work and daily activities."

Consider what will occur in therapy, how often, and for how long

"During therapy, I will definitely need to focus on teaching Mr. T. what he needs to do at home. He will be completing an extensive home program. Experts in the field of hand therapy suggest the home program should be completed three to four times daily. During therapy sessions, I will need to provide evaluation of progress, grading of sensory activities for the home program, and motivational strategies."

Ascertain the patient's endorsement of plan

"Mr. T. seems eager to complete therapy tasks right now, and if he follows through with his home program, that should further indicate his agreement with the plan of care."

Summary of Short-Term Goals and Progress

- Mr. T. will avoid injury to the right hand by demonstrating compensatory protective strategies during functional activities. The therapist instructed Mr. T. about risk of injury from sharp and hot objects and gripping forces. Mr. T. and the therapist discussed an appropriate routine for skin care and implementation of precautions in his daily routine. By the end of the second session, Mr. T. demonstrated good understanding of these techniques during home and simple work simulation activities.
- Mr. T. will tolerate touch of all textures over and around his scar area so that hypersensitivity does not interfere with functional hand use. Mr. T. ranked the 10 dowel textures from least to most irritating. At that time, he easily tolerated the first four textures as they were rubbed by the therapist over the scar area. He disliked touch from the fifth texture and was unable to tolerate textures 6 through 10. The therapist provided textures for a home desensitization program, beginning with textures 5 and 6. Mr. T. used these textures three or four times a day for scar desensitization. During therapy sessions, massage and vibration were provided around and over the scar area. At the end of 3 weeks, Mr. T. tolerated all textures and no longer reported discomfort from sleeve cuffs or inadvertent touch during functional activities.
- Mr. T. will demonstrate touch localization below 10 mm in the right palm to improve interpretation of tactile sensations during work activities. The therapist initiated a sensory reeducation program for touch localization using moving and static touch stimuli in the palm. Instructions were provided, and Mr. T. faithfully followed through with this program at home, four sessions per day. At the end of 3 weeks, localization in the palm measured 12–14 mm. The therapist initiated graphesthesia and texture discrimination activities in the palmar area. After 6 weeks of sensory reeducation, localization measured 9–10 mm, and Mr. T. could identify 50% of the letters and shapes drawn in his palm and 40% of the textures.

Assess the patient's comprehension

"Mr. T. not only understands his home program, but he is also learning when to progress to the next dowel texture without me needing to tell him."

Understand what he is doing

Compare actual to expected performance

"Mr. T. is progressing even faster than I expected he would in his desensitization program. His sensory reeducation is proceeding at the expected rate, consistent with the typical rate of neural regrowth."

Know the person

"Mr. T. demonstrated such good learning of techniques that, after these first 3 weeks, I could consider decreasing the frequency of therapy for his sensory deficits to once weekly. He will need to continue his home program at the same intensity of three to four sessions daily. Whether or not to decrease frequency of therapy will also depend on how his motor recovery is progressing."

Appreciate the context

Next Steps

Revised Short-Term Goals (1 month):

To improve interpretation of tactile sensations during work activities, (1) Mr. T. will demonstrate 100% correct graphesthesia and texture identification in his right palm; and (2) Mr. T. will demonstrate touch localization below 10 mm in the proximal phalanges of the right thumb, index, and middle fingers.

Anticipate present and future patient concerns
Analyze patient's com-

prehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. T. has made exceptional progress over the past 6 weeks and is eager to return to work, which will make attendance at therapy and completion of his home exercise program more difficult.”

“Mr. T. continues to need extensive home program activities to improve his sensation. He has learned his home program well and knows how to advance it.”

“Because recovery of the ability to differentiate small objects at the fingertips will probably not occur until 10–12 months after the nerve repair, he will require ongoing sensory reeducation for at least a year or more. It would be advisable to follow up with reassessment and program revision every 2–3 months during that time period. This will also help Mr. T. to be more motivated to continue his home program throughout this long time period.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Transition of Sensory Reeducation Program from Early Phase to Late Phase

Mr. T. will begin the second phase of sensory reeducation at the fingertips approximately 6–8 months after his surgery to repair the median nerve. What reassessment findings will indicate the appropriate time for Mr. T. to begin late-phase sensory reeducation? What treatment activities and home program activities would be appropriate for Mr. T. as he begins this phase? What work simulation activities could be incorporated into his therapy program during sensory reeducation?

SUMMARY REVIEW QUESTIONS

1. What is the rationale for sensory reeducation after peripheral nerve injury and CVA?
2. What are the differences and similarities between early-phase and late-phase sensory reeducation for patients with peripheral nerve injury?
3. Describe or demonstrate intervention techniques for a patient with hypersensitivity after a fingertip amputation.
4. List five mechanisms of injury for skin areas with absent or diminished protective sensation. For each of the five mechanisms of injury, describe appropriate preventive education and/or adaptive strategies.
5. What should be done if a patient with sensory loss develops an area of skin redness?

ACKNOWLEDGMENT

I extend my appreciation to Paul Petersen and Melanie Seltzer for their assistance with some of the photography for this chapter.

CHAPTER 28

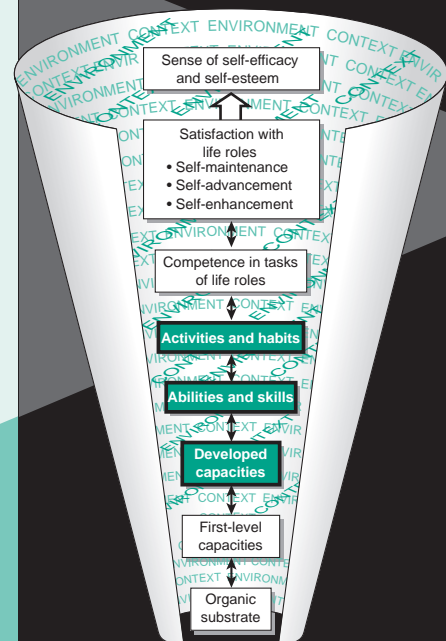

Optimizing Vision, Visual Perception, and Praxis Abilities

Lee Ann Quintana

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Identify and describe specific treatments for **low vision** and oculomotor dysfunction.
2. Identify and describe five treatment approaches for unilateral neglect.
3. Identify and describe specific treatment for apraxia, including limb, constructional, and dressing apraxia.

Glossary

Glossary

Anchoring—Method of providing a cue on the side contralateral to the brain damage, in the presence of unilateral neglect.

Chaining—Method by which a task is broken down into steps. The client learns the first step, then the next, and then puts the two together, after which he or she then learns the third step and puts them all together, and so on. In backward chaining, the therapist completes the task except for the last step, which the client does; then the therapist completes all except the last two steps, which the client does; and so on.

Extinction—Phenomenon of neglect that occurs when stimuli are presented in both visual fields or both sides of space at one time and only one stimulus is reported, whereas if presented to either side individually, the client reports the stimulus.

Fresnel prism—Temporary prism used with a client with hemianopsia or unilateral neglect; applied to the client's glasses, it shifts the visual field toward the intact side.

Low vision—Any condition in which a person's vision is not adequate for his or her needs.

Occlusion—Covering part or all of the visual field of the eye.

Prism—Type of lens that is thicker on one side than the other; the purpose is to bend the light and move the image coming onto the fovea.

Vision therapy—Intervention generally prescribed and carried out by or under the supervision of the eye care professional.

Occupational therapists working with adults with brain injury have traditionally emphasized evaluation and treatment of perceptual dysfunction (Abreu & Togliola, 1987; Warren, 1993a). Although the literature on the identification and evaluation of perceptual dysfunction is extensive, information on the effectiveness of treatment is limited. Much of the research on diagnosis and evaluation has been carried out by psychologists and neuropsychologists who have only recently begun to focus on function. Unfortunately, occupational therapists, who see the effects of perceptual dysfunction on a person's daily living skills, have been slow to generate research and hence support for their treatment.

Remediation of perceptual deficits generally falls under the realm of cognitive rehabilitation, which is provided by occupational therapists, speech and language pathologists, neuropsychologists, and psychologists (Harley et al., 1992). Historically, occupational therapists have emphasized the area of perception, whereas speech and language pathologists and psychologists have emphasized cognition.

Rather than focus on high-level perceptual skills, this chapter discusses specific treatment for visual foundation skills including low vision and ocular motor dysfunction, unilateral neglect, and apraxia, including limb, constructional, and dressing apraxias (see Chapter 8 for detailed descriptions and definitions). Treatment approaches and general treatment principles specific to optimizing cognitive function are discussed in Chapter 29.

VISUAL FOUNDATION SKILLS

Warren (1993a) developed a hierarchy of visual perception (see Fig. 8-1). The base of this hierarchy consists of the

visual foundation skills, which include acuity, visual fields, and oculomotor function. Following a screening of these skills, clients may then be referred to an eye care specialist for further evaluation and diagnosis of deficits. These specialists diagnose the problem and may recommend medical treatment, such as medication, surgery, optical changes, use of assistive devices, and/or **vision therapy** to improve the visual function of the client.

With the aging population, vision loss is the third most common chronic condition requiring assistance with activities of daily living (ADL) (Colenbrander & Fletcher, 1995). At the same time, people may not be aware of or complain about their difficulty and just accept it as a part of aging. Some age-related changes and diseases increase the likelihood of vision loss (Table 28-1). As a result, occupational therapists work with many clients who have a vision loss of one kind or another and who may or may not be labeled as having low vision.

Low Vision

“Low vision can be considered any condition in which a person's visual function is not adequate for his or her visual needs” (Kern & Miller, 1997, p. 495). Based on acuity, low vision (LV) covers anywhere from 20/80 vision to total blindness, which denotes *no* residual vision at all (Definition 28-1) (Colenbrander & Fletcher, 1995; Kern & Miller, 1997).

The focus of occupational therapy in LV rehabilitation is “training the patient to use remaining vision as efficiently and effectively as possible to complete daily activities and includes training in use of optical devices” (Warren, 1995, p. 877). Occupational therapy treatment includes environmental adaptation, compensatory techniques, assistive devices, and client/family education (Warren, 1999b).

Table 28-1. Age-Related Changes in Vision

Condition	Definition
Cataracts	A cloudiness of the lens of the eye that dulls color and visual detail (Mogk, 2000). Acuity can improve with increased contrast. Surgical treatment is typically successful.
Glaucoma	Causes increased pressure in the eye, which damages the optic nerve and results in decreased peripheral vision, or tunnel vision. It is generally treated medically with eye drops and laser treatment.
Diabetic retinopathy	Bleeding from small blood vessels in retina can lead to serious vision loss. A person can develop scotomas, decreased contrast sensitivity and color discrimination, decreased night vision, and fluctuations in vision (due to fluctuations in blood glucose levels) (Mogk, 2000).
Age-related macular degeneration (ARMD)	Results in loss of central vision. Two types: dry ARMD is the most common type (90%), it develops gradually, and there is no effective medical or surgical treatment; wet ARMD has a rapid onset, and treatment consists of laser surgery.
Lens tends to yellow	Changes color perception; glare may be a problem.

**DEFINITION 28-1***definition***Low Vision Definitions****Normal Vision**

Normal—20/12, 20/16, 20/20, 20/25; able to read a standard letter size at a standard distance (e.g., approximately 8-point print at 40 cm)

Near-normal—20/30 to 20/60; generally able to read newsprint by bringing the print closer (may need stronger reading prescription)

Low Vision

Moderate low vision—20/80 to 20/160; must bring the print very close, which isn't comfortable for prolonged use, but can maintain nearly normal reading speeds with assistive devices (i.e., base in prisms, reading glasses, magnifiers).
Severe low vision—20/200 to 20/400 or visual field of 20° or less; must bring print so close that binocularity is no longer possible and must use the best eye to read; as a

result, reading is slower than normal and vision substitution (i.e., listening to the radio rather than reading) comes into use. 20/200 is considered legally blind, but a person still has usable vision.

Profound low vision—20/500 to 20/1000 or visual field of 10° or less; must bring print to within less than 2 inches, so reading is limited to essential materials; use of video magnification may be mandatory as well as use of vision substitution.

Blindness

Near blindness—20/1250 to 20/2500; vision is unreliable and is used as an adjunct to other senses; emphasis is on vision substitution techniques and devices.

Total Blindness—no residual vision at all (Colenbrander & Fletcher, 1995; Freeman, 2002; Warren, 2000).

Low Vision Specialists

Rehabilitation Teacher

Emphasis on effect of visual impairment on ADL, patient, and family. Teach techniques, technology, and use of devices for persons with low vision or blindness.

Orientation and Mobility (O & M) Specialist

Teach orientation techniques (use of sensory information to determine position in space relative to the environment) and mobility skills (use of canes, sighted guides, travel aids, dog guides) for safe and independent travel.

Rehabilitation Counselor

Provide counseling related to occupation and employment, provide career guidance, assist with job placement (from teaching interviewing skills to adjusting to the workplace).

Certified Low Vision Therapist (CLVT)

Teach clients to use their vision more efficiently, with and without optical devices, environmental modification, and visual skills training.

Table 28-2. Environmental Factors and Adaptations

Environmental Factor	Adaptation
Lighting	Control glare: Window coverings; cover shiny surfaces; positioning and type of lamp used. Special lenses or sunshield may be prescribed by low vision specialist. Decrease the distance between the light and the task. Increase wattage of light bulb. Try alternate types of bulbs (florescent, incandescent, halogen). Task lighting: Position the light opposite the writing hand or nearest to best-seeing eye (Fig. 28-1).
Contrast	Change the background to increase contrast: A solid color rather than a busy pattern; light against dark and vice versa. For example, use a dark cutting board to cut up an egg and a white cutting board to cut up broccoli (Fig. 28-2).
Color	Bright colors are easiest to see. They can be used to highlight points of interest (e.g., mark a certain temperature on a toaster oven) or to provide a warning (e.g., bright tape on the leading edge of a step).
Pattern	Keep the environment uncluttered and simple.
Print size	Enlarge print, increase contrast, increase print quality.
Working distance	Important for both near and far activities, but especially with bifocal and trifocal lenses, which are distance specific. Normal working distance is about 16 inches.

From Sokol-McKay & Michels, 2005; and Watson, 2001.

Most occupational therapists do not specialize in treating LV per se but, instead, encounter LV as a complication in clients with other functional impairments and medical conditions (Kern & Miller, 1997). Occupational therapists are in a unique position to aid LV specialists (Definition 28-1) by providing input on the client's functional impairment and how this may affect the selection and use of assistive devices. For example, the client with tremors may not benefit from a hand-held magnifier or may require certain positioning before using the device. Occupational therapists should have supervision and/or specialized training to recommend and train clients in use of prescribed LV aides (Kern & Miller, 1997).

Many basic self-care activities can be completed with minimal vision, but LV becomes more of a problem with such ADL activities as meal preparation, managing finances, and community activities. Generally, when working with clients who have LV, we should consider both the functional implications and environmental factors involved (Lampert & Lapolice, 1995). For example, clients with poor contrast sensitivity require increased contrast and lighting and have difficulty with curbs, stairs, and finding objects in a low light, while a person with visual field loss will have more difficulty in a busy, moving environment. Environmental factors (Table 28-2) can be manipulated to improve the person's ability to perform a task. For example, with the client who is having difficulty with meal preparation, consider changing the lighting, marking the controls with bright contrasting colors, organizing the kitchen and keeping items in their assigned places, and marking containers with large-print labels.

Figure 28-1 The use of task lighting and a check guide to facilitate check writing.

Figure 28-2 Changing the color of the cutting board to increase contrast with the item that is to be cut.

In addition to manipulation of the environment, compensatory techniques include use of optical devices, such as lenses and telescopes, and non-optical devices, such as large print, contrasting tape to mark stair steps, felt tip pen, and a computer (Beaver & Mann, 1995). Magnification (Table

28-3) is a fundamental means of improving vision by making an object larger and thus more visible (Nowakowski, 2000). The client and family should be taught what the limitations are and how to compensate and manipulate the environment so that they can transfer the techniques to new situations as they arise.

Ocular Motor Dysfunction

Ocular motility refers to the ability of the eyes to move smoothly and with coordination through full range of motion. Ocular motor dysfunction includes problems with binocular vision, accommodation, scanning, and saccades. Problems with binocular vision typically result in diplopia or double vision. Treatment includes lenses, **prisms**, or **occlusion**. Lenses are used to treat a variety of refractive, accommodative, and binocular disorders. In most cases, they are used as a means of compensation to allow the person to function despite the disorder (Scheiman, 1997). A prism is a type of lens that is thicker on one side than the other. Its purpose is to bend the light coming into the eye, moving the image onto the fovea, allowing single vision. Lenses and

Table 28-3. Magnification

Principles	<ul style="list-style-type: none"> • Does not necessarily make vision clearer, it enlarges the object of regard, which is then more recognizable. • The stronger the magnification, the smaller the field of view and the closer the magnifier is held to the eye. • Special training is usually required by a low vision therapist.
Relative size magnification	Increasing the size of the object: large-print book, large-number measuring cups.
Relative distance magnification	Moving closer to an object makes it relatively larger, for instance, holding a book closer to the face.
Optical magnification	<ul style="list-style-type: none"> • Optical devices are generally prescribed by an optometrist or ophthalmologist. • Clients should wear their own eyeglasses while using the optical device unless instructed otherwise by the doctor. • Hand-held magnifiers: <ul style="list-style-type: none"> • Must be held at a predetermined distance from what is being read. • If wearing bifocals, client should look through the top part of the glasses. • Stand magnifiers: <ul style="list-style-type: none"> • Magnifier rests on a surface while the hand guides it (better choice for a client with tremors). • Must hold the lens a specified distance from the eye. • If wearing bifocals, client should look through the bottom part of the glasses. • Microscopic glasses: <ul style="list-style-type: none"> • Can be a half-eye, bifocal, or full lens. • Allows the hands to be free. • Object of regard must be held close to the face. • Usually involve only the better eye. • Telescopes: <ul style="list-style-type: none"> • Primarily used to view distant objects. • Usually a monocular device. • May be hand held or mounted on eyeglasses.
Electronic	Closed-circuit television (CCTV): <ul style="list-style-type: none"> • Allows greatest amount of magnification and field of view. • Disadvantages: not portable, cost.

? CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of Low Vision on a Functional Task

Based on an optometrist's report for a patient, J.K., his best corrected acuity is 20/160. He has a cataract in the right eye and glaucoma in both eyes, for which he is receiving medication.

How might this affect his ability to complete his self-care activities, meal preparation, and financial activities? What modifications could be made to his environment? What assistive devices could he use?

prisms are recommended by the eye care professional, who is responsible for the strength of the lenses and prisms and any exercise programs. The occupational therapist assists the client with follow-through of the eye care professional's recommendations and encourages compliance with the wearing schedule.

Occlusion should be carried out in consultation with the eye care professional. It may be either total or partial. Total occlusion is achieved by means of a patch

or opaque tape on the client's glasses (Fig. 28-3). Compliance with this method is often poor for the following reasons: (1) total occlusion can cause clients to feel off balance because of loss of peripheral and central vision input to the central nervous system, and it reduces depth perception; (2) monocular vision can cause discomfort, especially when the dominant eye is occluded (Warren, 1999a). The recommendation is to avoid total occlusion if at all possible (Hellerstein & Fishman, 1997) and, if it is necessary, to alternate occlusion between the eyes every hour (Warren, 1999a). Partial occlusion appears to have better compliance. In this case, an opaque material added to the client's glasses blocks input to the central visual field, leaving the peripheral field unobstructed (Fig. 28-4). Since diplopia in the central visual field is the most bothersome, the tape is applied to the nasal portion of the glasses of the non-dominant eye (Warren, 1999a). As the client focuses on a target, the tape is applied as far centrally as the client reports diplopia. As the muscles get stronger, the occluded area is decreased. When using occlusion, the client should do range-of-motion exercises to prevent contractures to the unaffected eye. Warren (1999a) recommends that exercises first be done with the unaffected eye covered and then with both eyes together.

Figure 28-3 Total occlusion. **A.** Pirate patch. **B.** Opaque material covering lens of glasses.

Figure 28-4 A method of partial occlusion to alleviate diplopia.

Vision therapy “is an organized regime used to treat a number of neuromuscular, neurophysiological, and neurosensory conditions that interfere with visual function” (Scheiman, 2002, p. 129). Vision therapy can range from the use of an eye patch to more complex treatment involving instrumentation and computers and is generally used to treat disorders of binocular vision, accommodation, ocular motility, strabismus, and visual information processing (Scheiman, 2002). The occupational therapist who has not been trained in prescribing and training clients with lenses, prisms, and occlusion should not provide vision therapy unless supervised by an eye care professional (Hellerstein & Fishman, 1999). The occupational therapist can work closely with the eye care professional to provide input as to the client’s functional needs and situation and then follow through with training that is set up by the eye care professional.

UNILATERAL NEGLECT

Unilateral neglect (UN) is referred to by a variety of names, including hemi-inattention, hemispatial neglect, and unilateral spatial agnosia. It is manifested by a failure to respond or orient to stimuli presented contralateral to a brain lesion (Heilman, Watson, & Valenstein, 1993). It is observed functionally in the client who eats the food on only half of the plate, shaves only one side of the face, and walks into objects on the side contralateral to the brain lesion. It has been suggested (Bisiach et al., 1990; Coslett et al., 1990; Tegner & Levander, 1991) that there are two types of neglect: motor or output neglect (impaired initiation or execution of movement into contralateral hemisphere by either limb) and sensory or input neglect (awareness of stimuli on one side of the body or one side of space). The presence of UN has a negative effect on the rehabilitation of right brain-damaged (RBD) patients (Gillen, Tennen, & McKee, 2005; Paolucci et al., 2001).

The treatment of unilateral neglect can be approached in a variety of ways. First, the client must be aware of the problem. If aware that they have a problem, many of these clients can voluntarily orient, even though they have difficulty with automatically orienting (Ladavas, Carletti, & Gori, 1994). If they are unaware and unable to orient voluntarily or automatically, the only recourse is to modify and simplify the environment (Warren, 1999a).

Some of the early work on the treatment of neglect was done by Weinberg et al. (1977), who developed a training program that included reading, writing, and calculation. It was expanded to include sensory awareness and spatial organization and tasks to increase complex visual perception (Weinberg et al., 1979, 1982). Unfortunately, although improvement was seen, it tended to be task specific, with little generalization to other tasks or areas of self-care. Therefore, it is important to train persons in a functional setting using objects readily available in the environment.

The areas of treatment for neglect include sensory manipulation, attention training, scanning, spatiomotor cueing, patching, prisms, and compensation. Documentation of the effectiveness of these approaches is scarce and unproven (Bowen, Lincoln, & Dewey, 2002); even scarcer is documentation of the influence of treatment on a person’s functional ability. Since sensory manipulation, including caloric stimulation, optokinetic stimulation, and use of medication, is not within the scope of occupational therapy practice and the effects so far are transitory and without carryover, this area is not addressed.

Attention Training

One theory of UN is that the problem is due to a deficit in attention. If this is the case, a treatment program aimed at

increasing attention and general level of alertness should improve UN. Robertson et al. (1995) trained patients with RBD and UN to self-alert during activities. With 5 hours of training, they could mentally tell themselves to pay attention frequently during tasks. Improvement in UN and sustained attention lasted 1–14 days.

In another study, Robertson et al. (1998) found that providing a warning tone as a means of alerting the patient that something was going to happen prior to a task increased perceptual processing and shifting of spatial attention to the left. This was developed further with a limb-activation device (Robertson et al., 2002) that is programmed to emit a tone if there is no movement within a set period of time (2–120 seconds) and can attach to the arm, leg, or shoulder. They found a significant effect on motor function of the arm and leg, which persisted for 18–24 months.

Another method of self-activation is the patient's use of the contralateral extremity as a cue (e.g., to mark the left side of the page while reading or to move the extremity while walking to increase attention to that side). Robertson et al. (1994) found that patients who moved their contralateral hand when walking through a doorway exhibited a decrease in neglect.

Scanning

Visual scanning training is frequently used in treatment for UN. This can include paper and pencil tasks; computer programs; scanning in a functional setting, such as a grocery store; and use of the Dynavision (Fig. 28-5). Research supports improvement on visual perceptual tasks, reading, and academic work with this type of training, but it does not generalize to gross motor tasks (Wagenaar et al., 1992).

Figure 28-5 Dynavision.

The literature indicates that the effects of scanning training are specific to the situation. If the goal is to improve the client's ability to read or scan at tabletop, tabletop scanning training is appropriate; but if the therapist wants to improve a client's ability to scan in the community, practice in the community is needed. Warren (1993b) provided guidelines for selection of treatment activities for clients with deficits in visual attention and visual scanning (Table 28-4).

Niemeier (1998) developed a visual imagery technique called the lighthouse strategy in which clients are taught to visualize themselves as a lighthouse and use the eyes to sweep the environment. This method was found to increase attention to the neglected side of space. Paolucci et al. (1996) used a training program for neglect that included scanning, copying, and description of scenes in addition to a rehabilitation approach and found that there was an improvement not only on tests of neglect, but also on function. On the other hand, although Bailey, Riddoch, and Crome (2002) found an improvement with scanning and cueing, no generalization to functional activity was present. It seems that scanning tasks and cueing should be included in functional activities whenever possible to facilitate transfer to functional tasks.

Clients who are being trained to scan must learn to take in the information in an organized manner, such as left to right. **Anchoring** (supplying a cue on the impaired side to indicate starting position) can be used to help the client bring attention back to the neglected side

Table 28-4. Training Guidelines for Visual Attention and Visual Scanning

Train patients to reorganize their scanning strategy.	Use of anchoring techniques and scanning devices (Weinberg et al., 1979).
Broaden visual field that patient must scan.	Use of activities that require the patient to turn the head or change body positions to complete the task (e.g., scanning items on a kitchen shelf).
Reinforce visual experience with sensorimotor experiences.	Use of activities in which the patient is required to manipulate what is seen (e.g., reach for or touch items scanned).
Emphasize conscious attention to detail and careful inspection of objects.	Use of matching tasks in which the patient may be encouraged to slow down and double-check interpretation of what is seen.
Practice the skill in context to ensure carryover.	Treatment may begin in the clinic, but strategies must be practiced in a variety of real-life situations.

Reference: Warren, M. (1993b). A hierarchical model for evaluation and treatment of visual perceptual dysfunction in adult acquired brain injury, part 2. *American Journal of Occupational Therapy*, 47, 55–66.

(Table 28-5). During practice of scanning using cancellation tasks, a structured array (symbols arranged in neat, straight rows across the page) should be used at first because patients with RBD have difficulty with organized search (Weintraub & Mesulam, 1988). This array can be made increasingly more complex (e.g., requesting two target letters, decreasing the spacing between letters, or decreasing the size of the letters) as the client progresses (Cooke, 1992). Scanning tasks must be practiced in a variety of settings because clients can improve on a task without an improvement in neglect. An excellent therapeutic intervention is the use of Toglia's (1991) multi-context treatment approach. An example of levels of transfer for a letter, consisting of crossing out a specific letter on a page of four rows of random letters, can be seen in Table 28-6.

Table 28-5. Anchoring Technique

Sequence of Cueing	Task Demand
<p>1. A vertical anchoring line is used on the left side; the beginning and ending of the line are sequentially numbered.</p> <p>Example: 1 The law was passed to allow the 1 2 state to conduct a national FBI 2 3 criminal records check before 3 4 certifying teachers. 4</p>	<p>Patient uses the vertical line to find the beginning and the numbers to avoid skipping lines.</p>
<p>2. A vertical anchoring line is used on the left side, only the beginning of the line is sequentially numbered.</p> <p>Example: 1 Family members, followed by 2 coworkers, are the most 3 frequent targets of 4 anger.</p>	<p>Patient uses the vertical line and numbers on the left; the number cue on the right has been eliminated.</p>
<p>3. A vertical anchoring line is used on the left side.</p> <p>Example: Environmental groups hope to minimize the divisiveness and avoid mistakes made in the Pacific Northwest.</p>	<p>Patient uses only the vertical line to find left side.</p>
<p>4. No cues are provided.</p> <p>Example: The state distributes its lottery proceeds without regard to which communities generate the revenue.</p>	<p>Patient must read without any cues.</p>

Table 28-6. Levels of Transfer for a Letter Cancellation Task

Transfer Distance	Task
Near	Patient is instructed to cross out the number 5 (number cancellation task).
Intermediate	Four horizontal rows of various coins are presented. Patient is instructed to place a marker over all the nickels (tabletop task).
Far	Patient is presented with a spice rack and is asked to pick out all of the jars that need to be refilled (standing and reaching at kitchen cabinets).
Very far	Patients is evaluated on the ability to initiate spontaneously left-to-right scanning in the context of simple, everyday life tasks (reading four lines in a large print magazine or locating an item in the medicine cabinet or on a shelf).

Spatiomotor Cuing

If there are two types of neglect, as has been suggested (Bisiach et al., 1990; Coslett et al., 1990; Tegner & Levander, 1991), it is reasonable to expect that each has its own form of treatment. For a client with primarily a motor or output neglect, encouragement of left-hand activation may reduce neglect to a greater extent than visual perceptual cuing. An example might be having the client move the left hand (whatever movement is available) while performing a scanning task instead of using a visual anchoring technique (supplying a visual cue on the impaired side to indicate starting position). Robertson and North (1992) found that left motor activation in left hemispace reduced neglect more than did left motor activation in right hemispace, right motor activation in left hemispace, or visual cuing. Robertson (1992) further reported that (1) left lower extremity activation reduced neglect, (2) passive movement of the left extremity had no effect on neglect, (3) bilateral movements produced no effect, and (4) there was no effect if the movement became automatic. In a further study, Robertson and North (1994) found that simultaneous activation of right and left hands produces a phenomenon similar to **extinction**, such that the advantage gained by activating the left hand is lost. Only single left-hand movement produced a large reduction in neglect. This could have implications for use of bilateral activities, such as those used in the Bobath technique. Opportunity for unilateral activation of the hemiplegic arm should be provided as well as bilateral activation (Robertson & North, 1994).

If the client has more of a sensory or input neglect, he may benefit from visual cuing such as anchoring (Table 28-5) or reminders to look to the left. Training the client to use the left upper extremity as an anchor during functional activities provides both a perceptual anchor and a means of left-limb activation (Robertson, North, & Geggie, 1992).

Patching

Eye patching techniques for UN include single-eye patching (Fig. 28-3) and half-field patching (Fig. 28-6). For the client with neglect, either the entire eye ipsilateral to the lesion is covered or the hemifield of both eyes is covered (i.e., in the case of left UN, the right eye or right hemifields of both eyes).

Patching one eye is believed to influence the central nervous system by way of the superior colliculus (Posner & Rafal, 1987), increasing eye movements to the contralateral side and decreasing neglect. Patching the ipsilateral hemifield is felt to increase activation of the involved hemisphere, resulting in increased attention to the contralateral side.

Butter and Kirsch (1992) found that patching the right eye of patients with left neglect decreased the patients' left neglect score. When lateralized visual stimulation was added, the relative benefits were larger. The beneficial

effects, however, were present only when the eye patch was on, and the study did not include generalization to functional tasks.

Beis et al. (1999) followed 22 patients with UN: 7 wore glasses with patches covering the right eye, 7 wore glasses with right half-field patches, and 8 controls had no patching. The patches were worn up to 12 hours a day for 3 months. The results of the patients with the right half-field glasses were significantly different from those of the controls, with the right half-field patients exhibiting an increase in total *Functional Independence Measure* score (Uniform Data System for Medical Rehabilitation, 1997) and increased time looking to the left.

Arai et al. (1997) also looked at the effects of half-field patching with 10 RBD patients. They found a decrease in neglect, improvement on pencil and paper tasks, and good functional return in one patient. Harrell, Kramer-Stutts, and Zolten (1995) also found an improvement of neglect in patients wearing goggles with half-field glasses.

In summary, patching has many benefits. It can be used throughout the day during a variety of functional activities and does not rely on memory and training. Patching is simple, inexpensive, and usable by a variety of disciplines.

Prisms

In the case of UN or heminopsia, the prisms used are called yoked because the base of the prisms are on the same side for each eye (Scheiman, 2002). They function by shifting the visual field toward the intact side and thereby providing the patient with the ability to see things on the involved side. These prisms may involve the whole visual field or partial field. They can be the more temporary **Fresnel prism**, which is a flexible plastic sheet with small ridges that can be cut to shape and stuck to the patient's glasses, or a more permanent prism that is part of the patient's prescription. Advantages of the Fresnel prism are that it is inexpensive and temporary and can be applied and removed easily. The disadvantages are that it may distort visual acuity and tends to bubble and increase distortion (Gianutsos & Suchoff, 2002; Hellerstein & Fishman, 1997).

Gianutsos and Suchoff (2002) recommend the use of the Fresnel prisms as a temporary or diagnostic device. They have found that the partial Fresnel prisms (covering half of the patient's glasses) are not as beneficial as yoked prisms ground into the patient's prescription.

Rossetti et al. (1998) used prisms to shift the visual field (VF) to the right in 16 RBD patients with left UN. Initially the patients exhibited a shift to the left when pointing straight ahead. Following adaptation, patients were given tasks including line bisection, line cancellation, copying, drawing from memory, and reading. Patients in the experimental group exhibited an improvement in neglect, which was maintained for 2 hours. Frassinetti et al. (2002) expanded this and found that the prism adaptation was

Figure 28-6 Right hemifield patching for left visual neglect.

maintained for at least 5 weeks and, for some subjects, was maintained for up to 17 weeks.

Rossi, Kheyfets, and Reding (1990) found that the use of Fresnel prisms improved visual perception in stroke patients with homonymous hemianopsia or unilateral visual neglect. Another study found that, although prisms improved exploration of space, the information obtained may still be neglected or less salient (Morris et al., 2004).

The advantages of using prisms include: effects can be obtained within a short period of time, they do not require voluntary orientation of attention to the involved side, and they are non-invasive and can be used anywhere (Frassinetti et al., 2002).

Compensation

Compensation can be environmental or cognitive. Adaptation of the environment includes such things as arranging

the client's bed so that the uninvolved side is toward the activity in the room and always interacting with the client on the uninvolved side. Although this might be a good idea initially to evaluate clients and to keep them from harming themselves, it does nothing to help them overcome the deficit. It is recommended that both the remedial and adaptive approaches be used.

Cognitive compensation includes metacognitive training (Toglia, 1991), use of video feedback (Soderback, et al, 1992), and teaching the client a routine to complete a specific activity (i.e., donning a shirt) with clients cognitively cueing themselves through each step. Clients must be aware that there is a problem before they can use compensatory techniques (Crosson et al., 1989; Tham, Borell, & Gustavsson, 2000). These techniques must be practiced, and eventually, if the client becomes an active problem solver, the techniques can be generalized to new situations.

CASE EXAMPLE

S.D.: Occupational Therapy Intervention to Address Problems with Visual Scanning

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
Patient Information S.D., a 21-year-old man who is 15 months post right cerebrovascular accident, participated in an outpatient occupational therapy assessment, and the following problems were identified: (1) decreased ocular motor skills including decreased convergence, decreased accommodation, and inefficient saccades and smooth pursuits; and (2) unilateral neglect.	Appreciate the context	See Chapter 8 for description of the assessment process and patient's background.
	Develop intervention hypotheses	"I believe that S.D.'s visual skills are limiting his ability to read and participate in school. These abilities are further limited by his unilateral neglect. He is motivated to continue in school and participate in sports in a different way. This should facilitate his learning and participation in therapy."
	Select an intervention approach	"I think that S.D. would benefit from visual scanning training, using various compensatory techniques, which, according to the research, is successful although task specific. He will probably need to learn compensatory techniques that he can apply to various functional situations. Participation of his family and personal care attendant (PCA) will be very important in follow through with the program."

Reflect on competence

“I’m afraid that S.D. is going to have to learn to compensate cognitively and may continue to require environmental compensations. Clients I’ve had with his degree of denial in the past either required a large increase in time to complete a task correctly or continued to require cues.”

Recommendations

The occupational therapist recommended 1-hour treatment sessions twice a week for 8 weeks. In collaboration with S.D., the occupational therapist established the following long-term goals: (1) S.D. will read his homework with accuracy and good speed; (2) S.D. will demonstrate the ability to maneuver throughout familiar and unfamiliar environments independently; and (3) S.D. will independently use appropriate compensatory strategies for unilateral neglect as needed during functional activities.

Consider what will occur in therapy, how often, and for how long

“I feel that S.D. would benefit from therapy 2 times a week, but his family and PCA will be instrumental in assisting him to follow through with compensatory techniques. Hopefully, they will be able to attend some of the therapy sessions.”

Summary of Short-Term Goals and Progress

1. S.D. will demonstrate improved use of scanning strategies such that he is able to copy information from 5 feet away to a sheet of paper at near distance with 80% accuracy.

S.D. is having difficulty with accommodation, which interferes with participation in his college classes because he is unable to copy information from the chalkboard. The task was varied by the size and location of the information on the board; by the density of the information; and by the organization of the information (he was a math major and math problems do not tend to be presented in as organized a manner on the board). Goal of 80% was met.

2. S.D. will maneuver his wheelchair through an unfamiliar environment with minimal verbal cues.

Since S.D. was having difficulty maneuvering his wheelchair without running into objects on the left side and locating items in the kitchen, it was decided to work on a task that involved both, namely, maneuvering down a hallway or in a room while at the same time being asked to locate items/numbers placed at various height/locations around the room. Upon recommendation of the optometrist, partial occlusion was used as one means of compensation for the left neglect. Although he was usually able to find 90–100% of the objects, it took him a very long time to do so; therefore, he was taught to use the lighthouse strategy. He met the goal, requiring minimal verbal cues to locate items on the floor to his left side, and in addition, his scanning strategy improved, as evidenced by increased speed of locating objects.

Assess the patient’s comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

“When he first started, S.D. had difficulty because he tended to move his head rather than his eyes. We spent some time working on visual tracking exercises without moving his head, and he can now use the glasses to a better advantage. I am encouraged that this has worked for him.”

“S.D. was able to use the partial occlusion glasses at home as well as during therapy. At first, the family was hesitant, but they have been working with him and gradually been able to decrease assistance and verbal cues.”

“After observing activities done in therapy, the PCA was able to follow through and encourage use of the lighthouse strategy throughout the day and in many different functional situations.”

Next Steps

Revised short-term goals (1 month):

1. S.D. will demonstrate improved use of scanning strategies such that he is able to copy words from one sheet of paper to another with 90% accuracy.
2. S.D. will initiate scanning strategies with no more than general cues while navigating in a community setting.
3. S.D. will be able to maneuver his wheelchair in unfamiliar environments with 2–3 verbal cues and independently in familiar environments.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“S.D. has made progress over the past month. His accuracy and use of scanning strategy have improved, but they will need to improve more if he is to continue with his classes. He is also managing his wheelchair mobility better in familiar settings, but he needs to be challenged by new situations. I’d like to start working with him in the community, gradually increasing the amount of distraction.”

“I feel that S.D. is progressing and would benefit from continued therapy.”

Evidence Table 28-1 Best Evidence for Occupational Therapy Practice Regarding Unilateral Neglect

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Prisms	Adaptation to base left wedge prisms (causing a 10° shift of the visual field to the right); 18 straight-ahead pointing trials before and after adaptation.	12 RBD patients with neglect: prism and control groups.	One 2- to 5-minute session of prism exposure.	Randomized controlled study. IC2b (small sample size)	Yes. Following adaptation, patients with neglect showed shifts to the left that lasted 2 hours after the prisms were removed.	$p < 0.05$	Rossetti et al., 1998
Lighthouse strategy (LS)	Patients were taught to visualize themselves as a lighthouse whose lights (eyes) are required to sweep from left to right. The LS was used by the rehab team and family.	31 stroke patients with RBD or LBD: treatment group, n = 16; control group, n = 15.	Four 30-minute training sessions, and then the LS was used as an adjunct in other therapy sessions over average length of stay of 25 days.	Non-randomized controlled study. IIC2b (small sample size)	Yes. Those in the treatment group significantly increased attention to the right or left.	$p < 0.007$ on attention rating scale. $p < 0.002$ on reduction of error on tests of neglect.	Niemeier, 1998

<p>Right hemisphere activation approaches</p>	<p>Reviewed studies related to (1) lateral task approach, (2) controlled sensory stimulation, and (3) limb activation.</p>	<p>Varied.</p>	<p>Meta-analysis of 9 group design studies and 22 single-subject studies.</p>	<p>Yes. Unilateral neglect appears to be amenable to change by way of activation of the right hemisphere.</p>	<p>Mean effect size for group design studies, $r = 0.77$; for single subject studies, $r = 0.89$.</p>	<p>Lin, 1996</p>
<p>Table top scanning activities</p>	<p>Exercises included visual scanning, reading and copying, copying of line drawings, and descriptions of scenes.</p>	<p>Specific training for 5 1-hour sessions/week for 8 weeks alternated with cognitive stimulation 3 times a week for 1 hour for 8 weeks.</p>	<p>Not randomly assigned to the groups. IIBzb (effect of involvement in rehabilitation program was not controlled)</p>	<p>Yes. Improvement of motor skills and function.</p>	<p>Statistically significant pre-post improvement: Barthel Index ($p < 0.001$) and tests of neglect, $p < 0.001$.</p>	<p>Paolucci et al., 1996</p>

APRAXIA

Apraxia is the inability to carry out purposeful movement in the presence of intact sensation, movement, and coordination (Heilman & Rothi, 1993). Three types of apraxia are addressed: limb, constructional, and dressing. Although there are volumes of literature describing apraxia, little is written on treatment.

Limb Apraxia

Clients with limb apraxia can often complete daily activities, but they tend to be clumsy and/or produce action, tool, or sequencing errors. This is the person who tries to eat soup with a knife or has difficulty opening a soft drink can. Treatment recommendations are just beginning to be tested in controlled research to determine outcome. The lack of research on treatment is most likely a result of the following (Maher & Ochipa, 1997):

- Many patients are often unaware of the deficit (involvement of the non-dominant extremity) or do not complain (often associated with aphasia).
- Many treatment personnel believe that patients will recover spontaneously.
- The method of identification of apraxia is usually by pantomime (which we do not use on a day-to-day basis), and praxis usually improves with tool use. Therefore, many believe that it will have little impact on the patient's life.

The therapist should ask whether the client's clumsiness and/or difficulty with gestures interferes with daily living skills. If so, then this area should be addressed. In the case of the client who has difficulty with actual tool use, the need for treatment is more obvious. Manipulation of the clients' environments or their interaction with the environment is one means of managing apraxia. Usually these changes are related to tool use and/or clumsiness (Table 28-7).

Suggested treatment activities include gross motor activities involving interpretation and use of tactile, kinesthetic, and proprioceptive stimulation to influence motor patterns; manual contact or guiding of the apraxic extremity through the task; and **chaining** techniques (Farber, 1993; Zoltan, 1996). The therapist should keep verbal commands to a minimum and ask the client to perform activities in the environment in which they would normally be done. Furthermore, the client can be asked to visualize the movement before attempting to carry it out (Zoltan, 1996). The therapist may have to break down the activity into component parts and teach each part separately; then, as each is learned, the parts are integrated into more complex activities.

Table 28-7. Management of Apraxic Deficits

If tool use is a problem:

- May need to limit patient's access to tools that may be dangerous (e.g., power tools).
- Have patient involved in tasks requiring no tools or a minimum of tools.
- Limit the number of tools for a given task.
- Avoid series of tasks.
- Have the patient perform tasks with which they are most familiar.

If clumsiness or accuracy of production is an issue:

- Use proximal movement whenever possible.
- Decrease the complexity of the required movement.

From Maher & Ochipa, 1997.

In a study using physical manipulation and verbalization of task elements, improvement was noted in areas trained but did not generalize to other tasks (Pilgrim & Humphreys, 1994). Maher and Ochipa (1997) looked at the effects of treatment (verbal instructions, practice, and feedback) on specific error types (external configuration, movement, and internal configuration) and found that the treatment was task specific. An improvement in one error type did not generalize to another error type, and treatment of a specific error type did not improve across gestures.

Current research supports gestural or strategy training for apraxia following left brain damage (LBD) (Cicerone et al., 2005). Smania et al. (2000) developed a training program consisting of gesture-production exercises. Experimental subjects were trained in production of transitive gestures (those involving objects), intransitive symbolic gestures (wave goodbye), and intransitive non-symbolic gestures (put your hand under the chin). The control subjects received an equal amount of aphasia training. They found a significant improvement on tests of ideational apraxia and ideomotor apraxia that indicated a generalization to untrained tasks. It was thought that their positive results were possibly due to the extensive training, which was aimed at a wide range of gestures and error types. How this training generalized to daily life was not addressed in this study and should be researched further.

Van Heugten et al. (1998) developed a program in which patients were taught strategies to compensate for their apraxia. ADL activities are broken down into three phases (initiation, execution, and control), and the patient may have difficulties in any of these areas. The therapist provides instruction, assistance, and feedback (Table 28-8). The therapist may provide instruction if the person is having difficulty initiating an activity. If more assistance is needed, the therapist can hand the object to the client or provide verbal assistance. If clients are unaware of problems with their performance, the therapist can provide feedback (e.g., verbally

Table 28-8. Sample Interventions for Apraxia

Stage	Intervention
Instructions	<ul style="list-style-type: none"> • Start with verbal instruction • Use gestures, point to the object • Demonstrate part of the task • Show pictures • Write instructions • Adjust task to make it easier for the patient
Assistance	<ul style="list-style-type: none"> • Verbal assistance to: <ul style="list-style-type: none"> • Stimulate verbalization of the steps of the activity • Name objects • Direct attention to the task at hand • Use gestures and vary intonation of your speech • Show pictures of correct sequence of steps • Physical assistance can include: <ul style="list-style-type: none"> • Guiding of the limb • Positioning of the limb • Use of sensory or neurodevelopmental treatment to provoke movement
Feedback	<ul style="list-style-type: none"> • Verbal feedback: <ul style="list-style-type: none"> • In terms of the result • To encourage the patient to consciously evaluate the results (see, hear, feel, smell, taste) • Physical feedback as to: <ul style="list-style-type: none"> • Posture of the patient • Support of the limbs • Pointing or handing the object to the patient • Verbal and physical feedback to assist patient's knowledge of performance: <ul style="list-style-type: none"> • Place a mirror in front of the patient • Video record performance and then review together.

Adapted from van Heugten et al., 1998.

or by use of a mirror to show them what is happening). The researchers found that patients improved on all ADL measures. Donkervoort et al. (2001) incorporated this strategy training into a patient's usual occupational therapy rehabilitation program and compared this with a group that received just the usual occupational therapy program. They found that occupational therapy and strategy training was more effective in improving ADL than usual occupational therapy alone. They did not find a long-term effect in favor of strategy training but felt that this was due to patients in

the usual occupational therapy group requiring more therapy to reach a similar level of independence.

Constructional Apraxia

Clients with constructional apraxia (CA) cannot “correctly draw or assemble parts to form a unitary structure” (Sunderland, Tinson, & Bradley, 1994, p. 916). The client with constructional apraxia has difficulty with drawing and constructing designs or objects in two and three dimensions and, therefore, demonstrates difficulty putting together a puzzle or a child's bicycle and following a map. This may be caused by any number of problems (e.g., executive, perceptual). Little can be found in the literature on the treatment of CA, possibly because treatment should be based on function and focus on the underlying cause.

Neistadt (1992) compared the effects of adaptive training (preparing snacks and beverages) and remedial training (using parquetry blocks) on head-injured patients' performance. She found that those patients who received training with parquetry blocks improved most on the parquetry block test and least on the food preparation task, whereas those who received the functional training improved more on the food preparation task. The results suggested that learning in adult head-injured men, at least 6 months after injury, is task specific; this supports the use of the functional approach.

Information can be found in the literature on how to improve performance on drawing tasks and construction tasks (Hecaen & Assal, 1970; Neistadt, 1989; Warrington, James, & Kinsbourne, 1966; Zoltan, 1996), but because these are not based on function, they appear not to be useful in today's health care environment. Some of the ideas, such as practice, use of a model, use of cues and landmarks, and progressing from simple to complex, can be applied to performance of functional tasks.

Dressing Apraxia

Dressing apraxia refers to an inability to dress oneself despite adequate motor skills and know-how. Little is written specifically regarding treatment. Treatment generally consists of teaching the patient a pattern of dressing. Cognitive cues, such as using the label to tell front from back and talking through the steps of putting on each item of clothing, are used, and the patient eventually learns through practice (Zoltan, 1996). Cook, Luschen, and Sikes (1991) described the use of an audiotape and a specific method of stacking (sequencing) clothing to improve dressing in an elderly woman with cognitive and perceptual impairments. If the basis for the dressing apraxia is found to be constructional apraxia, unilateral neglect, or body scheme disturbances, treatment is aimed at ameliorating those deficits.

Evidence Table 28-2 Best Evidence for Occupational Therapy Practice Regarding Apraxia

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Gesture production exercises	Study group received treatment in: transitive, intransitive, symbolic, and intransitive-nonsymbolic gestures. Control group received conventional treatment for aphasia.	13 patients with unilateral LBD and the presence of limb apraxia of at least 2 months duration (range 2–36 months). Study group: n = 6. Control group: n = 7.	50 minute sessions 3 times per week for a maximum of 35 sessions.	IC2b	Yes. Study group demonstrated significant improvement on performance of tests of ideational and ideomotor apraxia, which included gestures not practiced. The control group did not show improvement.	Ideational apraxia: $p = .039$, Ideomotor apraxia: $p = .043$.	Smania et al., 2000.
Strategy training	Patients were taught strategies to compensate for their apraxia. The occupational therapist used instruction, assistance, and feedback, which were varied depending upon the patient.	33 stroke patients with apraxia.	Seen 30 minutes 3 to 5 times a week for 12 weeks	IIIB2a	Yes. Improvement was seen on all ADL measures.	For ADL observations, Barthel Index, and ADL questionnaire $p < 0.001$. Effect size: strong in ADL observations (.92), Barthel Index (.86)	van Heugren et al., 1998
Strategy Training	Study group received training in use of internal and external compensations for apraxic movements during ADLs. They received strategy training and occupational therapy. Control group received conventional OT only.	113 LBD patients with apraxia. Strategy training: n = 56; Usual treatment: n = 57.	15 to 19 hours of treatment over 8 weeks.	IA2b	Yes. Patients in the strategy training group improved more on ADL observations than those in the usual treatment group.	$p = .03$ Effect size = .37 (medium, which the authors felt was good since this intervention was only a part of the total rehabilitation process).	Donkevoort et al., 2001

SUMMARY REVIEW QUESTIONS

1. List three compensatory techniques for use with clients with low vision and give two examples of each.
2. You have a client with double vision. What should you do first?
3. Based on an optometrist's report, your client's best corrected acuity is 20/160. He has a cataract in the right eye and glaucoma in both eyes, for which he is receiving medication. How might his low vision affect his ability to do self-care, meal preparation, and money management?
4. Summarize guidelines for visual scanning training.
5. How does the use of occlusion for diplopia differ from that used for unilateral neglect?
6. Your client with left unilateral neglect is having difficulty finding things in the kitchen cabinets during meal preparation. What activities might you plan for your therapy session?
7. Describe four activities to use with limb apraxia.
8. Your client is a 40-year-old dentist who has apraxia. He can use tools but is clumsy. How would your treatment of this client differ from the treatment of a 70-year-old retired man with the same clumsiness?
9. Deficits in what areas can cause dressing apraxia? Indicate how intervention may differ according to the hypothesized underlying cause of this problem.
10. Why is it important for occupational therapists to become involved in research?

ACKNOWLEDGMENT

Thanks to Liz Stuewe, MS, OTR, for her assistance with preparation of the case study and to Sheri Riggs for her assistance with the photographs.

CHAPTER 29

Optimizing Cognitive Abilities

Mary Vining Radomski and Elin Schold Davis

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Compare and contrast remedial and adaptive therapy specific to optimizing a client's cognitive abilities.
2. Describe how remedial cognitive retraining can be incorporated into an occupational therapy intervention plan.
3. Analyze how changes in the physical or social context contribute to improved cognitive function.
4. Outline methods for helping clients reestablish routines and habit sequences.
5. Discuss how various compensatory cognitive strategies can be used to override cognitive impairments and inefficiencies.

Glossary

Cognitive compensatory strategies—Array of techniques, devices, and aids that people use to circumvent cognitive limitations.

Cognitive rehabilitation—Multidisciplinary field and a broad category of intervention methods aimed at improving cognitive function.

Cognitive retraining—Remedial therapy aimed at restoring cognitive capacities through practice, exercise, and stimulation.

Habits—A continuum of automatic physical, emotional, and social behaviors that become increasingly effortless with repetition within the same context.

Routines—Habit behavior that takes the form of semi-automatic clusters of activities that are prompted by physical context and are fairly consistent for each individual on a day-to-day basis.

A person's ability to concentrate, remember, and solve problems is central to the ability to fulfill valued self-maintenance, self-advancement, and self-enhancement roles. Many people who are referred to occupational therapy services have organic cognitive impairments or short-term cognitive inefficiencies related to illness, injury, pain, or emotional distress. These impairments and inefficiencies are often the primary barriers to occupational functioning and therefore are the primary targets of occupational intervention. This chapter presents a working definition of cognitive rehabilitation, discusses linkage with occupational therapy, and describes specific approaches used in occupational therapy to optimize cognitive abilities.

COGNITIVE REHABILITATION AND LINKS WITH OCCUPATIONAL THERAPY

The term **cognitive rehabilitation** describes both a multidisciplinary field and a broad category of intervention methods aimed at improving cognitive function. Many rehabilitation disciplines, including occupational therapy, speech-language pathology, special education, and neuropsychology, attempt to help patients optimize cognitive abilities, with occupational therapy and speech therapists most often providing cognitive rehabilitation services (Stringer, 2003). With many parallels to occupational therapy treatment planning, contemporary cognitive rehabilitation practice places less emphasis on the drill and practice models of its beginnings and more emphasis on human cognition and its interfaces with health, emotion, individual differences, and context (Sohlberg & Mateer, 2001; Togliola, 2005). For occupational therapists, a client's problems with cognition are always incorporated into a broader treatment plan that may also address motor, perceptual, social, or emotional issues. Whether occupational therapists characterize their efforts to optimize cognitive function as cognitive rehabilitation, occupational therapy, or both, the aim is the same: to help clients fulfill their

own role aspirations with minimal interference from cognitive limitations.

The development of cognitive rehabilitation has been and continues to be plagued by the lack of standard, agreed-upon definitions (Carney et al., 1999). In general, the term cognitive rehabilitation simply means the rehabilitation of people with cognitive deficits (Sohlberg & Mateer, 2001). The Commission on Accreditation of Rehabilitation Facilities (CARF) provides a useful working definition for this chapter. CARF suggests that cognitive rehabilitation is a systematic intervention that is directed to achieve functional changes by reinforcing, strengthening, or reestablishing previously learned patterns of behavior or establishing new patterns of cognitive activity or mechanisms to compensate for impaired neurological systems (CARF, 2004).

TREATMENT APPROACHES IN OCCUPATIONAL THERAPY TO OPTIMIZE COGNITIVE FUNCTION

Occupational therapists use the same broad approaches described in Chapters 1 and 3 to optimize clients' cognitive abilities—remedial therapy and adaptive therapy—which are further characterized as changing the context, establishing habits and behavioral routines, and acquiring compensatory skills and strategies. In selecting a primary treatment approach to optimize cognitive abilities, therapists ask themselves a number of questions about the client and the anticipated outcomes of therapy including the following:

- Who is considered the primary recipient of occupational therapy intervention: the patient, the client–family team, or the significant other? What social or cultural factors have a bearing on the outcome of intervention?
- What is the nature of the client's cognitive problems? Are the client's problems attributed to organic impairments in primary cognitive abilities or characterized as a shorter term cognitive inefficiency? Is the client in the

process of recovering, or is his or her condition likely to result in progressive deterioration?

- How are other systems, such as motor, visual, and perceptual systems, functioning? (Schwartz, 1995)
- Is the client aware of the cognitive problems and motivated to improve function in this area?
- Does the client appear to have the capacity to transfer skills learned in therapy to new situations? Does he or she have the resources (e.g., time, financial, emotional) to participate in therapy for the length of time necessary to achieve transfer of training?

Each approach to improving cognitive function is described in detail (Table 29-1). In practice, however, it is almost impossible to separate these approaches (Ben-Yishay & Diller, 1993). Consider a client who is learning to use a day planner to compensate for memory impairment. Although the primary treatment approach centers on acquiring compensatory skills and strategies, successful outcome depends on teaching the individual's family to provide the right prompts and reinforcement (changing the social context) and creating a daily planning routine in which the person reviews and adds notes to the planner (establishing behavioral routines). Furthermore, it is possible that the learning process challenges the attentional and memory systems in such a way as to stimulate neuroanatomical and physiological changes (remediation).

Remediate Deficits

Remedial therapy for cognitive problems, or **cognitive retraining**, is the therapeutic effort to restore cognitive capacities through practice, exercise, and stimulation (Wilson, 1997) with the expectation that these gains will translate to improvements in the tasks and activities to which these capacities and abilities relate (Radomski, 1994; Sohlberg & Mateer, 2001). In this approach, the therapist identifies impaired cognitive domains, such as attention, visuospatial, or memory, and provides graded activities that challenge the weakened process. Cognitive exercises, typically pencil and paper, tabletop, or computer-based exercises, are a means of attacking the deficient cognitive capacity but may have little inherent value in and of themselves (Sohlberg & Mateer, 1989). The therapist collects data on the patient's performance, such as percent correct and speed of performance. As the patient masters therapy tasks or meets criterion levels, the therapist raises the complexity or difficulty of the cognitive exercises, still challenging the original weakened process or capacity (Sohlberg & Mateer, 1989). This progression culminates with rehearsal of a naturalistic activity supported by the previously weakened cognitive capacity (Sohlberg & Mateer, 2001). This intervention sequence is founded on the premise that one cognitive capacity may be treated in isolation from other dimensions of cognition.

Table 29-1. Using Multiple Treatment Approaches to Help a Client with Cognitive Impairment to Optimize His Cognitive Abilities (see Case Example)

Treatment Approaches Described in Chapter 1	Remedial Therapy		Adaptive Therapy		
	Intervention method	Remediate the impairment	Change the context	Establish behavioral routines and habits	Learn cognitive compensatory strategies
Treatment fraction (see Chapter 3)	10% of therapy efforts devoted to this approach	25% of therapy efforts devoted to this approach	35% of therapy efforts devoted to this approach	30% of therapy efforts devoted to this approach	
Example	Given D.B.'s interest in "fixing" his memory and the recency of his injury, the therapist used paper and pencil activities as part of his homework that were geared toward challenging and improving his attentional system.	The therapist helped D.B. determine how to change the physical environment to optimize his attention and concentration. The therapist also attempted to change the social context by teaching D.B.'s brother appropriate ways to provide cues.	Checklists were developed specific to key self-maintenance tasks (initially ADLs and use of the planner) in the hopes that, with enough consistent repetition, D.B. would maintain these habits and routines without cues.	D.B. was assisted in selecting a number of memory prostheses including day planner, alarm watch, and medication container. The therapist provided numerous opportunities for D.B. to rehearse use of these strategies in increasingly novel situations.	

CASE

EXAMPLE

D.B.: Using Multiple Approaches to Optimize Cognitive Functioning after Traumatic Brain Injury

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist’s Internal Dialogue
<p>Patient Information</p> <p>D.B., a 26-year-old man who is 3 months post traumatic brain injury, participated in an outpatient occupational therapy assessment, and the following problems were identified: (1) decreased initiation of ADL and IADL; (2) decreased productivity due to poor stamina and limited appropriate avocational outlets; (3) memory impairment and inadequate repertoire of memory compensation strategies; and (4) decreased awareness of cognitive deficits interfering with compensatory strategy use.</p>	Appreciate the context	See Chapter 9 for description of the assessment process and client’s background.
	Develop intervention hypotheses	“I believe that D.B.’s cognitive problems are the most salient barriers to his occupational functioning at present, specifically, his limited awareness of his cognitive deficits. I think that he could better adapt to his physical limitations if he employed an array of strategies to compensate for his cognitive limitations. His motivation and family support are real facilitators of his occupational functioning and recovery.”
	Select an intervention approach	“I will develop an intervention plan that emphasizes compensation for deficits because, given the severity of his brain injury, D.B. will likely have long-term cognitive challenges. I will provide D.B. with drill and practice cognitive activities to fill some of his free time and use them to help him gain insight about his cognitive functioning (remediation). D.B. will no longer need assistance from his brother if I help him reestablish an ADL routine. I know that I will also want to work with D.B.’s family to change the social context so that they are not providing him more cues and assistance than is really necessary.”
	Reflect on competence	“D.B. reminds me of 3 or 4 other clients I’ve worked with in recent years. I’m a little concerned that I may not be able to satisfactorily address emotional or adjustment issues that might emerge as he gains insight, and so I need to start thinking about a counselor I might refer him to later.”
<p>Recommendations</p> <p>The occupational therapist recommended 3 treatment sessions each week for 8 weeks. In collaboration with D.B. and his brother, the occupational therapist established the following long-term treatment goals: (1) D.B. will independently initiate and carry out all self-care and selected light house-keeping tasks (through use of external memory aids); (2) D.B. will increase his level of productive activity at home such that he initiates avocational activities at least 3 times per week; (3) D.B. will follow through on intended tasks at least 85% of the time through use of external memory aids and strategies. D.B.’s brother indicated a willingness to provide transportation to appointments and to attend at least weekly.</p>	Consider the client’s appraisal of performance	“I think that a fairly intensive outpatient program is warranted because of the scope of our goals and D.B.’s motivation and potential to make progress. I have real hope for D.B.’s recovery for many reasons, including his level of cooperation, his cognitive strengths, and his brother’s commitment to the therapy process. D.B. seems agreeable to the plan, but I really don’t know how much he truly understood what I’m proposing and why.”
	Consider what will occur in therapy, how often, and for how long	
	Ascertain the client’s endorsement of plan	

Summary of Short Term Goals and Progress

1. D.B. will independently initiate notetaking when presented with occupational therapy homework (at least 60% of the time) and thereby improve his follow-through on intended tasks.

The therapist ascertained that D.B. would be most likely to carry a memory aid if it was highly portable. Therefore, she assisted D.B. in selecting a commercially-available, pocket-sized week-at-glance planner. The therapist created opportunities for D.B. to practice filing and locating information in function-specific planner sections. The therapist used an event record to log each of the three to four homework assignments she presented to D.B. during all treatment sessions, taking note of the extent to which D.B. required cues to initiate notetaking. Any level of notetaking initiation was verbally reinforced. Progress in this realm was reviewed at each session, graphing both notetaking initiation and homework completion as reinforcement and to improve insight. During the last week of this period, D.B. averaged a 65% independent notetaking rate and a 70% homework completion rate.

2. D.B. will initiate and employ consistent routines for self-care tasks (including medication management) through use of checklists and alarm cueing devices.

Based on the therapist's recommendation, D.B. purchased a container for medications taken each week as well as an alarm watch. The therapist set the alarm to sound at 5:00 p.m. as a prompt to refer to his medication checklist and take medications. D.B. required cueing and supervision with this system for 2 weeks but by the end of the month, took medications on schedule, once his brother filled the medication container. A "morning checklist" (D.B.'s hygiene sequence) was posted in D.B.'s bathroom and after 1 month, he progressed to the point that he required his brother's cueing to initiate these activities only 1–2 times per week.

3. D.B. will improve his attention to detail such that he has an error rate of less than 10% on pencil-paper tasks.

D.B. was highly motivated to "fix" his memory and eager to carry out any exercises that might help. To that end, he agreed to work on various attention-concentration worksheets as part of his homework while experimenting with various strategies that might help him focus on the task. For example, he tracked and compared his performance under various conditions: while watching television versus sitting in a quiet room; in the morning when rested versus after dinner; working in a space crowded with many papers and belongings versus a corner of his bedroom from which his "stuff" was not visible.

Assess the client's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"At first when I started giving D.B. homework, he simply sat and nodded his head as if to confirm that he understood and would remember. It was hard for me to say nothing and 'let the chips fall where they may'. It was uncomfortable for a while when he would argue with me at our next session, telling me that I had never assigned him anything. But as I showed him my log and how to use his planner, he seemed to realize that it's o.k. to write things down rather than trying to memorize everything. I'm seeing progress."

"I am so glad that D.B.'s brother is part of the team. Ordinarily I like to allow patients to go ahead and make forgetting errors as a means of helping them improve awareness but I simply can't allow that when it comes to remembering to take medications on schedule."

"D.B. would rather 'fix' his memory than learn to compensate for memory problems but the research evidence just doesn't support the notion that repetitive cognitive exercises lead to functional changes. I don't want to create any false hope but have tried to both give him some activities to fill his time at home and create a structure in which he can think about his thinking. He still needs a lot of help to understand the circumstances under which he performs at his best but he seems to feel that these activities give him something important to do during his days off from therapy."

Next Steps

Revised short term goals (1 month):

1. D.B. will use his daily planner and planning checklists in order to schedule and carry-out at least two housekeeping tasks and three avocational activities each week.

2. D.B. will be able to use compensatory strategies to independently take medications on schedule (once his brother sets up the medication box each week).

3. D.B. will demonstrate improved awareness of his current problems with memory by independently initiating notetaking to the presentation of homework at least 85% of the time and at least 75% of the time when his brother provides instructions.

Anticipate present and future client concerns

Analyze client's comprehension

Decide if he or she should continue or discontinue therapy and/or return in the future

"D.B. has made great progress over the past month but is not yet ready to be living on his own, which remains his primary goal. He really needs to be able to handle self care tasks (including medications) and perform critical household tasks in order to do so. I would like to help D.B. prepare himself to do some sort of volunteer work within the next couple of months and he has indicated at least preliminary interest in doing so. He'll need to be quite proficient with his planner to be a successful volunteer."

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Influence of Awareness on Treatment Approach**

D.B. appeared to have limited awareness of his cognitive deficits and the implications of these problems on his functioning and future.

How might the "treatment fraction" (see Table 29-1) have been different if D.B. was keenly aware of cognitive impairments and highly motivated to minimize their influence on his life?

Many factors are believed to explain and influence recovery based on a remedial therapy. The emerging understanding of brain plasticity and neural reorganization suggests a greater degree of plasticity in the adult brain than was previously believed (Sohlberg & Mateer, 2001). The successful outcome of the remediation approach is predicated on the therapist’s ability to select the foundational skills likely to respond (Cicerone et al., 2005).

Graded Cognitive Exercises

To optimize cognitive capacities, Abreu and Togli (1987) recommended that therapists present targeted exercises and activities that “gradually increase demands on the information processing system” (p. 443). They described three phases of activity presentation in an effort to illustrate the progression from simple to complex and automatic to effortful and the ability to respond to the external environment versus the ability to manipulate the internal environment. Blundon and Smits (2000) surveyed Canadian occupational therapy programs and found the most common cognitive rehabilitation activities to be pencil and paper tasks, such as mazes and work sheets; computer-based activities; and board games.

Pencil and Paper and Tabletop Activities

Therapists often use activities such as mazes, math, or seek-and-find work sheets to challenge weakened cognitive ca-

pacities. The following is an example of using a worksheet to address attention and concentration. The patient is presented with a worksheet consisting of random symbols and letters spread across the page in rows. The patient is instructed to find and circle a specific target, such as a triangle. The therapist encourages the patient to work as quickly as possible while maintaining accurate performance. The therapist times the activity and episodes of off-task behavior, and together, the patient and therapist score the worksheet for accuracy (Fig. 29-1). Since a remediation approach requires a great deal of repetition and rehearsal to be effective (Chen et al., 1997), the patient performs attention-challenging exercises and activities at home as well as at subsequent sessions. The Attention Process Training (APT) exemplifies cognitive exercises that are designed to remediate and improve attentional systems (Sohlberg & Mateer, 2001). These treatment activities are “drill and practice” oriented and targeted to stimulating isolated components of attention (Sohlberg & Mateer, 2001). Table 29-2 lists other examples of using worksheets and tabletop tasks to improve attention.

Computer-Based Exercises

Computer-based cognitive remediation optimizes the ability to provide repetition and consistency of administration of cognitive stimuli (Fig. 29-2) (Goldstein et al., 1996; Lynch, 2002). Computer-based activities can serve as an effective adjunct to the clinic-based intervention by

Task description: <i>check writing worksheets</i>		
Session date: <i>10/20</i> Time of day: <i>10 a.m.</i> Location: <i>O.T. clinic</i>		
Target behavior	Tally: The frequency of behaviors	Comments/observations: Describe performance antecedents or patterns
♦ Off Task - a break in ability to maintain attention (internal)	<i>3</i>	<i>Occasionally D.B. simply stopped working + didn't restart until therapist offered specific cues</i>
♦ Off Task - in response to an interruption (external source)	<i>5</i>	<i>Pt chose to sit near entrance to clinic - looked away from work every time someone entered</i>
♦ Accuracy rate	<i>62 %</i>	<i>Accuracy improved mid-task w/ therapist reinstruction</i>
♦ Performance time	<i>Total work time - 18 minutes</i>	

Figure 29-1 A work sheet is used to record observations during performance of cognitive retraining activities.

Table 29-2. Examples of Ways to Circumvent Cognitive Impairment and Inefficiency		
Technique or Strategy	Description of Its Use	Means by Which It Minimizes Demands on Internal Information Processing
Establish a behavioral routine	Tien proceeds down her checklist of hygiene activities each morning, confident that she has not forgotten an important step.	As consistent repetitions of this sequence accrue, the activities become increasingly automatic, placing less demands on attention and memory.
Change the context	Anton's mother sets out his clothing each evening so that he can easily determine what to put on the next morning.	Removes need to locate clothing and make determinations about what to wear, what articles match, and how recently the combination has been worn.
Learn compensatory strategies: day planner	Kara writes down all of her appointments and tasks in function-specific sections of the planner. She brings the planner with her and then places it in a consistent location at home for easy access. She carries out a formal planning procedure each day to add information and review previous entries.	Allows for reliable storage and retrieval of information while placing minimal demands on memory.
Learn compensatory strategies: alarm watch	As part of her daily planning routine, Maya sets her alarm watch as a prompt to carry out time-specific tasks. For example, by setting the alarm to go off 30 minutes before she needs to leave for an appointment, Maya finds that she is no longer late.	Minimizes need for ongoing attention to the passage of time by prompting the individual to take action (such as checking his or her planner) at a specific time.
Learn compensatory strategies: "divide and conquer"	James often avoided unstructured projects because he felt overwhelmed without an obvious sequence of steps. However, by using a "divide and conquer" worksheet, he is able to create and then follow his own written step-by-step instructions.	Provides a means by which a person can "dump" all of his or her ideas out of working memory onto paper rather than trying to internally manipulate information.

extending training into the home. Specialized or commercially available software offer the opportunity for structured, monitored, and engaging home repetition (Lynch, 2002). Specialized cognitive remediation software, such as Captains Log (Resources 29-1), offers evaluation and treatment modules that target underlying cognitive capacities, such as attention and memory. They use a combination of graded, game-style, attention-

friendly activities. One activity, for example, requires the patient to scan the screen from left to right and top to bottom and respond each time a target that is the same color as the border appears. The speed and length of presentation progress as the patient improves task performance. Specialized cognitive rehabilitation software often collect data on patient performance, such as speed of response and accuracy over trials. This may be a desired feature for tracking progress and offering feedback and may not be available with commercially available computer games. It is advisable to select software with an option for independent practice. Commercial computer games also stimulate attention, memory, and processing speed at a more affordable price

Figure 29-2 Computer-based cognitive remediation allows for extensive rehearsal and repetition.

Effectiveness of Cognitive Remediation

Proponents of this approach suggest that remediation that targets specific cognitive deficits enhances the biological recovery mechanisms during acute recovery from brain injury and facilitates functional reorganization of the brain regardless of the time post injury (Sohlberg & Mateer, 1989). Unfortunately, neither claim has been well supported empirically, and a definite link has not been established between improvements in specific cognitive capacities and functional performance (Carney et al.,

A growing number of internet sites are devoted to providing information, resources, and devices for persons with cognitive disabilities. Examples include:

- <http://www.bindependent.com/>
- http://www.heath.gwu.edu/links/general_organization_Links.htm
- <http://www.familyvillage.wisc.edu/index.html>

1999; Malec & Basford, 1996). Some evidence, however, correlates drill and practice in areas of attention and memory with improvement in these areas on neuropsychological testing (Carney et al., 1999).

Based on their review of studies of outcomes after acute brain injury, Malec and Basford (1996) suggested that there may be secondary benefits from a remedial approach. They posited that it may facilitate the patient's initial acceptance that a problem exists and promote improved awareness of deficits (Procedures for Practice 29-1). Similarly, Gianutsos (1992) suggested that therapy should begin with remediation as the goal "even if that goal is remote" (p. 27) because, if the patient is satisfied that every attempt was made to restore function, he or she may be more inclined to work on compensating for the deficit.

Adaptive Therapy

As previously mentioned, adaptive therapy is characterized as intervention aimed at circumventing impairments and inefficiencies through changes in context, habits and routines, and strategies. These three synergistic focuses of intervention are based on what we describe as cognitive ergonomics, that is, use of human information-processing principles to decrease the demands on working memory.

Change the Context

When intervention centers on changing the context, the therapist or family makes changes that lower the cognitive demands placed on the patient to optimize his or her suc-

PROCEDURES FOR PRACTICE 29-1

Helping Patients Improve Self-Awareness

Occupational therapists use a variety of techniques to help patients become more aware of their cognitive strengths and weaknesses:

- Appreciate the different contributions of organically based unawareness and adjustment-based denial. Anticipate that sometimes, as patients become more aware of impairments, they may feel emotional distress, including depression and anxiety (Fleming & Strong, 1995).
- Recognize levels of awareness and focus intervention on helping the patient move up the hierarchy (see Chapter 9). For example, therapists try to help patients who are unaware of their cognitive impairments first to develop intellectual awareness of the problem and then to progress toward emergent or anticipatory awareness (Crosson et al., 1989).
- Create opportunities for the patient to monitor and judge his or her own performance, analyze the results, and determine what to continue or do differently next time. Dougherty and Radomski (1993) recommended a graded approach to performance analysis that consisted of three levels: (1) using an answer key to self-correct, (2) answering multiple choice questions about various aspects of performance after performing the task, and (3) making predictions about performance ahead of time, comparing actual performance to predictions, and determining how to modify performance in the future.
- Introduce therapeutic structured failure when appropriate. That is, do not interfere with the natural consequences of the cognitive impairment during selected supervised activities. For example, if the patient fails to initiate a cognitive compensatory strategy in response to general or specific cues, do not provide further instruction but rather create an opportunity for the patient to observe what happens when the strategy is not used.
- Collaborate with family members to provide feedback. Some family members should focus on maintaining harmony in the household and appropriately prefer that the therapist assume the responsibility of providing any negative feedback to the patient. In other cases, family members or coworkers are so afraid of offending or discouraging the patient that they insulate the patient from any and all challenges or avoid mentioning errors and, as a result, deprive him or her of information that might improve self-awareness.
- Respect the patient's readiness to participate in therapy. Avoid badgering the patient into improved awareness of deficits by maintaining a therapeutic partnership so that he or she will want to return for services in the future.

cess in carrying out tasks (Procedures for Practice 29-2). That is, the client is not expected to change, but the physical properties of the context or social expectations do. This strategy is particularly appropriate for persons suffering from a dementia.

Physical Context

In manipulating the physical context, the therapist looks for ways to use the physical properties of the space to provide information or cues. For example, needed items are strategically placed so as to attract the patient's attention. Drawers can be labeled to help the patient locate items, or important information is positioned so that the patient will see it often (Fig. 29-3). The physical space may also be altered to minimize its stimulus-

PROCEDURES FOR PRACTICE 29-2

Changing the Context

Suggestions for changing the physical context include the following:

- Place the notebook open to today's page in a consistent spot on the counter.
- Use a large wall calendar so all family members can check for needed information.
- Place items in consistent places by using hooks or baskets as receptacles.
- Install a range timer set at a 30-minute delay. The stove will automatically turn off after 30 minutes, eliminating the risk of forgetting to turn a burner off.
- Remove clutter to minimize the stimulus arousal properties of work space.

Suggestions for changing the social context include helping family members do the following:

- Shift roles. The spouse may fill out the schedule each day before leaving for work. The patient's responsibility may be to refer to the schedule regularly and retrieve the information at the correct time. The expectation that the patient will record information on the schedule has been eliminated.
- Simplify tasks so that the patient can participate. For example, setting out supplies for an activity decreases the memory and problem-solving demands on the patient.
- Wait to pass on schedule or to-do information until the patient is seated with paper and pen in hand to maximize the opportunity for the patient to initiate note taking. Sometimes family members benefit from recognizing their contribution to a forgetting error, such as passing on the time of an appointment to the patient who is cooking dinner.

Figure 29-3 A, B. Simple changes in the kitchen let a person with cognitive limitations easily find important information.

arousal properties. Items that provoke distraction or worry, such as the mail or unpaid bills, are stored so that the patient will not see them when attempting to concentrate on other tasks. Finally, demands of the physical context can be lowered through use of tools and appliances that eliminate memory requirements by, for example, turning themselves off.

Social Context

Therapists also focus on teaching the family members to set the stage for the client's success. This may mean temporarily or permanently changing roles and responsibilities in the family and learning to capitalize on the client's strengths. Consider the patient who loves to cook but whose memory and judgment problems make this an unsafe activity. The family members understand the patient's limitations and adapt their approach to cover what is difficult, such as remembering to gather the correct ingredients, but facilitate what the patient can do, such as measure and mix. The patient's cognitive abilities

are also optimized as families learn appropriate ways to offer prompts and cues (Procedures for Practice 29-3). See Procedures for Practice 29-4 for examples of how changing the context can be used along with other approaches.

Establish Behavioral Routines and Habit Sequences

Automatic **habits** and **routine** enable us to carry out many of our everyday tasks with little or no mental energy, freeing us to think and react to new events in the environment (Jog et al., 1999). For example, we employ consistent and specific procedures for frequently performed activities such as showering, brushing our teeth, and shoe tying, rendering them effortlessly accurate as we deploy our mental resources for mulling over the events of the day ahead. Illness, disability, aging, and life changes disrupt long-standing habits and routines (Dyck, 2002; Wallenbert & Jonsson, 2005). As a result, previously simple activities become taxing and time consuming. The loss of effortless predictability in one's performance has a

PROCEDURES FOR PRACTICE 29-3

Graded Cues

Graded or vanishing cues are used in cognitive rehabilitation to enable the patient to perform tasks with the least amount of cueing (Dougherty & Radomski, 1993). The following terms (from Sohlberg & Mateer, 1989) are useful when writing goals and documenting progress.

- A general or non-specific cue alerts the patient to monitor performance. It usually takes the form of a statement such as, “You’ll need to make sure you remember to do this before our next session.” The therapist or family offers a general cue if the patient fails to recognize situational or environmental conditions that might otherwise prompt use of a compensatory strategy or behavior.
- A specific cue, which is presented if the patient does not respond to a general cue, reminds the patient he or she must act. It often takes the form of a question such as, “What do you need to do to make sure you remember to do your homework before our next session?”
- An explicit instruction, the most directive of the graded cues, is sometimes provided if the patient does not initiate the desired strategy or behavior upon first receiving a general cue and then a specific cue. For example, the patient may be asked to take out the planner and record the assignment to ensure follow-through before the next session.

PROCEDURES FOR PRACTICE 29-4

Using Multiple Approaches for Persons with Dementia

Problem to Address	Considerations	OT Approach and Interventions
Family is concerned with safety at home. Client with acute dementia wanders and he may leave the house even when others are at home.	Client is living at home with 24-hour care. Family wishes to continue home-based care. Through situational analysis, therapist observes wandering in response to the cue of the door in the kitchen.	Change the context (Silverstein, Flaherty, & Tobin, 2002): Change the environmental context. Wallpaper the door to match the walls, to eliminate the cue of the exit. This recognizes that the stimulus for the wandering behavior was noticing the door and not seeking an exit.
Early complaints of forgetting (mild dementia, early intervention). The client with early dementia frequently has decreased knowledge of new or recent events or acquaintances (Gitlin & Corcoran, 2005).	Research indicates potential benefit from cognitive rehabilitation to optimize remaining memory capacity at the early stages of the disease process (Clare et al., 2003; Gitlin & Corcoran, 2005).	Remediate: Teach a name recollection strategy to recall names of importance such as card club members. The mnemonic strategy described in Table 29-4 involves association and repetition. Encourage cognitively challenging activities such as crossword puzzles or Sudoku.
Client forgets aspects of morning hygiene routine, and others complain of offensive odor.	Developing a hygiene routine can be a strategy for creating successful caregiver interaction in harmony with the performance pattern of self-care.	Routines: Establish a morning routine supported with physical cues (such as a checklist) and set-up ritual (basket on counter for supplies) for consistent hygiene routine.
Client describes a desire to arrive at meals without others needing to remind him.	Cuing devices offer an external prompt to recall information. An alarm requires access to internal recollection to be effective. A cuing device relying only on external information would pair the alarm with a recorded message or written note.	Compensation: Caregiver programs wrist watch to ring 15 minutes before meal time. In addition to the alarm, the digital watch displays “Dining room.” The single purpose for this cue is associated with meals.

profound impact on an individual's energy level and sense of continuity, competence, and self (Charmaz, 2002).

Although the occupational therapy profession has its roots in “habit training” (Taylor, 1929; Zemke, 1994), habits and routines have only recently resurfaced as a focus of theory development and in the profession's official terminology (American Occupational Therapy Association [AOTA], 2002). Despite the reemergence of scholarly and clinical interest in habits in a number of academic disciplines, the concepts of habits and routines have not been clearly defined (Clark, 2000), and there are no evidence-based guidelines for how habits and routines are measured or reestablished in clinical practice.

Terminology

The term “habit” denotes a continuum of automatic physical, emotional, and social behaviors that become increasingly effortless with repetition within the same context (Camic, 1986; Kielhofner, 1995; Rogers, 2000). This continuum represents the spectrum of automatic human responses ranging from distinct motor sequences prompted by concrete, localized environmental stimulus cues at one extreme to less observable attitudinal or dispositional responses prompted by abstract, situational triggers at the other extreme (Bargh, 1997; Camic, 1986).

Habits and routines appear to be exemplars of the same phenomenon: goal-directed human behavior that, with enough repetition in the same context, occurs with little or no mental effort. Both are acquired through frequent repetition and activated by consistent goals, anticipated outcomes, or end states and stimulus characteristics of the context or environment (Aarts & Dijksterhuis, 2000; Wood, Quinn, & Kashy, 2002) and are regulated and influenced by culture (Ludwig, 1998). The constructs of micro-habit and routine appear to differ in terms of degree rather than substance. Micro-habits, such as the precise mechanics and sequence used to tie shoes, tend to be comprised of smaller sequences of actions (Rogers, 2000) that may be so automatic as to appear involuntary. Routines take the form of semi-automatic, context-specific scaffolding that provides order and consistency to the typical flow of tasks and activities in a person's daily life (Kielhofner, 1995) and extend through a considerable portion of time (Seamon, 2002). Consider the distinction and overlap between the following two types of habit behavior. Mr. R. always hangs his car keys on a hook near the door as he enters his home, doing so with no conscious awareness whatsoever. Even if the hook is temporarily removed, Mr. R. reaches for the hook upon entering the home despite his best intention to set the keys elsewhere. This micro-habit is embedded in his coming home from work routine, a sequence of semi-automatic tasks comprising letting out the dog, checking the answering machine, and thumbing through the mail.

Habit Learning

As discussed in Chapter 14, learning is believed to be built on two different memory systems: one is the basis of knowledge and expectation (explicit memory), and the other is the basis of non-cognitive habits and skills (implicit memory) (Mishkin & Appenzeller, 1987). Implicit memory (sometimes called non-declarative or procedural memory) refers to an unconscious change in behavior that results from previous experience (Eldridge, Masterman, & Knowlton, 2002) and is closely tied to the original learning situation and, hence, less flexibly applied to novel contexts (Reber, Knowlton, & Squire, 1996). Habit learning is a form of implicit learning (Squire, Knowlton, & Musen, 1993).

Habit learning appears to be independent of the brain structures that underlie explicit learning (medial temporal lobe and hippocampus) (Eldridge, Masterman, & Knowlton, 2002) but instead relies on the basal ganglia, a collection of nuclei deep in the white matter of the cerebral cortex. It is widely accepted that the basal ganglia are involved in motor programming, execution, and control (Krebs et al., 2001; Wu, Kansaku, & Hallett, 2003). Findings from recent animal and human research, however, suggest that the basal ganglia also mediate the formation of habits through stimulus-response associations that are incrementally acquired (Packard & Knowlton, 2002).

Mechanism Underlying the Automaticity of Habits and Routines

The term “automaticity” refers to the ability to perform a skilled task with minimal or no processing resources (Brown & Bennett, 2002). It describes the phenomenon that accounts for the fact that, with enough practice in a consistent setting, features of the environment trigger habits without any mediation by conscious choice or reflection (Bargh, 1997; Logan, 1988a). Instance theory (Logan, 1988a, 1998b; Logan, Taylor, & Etherton, 1999) suggests that each encounter with a stimulus is encoded, stored, and retrieved separately. That is, each processing episode consists of the goal the person is trying to achieve, stimuli encountered in pursuit of the goal, interpretation of the stimuli, and the responses made to the stimuli (Logan, 1988a), and each episode results in a new trace stored in memory (Logan, Taylor, & Etherton, 1999). Instance theory suggests that, when the person subsequently encounters the stimulus, his or her response will be the result of a race between memory retrieval and algorithmic computation and whichever “wins” controls the response (Logan, 1988a). As more and more processing episodes are encountered, stored, and activated, performance is less often controlled by algorithmic computation (whose finishing time remains fixed) and increasingly based on single-step direct access retrieval of prior solutions from memory (whose finishing time decreases with

repetition) (Logan, Taylor, & Etherton, 1999). Single-step retrieval, the hallmark of automatization, likely involves few resources compared with multistep algorithms, accounting for increasing ease and speed of performance with practice (Logan, 1988b). Automatization, then, is a relative phenomenon in that, while it may occur after only a few trials, it may never be complete (Logan, 1988a). Memory strengthens automaticity progressively with practice (by virtue of additional representations in memory), thus, performance may be more automatic after 100 repetitions than after 50.

Automatic behaviors such as habits are triggered and constrained by contextual features (Aarts & Dijksterhuis, 2000; Bargh & Chartrand, 1999; Gallimore & Lopez, 2002; Logan, 1988b). Ease of retrieval is a function of the similarity between encoding and retrieval contexts—the more similarity there is, the greater the ease and speed of retrieval (Logan, 1988b). The context at encoding becomes associated with the processing episode and resultant memory trace while context at retrieval serves as an important cue. That is, context- and task-relevant information are encoded together, and contextual consistencies should be strengthened with practice (Logan, 1988b). Performance of the same task in different contexts may inhibit retrieval of task-relevant information, explaining why, for example, one's morning hygiene routine is more effortful and time consuming when performed in a hotel room rather than at home.

Guidelines for Establishing Habits and Routines

Numerous case examples and single-subject research studies in the rehabilitation literature describe the use of applied behavioral analysis to establish or reestablish self-care and/or home-management routines and habit sequences for persons with cognitive impairment (Giles & Clark-Wilson, 1988; Giles & Shore, 1989a; Giles et al., 1997; Katzmann & Mix, 1994; Kime, Lamb, & Wilson, 1996; O'Reilly, Green, & Braunling-McMorrow, 1990; Schwartz, 1995; Zanetti et al., 1997). The following principles of applied behavioral analysis frame occupational therapy intervention to establish routines and habit sequences.

- With input from the patient and caregiver, the therapist selects a key behavioral sequence that becomes the target of intervention (Giles, 1998). Giles emphasized the importance of selecting behaviors and prospective routines with clinical and personal significance. Be sensitive to client readiness to address habits and routines. Wallenbert and Jonsson (2005) reported that stroke survivors may be reluctant to create new habits that they believe will preclude continued physical recovery.
- The therapist analyzes the physical and social context in which the routine or sequence is expected to occur to identify built-in cues or determine where to create

them (Schwartz, 1995). At a minimum, significant others participate in the selection of target behavioral sequences and appreciate the methods and benefits of intervention. Since routines and habit sequences are thought to be context specific, training is most effective if it occurs in the environment in which the routines will ultimately be performed (Giles, 1998).

- A task analysis is performed on the target behavioral routine or sequence (Giles, 1998; O'Reilly, Green, & Braunling-McMorrow, 1990). Task analysis involves examining each step of the task as well as the setting, stimulus events, and consequences (Gelfand & Hartmann, 1984).
- The therapist and patient decide on an optimal sequence of steps and use chaining, prompting, and reinforcement each time the sequence is performed (Giles et al., 1997). Giles et al. suggested that “[routine] tasks can be thought of as complex-stimulus-response chains in which the completion of each activity acts as the stimulus for the next step in the chain” (1997, p. 257). They also recommended the use of the whole-task method, in which each step of the chain is trained on each presentation. The therapist often creates a checklist that outlines each component of the task so that the desired sequence of steps remains invariant (Davis & Radomski, 1989) (Fig. 29-4).

For some patients, prompts and reinforcers are established. The checklist itself may be both a prompt if placed in an obtrusive location and a reinforcer as the patient checks each completed step. Technology may also be employed. Schwartz (1995) reported use of a daily tape-recorded message activated by an automatic timer that prompted initiation of a self-care routine. Wilson et al. (1997) described how NeuroPage, a time- and task-specific vibrating prompt that is described later, appeared to facilitate establishing routines related to taking medication and checklist use. Family members may also be enlisted to provide prompts and reinforcement, typically social praise. In our practice, the final step on many patients' checklists requires that they call and leave a voicemail message stating they completed the sequence as an incentive and a reinforcer of the routine.

The therapist facilitates consistent repetition of the behavioral routine or sequence beyond mastery to promote overlearning (Giles, 2005). As discussed in Chapter 14, full automaticity requires at least 200 trials of a task but begins with as few as 10 consistent repetitions (Sternberg, 1986). As the patient frequently and consistently performs the behavioral sequence, steps begin to prompt one another and may be removed from the checklist (Katzman & Mix, 1994). The therapist tracks ongoing compliance with the target behavioral sequence; monitors the patient's perceptions of ease, accuracy, and speed (evidence of increasing automaticity); and, with the

Morning planning checklist

Directions: Check-off each step after it is completed.

	M	T	W	Th	F	Sa	Su
1) After breakfast, open planner to yesterday's page.							
2) Check off all of the tasks you completed yesterday.							
3) Draw an arrow in front of undone or incomplete tasks							
4) Re-write these tasks on today's page.							
5) Move the bookmark to today's planner page.							
6) Review your schedule.							
7) Ask your wife if there are any tasks or appointments that you should write down for today.							
8) Write down at least 3 tasks you intend to complete today.							

Wind-down routine

Directions: Check-off each step after it is completed.

	M	T	W	Th	F	Sa	Su
1) When your MotivAider vibrates at 9:00 p.m, discontinue your current activity.							
2) Make notes where you left off on your project.							
3) Put on your pajamas.							
4) Brush your teeth.							
5) Wash your face.							
6) Gather your magazines and go to your recliner.							
7) Set the MotivAider for 30 minutes and peruse your reading material.							
8) When cued by the MotivAider, retire to bed.							

Figure 29-4 Checklists like these are used to help patients reestablish routines and habit sequences.

patient, determines when applied behavioral analysis methods should be employed to make another important task routine.

Whether because of damage to neural pathways or as a consequence of lack of daily consistency, many persons with cognitive impairment or inefficiency benefit from intervention focused on establishing behavioral routines or habit sequences. Most adults, however, are embarrassed to admit that they make frequent errors on tasks that are supposed to be easy and may be reluctant to bring these problems to the attention of the therapist. In our clinical practice, patients are often relieved that these errors in everyday tasks can not only be explained but also addressed.

In summary, the goal of establishing automatic behavior is to return frequently performed self-management tasks to their status as background activities in everyday life, as described so eloquently by a man with brain injury:

“Routine is a constant reference as to when and where I am. . . . Routine allows me to compensate for my lack of initiative. I may not notice that the house needs vacuuming, but I know that on Mondays I vacuum. . . . Many people view routine as boring. ‘Boring as compared to what?’ I ask. ‘Boring as compared to being confused and inactive?’. . . I get my variety because routine keeps the distractions at bay.” (Strand, 2000, p. 9)

Learn Compensatory Strategies

In addition to context-specific habits and routines, many recipients of occupational therapy services need new strategies that allow them to compensate for cognitive impairments or inefficiencies in a variety of settings. As previously mentioned, the client’s awareness of his or her propensity for forgetfulness, however superficial, is prerequisite to occupational therapy aimed at teaching the client to use compensatory strategies (Dirette, 2002). People will not bother to enter information into a memory aid for events that they expect to remember (Wright et al., 2001). If the client denies having cognitive problems, he or she will likely be unable to muster the effort and resolve that learning compensatory strategies requires.

Implicit in this approach is the expectation that the client will use compensatory cognitive strategies, such as aids, devices, and thinking techniques, in multiple contexts, and so intervention is designed to promote the likelihood of generalization. Toglia’s multicontext approach (1991, 2005) informs the intervention model adapted from Sohlberg and Mateer’s (1989) memory notebook training protocol.

Multicontext Approach

Toglia’s (2005) Dynamic Interactional Model of Cognition is based on the premise that cognition is a product of

the dynamic interaction between the person, the activity at hand, and the environment in which the activity occurs. According to this model, cognitive dysfunction results from a mismatch among personal (such as cognitive capacities or cognitive strategies), task, and environmental variables. This approach emphasizes the facilitation of client self-awareness, acquisition of new information-processing strategies, establishment of transfer criteria, and practice in the context of varied activities and environments (Table 29-3). Client-specific processing strategies are selected or designed and then practiced in a variety of graded tasks and settings. The therapist guides the transfer of learning by asking the client to employ the new strategy first on similar tasks and then in the context of those that are increasingly dissimilar (Toglia, 1991).

A General Model for Learning Cognitive Compensatory Strategies

Schmitter-Edgecombe et al. (1995) adapted Sohlberg and Mateer’s (1989) schema for memory notebook training, and this model applies to helping clients acquire and use any **cognitive compensatory strategy**. Intervention is organized around four training phases, which are anticipation, acquisition, application, and adaptation, and in addition to learning new skills, intervention is typically aimed at improving self-awareness (see Procedures for Practice 29-1).

- **Anticipation**—Through the use of homework, feedback, and possibly structured failure, clients with low insight experience the consequences of cognitive deficits to heighten motivation for treatment. Patients receive information about human information processing and possible solutions for cognitive problems.
- **Acquisition**—Through drill and practice exercises, clients learn the mechanics of using the compensatory tool or strategy. For example, with coaching and written instructions from the therapist, clients rehearse setting their alarm watches or practice filing and finding information in function-specific sections of their planners.
- **Application**—Clients use the compensatory strategy during clinic-based simulated work tasks. These tasks are designed to require use of the targeted strategy. In our practice, they consist of clerical or clinic maintenance projects or crafts. With guidance from the therapist, clients also directly apply the compensatory strategy to real-life problems at home or work.
- **Adaptation**—Once the client has experience with the strategy in simulations and real-life tasks, the strategy may be further adapted to the client’s personal preferences and the demands of additional areas of application in daily life.

Table 29-3. Components of the Multicontext Treatment Approach

Component	Definition	Example
Consideration of personal context	Gaining understanding of the client's pre-morbid personality characteristics, beliefs, valued occupations, and previous lifestyle	Interviewing the client about his or her pre-morbid everyday routines and exploring how those routines have changed after injury or illness and using this information to inform occupational therapy assessment and intervention
Awareness training	Methods designed to enhance the client's understanding of his or her strengths and limitations that are incorporated into every treatment session	<ul style="list-style-type: none"> Asking the client to anticipate and identify specific challenges or obstacles that might occur in performance of a therapy task Instructing the client to watch the therapist perform a task during which client-relevant errors are demonstrated (such as distractibility). Asking the client to identify problems and recommend strategies
Processing strategies	Small units of behavior that reflect internal or external cognitive techniques that contribute to the effectiveness of performance	<ul style="list-style-type: none"> Mental repetition, visual imagery (examples of internal processing strategies) Memory notebooks, alarm cuing devices, use of checklists (examples of external processing strategies)
Activity analysis	Identifying, manipulating, and/or stabilizing salient activity parameters (e.g., physical features, number of items, number of steps or choices involved in the task)	As part of her therapy, a homemaker who has difficulty attending to visual details locates the soup spoons in a drawer of unsorted spoons, forks, and knives. As she progresses, she will locate a set of soup spoons in a drawer of unsorted spoons of different sizes (teaspoons, soup spoons, serving spoons). Note how differentiating between spoons of different sizes requires greater visual attention than differentiating between spoons, forks, and knives.
Establishment of criteria for transfer	Identify series of tasks that decrease in degrees of physical and conceptual similarity to the original task	Task: Donning a pullover T-shirt in the therapy area
	Near transfer: only one or two surface characteristics changed	Donning a pullover sweater (color and texture different from tee shirt)
	Intermediate transfer: 3–6 surface characteristics change; tasks share some physical similarities	Donning a button-down cotton shirt in the client's room (type of clothing, color and texture, fine motor requirements, and environment changed)
	Far transfer: tasks are conceptually similar; surface characteristics are different or only one surface characteristic is similar	Donning outerwear (coat, jacket), pajamas, undershirt or camisole (different types of upper body clothing)
	Very far transfer: generalization, spontaneous application of what is learned to everyday life	Donning pants (strategy of dressing affected side first remains the same for lower body dressing)
Practice in multiple environments	Strategies are used in a variety of situations (e.g., tasks and locations) to demonstrate their applicability and utility to the client	The strategy of left-to-right scanning is practiced on letter cancellation tasks and then used to locate items in a medicine cabinet or to count books on a shelf.

An exhaustive review of all possible methods to circumvent cognitive impairments or inefficiencies is beyond the scope of this chapter. Instead, we provide an overview of three categories of compensatory cognitive strategies: internal information-processing strategies, memory prostheses, and problem-solving schemas.

INTERNAL INFORMATION-PROCESSING STRATEGIES

Occasionally occupational therapists teach patients to use mental strategies that facilitate the encoding and storage of information (Parenté & DiCesare, 1991). Theoretically, the techniques outlined in Table 29-4 enable the client to keep information in working memory and thereby facilitate encoding. Given the extensive rehearsal involved in learning these techniques, intervention based on internal information-processing strategies has similar features to a remedial approach. Most people find internal information-processing strategies time consuming to learn and inconvenient to employ. Rather than concocting a first-letter mnemonic to make sure that one purchases everything one needs at the grocery store, one simply makes a list. Internal information-processing strategies may be helpful, however, when the client needs to memorize frequently used, rarely changing information such as his or her social security number or a personal identification number.

MEMORY PROSTHESES: DAY PLANNERS

Many persons with and without memory problems use day planners to help them keep track of information. Routine use of prosthetic memory aids such as day planners, also known as diaries or memory notebooks, is frequently cited in the rehabilitation literature as a means of circumventing memory impairments and inefficiencies. For example, in a small study in which persons with severe

brain injury were randomly assigned to one of two conditions, patients receiving memory notebook training reported significantly fewer observed everyday memory failures at discharge than those receiving supportive treatment (Schmitter-Edgecombe et al., 1995). Seventy-five percent of the patients in the notebook condition were using the notebooks at 6 months of follow-up (Schmitter-Edgecombe et al., 1995). Zenicus, Wesolowski, and Burke (1990) compared the effectiveness of three memory strategies (written rehearsal, verbal rehearsal, and acronym) with notebook use in terms of clients' assignment completion rates. They found the notebook condition to be the clearly superior technique for assignment completion. In another multiple-baseline study, Zenicus et al. (1991) examined the effectiveness of memory notebook training on the ability to remember assignments and appointments in four survivors of severe brain injury. The results suggested that all four participants demonstrated improved follow-through on assignments with notebook use compared to baseline.

To use a day planner effectively to compensate for cognitive impairment or inefficiency, the user must religiously record important information in the appropriate notebook sections, carry the planner about, and look at it regularly during the day. Despite the appearance of an easy, straightforward method to compensate for memory problems, successful intervention is often time consuming. Schmitter-Edgecombe et al. (1995) described an 8-week protocol of 16 sessions, and Donaghy and Williams (1998) used a 9-week protocol of 27 sessions for patients with brain injury to learn to use memory aids of this nature. Good outcome also appears to be linked to patient characteristics, such as strong motivation, some degree of insight, and absence of aphasia and motor deficits that interfere with handwriting (Donaghy & Williams, 1998).

Table 29-4. Internal Compensatory Strategies

Technique	Description
Rehearsal	Patient repeats the information to be remembered out loud or to self.
Visual imagery	Patient consolidates information to be remembered by making a mental picture that includes the information (e.g., to remember the name <i>Barbara</i> , the patient pictures a barber holding the letter A).
Semantic elaboration	Patient consolidates information by making up a simple story (e.g., patient who has to remember the words <i>lawyer</i> , <i>game</i> , and <i>hat</i> develops a sentence such as "The lawyer wore a hat to the game").
First-letter mnemonics	Parenté's NAME mnemonic adds rules to observing features and drawing associations when remembering names: N otice the person with whom you speak, A sk the person to repeat his or her name, M ention the name in conversation, and E xaggerate some special feature.
PQRST rehearsal method	Patient: (1) P reviews (skims the material for general content), (2) Q uestions (asks questions about the content), (3) R eads (actively reads to answer the questions), (4) S tates (rehearses or repeats the information read), and (5) T ests (tests self by answering the questions).

Information from Malec & Questad, 1983; Milton, 1985; Wilson, 1982; Parenté & Herrmann, 2002.

Figure 29-5 Use of function-specific portions of the planner page helps the patient organize notes about the day.

Patients may purchase commercial day planners or obtain them from clinicians who create computer-generated forms and calendars (Fig. 29-5). Day planners are composed of a limited number of function-specific sections such as daily log, assignments and appointments, current work, and long-term information (Dougherty & Radomski, 1987). Table 29-5 summarizes the treatment protocol used at the Brain Injury Clinic at Sister Kenny Rehabilitation Services in Minneapolis. Treatment addresses only learning objectives that are appropriate for the individual and incorporates other compensatory cognitive strategies, such as use of alarm cueing devices, checklists, and problem-solving schemas.

Table 29-5. Example of a Compensatory Strategy Training Protocol Used in the Outpatient Brain Injury Clinic at Sister Kenny Rehabilitation Institute

Sample Long-Term Goals	
<ol style="list-style-type: none"> 1. The client will be able to accurately and efficiently file and locate information in his or her planner. 2. The client will be able to get to appointments and complete intended tasks on time through use of compensatory cognitive strategies (such as planner, daily/weekly planning checklists, and alarm watch). 3. Through use of compensatory cognitive strategies, the client will be able to carry out routine personal, household, and work tasks accurately and efficiently without omissions or repetitions. 4. The client will initiate note taking at such times and in such ways that information stored in and retrieved from the planner is accurate and meaningful upon later reference. 5. The client will be able to carry out novel, multistep tasks through employment of compensatory cognitive strategies. 	
Training Hierarchy and Sample Short-Term Goals	
<i>Learning objective</i>	<i>Client learns to:</i>
Information retrieval	Select and obtain an appropriate planner, with assistance of therapist. Locate information in function-specific notebook sections. Use written instructions to set an alarm cueing device. Refer to time-specific entries in the planner in response to the alarm. Use asterisk recorded by therapist to prompt reference to other sections of the planner.
Basic planning	Use a checklist to regularly engage in daily and weekly planning. Create daily to-do lists that reflect realistic scheduling and prioritization. Recognize situations in which time-specific prompts would be of help and initiate alarm settings that are pertinent to daily schedule.
Basic information entry	Record appointments, to-do's, and lists in the correct sections of the planner. Initiate use of an asterisk on daily planner pages to cross reference to other planner sections. Routinely use the following note taking mechanics: include date and topic, organize notes by steps or points, check off completed steps or tasks, orally verify accuracy after recording notes.
Complex information entry	Use "People Logs" to record information pertaining to conversations with significant people. Use the main idea/example mnemonic as a means of keeping track of what he or she wants to say during a discussion. Use a tape recorder in conjunction with note taking and identify situations when use of this combination would be most appropriate. Use customized forms to record information pertaining to specific work or household situations.
Complex planning	Analyze long-term projects or tasks in terms of a breakdown of sequential steps. Incorporate project plans and goals into the weekly planning process.

MEMORY PROSTHESES: DEVICES

Alarm watches, pagers, and palm-top computers are often used in conjunction with or as an alternative to day planners (Lynch, 1995). A variety of devices may also be used to minimize cognitive burden (see Resources 29-1), including those that help individuals manage their medications (Fig. 29-6). Giles and Shore (1989b) described the successful use of a Psion Organizer, a palm-top computer, by a woman with acquired brain injury. Among other features, this device provides time-specific prompts for information related to schedule, appointments, and tasks. With 4 hours of therapy and 6 hours of supervised practice with family, this patient with memory impairment but normal intelligence could independently program the device, and she preferred it to a day planner because of its alarm functions. Kim et al. (1999) also used a Psion Organizer but with an inpatient with severe cognitive impairments. Staff programmed the schedule and alarms into the device; it improved the patient's punctuality at therapy sessions and, after 5 days, was effective in prompting the patient to take medications. Wilson et al. (1997) conducted a study using NeuroPage, more recently called LifeMinder, with 15 neurologically impaired subjects, all of whom had significant everyday memory impairment or problems with planning and organization. NeuroPage is a simple portable paging system with a screen that can be attached to a belt (Hersh & Treadgold, 1994). It uses micro-computers linked to conventional computer memory and a paging company. Information about the patient's schedule is entered into the computer, and on the appropriate date and time, NeuroPage accesses the user's data files, determines the reminder to be delivered, and transmits the information (Wilson et al., 1997). These researchers reported that all 15 subjects benefited from the pager and showed signifi-

cant improvement on task follow-through. Furthermore, even when the pager was removed after 3 months, some subjects were able to maintain the routines initially prompted by the device, such as taking medication on time and using checklists. Wilson et al. (2001) found similar benefits of NeuroPage in the completion of everyday tasks in a larger study involving 143 participants with memory and planning deficits (ages 8–83 years). Pre-programmed electronic memory aids have also been demonstrated to help outpatients with mild to moderate dementia remember to do time-specific tasks, significantly more so than use of written lists or trying to recall without any memory aid (Oriani et al., 2003).

CONSIDERATIONS FOR SELECTING CLIENT-SPECIFIC MEMORY AIDS

Clinician preferences and competence seem to influence the type of memory aid that therapists recommend for their clients. In a study of 94 people with brain injury, Evans et al. (2003) found that most subjects used calendars, wall charts, and notebooks, but only 7.4% used an electronic device as a memory aid. Many experts suggest that despite clients' motivation to use high-tech devices (Wright et al., 2001), electronic memory aids may be under used because clinicians do not have a good working knowledge of these devices (Evans et al., 2003) and lack confidence in guiding clients to use them (Hart, O'Neil-Pirozzi, & Morita, 2003).

Client factors, not clinician preferences, are the most important determinants in the selection of the memory aid. In addition to at least superficial awareness of deficits, premorbid use of memory aids is predictive of effective use of memory aids after acquired brain injury (Evans et al., 2003). In their study of 101 people with acute brain injury, Evans et al. also found that age, time since injury, and attentional ability were important predictors. The younger the person was, the more likely they were to use memory aids, possibly because of their necessity relative to return to work. In this study, the longer the time since injury, the less memory aids were being used. Finally, attention and speed of information processing proved to have a strong relationship with the use of memory aids, possibly because of the importance of attention in the process of learning to compensate for persisting deficits.

The use of electronic aids may place even greater demands on learning than low-tech aids such as day planners. Giles and Shore (1989b) recommended that good candidates have average or nearly average intelligence, retained or mildly impaired reasoning skills, insight into deficits, adequate ability to initiate behavior, and some form of functional disorder resulting from significant memory impairment. Many electronic memory aids require that clients carefully follow multistep instructions for inputting information, and clients may be at risk of

Figure 29-6 A variety of medication containers facilitate compliance with medication regimens.

losing information because of error or system shutdown. Electronic memory aids, however, typically offer one important feature not available in low-tech (notebook) alternatives—time-specific auditory or vibrating prompts. An alarm watch, for example, can be set to remind the client to take his medication, check his day planner, or leave home for an appointment. Therefore, many clients benefit from a memory aid system involving both a day planner and some sort of time-specific alarm prompt, especially when caregivers or family members of persons with severe impairment assume responsibility for programming the device.

PROBLEM-SOLVING AND DECISION-MAKING SCHEMAS

The enterprise of human problem solving is thought to be comprised of the situation (a conglomeration of task, environment, and person variables) and process (problem definition, evaluation of alternative solutions, determining and implementing a plan, and evaluating the results) (Radomski, 1998). The demands on problem solving can sometimes be minimized by changing the environment, establishing consistent routines, or employing problem-solving schemas. Means–ends analysis and the IDEAL Problem Solver (Bransford & Stein, 1984) are examples of these schemas.

Means–ends analysis, which is known to our patients as divide and conquer, is used to organize multistep, unstructured projects—those that have no obvious first steps and that can be carried out in any number of ways. It entails a four-step process:

1. List the major task components.
2. Under each component, write down all the substeps you can think of (in no particular order).
3. Number the substeps.
4. Decide on deadlines if desired (Fig. 29-7).

The IDEAL Problem Solver was developed for a college course in which students learned problem-solving techniques, learned about the process of solving problems, and uncovered their own strengths and weaknesses in this realm (Bransford & Stein, 1984). The IDEAL acronym stands for the five steps of problem solving: I, Identify the problem; D, Define the problem; E, Evaluate all possible solutions; A, Act; and L, Look back.

Although problem-solving schemas are useful because they are applicable to a wide range of situations, they place much greater demands on patients' metaprocessing abilities (executive functions and metacognition) and require much more training time than simply changing the environment or establishing a routine (Radomski, 1998). Sternberg (1987) questioned whether a program of less than a semester would be adequate for teaching college students to learn and use problem-solving schemas, and

therefore, occupational therapists are advised to be selective in using this approach in treatment.

EVIDENCE AND GUIDELINES IN COGNITIVE REHABILITATION

As an emerging, multidisciplinary practice area, cognitive rehabilitation has been praised and criticized (Ylvisaker, Hanks, & Johnson-Greene, 2002). Questionable practices involving unsystematic exposure of clients to video games, cognitive retraining software, or workbooks have prompted skepticism and ethical questions about the efficacy of cognitive rehabilitation intervention (Ylvisaker, Hanks, & Johnson-Greene, 2002). Recent systematic reviews of cognitive rehabilitation research, however, enable clinicians to use evidence to shape intervention plans (Cappa et al., 2003; Cicerone et al., 2000, 2005).

The Brain Injury Interdisciplinary Special Interest Group of the American Congress of Rehabilitation Medicine (ACRM) conducted two evidence-based reviews involving cognitive rehabilitation research published through 2002 (Cicerone et al., 2000, 2005). Based on the strength of the research design and study findings, Cicerone et al. developed practice standards (interventions with *substantive* evidence of effectiveness), practice guidelines (interventions with evidence of *probable* effectiveness), and practice options (interventions with evidence of *possible* effectiveness). A panel of experts from the European Federation of Neurological Societies conducted a similar review with findings consistent with that of ACRM (Cappa et al., 2003). Clinicians who serve clients with cognitive impairments are advised to read these important reviews in detail, but here are some of the central findings:

- Strategy training to address attentional deficits is recommended for outpatients in the post-acute phase of recovery (Practice Standard), but there is insufficient evidence to support it during the acute or inpatient phases (Cappa et al., 2003; Cicerone et al., 2000, 2005).
- Compensatory training is recommended in which the use of notebooks, electronic devices, and internal strategies are directly applied to functional situations (Practice Standard) (Cappa et al., 2003; Cicerone et al., 2000, 2005).
- Training in which problem-solving strategies are applied to functional situations is recommended during post-acute rehabilitation (Practice Guideline) (Cicerone et al., 2005).
- There is no evidence for effectiveness of intervention to restore memory function in persons with severe impairment (Cappa et al., 2003).

Project title: Clean the garage

ORDER	STEPS	COMPLETION DATES
	Remove the debris	
4	Collect items for recycling	9/4
5	Bring to recycling center	9/4
2	Collect trash	9/1
1	Purchase large trash bags	9/1
6	Bring unwanted items to thrift store	9/4
	Clean the floor	
12	Get everything off the floor	9/10
13	Sweep	9/10
14	Rinse down the floor	9/10
15	Put everything back	9/10
	Organize storage	
3	List the items I plan to store	9/1
7	Decide on what add'l storage is needed	9/5
8	List supplies needed + measurements	9/5
9	Purchase supplies	9/5
10	Install	9/5
11	Put items away	9/5

Figure 29-7 Means–ends analysis (also known as divide and conquer) helps patients break large, unstructured projects into a sequence of steps: (1) List major task components (shaded boxes). (2) Write down substeps under each task component in no particular order. (3) Number the substeps. (4) Set completion dates if desired.

- Sole reliance on repeated exposure and practice on computer-based and workbook tasks without involvement of the therapist is not recommended (Cicerone et al., 2000, 2005).

In summary, when planning intervention to optimizing clients' cognitive function, occupational therapists develop intervention plans involving multiple approaches. Ylvisaker, Hanks, and Johnson-Greene (2002) describe this as a "contextualized approach" to cognitive rehabilitation.

This paradigm up-ends the traditional intervention sequence (reduction of impairments followed by compensatory training) by either using remedial and adaptive approaches simultaneously or in reverse. Clinicians may begin with intervention aimed at enabling participation by changing the environmental or social supports followed by reducing disability through compensatory training and ultimately reduce the cognitive impairment with internalization of well-rehearsed strategies and behaviors (Ylvisaker, Hanks, & Johnson-Greene, 2002).

Evidence Table 29-1 Best Evidence for Interventions Used in Cognitive Rehabilitation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Computer-aided retraining of memory and attention	All participants received individualized intervention based on a computer training program entitled, RehaCom. The experimental group performed memory and attention procedures; the control group performed visuo-constructional and visuomotor re-training procedures.	77 adult outpatients with multiple sclerosis who had complaints of poor attention and memory, which were confirmed by neuropsychological testing (mean age = 44 years).	All subjects participated in training for 45 minutes, twice a week for 8 consecutive weeks.	Randomized double-blind controlled trial. Level IB1a (moderately sized groups)	Negligible benefit. No group differences in any of the 8 neuropsychological measures of attention or memory except for word list generation.	Word list generation at 8 weeks ($p = 0.016$, $r = 0.24$) and 16 weeks ($p = 0.035$, $r = 0.20$).	Solari et al., 2004

continued

Evidence Table 29-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Change the context (social, environmental)	All participants received OT assessment within the home. Treatment group received a second home visit, at which time OT recommendations regarding caregiving and environmental modifications were reviewed with caregiver. A written report was also provided. Control group received no further contact during the study but received a copy of written recommendations after the study was over.	40 adults diagnosed with probable Alzheimer's disease and their 40 caregivers (mean age = 77.08 years for those with Alzheimer's disease).	2 at-home sessions (1 assessment, 1 30-minute session to review recommendations).	Pre-test-post-test control group design (random assignment). Level IB2a (small number of subjects per group, unblinded)	Yes. The persons in the treatment group realized improvements in quality of life.	Significant MANCOVA main effect for caregiver burden, positive affect, activity, and self-care status for treatment group. $F_{(4,31)} = 7.34, p < .001$, effect size (eta squared) = .49.	Dooley & Hinojosa, 2004
Learn cognitive compensatory strategies	The treatment group received memory notebook training; subjects in the comparison group participated in supportive group therapy.	8 participants who were at least 2 years post traumatic brain injury (4 subjects per group); mean age = 28 years.	Two 60-minute sessions per week for 8 weeks.	Pre-test-post-test control group with randomized assignment. Level IC2a (small numbers of subjects in groups, unblinded)	Yes. Decrease in observed everyday memory failures for treatment group at post-test (but not at 6-month follow-up).	Observed everyday memory failures ($F_{(1,5)} = 7.15, p < 0.05, r = 0.77$)	Schmitter-Edgecombe et al., 1995

SUMMARY REVIEW QUESTIONS

1. Describe diagnoses of patients who are likely to have organically based cognitive impairments. What types of circumstances or conditions result in cognitive inefficiency?
2. Analyze the relative costs and benefits of a remedial approach to cognitive problems versus an adaptive approach.
3. How would your efforts to optimize cognitive function be different for a person with Alzheimer's disease compared with a patient in acute recovery from a traumatic brain injury?
4. Write down the steps to one of your daily routines or habit sequences. Now change the order of steps and, next time, try to follow this revised sequence. How do the attentional requirements change? How do these changes impact your speed of performance?
5. Describe three changes you could make to your own living environment to decrease its cognitive demands.
6. What cognitive compensatory strategies, if any, are a part of your information-processing repertoire?
7. Consider practices or habits that optimize your memory performance and ability to concentrate, plan, and problem solve. How might these same strategies be used by an individual with cognitive impairment?

ACKNOWLEDGEMENT

We appreciate Cathy Trombly's assistance in calculating the effect sizes included in Evidence Table 29-1 in this chapter.

CHAPTER 30

Restoring the Role of Independent Person

Anne Birge James

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the use of occupation-as-end as a therapeutic medium.
2. Distinguish between basic activities of daily living and instrumental activities of daily living.
3. State principles to restore adapted function to persons with various functional limitations.
4. Modify tasks and the environment to promote independence.
5. Prescribe and evaluate the use of assistive devices to promote safe independence.
6. Guide problem solving and implementation of solutions to unique situations for persons with a variety of functional limitations.

Glossary

Glossary

Active learning—A process in which a learner is engaged physically and/or cognitively in a learning task. Learners are engaged in finding a solution to a problem (for example, identifying three ways cooking can be modified to save energy) and/or engaging in actual practice of the solution (for example, practicing putting on a sock with a sock aid).

Adaptation—Process of learning to function in an environment. Occupational therapists enable that process by modifying a task, the method of accomplishing the task, and/or the environment to promote independence in occupational functioning.

Blocked practice—Practice consisting of drills that include many repetitions of the same task performed in the same way (Schmidt & Lee, 2000).

Random practice—Practice of several related tasks within one session; sequence of tasks varies randomly (Schmidt & Lee, 2000).

Self-efficacy—The judgments people have of their capabilities to do or learn a task (Gage & Polatajko, 1994). Self-efficacy is task specific and is dependent, in part, on an individual's past experience with a task or similar tasks.

Shaping—A behavior modification technique in which, at first, any approximation of the desired behavior is rewarded. As the person is able to produce the behavior consistently, only the next higher level of performance is rewarded and so forth until the desired behavior is performed consistently well. Rewarding feedback is then faded.

Task parameter—A property or characteristic of a task that can be measured and addressed in treatment. Independence is the most commonly used parameter, but other parameters might include duration of task, quality of performance, and level of fatigue resulting from task performance.

People who are satisfied with their life roles have the resources and capabilities needed to accomplish their everyday tasks, whether or not they actually perform the task themselves. Self-maintenance roles include participation in activities of daily living (ADLs) (Trombly, 1995). The occupational therapist is the rehabilitation specialist responsible for teaching the patient to accomplish these tasks. The assumption is that people want to care for themselves to the best of their ability. This may include directing and/or delegating to others tasks that are beyond the person's capabilities.

The term *basic activities of daily living* (BADLs) is synonymous with self-care. BADL include feeding, grooming, dressing, bathing, toileting, bowel and bladder management, personal device care, sexual activity, functional mobility, sleep/rest, and eating (chewing, swallowing) (American Occupational Therapy Association [AOTA], 2002). These universal tasks are necessary to maintain health. The first eight BADLs are included in this chapter. Functional mobility, including bed mobility, transfers, and wheelchair mobility, is addressed in Chapter 31 and chewing and swallowing are addressed in Chapter 48. Although every human engages in most or all BADLs to some degree, the way that each is done and the importance attached to each differs culturally. BADL is the focus of most insurance coverage for rehabilitation. Baseline measures and examination of progress is documented by such evaluative measures as the *Functional Independence Measure (FIM)* (see Chapter 4).

Suggesting that a person is independent in self-maintenance if they can complete their BADLs gives a false impression of independence. People can be independent in BADL but unable to live without assistance. True independence also requires participation in *instrumental*

activities of daily living (IADLs), including but not limited to management of one's own medications, food, shelter, and finances; caring for other people or pets; communication device use; and community mobility (AOTA, 2002). IADLs include a range of diverse tasks that often require greater interaction with the physical and social environments and may have more demanding physical and/or cognitive demands than BADLs (Rogers & Holm, 2003).

OCCUPATION-AS-END

When remedial therapy can correct performance skills/patterns or client factors that interfere with ADLs, patients are often able to resume meaningful tasks and activities as they become able. Intervention that targets ADLs directly is necessary for those who do not regain full capabilities or prefer not to engage in remedial therapy. Occupation-as-end is an intervention focused on learning how to accomplish the activities and tasks that constitute roles in an adapted way (Trombly, 1995). The therapist can employ a modification approach that enables patients to accomplish their everyday tasks by changing the task and/or environment and providing appropriate patient and/or caregiver education (Holm, Rogers, & James, 2003). The modifications recommended by the therapist may be aimed at the patient and/or the caregiver (Chen et al., 2000). Intervention is frequently aimed at improving independence in ADL, that is, the person's ability to complete the task without assistance from others. Intervention, however, may also be used to address other important **task parameters**, including safety and adequacy conditions, such as perceived difficulty or ease of

performance, pain, fatigue or dyspnea precipitated by activities, length of time to complete a task, and the ability to complete tasks in a way that meets personal and societal expectations (Holm, Rogers, & James, 2003). For example, a patient with rheumatoid arthritis may be independent in cooking but may experience significant pain that makes her unwilling to engage in the task. The therapist may instruct her in the use of adapted methods of cooking that protect painful joints to help her cook both independently and without pain.

The extent and focus of services offered to a particular patient depends on the person's motivation and the level of independence he or she needs. The patient's perceptions of ADL capabilities may differ from those of staff (Atwood, Holm, & James, 1994) and affect the patient's investment in treatment. Use of an instrument such as the *Canadian Occupational Performance Measure (COPM)* or the *Melville-Nelson Self-Identified Goals Assessment* (<http://www.meduohio.edu/allh/ot/melville/siga.html>) can identify patients' perceptions, values, and goals. Independence in BADL may be sufficient for a person returning to a sheltered and supportive living situation in which IADL needs are few and willingly assumed by others, but it is never enough for a person who expects to reintegrate into community life. This person not only must learn solutions to BADL and common IADL tasks but also must learn to identify and solve problems that prevent accomplishment of unique tasks. On the other hand, independence in only one activity, such as transferring or toileting, may determine whether discharge is to home or an institution. Therefore, full effort should concentrate on achievement of this goal for a person who has otherwise limited potential for full independence.

Intervention by occupation-as-end, then, is a compensatory approach that uses education of adapted methods, assistive technology, and **adaptation** of physical and/or social contexts to enable people to participate in desired roles with a permanent or temporary disability.

EDUCATION

In the modify approach, the therapist is teacher, and patient and caregivers are learners. Both teaching and learning are active processes. The patient must be motivated to learn and must be able to learn. Assessing a client's readiness to learn can help the therapist select appropriate tasks and educational methods to maximize client outcomes.

Readiness to Learn

Patients' **self-efficacy** can have a significant impact on learning and can be evaluated and addressed in the context of ADL intervention. Self-efficacy is defined as the judgments people have of their capabilities to do or learn

a task (Gage & Polatajko, 1994). Self-efficacy has been demonstrated to be positively related to actual performance and helps people to persist in tasks, even when faced with tasks that are difficult or new (Gage & Polatajko, 1994). Persons with a new disability may have low self-efficacy for engaging in ADL because they lack experience with their limitations in the context of familiar tasks. Self-efficacy can be measured by asking patients to predict their performance on a given task using a Likert-type scale (e.g., 1 = very unlikely to learn this task, 5 = very likely to learn this task). A baseline self-efficacy measure can be used to determine the need for intervention to address self-efficacy along with the ADL skills training to enhance goal achievement.

Depression is another factor that can impede learning and occurs concurrently with a wide variety of physical disabilities. Depression has been demonstrated to have a negative relationship with functional outcomes for clients with varied physical disabilities, e.g., stroke (Herrmann et al., 1998) and Parkinson's disease (Weintraub et al., 2004). Depression may impact functional outcomes in clients by reducing self-efficacy needed for learning. Identifying depression in clients and referring them to physicians for prescription of anti-depressant medications may facilitate functional outcomes in patients engaged in ADL programs. Reducing depressive symptoms can have a direct positive impact on functional performance (Lin et al., 2003). In addition, structuring occupational therapy treatment that addresses the client's needs related to the depression (e.g., providing structure that helps clients initiate participation in ADL or selecting tasks that challenge clients, while also enabling them to experience success) will increase self-efficacy for future performance.

Several additional factors may interfere with patient learning. Learning is more difficult for patients with cognitive deficits (see Chapters 9 and 29). Persons with severe cognitive deficits may not be candidates for ADL training. The caregiver should be taught appropriate methods for assisting the patient and told to seek reevaluation if the patient's cognitive status improves. Patients with severe receptive aphasia or who speak a different language from the therapist have communication limitations that may impact learning. Therapists should use demonstration for patients who do not understand verbal instructions. A translator can be used to support learning for patients who speak another language. Pain may interfere with learning and should be addressed directly or by selecting adaptive methods that minimize pain. Patients with low literacy will not be able to use written materials to supplement learning, so other methods must be explored that support carry-over of new skills outside of therapy. See Chapters 10 and 14 concerning ways to reduce the effects of low literacy.

Clients may require adaptive equipment to maximize independence in ADLs; however, attitudes toward using adaptive equipment can impede learning and performance.

Some people do not want to use a special tool to do a task most people do without such a tool. Persons with disabilities have reported that assistive devices have both positive and negative connotations (Lund & Nygård, 2003; McMillen & Söderberg, 2002). People value a device if the task is important and cannot be done any other way (McMillen & Söderberg, 2002; Parker & Thorslund, 1991; Rogers & Holm, 1992; Tyson & Strong, 1990; Wielandt & Strong, 2000), but they dislike the stigma associated with device use. Disabled persons who participated in a study by McMillen and Söderberg reported that they not only had to learn to use the device, but they also had to “learn” to go out in public with it. Assessing a client’s “gadget tolerance” can help therapists tailor their approach to clients when presenting adaptive equipment as an option. Patients with a low tolerance for “gadgets” may need to have a higher trust in their therapist before they are willing to consider equipment. Building this trust may become an important component of the therapeutic intervention for maximizing independence.

Finally, the motivation to learn is influenced by the learner’s values, which guide actions and effort (Trombly, 1995). Therefore, therapists must collaborate with patients to identify those tasks that will be within their capabilities and are also consistent with their values and goals. Attending to the many factors that may impact a client’s ability to learn helps the therapist select the most appropriate learning strategies to enhance a patient’s performance of ADL.

Teaching Strategies for Effective Learning

Points of effective teaching are noted as follows and summarized in Procedures for Practice 30-1.

1. Identify potential barriers to learning and develop teaching and learning strategies to minimize them.
2. Determine what routines and skills the learner has retained and whether he or she does them safely, including the ability to figure out adapted methods independently.
3. Identify patients’ goals and what they must learn to reach their goals (Shotwell & Schell, 1999). These become learning objectives, which are goals expressed in behavioral terms, such as “The patient will brush his teeth independently in fewer than 5 minutes.” Although patients vary, toileting is often a priority for patients because dependence on others has a negative impact on self-esteem (Clark & Rugg, 2005).
4. Present the material in a way that requires patients to be active in the learning process (Shotwell & Schell, 1999). Verbal or written instructions and demonstration are passive learning strategies and are often insufficient for mastering a new task. **Active learning** requires learners to apply new knowledge to real-life

PROCEDURES FOR PRACTICE 30-1

Effective Teaching

1. Identify and address barriers to learning.
2. Determine what the learner knows.
3. Identify the patient’s learning needs.
4. Use active learning strategies.
5. Engage the patient and/or caregivers in a collaborative learning process.
6. Select learning activities that present the “just right challenge.”
7. Adapt the presentation to the learner’s capabilities.
8. Provide opportunities for practice, considering context and schedule.
9. Facilitate the learner’s use of internal feedback and provide appropriate external feedback.
10. Test the learner in the appropriate context(s) to confirm that learning has occurred.
11. Discuss progress toward goals with the patient and revise teaching–learning strategies, as indicated.

problems. For example, patients learning principles of energy conservation may be asked to describe a typical day, identify ways that they could conserve energy, and then practice strategies in an actual task, e.g. cooking. Active learning is vital when the patient is learning a motor task, such as putting on a shirt with one paralyzed arm, and should be guided by motor learning principles (see Chapter 14).

5. Use a collaborative approach, recognizing that each participant in the learning process (therapist, patient, and/or caregiver) has experience and expertise to contribute to the learning task. Many techniques commonly in use have been developed by therapist–patient collaboration. Engaging patients and caregivers in the intervention process helps improve problem-solving skills and increases “ownership” of their functional gains, which enhances self-efficacy. Allowing patients to participate in the selection of equipment appears to have a positive influence on compliance (Wielandt & Strong, 2000).
6. Select the “just right challenge.” When first learning an activity, the challenge should be kept low to enhance self-efficacy by reducing anxiety and promoting success (Gage & Polatajko, 1994). For example, if the patient is learning to eat with adapted utensils, begin training with sticky foods that do not easily slide off of the spoon and progress to more difficult foods, such as spaghetti and peas.

7. Adapt the presentation to the particular learner, given his or her abilities and deficits. For patients without brain damage and with average intelligence and literacy, teaching methods can include discussion, demonstration, and printed instructions (Schemm & Gitlin, 1998). Printed materials should be written simply and directly because over 50% of the U.S. population has moderate to severe difficulty understanding simple written content, although this is not detectable through conversation (Thomas, 1999). Persons with intact cognition should be taught strategies and trained in varied contexts and situations so that they become independent problem solvers. Effective problem solvers have an accurate awareness of their abilities and limitations and the ability to identify and define problems. They can select appropriate solutions to a problem from past experience or create a new solution when prior strategies are inadequate. Finally, effective problem solvers assess the outcome of the problem solving, which helps them organize the learning experience so that it is accessible for solving problems in the future.

Patients with brain damage require a different approach to the teaching-learning process. If the patient cannot do the task automatically using old habit programs, he will be learning a new skill. Behavior modification, including a step-by-step structure, **shaping**, verbal cues, physical cues, and social praise after completion of the whole task, is effective for patients with cognitive deficits (Giles et al., 1997; Katzman & Mix, 1994). For example, a step-by-step program that subjects had to memorize and verbalize was effective for patients with Parkinson's disease (Kamsma, Brouwer, & Lakke, 1995). Brain-damaged patients often have difficulty processing abstract information or large chunks of information at a time, so instructions should be reduced to one- or two-word concrete cues. Given consistently over the course of practice sessions, these key word cues help the patient chain the task from beginning to end. For tasks that can be easily broken into isolated subtasks, it may be helpful for the patient to practice one step at a time, combining steps as learning progresses, e.g., begin brushing teeth with the toothpaste already on the brush. For some tasks and some patients, however, performance of the whole task will enhance learning (see Chapter 14). Use a variety of contexts for practice (Katzman & Mix, 1994). Even with this kind of practice, the learning may or may not transfer to other tasks or contexts; therefore, the patient must practice each task until it is learned within all the contexts in which it will be required.

Patients with brain damage may not become problem solvers, and their prognosis for independence outside of a sheltered or familiar environment may be limited. ADL tasks that may result in injury if precau-

tions are not practiced, such as cutting with a sharp knife or standing to pull up pants, require supervision for as long as judgment is impaired.

Some profoundly brain-damaged yet teachable patients benefit from backward chaining, an adaptation of Skinner's (1938) Law of Chaining: One step acts as the stimulus for another. In backward chaining of dressing skills, for example, assistance is given to do the task until the last step of the process is reached. The patient performs this one step independently and gets the satisfaction of having completed the task. Once the patient has mastered the final step, the therapist assists only to the next to the last step, and the patient completes the two remaining steps. This process continues until the patient can do the entire task from start to finish independently. Progress in learning ADL for those with brain damage is slow (Schwartz, 1995). Given the economic constraints, it is unrealistic to expect to teach such patients in the brief period of treatment authorized. The therapist should teach the caregiver how to help the patient learn some ADL skills at home.

Patients with damage to their dominant hemispheres usually have difficulty processing verbal or written language but may benefit from demonstrated or pictorial instruction. Those with damage to their non-dominant hemisphere may have difficulty with spatial relationships that make it difficult to interpret pictures and demonstrations but be able to process step-by-step verbal instruction.

8. Arrange appropriate practice schedules. Motor skills are learned only through practice. Motor skills learned with contextual interference (**random practice**) were retained better than when practiced in repetitive drill (**blocked practice**) (Hanlon, 1996). Chapter 14 has a discussion of practice schedules.
9. Provide opportunities for internal feedback and use appropriate external feedback. External feedback comes from a source other than the patient, typically the therapist, and can be provided in many forms. Motivational feedback ("Looks good!"; "Keep trying!") has some benefit, but specific feedback about what was correct and what was not correct during a particular trial has more definitive benefit. Occasional feedback concerning the performance ("keep your elbow straighter next time") offered immediately after a trial is helpful. Persons who are not aware of the outcome of their efforts benefit from external feedback so that they gain knowledge of the results of their efforts, which is a requirement for learning (Schmidt & Lee, 2000). Although external feedback from the therapist is an effective teaching method, patients must eventually respond to internal and task feedback, that is, feedback from their own sensory system or the outcome of task performance ("my pants are on, but are twisted and uncomfortable"). Asking patients to

articulate internal feedback before providing external feedback can support their ability to rely on internal feedback when faced with novel tasks outside of therapy when external feedback is unavailable.

10. Test whether the learner has acquired the knowledge or skill by requiring that it be done independently at the appropriate time and place.
11. Discuss progress toward goals and revise teaching strategy or goal as indicated (Shotwell & Schell, 1999). Gagné and Hoppes (2003) found that patients in a rehabilitation center who regularly discussed and updated their goals with their therapists made greater gains in ADL than patients whose treatment did not emphasize goal attainment.

ADAPTATION

Adaptation is the process by which a person maintains a useful relationship to the environment (Thoren Jonsson, Moller, & Grimby, 1999). It is a cumulative process that evolves over time (Spencer et al., 1999). Therefore, older people have a rich repertoire of adaptive strategies based on personal experience that may be helpful in dealing with disability.

Adaptive therapy refers to modifying the task, the method of accomplishing the task, and/or the environment to promote independence in occupational functioning. Examples of modifying the task are to switch to loafers instead of tie shoes or to order from catalogs instead of going to the shops. Adapted methods of dressing for persons with loss of the use of one side of the body or weakness of all four extremities (discussed later) are examples of modifying the method of accomplishing a task. Installation of grab bars in the bathroom to enable safe transfers and storing often-used items within easy reach

Figure 30-1 Doorknob extension. (Courtesy of Sammons Preston, Bolingbrook, IL.)

Figure 30-2 Good Grips button hook. (Courtesy of North Coast Medical, Morgan Hill, CA.)

are examples of modifying the physical environment. Teaching wheelchair users ways of interacting with individuals who are not disabled so that they present themselves as self-assured, capable people is an example of adapting the social environment.

Prescription of and training in the use of assistive devices or adapted tools and utensils to enable occupational performance by persons who are physically disabled is a primary function of occupational therapy. Examples are use of a buttonhook to button a shirt and adding extensions to keys and door handles to extend the force arm and reduce the force required to turn the key or knob (Figs. 30-1 and 30-2). Grasp, a problem for many patients, can be helped by using enlarged handles (Fig. 30-3). A therapist may experiment with adaptations to utensils by wrapping a washcloth, foam rubber, or other material around the handle and securing it with a rubber band. If enlarging the handle improves performance, permanent adaptation is prescribed and purchased or, if necessary, custom built. Low-tempera-

Figure 30-3 Good Grips garden tools with large handles. (Courtesy of Sammons Preston, Bolingbrook, IL.)

ture thermoplastic materials that bond to themselves can be used for this purpose (see Chapter 17), or thermoplastic pellets can be heated and shaped into handles.

Adaptation entails the following seven aspects, which are summarized in Procedures for Practice 30-2:

1. Analyze the activity. Determine the essential demands of the activity. The activity demands are a combination of the performance requirements of a task, such as lifting, reaching, and manipulating, and the contextual demands. Contextual demands include the physical environment, such as counter height or location of faucets in the bathtub, as well as social demands, such as the ability to communicate with others, and temporal demands, such as the need to complete a morning care routine within 45 minutes to get to work on time. Performance requirements must be quantified: What is the weight to be lifted? How high must it be lifted? and so on. Examination of these objective dimensions of the activities suggests how the environment and equipment can be adapted to meet the capabilities of the person (Clark, Czaja, & Weber, 1990). Studies are beginning to appear that evaluate specific performance requirements of particular ADL tasks, such as the minimal wrist ranges of motion needed to accomplish ADL (Ryu et al., 1991), pinch and grasp strength requirements to open containers (Rice, Leonard, & Carter, 1998), and the effect of reacher length on muscle strength needed to lift objects (Pinkston, Boersma, & Spaulding, 2005).
2. Identify the problem. Why can't the person do what the task demands? It is helpful to consider the problem from two perspectives, patient limitations and context-

tual features. For example, the patient is unable use the left hand, but toothpaste with a screw cap requires the use of two hands. Or, the patient has precautions against bending over, but pots needed for cooking stored in low cabinets cannot be reached. Linking the performance limitations with contextual features helps the therapist identify appropriate solutions.

3. Know the principles of compensation. Principles of compensation for common functional limitations are presented in Procedures for Practice 30-3.
4. Propose solutions. Consider creative ways that the principles of compensation can be applied to a particular task to enable the particular person to do it. Collaboration with the patient or a group of similarly involved patients often generates solutions and increases compliance with assistive devices (Wielandt et al., 2001).
5. Know the resources for implementing the solution. For example, it is important to know what reliable and safe equipment is available to solve the problem. Sources of equipment are rehabilitation supply stores, mail-order or web-based businesses, and gadget stores (Resource 30-1). The occupational therapist needs to know and evaluate each piece of equipment being recommended. The fact that a piece of equipment is sold does not mean that it is effective or safe (Conine & Hershler, 1991). The therapist must know construction techniques needed to implement the solution when environmental modification is needed (e.g., anchor grab bars in studs) and should be familiar with local contractors who provide quality home modifications.
6. Check it out. The assistive device or environmental modification should be checked out for reliability (always works as it should), durability (can withstand repeated use at the force levels the person will apply to it), safety, effectiveness, and patient satisfaction.
7. Train the person. The person must understand and be able to implement the safe use of the assistive device, environment, or method. Gitlin and Burgh (1995) suggest five aspects to device training: develop an activity in which to introduce the device; choose a site for instruction; determine the best time in the rehabilitation process to introduce the device; provide instruction that meets the patient's needs; and reinforce device use with the patient and caregivers. Guidetti and Tham (2002) reported that therapists also use important over-arching strategies, such as building trust and motivating their clients, collaborating on goals, and selecting training methods uniquely suited to each client, so that the therapists adapt themselves "like a chameleon" to meet their clients' needs.

It is important to some people that assistive devices be transparent (McCuaig & Frank, 1991), that is, not call attention to the person as disabled or reveal the extent of

PROCEDURES FOR PRACTICE 30-2

Adaptation Process

1. Analyze activity demands, including performance and contextual requirements.
2. Identify the problem: what performance and/or contextual requirements prevent the person from accomplishing the task?
3. Know principles of compensation for the given limitation.
4. Creatively apply principles of compensation to solve the problem.
5. Select appropriate adapted methods, assistive devices, and specify environmental adaptations to implement the solution.
6. Check out all modifications to verify that they solve the problem.
7. Train in safe use of the assistive devices or modified environment.

Compensation Principles for Particular Impairments

Weakness

- Use lightweight objects, utensils, and tools.
- Let gravity assist.
- Provide external support, e.g., sit if trunk or lower extremities are weak or splint a weak wrist.
- Use assistive devices or methods to replace lost functions such as grasp.
- Use power tools and utensils.
- Use biomechanical principles of levers (e.g., lengthen the force arm in relation to the resistance arm) and friction (e.g., increase friction to decrease power required for pinch or grasp).
- Use two hands for tasks ordinarily done with one hand.

Low Endurance

- Use energy conservation methods (see Procedures for Practice 30-4).
- Pace work to prevent fatigue.
- Use principles listed for weakness that reduce workload, such as lightweight utensils and power equipment.
- Match activity demands to ability.
- Avoid stressful positions and environmental stressors.

Limited Range of Motion

- Use long-handled tools and utensils to increase reach and/or eliminate the need for bending over.
- Build up handles to compensate for limited grasp.
- Store frequently used things within easy reach.
- Use joint protection techniques for rheumatoid arthritis (see Chapter 44).

Incoordination

- Stabilize the object being worked on.
- Stabilize proximal body parts so that need to control is reduced to the distal body parts.
- Use assistive devices that reduce slipperiness or provide stability.
- Use heavy utensils, cooking equipment, tools, and so on.
- Use adaptations that substitute for lack of fine skill.

Loss of the Use of One Side

- Provide assistive devices that substitute for the stabilizing or holding function of the involved upper extremity.
- Teach one-handed methods for activities ordinarily done with two hands.
- Provide assistive devices that change the few truly bilateral tasks into unilateral tasks.
- Improve dexterity of the uninvolved upper extremity if the dominant arm is the involved one.

Limited Vision

Blindness

- Organize the living space so that there is a place for everything and stress the importance of putting everything in its place af-

ter use (e.g., in the pantry cabinets, on refrigerator shelves, and in the medicine cabinet).

- Use Braille labels or optical scanners to distinguish canned goods, medications, clothing colors, etc.
- Use devices that operate through voice commands.
- Use assistive devices that provide auditory, tactile, or kinesthetic feedback to compensate for low vision and blindness.
- Eliminate environmental clutter.
- Expect tasks to require extra time.

Low Vision

Some of the principles for blindness are useful for those with low vision. Others include:

- Provide high color contrast (e.g., white mug for coffee, colored towels in a white bathroom).
- Increase the light on a task by bringing the light closer, increasing wattage, or changing the background to increase contrast (Lampert & Lapolice, 1995).
- Use techniques and devices that magnify type or images.
- Reduce visual clutter.
- Use organized scanning techniques (e.g., left to right, top to bottom) when functioning in a stationary environment.

Decreased or Absent Sensation

- Protect the anesthetic part from abrasions, bruises, cuts, burns, and decubiti.
- Develop habit of using areas with intact cutaneous sensation to test temperature (e.g., test bath water temperature with the forearm if finger sensation is impaired).
- Substitute vision for poor awareness of limb position and limb movement or to detect texture.
- Develop habits of directing attention to the affected part.

Poor Memory and/or Organizational Skills

- Use assistive devices that substitute for memory or poor organizational skills (e.g., pill minders, day books, electronic reminder devices, sticky notes, watches with programmable multiple alarm systems, palm-size computers and organizers).
- Teach strategies such as writing memos to self, making to-do and other lists, and placing objects together and at the point needed ahead of time.
- Develop habits regarding time use and how activities are to be accomplished.
- Teach self-awareness strategies to improve carry over of adapted methods or devices.

Low Back Pain

- Teach body mechanics for moving and lifting (e.g., hold objects close to the body, squat to lower the body rather than bending over).
- Use long-handled or bent-handled equipment or sit to substitute for bending over.
- Change position frequently.
- When standing, put one foot up on a step to rotate the pelvis.
- Rest before fatigue results in awkward, careless movements.
- Avoid twisting the trunk.

disability. Use of conventional devices or gadgets that are sold to the general public qualify as transparent. Examples are felt-tipped pens, slip-on shoes, lightweight pots and pans, and magnifying makeup mirrors. They become adaptive because of their specific application. This perception of transparency and its importance are unique to the individual. Transparency is becoming easier because the principles of universal design have been found to be profitable by manufacturers of personal care and home products (One Shape Serves All, 1998).

ACTIVITIES OF DAILY LIVING

This chapter describes methods and devices suggested by occupational therapy practitioners and former patients to enable independence in BADL and IADL. These suggestions are presented according to the problem. Many patients have more than one problem. For example, persons with rheumatoid arthritis have weakness as well as limited range of motion. Persons with spinal cord injury have decreased sensation as well as weakness. The therapist will have to use information from pertinent sections for a patient with particular combinations of impairments. Procedures to enable BADL are presented. Although the need to do these activities and the task demands of each are fairly universal. However, each person has unique constellations of IADL that describe their roles (Trombly, 1993, 1995); thus, only representative IADL can be included as examples of solutions for particular problems.

All tasks that the patient expects to perform independently after discharge must be practiced as they will be done. For example, if a patient will bathe in a tub at home,

it is inadequate to practice only sponge bathing while he or she is hospitalized. It is also crucial to address the more intermittent activities inherent in ADL, such as nail care, ear care, and menstrual care, and those ADL that are not universally engaged in, such as managing contact lenses, handling catheters, or flossing teeth. Do not assume that all self-care tasks that a particular person may need to learn are listed on an evaluation checklist.

Techniques and equipment for self-care presented in this chapter are not the only methods of accomplishing these particular tasks. This presentation is meant to provide the student therapist with a repertoire of basic skills with which to approach patients with confidence. The principles of compensation for each problem are key pieces of information that allow the student to evaluate other techniques or equipment to meet the needs of the patient. For many tasks not mentioned here, either no adaptation is required or the adaptation can be extrapolated from the examples cited.

As each task is taught, all equipment should be close at hand. For early training in dressing, clothing that is a size too large should be used because it can be managed more easily. The patient's attention should be called to design details of clothing, as persons with certain disabilities find it difficult to don some designs. The details to be considered are the cut of the garment, sleeve style, type of fabric, and type of closure or fasteners (Dallas & White, 1982). Clothing especially designed for people with disabilities is now commercially available (see Resource 30-1).

Weakness (Procedures for Practice 30-3)

For other information and suggestions see Chapters 13, 19, 40, and 43.

Suggestions for BADL

When muscle weakness affects all four extremities, the techniques and devices are extensive; therefore, this section focuses on compensation for involvement of all four extremities. If the patient is paralyzed in the lower extremities but has normal upper extremities, many of the techniques or devices are unnecessary. Some of the principles apply to limited weakness as well, such as weak pinch secondary to osteoarthritis of the carpometacarpal joint.

When paralysis is extensive, a personal care assistant is needed to carry out BADL. The patient must learn to hire, supervise, instruct, compensate, set limits for, and terminate personnel (Personal Care Assistant, 1994; also see Resource 30-1).

Feeding

The problem with feeding is the inability to grasp and/or bring the hand to the mouth. A universal cuff can be used

PROCEDURES FOR PRACTICE 30-4

Energy Conservation Methods

- Plan ahead. Organize work.
- Eliminate unnecessary tasks.
- Sit to work when possible.
- Have all required equipment and supplies ready before starting the task.
- Combine tasks to eliminate extra work.
- Use electrical appliances to conserve personal energy.
- Use lightweight utensils and tools.
- Work with gravity assisting, not resisting.
- Rest before fatiguing.

RESOURCE 30-1

The Internet has supported an explosion of online resources for persons with disability and the professionals who work with them. This section is organized by topic area. Books that are included in this section can all be purchased through an online book vendor, such as www.amazon.com or www.barnesandnoble.com.

General Online Resources

AARP—American Association of Retired Persons.
<http://www.aarp.org/>

ABLEDATA—Database funded by the U.S. Department of Education National Institute on Disability and Rehabilitation Research. It lists 17,000 products from 2,000 companies and 8,000 items no longer commercially available, customized devices, and non-commercial prototypes.
www.abledata.com

The Boulevard—Quarterly online magazine (previously *Accent on Living*) that addresses all aspects of living a full life with a disability and makes good suggestions for solving problems of persons with physical disabilities.
www.blvd.com/accent

disABILITY Information and Resources—Offers a wide range of links to information, vendors, and services. Maintained by Jim Lubin, a man with C2 quadriplegia.
<http://www.makoa.org/index.htm>

NARIC (National Rehabilitation Information Center, formerly REHABDATA)
1010 Wayne Avenue, Suite 800
Silver Spring, MD 20910
Phone; (800) 34-NARIC
A bibliographical database of documents on rehabilitation that includes journals, unpublished documents, audiovisual materials, commercial publications, and government reports.
<http://www.naric.com/search/>

Consumer Information Catalogue—U.S. Government Publications, Pueblo, CO 81009.
www.pueblo.gsa.gov

American Occupational Therapy Association—AOTA's *Occupational Therapy Buyer's Guide*, a yearly supplement in OT Practice.
www.aota.org

Adaptations and Specialized Equipment for ADL for Physical Disabilities**General Information**

Greenstein, D. B. (1997). *Easy things to make things easy: Simple do-it-yourself home modifications for older people and others with physical limitations*. Cambridge, MA: Brookline Books.

Online Vendors for Persons with Disabilities

Most vendors offer a wide array of products. Specialty vendors are indicated with a brief description.

Active Forever
<http://www.activeforever.com/home.asp>

Alimed, AliMed, Inc.
<http://alimed.com>

Andicap.com
<http://www.andicap.com>

DynamicLiving.com
Range of daily living needs for people with varied disabilities and needs.
<http://www.dynamic-living.com/gadgets.htm>

EnableMart
<http://www.enablemart.com/default.aspx?store=10>

Extensions for Independence: The Mouthstick Connection
Modular mouthsticks with adjustable lengths, varied tips, and mouthstick stands.
<http://www.mouthstick.net/>

Independent Care Needs
<http://independentneeds.com>

Invacare
Source for bathroom and other equipment for people weighing over 200 pounds.
www.invacare.com

North Coast Medical, Inc.
www.ncmedical.com

Sammons Preston Roylan
Enrichments catalog, P. O. Box 5071, Bolingbrook, IL 60440-5071. Phone: (800) 323-5547.
www.sammonspreston.com

Self-Wipe Toilet Aids

Sells a toilet aid for limited reach and grasp.
<http://www.selfwipe.com>

SeniorShops.com
Online store with adaptive equipment for BADL and IADL for a range of disabilities.
<http://www.seniorshops.com>

Online Vendors with Devices for the General Public

Several vendors are selling items aimed at making life easier for the general population. These products tend to be more “transparent” than those sold by medical vendors, and they are often less expensive because they cater to a much larger population.

Oxo International
Maker of “Good Grips” and many other products.
<http://www.oxo.com/>

The Wright Stuff
<http://store.wrightstuff.biz/index.html>

Comfort House
<http://www.comforthouse.com/>

Carol Wright Gifts
<http://www.carolwrightgifts.com>

Adaptations and Specialized Equipment for ADL for Specific Limitations**Resources and Products for Persons with Low Vision**

Access-USA
Supplier of Braille stickers (salt, pepper, food, beverage, spice tags) and other Braille products, such as menus and maps.
<http://www.access-usa.com>

Optelec
On-screen magnifier for low vision.
www.optelec.com

The Lighthouse Catalogue
www.lighthouse.org

Independent Living Aids, Inc.
<http://www.independentliving.com>

Sight Connection
<http://www.sightconnection.com>

to hold the utensil if grasp is absent (Figs. 13-12 and 30-4). This cuff fits around the palm and has a pocket for insertion of the handle of a utensil. Some universal cuffs include a wrist support if wrist extensors are weak. Alternatively, the handle can be woven through the fingers, with the index and ring fingers on top and middle and little fingers under, and held in place passively. A spork, a utensil that combines the bowl of a spoon with the tines of a fork (Fig. 30-5), can be used with the cuff to eliminate the need to change utensils. Some of these have a swivel feature to substitute for the inability to supinate. Gravity and weight of the food keep the bowl level on the way to the mouth. If the patient has weak grasp, lightweight enlarged handles can be used. The patient may use a wrist-driven wrist-hand orthosis to increase the strength of grasp (see Chapter 16). For cutting, a sharp serrated knife is used because less force is needed and it is less likely to slip. L-shaped rocker knives enable patients with weak grasp to apply force for cutting with stronger, larger proximal muscles.

An attachable open-bottomed handle can be added to a glass or soft drink can to permit picking it up in the absence of grasp. A mug with a T-shaped handle (Fig. 30-6) or a handle that allows all four fingers to be inserted provides leverage and stabilizes the fingers around the mug, allowing pick-up with a tenodesis grasp. A foam insulator can be used for a glass to provide friction to assist weak grasp. A long straw can be used to eliminate the need for lifting the cup to the mouth for drinking. Using a cup with a lid, such as a commuter mug, minimizes the risk of spills in the event that the cup slips, reducing the risk of

Figure 30-5 Spork (combination fork and spoon). This one also swivels.

injury and mess for people with weak grasp, especially when drinking hot liquids. Commuter mugs have the added benefit of being a transparent device.

A mobile arm support or suspension sling (see Chapter 16) may be required to enable patients with very weak proximal upper extremities to feed themselves. A table placed at axilla height offers support for the arm and eliminates the pull of gravity, allowing the patient with elbow flexors graded 3 or 3+ to bring the food to the mouth. As strength increases, the surface can be lowered. For pa-

Figure 30-6 Cup with T-shaped handle assists drinking when grasp is weak.

Figure 30-7 A. Aerosol can adapter that reduces the force needed to operate the spray. B. Operation of the adapter.

tients who lack active upper extremity movement, electronic feeders are available that are operated with a head or sip-and-puff switch (Hermann et al., 1999).

Grooming

Weakness in grasp and pinch are the most common barriers to grooming. Adaptations for makeup jars, tubes, and applicators have been suggested (Hage, 1988). Jar openers can be used to open twist-off caps or products can be selected that open more easily, given the patient's capabilities, for example proximal muscles can be used to dispense toothpaste in a pump container. A universal cuff or a splint can be used to hold a rattail comb, toothbrush, lipstick tube, or safety razor if grasp is absent. A handcuff can be constructed to hold an electric razor. If grasp is weak, lightweight enlarged handles may be enough. Applying friction material to the utensil or tool can provide added assistance. A small plastic brush with a cuff attachment may be used to assist in shampooing hair. Lengthening the force arm relative to the resistance arm may allow use of spray deodorant (Fig. 30-7) or nail care (Fig. 30-8).

Toileting

Transfers, handling of the body while raising and lowering clothing, and weak pinch and grasp are problems. For patients with spinal cord injury, concomitant loss of bowel and bladder control requires special procedures, including bladder irrigation, use of a catheter, or intermit-

tent catheterization (Medline Plus, 2004). Generally, the patient can push down the pants while in the wheelchair by leaning from side to side. If the patient cannot stand or has precarious standing balance, it is necessary to transfer back to the wheelchair before raising the clothing after toi-

Figure 30-8 Nail clipper and emery boards stabilized to allow one-handed use and with elongated handle to reduce force required. (Courtesy of Sammons Preston, Bolingbrook, IL.)

leting. If the patient uses an indwelling catheter or external drainage device, the collection bag can be emptied into the toilet without transfer or removal of clothing. Usually nurses or enterostomal therapists teach clean intermittent self-catheterization, but the occupational therapist should be aware of the process of this ADL:

1. Assemble the equipment.
2. Wash hands and penis or vulva and urethral opening.
3. Men lubricate the catheter tip with water-soluble lubricant, hold penis at sides, and insert catheter with firm, gentle pressure. Women separate labia, palpate meatus, and insert catheter into the bladder.
4. The patient pushes catheter in 2.5 cm (1 inch) after urine starts to flow.
5. The person allows urine to flow until it stops and then slowly removes the catheter, holding catheter tip as it is removed to prevent spilling.
6. Discard disposable catheters or clean reusable catheters with soap and water, rinse, dry, and store in a plastic bag.
7. Wash hands with soap and water (Medline Plus, 2004). Knee spreaders with a mirror help hold weak or paralyzed lower extremities in abduction and enable people with limited trunk control to see the urethral opening.

Patients on a bowel program may use suppositories or digital stimulation to initiate a bowel movement. Suppositories may be inserted while the patient is in the bed or on the toilet. When patients do digital stimulation or insert suppositories while on the toilet, a raised toilet seat with a space between the seat and toilet bowl rim is needed to allow them to reach the rectum. Suppository inserters for those with weak or absent pinch are commercially available and can be adapted with cuffs for patients who lack grasp. Some inserters have a spring ejector that releases the suppository after it is properly positioned in the rectum. An inspection mirror is needed if the patient lacks anal sensation. Bowel stimulators are available for patients who lack adequate digit control. Patients with weak grasp and pinch can wrap toilet tissue around the hand for use. For patients with very limited hand function, bidets can be fit to the toilet to clean and dry the perianal area. Menstrual needs can be met by adaptations to positioning, pants, pads versus tampons, and aids such as mirrors and knee spreaders (Duckworth, 1986).

Bathing

The problems with bathing include the transfer, dynamic sitting balance, lack of lower extremity movement (Shillam, Beeman, & Loshin, 1983), and lack of pinch and grasp. Transfer tub seats (Fig. 30-9) that have two legs in the tub and two legs outside the tub provide a safe means to transfer from the wheelchair to tub. Patients prone to decubiti need padded seats. Each patient's requirements

Figure 30-9 Transfer bath bench. (Courtesy of S&S, Colchester, CT.)

should be evaluated and a seat selected to fit them. Users of bath seats (both patients and caregivers) have reported that safety, adequate support, stability of equipment, and comfort are some of the most important considerations in selecting appropriate equipment (Pain & McLellan, 2003). The bath seat must be placed so that the faucets are within reach. Grab bars help during the transfer and while the patient is seated (Procedures for Practice 30-5). Non-slip material is used in the bottom of the tub. The faucets must have lever handles for ease in tapping them off and on with the fist. A hand-held shower that is adapted with a hook handle is used. No-scald faucets and shower heads should be used, but if they are unavailable, water temperature should be regulated by turning on the cold water first and then adding the hot water, which prevents scalding desensitized skin. Soap on a string or in a dispenser is helpful. A bath mitt is used if grasp is weak or absent. The person dries off before transferring back to the wheelchair. A towel placed in the wheelchair seat will dry the perianal area and can be removed when the patient transfers to the bed for dressing. Bathing and drying the feet and legs are particular problems for patients with poor trunk balance; such patients may prefer to do foot hygiene while in bed (Shillam, Beeman, & Loshin, 1983).

A custom-made shower stall and shower wheelchair provide the easiest bathing solution for a person with tetraplegia; however, it typically requires an expensive home modification. The shower area should have a raised slope to prevent the water from running out but allow the person to enter the shower on a shower wheelchair. Plans for such bath enclosures are shown in books on the Resources list. Shower wheelchairs have commode seats and can be positioned over the toilet for bowel programs, reducing the number of transfers required for morning care. For patients who prefer a bath, a number of electronic bath lifts are available that enable patients to transfer onto

PROCEDURES FOR PRACTICE 30-5

Grab Bars

Selection

Grab bars can be purchased from rehabilitation supply houses and some plumbing supply centers. Towel bars are not safe for use as a grab bar. Grab bars must be able to accept 200–250 pounds of force (more if the patient weighs more).

Horizontal bars are for pushing up; vertical bars are for pulling up. An L-shaped grab bar that includes both vertical and horizontal legs is a good choice for the bathtub or shower enclosure.

A clamp-on bathtub-mounted safety grab rail cannot be used on fiberglass tubs because those tubs cannot tolerate the stress.

The optimum diameter for grab bars is 1.25–1.5 inches for adults. The distance between the wall and the bar should be 1.5 inches. A wider space is dangerous because, if the arm slips, it may get caught between the wall and the bar and/or the person may fall (Salmen, 2000).

Placement

Locate bathtub grab bars where a person may be off balance, such as going into or out of the tub, turning in the tub or shower, or standing up from or sitting down on a bench or seat. One vertical bar outside the tub and one horizontal or diagonal bar on the wall along the length of the tub are recommended as basic installations. An L-shaped bar can be substituted for the bar on the wall along the length of the tub. If an L-shaped bar is used, locate the horizontal bar 16 inches above the tub rim and the vertical bar approximately 32 inches from the corner of the tub or as the placement suits the height and transfer and bathing process of the user.

Although the most common site for grab bars is in or near the bathtub enclosure, bars near the toilet (Fig. 30-10) are often necessary. Bars that look like armrests attach to the toilet; those that have legs that extend to the floor are most stable and safe.

Installation

Grab bars must be mounted to the wall with 2-inch stainless steel screws driven into the wall studs. Use a stud finder to locate the studs. It may be necessary to locate the studs

Figure 30-10 The Invacare Toilet Safety Frame and CareGuard by Invacare Raised Toilet Seat make the bathroom a safer environment for those with special needs. These products are recommended for combined use. (Courtesy of Invacare.)

from the other side of the wall if the bathroom walls are tiled. The typical mounting flange has three holes for three screws. Drill a small pilot hole before drilling holes in ceramic tile, using an eighth-inch masonry bit to drill three holes for the mounting screws. Only two screws will actually fit into the stud. Therefore, use a toggle bolt for the third screw. Grab bars from Invacare (see Resource 30-1) have screw holes that are oriented so that they all line up with the stud.

In new construction, double the studs and/or fasten half-inch plywood between the studs flush with the studs where grab bars are to be fastened. Some people cut into existing walls to add the necessary reinforcement and then replace the wall board.

a seat and then be lowered into the tub for independent or assisted bathing, depending on their needs.

Dressing

Dressing in less than an hour is considered reasonable for persons with tetraplegia (Weingarden & Martin, 1989); however, individuals must decide if this time frame is functional or if a personal care assistant is a better option. Prob-

lems with dressing include moving the paralyzed limbs to dress them, decreased sitting balance, and the need to compensate for the lack of pinch and grasp. While in bed, patients with spinal cord injuries at C6 and below can pull the knees up to dress the lower extremities by using their wrist extensors and elbow flexors. A dressing stick (Fig. 30-11) with a loop that goes around the wrist attached to the end opposite the hook can help. The person pulls against the loop, using wrist extension and leverage, to stabilize

Figure 30-11 Dressing stick. (Courtesy of the Rehabilitation Division of Smith & Nephew, Germantown, WI.)

tenodesis grasp of the stick. Loops of twill tape can be added to the cuffs of socks to facilitate pulling them on by hooking the thumb in the loop when pinch is absent.

A buttonhook attached to a cuff or with a built-up handle is used when fingers are unable to manipulate buttons (Fig. 30-2). The hook is inserted through the buttonhole to hook the button and pull it through the buttonhole. The other hand is used to hold the garment near the buttonhole. A loop of string or leather lacing may be attached to the zipper pull of pants or other garments so that, in the absence of pinch, the thumb can be hooked in the loop to close the zipper. Alternatively, a zipper hook can also be used.

Adaptation of clothes should also be considered to facilitate dressing, undressing, and toileting; to regulate temperature; to increase comfort; and to increase feelings of self-confidence (Kratz et al., 1997; see Resource 30-1). For business people who are wheelchair users, suit jackets, pants, and skirts tailored to accommodate the sitting position look better than off-the-rack suits.

Runge (1967) describes the following methods of dressing for persons with tetraplegia:

Pants and Underwear

1. Have the patient sit in bed with the back against the head of an elevated hospital bed or against the wall. Pants are positioned with the front up and legs over the bottom of the bed. The patient can position pants by tossing them or using a dressing stick with a wrist loop.
2. One leg is lifted by hooking the opposite wrist or forearm under the knee, and the foot is put into the pants

leg. The thumb of the other hand hooks a belt loop or pocket to hold the pants open. Working in a cross-body position aids stability for those with poor balance.

3. The other foot is inserted.
4. The palms of the hands are used to pat and slide the pants onto the calves and to get the trouser cuffs over the feet. The wrist or wrists are hooked under the waistband or in the pockets to pull the pants up over the knees.
5. The patient continues to pull on the waistband or pockets while returning to supine position to pull the pants up onto the thighs. This may have to be repeated. Hooking the wrist or thumbs in the crotch helps pull up the pants.
6. In a side-lying position, the thumb of the top arm is hooked in the back belt loop, and the pants are pulled over the buttocks. Then the patient rolls to the other side and repeats the process until the pants are on.
7. In a supine position, the pants can be fastened using a zipper pull loop and Velcro tab closing or buttonhook.
8. The pants are removed by reversing the procedures and pushing the pants off.

An alternative method for getting the pant legs over the feet may be useful for patients with limited forward reach. The pants are positioned parallel to the patient's legs. The first leg is lifted and crossed over the opposite leg so the pant leg can be slid all the way over the foot, up to the knee. The leg is uncrossed, and the second leg is slid in (Regional Spinal Cord Injury Center of Delaware Valley, 2001). To pull the pants over the hips, use the method described above.

Socks. Socks with tight elastic should be avoided. While sitting in the wheelchair or bed, the patient crosses one leg over the other and uses tenodesis grasp to put on the sock and the palms of the hands to help pull it on. If the patient cannot cross his or her legs, the foot can be placed on a stool or chair. Socks are removed by pushing them off with a dressing stick, long shoehorn, or the thumb hooked over the sock edge.

Shoes. Loafers that are a half to one size larger are most practical for patients who cannot walk. Shoes are put on by crossing one leg at a time as for putting on socks. The shoe is pulled onto the foot by balancing the sole of the shoe in the palm of the hand. Then with the foot moved to the floor or to the foot pedal of the wheelchair, the foot is pushed down into the shoe by pushing on the knee. A long shoehorn may be helpful for getting the heel into the shoe. Shoes can be removed by pushing them off with the shoehorn.

Cardigan Garments: Shirts and Blouses

1. Shirts may be donned in either the wheelchair or bed. The shirt is positioned with the brand label of the shirt facing down and the collar toward the knees.

2. The patient puts his or her arms under the shirt and into the sleeves and pushes them up over the elbows.
4. The shirt is gathered up by using wrist extension and by hooking the thumbs under the shirt back.
5. The shirt is placed over the head.
6. The patient shrugs to get the shirt down across the shoulders and hooks the wrists into the sleeves to free the axillae.
7. The patient leans forward and reaches back with one hand to rub on the shirt back to pull it down.
8. The shirt fronts are lined up, and buttoning begins from the bottom button up, using a buttonhook. Alternatively, shirts can be adapted with Velcro fasteners.

A cardigan garment is removed by pushing first one side and then the other off the shoulders and then alternately elevating and depressing the shoulders to allow gravity to assist in lowering the shirt down the arms. Then, one thumb is hooked into the opposite sleeve to pull the shirt over the elbow, and the arm is removed from the shirt.

With the exception of buttons, an overhead garment is put on in a similar manner and removed by hooking one thumb in the back of the neckline and pulling the shirt over the head. The sleeves are pushed off each arm.

Bra. Either a front- or back-closure bra can be used. Velcro can replace hooks for fastening, but some patients can manage the standard hook fastener if it is hooked in front at waist level. After the bra is hooked, it is positioned with the cups in front, and the arms are placed through the shoulder straps. Then, by hooking the opposite thumb under a strap, one strap at a time is pulled over the shoulder.

Sexual Activities

Many persons have concerns about their sexuality early after spinal cord injury, although they may not be ready to learn about the particulars of resuming sexual activities or procreation. Early on, they appreciate acknowledgment of their concerns and sources of information for when they are ready (McAlonan, 1996).

In a pioneering book, *Sexual Options for Paraplegics and Quadriplegics*, Mooney, Cole, and Chilgren (1975) explicitly described methods of sexual expression for people with spinal cord injury. They illustrated the process of getting ready for sex (emptying the bladder, washing). They addressed how to handle a catheter that is left in place during sex (bend the catheter and fold it over along the shaft of the penis where it will be out of the way, but do not anchor it until the erection has taken place to avoid pulling out the balloon of the Foley catheter; be sure the tubing and collection bag are not leaned on to prevent the flow of urine). They presented positions for genital and orogenital sexual expression, alternative means of sexual expression

(vibrators, touch, and talking), and how to achieve and maintain a reflex erection of the penis. They discussed fertility of men: ability to ejaculate depends on the level of the lesion, and production of sperm depends on healthy testicles. They pointed out that women remain fertile, and therefore, pregnancy is as possible as for able-bodied women. Although this book is out of print, it is available in many university libraries, and used copies are available through online booksellers, such as amazon.com and barnesandnoble.com. Also, other books have become available as sexuality for the disabled is fully acknowledged (see Resource 30-1).

Suggestions for Selected IADLs

For the persons with severe paralysis, high-tech adaptations, as described in Chapter 19, offer opportunities to engage in communication, leisure, and work activities. Some low-tech adaptations are suggested here.

Handling a Book

The person with tetraplegia encounters problems with holding a book and turning the pages, with writing or recording notes in business or school, and possibly in telephoning. Some book holders support a book on a table, whereas others are designed to hold a book when reading supine in bed. If a person is reading while supine and the book is not held directly above, prism glasses are needed to direct the vision to a 90° angle so that the book may be seen.

To turn pages, some solutions are as follows: (1) when wearing a splint, the patient can use a rubber thimble or finger cot on the posted thumb; (2) a pencil with the eraser end down can be used in a universal cuff (typing stick) or hand splint; (3) electric page turners automatically turn pages when activated by a microswitch or other means of control; and (4) a mouthstick with a friction tip end may be useful (Fig. 30-12). Mouthsticks with flat mouthpieces can be purchased commercially, and custom-molded mouthpieces that conform to the patient's dentition are also available (Regional Spinal Cord Injury Center of Delaware Valley, 2001). The mouthpiece has a lightweight plastic or aluminum rod to which an eraser or other type of end piece, such as pencil, pen, or paintbrush, can be added.

An alternative is books on tape or CD, which can be obtained from libraries and bookstores. The Library of Congress has a large collection of tapes, including many current issues of magazines, and tape players that are available to the blind and the physically disabled for no charge (see Resource 30-1).

Writing

Extensive writing is usually done with computerized word processing. Manual typing can be done with typing sticks or a mouthstick for hitting the keys. Voice recognition

Figure 30-12 A. Mouthstick. B. Patient using mouthstick on a computer keyboard.

software is a better option for people who need to regularly create large amounts of text. If speed is important, as in taking notes in the classroom or in business, a tape recorder can be used.

Handwriting is important for legal documents and personalizing cards and typed notes. Splints that provide pinch can be used to hold a writing instrument. If pinch is absent and the patient does not use a splint, a pencil holder (Fig. 30-13) that encircles the pencil, thumb, and index finger can be made of thermoplastic materials. Pens with textured grips provide friction to make a weak grip more effective. Felt-tipped pens require little pressure and are therefore easier to use than other types of pens. If the arms cannot be used, with practice, a mouthstick with a pencil attached can become an effective writing tool.

Telephoning

A person whose spinal cord was injured at C6 or below can pick up a traditional telephone receiver and bring it to his or her ear. An executive shoulder rest attached to the receiver holds it there until the conversation is finished.

Figure 30-13 Pencil holder made of thermoplastic material.

Persons with higher level injuries can wear headsets or use a speaker phone that precludes the need to hold the phone.

Push buttons can be depressed with a mouthstick or typing stick. Speed dial or memory dial reduces the number of buttons to depress. Many phones are now available with voice recognition dialing options.

Turning Electrical Appliances On and Off

The burgeoning field of electronic aids to daily living (EADLs), formerly known as environmental control units, includes remote control devices for TV, entertainment centers, VCR and DVD players, lights, door openers, electric beds, and appliances. Voice-activated remote controls are available in specialty stores for operating the TV, VCR, and DVD player. See Chapter 19 for a discussion of high-tech assistive devices that are useful for persons with severe weakness or paralysis resulting from a spinal cord injury or degenerative disease such as amyotrophic lateral sclerosis.

Low Endurance (Procedures for Practice 30-3)

For other information and suggestions, see Chapter 47.

Suggestions for ADLs

Patients of various diagnoses and circumstances (e.g., after bed rest) have low endurance, which may be temporary or chronic. Many disorders (e.g., cardiac and pulmonary disease, multiple sclerosis, rheumatoid arthritis, and chronic fatigue syndrome) cause a more or less permanent reduction of endurance to which patients must adapt. Patients with cardiac and pulmonary disorders have reduced ability to use oxygen needed for muscle, including cardiac muscle,

and brain functions. If oxygen deprivation is severe enough, neuropsychological changes involving memory, perception, and information processing occur, affecting the teaching and learning process as well as performance.

Adaptations for BADL and IADL involve awareness and reduction of the metabolic cost of activities and working within limits of cardiac and pulmonary capacity. Cardiac patients are cautioned to stop activity when they have angina or shortness of breath (SOB). Patients with pulmonary disease may need to have oxygen blood saturation levels monitored with a pulse oximeter (see Chapter 47) during initial ADL training to establish levels of activity that do not reduce blood oxygen to harmfully low levels. All patients with reduced endurance are taught to take rest periods throughout the day and use other energy-conserving techniques. Energy conservation methods are listed in Procedures for Practice 30-4 and elaborated on in Chapter 32.

Some activities require higher levels of energy than do others. One way to guide activity selection is to use metabolic equivalent (MET) tables. Most self-care activities require less than 3 METs; however, showering, tub bathing, toileting, sexual activity, and washing and setting hair require higher levels (Ainsworth et al., 1993, 2000). It should be remembered that MET charts are averages and do not account for particular circumstances and, therefore, cannot be used without also monitoring the patient's breathing, heart rate, blood pressure, and/or oxygen saturation levels. Dyspnea (SOB) signals the patient that the activity he or she is doing is beyond his or her capacity. Angina or excessive increase in heart rate (20 beats over resting rate) signals the cardiac patient that he or she has reached his or her limit. Activity restrictions and precautions vary depending on the nature and severity of the cardiac disorder (Goodman, 2003). Adapted methods may be used to compensate for activity restrictions, e.g., prolonged bending over may be avoided with long-handled utensils (described in this chapter in the section on limited range of motion). Patients with chronic obstructive pulmonary disease should learn to modify ADL methods to coordinate diaphragmatic and pursed lip breathing into activity routines to minimize dyspnea (Migliore, 2004).

Suggestions offered for persons with low endurance are as follows (Cristy & Sarafconn, 1990):

- Get sufficient sleep. Strategies for the patient who is having trouble sleeping include developing a bedtime routine and schedule; practicing relaxation techniques, such as visualization, listening to soothing music, progressive relaxation technique, and meditation; and avoiding upsetting or exciting activities just before bedtime.
- Consider your energy budget. Identify essential tasks and eliminate nonessential ones. Spread the performance of tasks that must be done throughout the day or week and delegate the rest to others.

- Do preventive maintenance and cleaning. A small chore left undone becomes an energy-consuming one later on.
- Organize work space. Organize to allow sitting without reaching, stretching, or bending while working.
- Use labor-saving products and techniques. Examples of ways to save energy include soaking dishes before washing them, paying bills online to eliminate writing and mailing checks, and purchasing pre-washed and cut vegetables.
- Organize work and errands. Organize tasks to eliminate backtracking and extra steps or trips and to allow planned rest periods. Keep commitments within manageable limits.
- Emotions, good and bad, use energy too. Consider the emotions when budgeting energy.

Sexual Activities

The American Heart Association (1999) booklet *Sex and Heart Disease* discusses the cardiovascular changes that occur during sexual intercourse, when the patient can resume sex after myocardial infarction or heart surgery, how other factors affect sex interest and capacity, guidelines for resuming sex, what to do if symptoms arise during sex, Viagra, and myths and misconceptions. The booklet can be helpful to both the patient and the health professional and can be ordered online at www.americanheart.org. Diaphragmatic breathing is facilitated in supine (Migliore, 2004), so pulmonary patients may find dyspnea is easier to manage when lying supine during sexual activities.

Limited or Restricted Range of Motion (Procedures for Practice 30-3)

For other information and suggestions, see Chapters 41, 42, 44, and 45.

Suggestions for BADLs

Feeding

The most common problems with feeding that occur with limited range of motion are the inability to close the hand enough to grasp the utensil or inability to bring the hand to the mouth. Enlarged or elongated handles can be added to spoons or forks. The elongated handle may have to be angled to enable the patient to reach the mouth. Remember that the longer the handle (resistance arm), the heavier and less stable the device; therefore, the handle should be only as long as is necessary and made of lightweight material.

A universal cuff, or utensil holder, can be used when grasp is not possible (Fig. 30-4). For some patients, such as those with arthrogryposis, independent eating may only

be possible with electric feeders. The device must be set up and cleaned up by an assistant, however, and some insurance carriers will not pay for both device and assistant. Another factor to be considered when prescribing this device is that, for an institutionalized person, being fed by another may be an opportunity for social contact that the device would eliminate (Hermann et al., 1999).

Grooming

The problems with grooming are the same as for feeding. Enlarged or extended handles can be attached to a comb (Fig. 30-14), brush, toothbrush, shampoo brush, lipstick tube, or safety razor. Aerosol deodorant, hair spray, powder, and perfume can be used by those with limited range. An assistant may be needed to wash and style hair if the person cannot reach the head to do it independently. A simple hairstyle may eliminate the need for blow drying and styling. For patients who have had hand surgery and are prohibited from getting the incision wet, a waterproof plastic mitten allows the patient to use the hand as much as possible during self-care and kitchen activities (Fig. 30-15).

Toileting

The problem with toileting is the inability to reach. The toilet tissue dispenser should be within reach. Wiping tongs can extend reach when using toilet tissue. If grasp is poor, the tissue can be wrapped around the hand. A bidet eliminates the need for wiping by hand. Gravity assists in pulling clothes down; loose clothes slide off easily. A dressing stick can be used to pull up the clothing (Fig. 30-11). Sanitary napkins with adhesive strips can be used more easily than tampons; the protective wrapper can be removed with the teeth. If limited range or movement

Figure 30-14 Long-handled comb. (Courtesy of North Coast Medical, Morgan Hill, CA.)

Figure 30-15 Plastic glove prevents operated hand from getting wet during washing of the other hand.

precautions prevent the patient from using a low commode, a raised toilet seat may solve the problem (Fig. 30-10).

Bathing

Tub transfers are facilitated by grab bars (Procedures for Practice 30-5). Non-slip material should be placed on the bottom of the tub. A tub seat is used when the patient is unable or not allowed to get down into the tub or up from the bottom of the tub (Mann et al., 1996). Different heights and styles of tub benches are available, and it is important to select the right one for each patient in terms of stability, ease of transfer, need for padding or back support, access to perianal area, and position of hips and knees (Fig. 30-9). A hand-held shower hose is used for rinsing if a tub seat is required. It is essential to provide practice of strategies to bathe the back, feet, and perianal area when bathing on a tub seat. Lever handles on faucets are recommended because they do not require grasp and they allow better leverage for turning on and off. For patients with hip precautions, it is important to position the tub seat so that faucets can be reached without excessive hip flexion. It is helpful if the soap is on a string, or use soap and shampoo dispensers that can be fixed to the wall in easy reach.

The same problems of reach and grasp encountered in dressing also interfere with bathing. When grasp is limited, a sponge or terry cloth bath mitt works well. A long-handled bath sponge can be used to reach the feet or back; some are designed to hold the soap inside the sponge, and others are designed especially for cleaning feet. A terry cloth bathrobe is effective for drying.

The following procedure is used for patients who cannot step over the edge of the tub and require a transfer tub seat (Fig. 30-9).

1. The patient walks to the side of the tub using assistive devices and weight-bearing precautions, as prescribed, and turns to face away from the tub.
2. The patient reaches for the back of the tub bench with one hand and the edge of the tub seat with the other.
3. The patient sits down on the tub bench and lifts both legs into the tub, turning to face the faucet, being careful to adhere to precautions while moving the involved leg.

Dressing

Lack of ability to reach and grasp and limited shoulder, back, hip, or knee range of motion are limitations that cause problems in dressing. For 2 months after hip replacement, patients will need to follow hip precautions. Most commonly, patients have a cemented total hip arthroplasty via a posterolateral surgical approach. Postoperatively, they are typically weight bearing as tolerated but must avoid flexing the hip past 90°, adducting the leg past midline, or externally rotating the leg (van Stralen, Struben, & van Loon, 2003). Other surgical techniques or complications may necessitate different precautions, so therapists must always confirm activity precautions prior to treatment (see also Chapter 41).

A dressing stick can be used to pull clothing over the feet or to reach hangers in the closet. Reachers can be used to remove clothes from shelves, to start clothes over parts of the body, and to pick up objects from the floor (Fig. 30-16).

Dressing the lower extremities is a particular problem. People who cannot reach their feet or who are not allowed to flex the hip can dress the lower extremities using a sock or stocking aid (Fig. 30-17). To use, the cone is inserted into the foot of the stocking; the top of the stocking is pushed down below the top edge of the cone. While the strings are held, the stocking aid with stocking in place is tossed over the toes, and the person's foot is moved into the foot of the stocking. The cone is then removed by pulling the strings, bringing it out of the stocking behind the heel. This brings the stocking within reach, and it can be pulled up the leg. One study found that patients identified the sock aid as the most useful device at the 2-week follow-up interview at home, but it was the most rejected aid at the time of dispensing in the hospital (Finlayson & Havixbeck, 1992).

Figure 30-16 A. Reacher with a pistol grip and suction cup tips. B. Reacher in use.

A long shoehorn assists in putting on shoes when the feet cannot be reached. Some long shoehorns have a hook on the opposite end that may be used as a dressing stick. Positioning the shoehorn between the legs, rather than on the lateral aspect of the foot, reduces the chance that the patient will move the hip into internal rotation when donning shoes. Slip-on shoes and elastic shoelaces avoid the need to tie shoelaces.

Dressing the upper body with limited upper extremity range of motion is easier when using button- or zipper-front garments rather than over-the-head garments. A dressing stick or reacher is used to bring the garment around the shoulders. Fasteners are particularly difficult, especially if limitation in the range of motion is accompanied by weakness. In a study of ability of 97 arthritic women to use clothing fasteners, zippers, especially easy-sliding, large-toothed plastic ones, were found to be easiest. Snaps and buttons were rated as difficult, although vertical buttonholes made buttoning easier (Dallas & White, 1982). Velcro tabs can replace buttons, snaps, or hooks if limited mobility in the fingers prevents buttoning or fastening. Since few clothes come with this type of fastener, the pa-

Figure 30-17 Stocking aid in use. (Courtesy of the Rehabilitation Division of Smith & Nephew, Germantown, WI.)

tient's clothing must be adapted. To preserve the look of a buttoned garment, the buttonhole is sewn closed and the button is attached over the hole. The hook-and-pile Velcro tabs are sewn to replace the buttons. Iron-on Velcro button tabs, complete with shirt buttons are available to simplify the process (www.easystreetco.com).

Sexual Activities

Intercourse should be planned for the time of day of highest energy level, and the patient should time pain relief medication so its effects are greatest during intercourse. A warm bath may reduce joint stiffness as well as serving as a part of foreplay. Satisfying sex includes romance and intimacy, even though engaging in intercourse may be too exhausting or painful. Patients should explore options for skin-to-skin contact that do not cause pain. The patient and partner can use a trial-and-error process of working out new, comfortable, and biomechanically safe positions for intercourse. For example, both partners may lie on their sides with the man entering from behind for a woman with hip problems; both partners may lie on their sides facing each other with the woman providing most of the hip movement, for a man with back problems (Houtchens, 1998).

Sexual activities such as touching, holding hands, and caressing can be resumed immediately after total joint replacement. Patients with total hip replacement can generally resume intercourse 6–8 weeks post-operatively or according to the surgeon's guidance. Whether male or female, the patient should take the passive position. After 4–6 weeks, patients with unilateral knee replacement no longer have restrictions on resumption of sexual activities except to avoid kneeling positions (Spica & Schwab, 1996).

Suggestions for Selected IADLs

Writing

Use rollerball pens that glide easily. If pinch is limited, the size of the writing instrument can be increased by using sponge rubber, passing it through the holes in a practice golf ball, using commercially available grips that slip on the instrument, or using a comfort-grip pen (Schwarz, 1997).

Telephoning

Cordless phones near where the person is sitting or working are useful, as is one-button automatic dialing. Speaker phones are helpful for patients who cannot hold the phone or hold it to their ear.

Shopping

Shop-at-home services by phone or computer are becoming more common, convenient, and economical. If the patient goes to the shops, he or she should go at off-hours so that clerks are available to get out-of-reach items too heavy to be obtained by use of a reacher.

Opening Containers

Jar openers, including rubber sheets, clamp style, and mounted style, or pliers can be used to open jars, bottles, and pill bottles. Pliers are also useful in other tasks that require pinch, such as weeding or sewing thick fabric. In one study, a pop-off lid was found to require approximately 13 pounds of force to open, and medicine bottles required 2 to 6 pounds (Rice, Leonard, & Carter, 1998). To avoid struggling with pill bottles, medications should be received from the pharmacy in easy-open, not childproof, containers.

Gardening

Choose low-maintenance perennial plants. Use seedlings rather than seeds. Wear a carpenter's apron with pockets for tools. Use tools with ergonomic grips (Fig. 30-3). Use a rolling or stationary stool to sit while working. Wear gloves to protect the skin and joints. Keep pruners sharp to make cutting easier. Use a sprinkler rather than a watering can (Arthritis Foundation, 1997).

Incoordination and Poor Dexterity (Procedures for Practice 30-3)

For more information and suggestions, see Chapter 40.

Suggestions for BADLs

The patient is taught to use the body in as stable a posture as is possible, to sit when possible, and to stabilize the upper extremities by bearing weight on them against a surface or by holding the upper arms close to the body, or both (Gillen, 2000). Stabilizing the head may improve a person's ability to control the upper extremities. Friction surfaces, weighted utensils, or weighted cuffs (see Fig. 13-15) added to the distal segments of the extremities and the use of larger and/or less precise fasteners all contribute to increasing independence by lessening the effects of the incoordination (McGruder et al., 2003). For involuntary movements, such as intention tremors or ataxia, splints may be used to stabilize selected joints, reducing the degrees of freedom that must be controlled by the patient during an activity (Gillen, 2000).

Feeding

The plate can be stabilized on a friction surface, such as a wet towel, wet sponge cloth, or non-skid mat. A plate guard or scoop dish can be used to prevent the food from being pushed off the plate. The utensil may be weighted for stability, may have an enlarged handle to facilitate grasp, and may be plastic coated to protect the person's teeth. Sharp utensils are to be avoided. A weight cuff on the wrist is often chosen rather than a weighted utensil because the cuff can be heavier; also, the cuff makes it unnecessary to weight each item that the patient will use. Weighted cuffs may improve food-to-mouth time, decrease spills, and diminish tremor during eating (McGruder et al., 2003) compared with feeding with no weight. The person may successfully drink from a covered glass or cup with a sipping spout or opening. Some may use a long plastic straw that is held to the side of the cup or glass by a straw holder attachment; the patient moves the head to the straw but does not touch it or the cup or glass with the hand.

Grooming

Weighted cuffs on the wrists may help some patients gain greater accuracy while grooming. Standing in a corner enables patients to stabilize their trunk and head on the wall to the side, and their forearms on the wall in front for activities involving the face, such as brushing teeth, shaving, and applying make-up (Gillen, 2000). Large lipstick tubes are easier to use than small ones. The arms must be stabilized to use lipstick. A simple hairstyle is the best choice. For a patient who has difficulty holding a large comb, a

military-style brush with a strap can be used. Stick deodorant is preferred to spray because it eliminates the risk of accidentally spraying the substance into the eyes. An electric razor is preferred to a safety razor both because it is more easily held and because a safety razor can cut if it is moved sideways over the skin. Patients with fairly good head control improve their accuracy by holding the electric razor steady and moving the face over the cutting surface. An electric toothbrush is also useful both because it is heavier and because it can be held steady while the head is moved. This same principle can be employed when filing the nails: fasten the emery board to a flat surface and move each nail over the emery board. Cutting the nails may be unsafe for incoordinated patients, so filing is recommended.

Toileting

Principles described above can be applied to toileting. Patients with incoordination who require self-catheterization may have difficulty inserting the catheter into the urinary meatus. For women, the Asta-Cath female catheter guide helps spread the labia and helps the patient guide the catheter accurately into the urinary meatus (available at www.aplusproducts.biz). Sanitary napkins with adhesive strips to hold them in place may be easier to use than tampons.

Dressing

Clothes that facilitate independent dressing are front-opening, loosely fitting garments with large buttons, Velcro tape closures, or zippers. Wrinkle-resistant and stain-shedding materials enable the person to look well groomed throughout the day. To overcome difficulty with buttoning, a buttonhook with an enlarged and/or weighted handle, if necessary, can be used. A loop of ribbon, leather, or chain can be attached to the zipper pull so that the person can hook it with a finger instead of pinching the zipper pull. Velcro can be substituted to eliminate the need to fasten hooks on a bra. To don the bra, it is easier for the patient to put it around her waist, which is thinner and puts less tension on the garment, and then fasten it in front where she can see what she is doing, turn it around, put her arms in, and pull it up into place. Elastic straps or elastic inserts sewn into the straps make this relatively easy.

Shoe style should eliminate tying. Tie shoes can be adapted using a variety of lacing aids. If a man wears a tie, he may choose to slide the knot down and pull the tie off over his head without undoing the knot.

Bathing

The patient may bathe independently but must adhere closely to safety precautions. Non-slip material is used in the bottom of the tub, and a non-skid mat is placed out-

side the tub to stand on while transferring. Safety grab bars should be placed where they would be most useful to the particular person's needs. A tub bench or seat can eliminate the difficulty of sitting in and getting up from the bottom of the tub and provides a stable position for the patient who is washing the feet. If a seat is used, a hand-held shower spray is necessary.

If the patient chooses to shower instead of bathe, the non-slip material, grab bars, and seat also must be provided. In either case, the water should be drawn once the patient has transferred in and is seated; a mixer tap is ideal, but if it is unavailable, the cool water should be turned on first with the hot water added progressively to prevent scalding. Soap on a string keeps the soap retrievable, or a bath mitt with a pocket to hold the soap is useful. The water should be drained before the person attempts to stand to transfer out of the tub. An extra large towel or large terry wrap-around robe facilitates drying.

Suggestions for Selected IADL

Communication

Writing and speech are problems for some persons with coordination deficits. See Chapter 19 for alternative communication systems and adaptations for computers that are appropriate for these patients. If the patient speaks understandably, the use of large-button phones reduces the fine motor requirements of dialing the telephone, or a speaker phone can be used.

Playing Games

Board game pieces can be weighted or turned into pegs for stability. Game boards can be reproduced to enlarge the squares. Card holders and card shufflers are useful. Computer games that use keyboarding or switches rather than a mouse or joystick are appropriate.

Loss of Use of One Side of the Body or One Upper Extremity (Procedures for Practice 30-3)

For other information and suggestions, see Chapters 38, 42, and 46.

Suggestions for BADLs

The methods described here pertain to the hemiplegic patient who has lost the use of one side of the body. Although most stroke patients can be independent in their BADL, some are prevented from developing independence, especially of the less automatic tasks, such as one-handed upper extremity dressing, by cognitive-perceptual impairments (Edmans & Lincoln, 1990; Walker & Lincoln, 1991; Walker & Walker, 2001). Motor planning deficits, such as ideomotor apraxia, may make learning new skills more difficult; however, patients have been able

to learn a new motor process, such as one-handed shoe tying (Poole, 1998).

The methods and equipment described here may also be used by a person with a unilateral upper extremity amputation or temporary or permanent upper extremity limitations resulting from trauma. Patients with upper extremity amputation or injury, however, need fewer adaptations because they have normal trunk and lower extremity function and normal perception and cognition.

Feeding

Feeding is essentially a one-handed task, except for cutting meat and spreading condiments on bread, and these tasks can be done with assistive devices. Food can be simultaneously stabilized and cut by use of a rocker knife, a knife with a sharp curved blade that cuts when rocked over the food (Fig. 30-18). Bread can be spread if stabilized on a non-slip surface or trapped in the corner of a spike board and spread toward the corner (Fig. 32-2). Soft spreads facilitate this process.

Grooming

Difficulties with grooming include care of the unaffected extremity and completing two-handed activities. Spray deodorant for the unaffected arm is easier to use than other types of applicators. Fingernails of the unaffected hand are cleaned by rubbing them on a small suction cup brush attached to the basin (Fig. 30-19). Fingernails of the affected hand can be trimmed with a stabilized nail clipper (Fig. 30-8), and those of the unaffected hand can be trimmed with an emery board fastened down to stabilize it. The fingernail is moved back and forth over the emery board. Toothpaste in pump bottles or a toothpaste dispenser can be used with one hand. A floss holder or disposable flossers enable patients to floss teeth with only one hand.

Figure 30-18 Rocker knife for one-handed cutting.

Figure 30-19 Suction cup brush for cleaning nails or dentures with one hand.

Using another suction cup brush fastened to the inside of the basin, the person can scrub dentures by rubbing them over the brush. Partially filling the basin with water and laying a face cloth in the bottom cushions the dentures if they are dropped. An electric razor is recommended for shaving for patients post stroke because accidents are possible with a safety razor.

Toileting

The primary difficulty with toileting is managing clothing, which is normally done with two hands. A grab bar mounted on the wall beside the toilet and/or a frame mounted on the toilet (Fig. 30-10) will assist transfers and maintaining standing balance. Once standing, pants are unfastened, and gravity takes them down. If the patient's standing balance is impaired, pants should be unfastened before standing, and the affected hand should be placed in the pocket, which prevents the pants from sliding below the knees where they are difficult to retrieve. A woman in a dress can raise her dress on the affected side and tuck it between her body and the affected arm. Then she lowers her underpants to knee level and pulls the dress up on the unaffected side. The toilet tissue should be mounted conveniently to the unaffected side. The patient can manage menstrual needs by use of tampons or adhesive sanitary napkins.

BATHING

The bathing arrangements described for patients with incoordination also apply to people with hemiplegia. Patients may also find a long-handled bath sponge with a pocket to hold the soap useful to allow bathing of the unaffected upper arm and the back. The lower arm of the unaffected side is bathed by putting the soapy washcloth across the knees and rubbing the arm back and forth over it, unless the patient has some return of function and can use a bath mitt on the affected hand. Pump bottles of liquid soap and shampoo are useful, as is soap on

a rope. If sensory impairment exists, extra precautions should be taken to be certain of water temperature. Patients with hemiplegia should dry off as much as possible while still seated on the bath seat before transferring out of the tub.

A person with a unilateral upper extremity amputation can bathe using similar strategies. A bath bench enables patients to place a washcloth on one leg to enable them to wash the unaffected arm without balancing on one leg, which may present a safety risk for patients who lack excellent balance.

Dressing

Certain prerequisite abilities are considered important for successful dressing. These are ability to reach each foot, stand unsupported for 10 seconds, and maintain sitting balance when reaching down. The most difficult tasks for both men and women were found to be pulling pants up, putting the shoe on the affected foot, and lacing shoes (Walker & Lincoln, 1990, 1991). Many people can manage fasteners with one hand. Patients who have difficulty with one-handed fastening may prefer Velcro fasteners, which are easier to use (Huck & Bonhotal, 1997).

Patients with hemiplegia should dress while seated on a stable surface, with both feet on the floor to increase stability (Ryan & Sullivan, 2004). As a general rule, the affected limb is dressed first and undressed last.

SHIRT OR CARDIGAN GARMENT: OVER-THE-SHOULDER METHOD (RYAN & SULLIVAN, 2004)

The over-the-shoulder method is the most similar to the customary method of dressing, and garments are less likely to get twisted than when using the overhead method that follows.

1. Put the shirt on the lap, label facing up, collar toward the knees, with the sleeve for the affected arm hanging between the knees (Fig. 30-20A)
3. Put the affected hand into the sleeve and lean forward to let gravity extend the elbow and to slide the sleeve onto the arm (Fig. 30-20B).
4. Use the unaffected arm to slide the shirt over the affected shoulder.
5. Grasp the collar at the point closest to the unaffected side (Fig. 30-20C).
6. Hold tightly to the collar, lean forward, and bring the collar and shirt around the affected side and behind the neck to the unaffected side (Fig. 30-20C).
7. Put the unaffected hand into the other armhole. Raise the arm out and up to push it through the sleeve (Fig. 30-20D).
8. To straighten the shirt, lean forward, work the shirt down over the shoulders, reach back and pull the tail

Figure 30-20 Patient with left hemiplegia putting on a shirt. **A.** Position the shirt with the collar toward the knees and the sleeve for the affected arm hanging between the legs. **B.** Guide the affected arm into the sleeve, lean forward, and pull the sleeve up to the shoulder. **C.** Hold the collar tightly. Lean forward and bring the shirt up, around, and behind toward the unaffected arm. **D.** Put the unaffected arm into the armhole. Extend the arm out and up to push it through the sleeve. Straighten the shirt and button it.

down, and then straighten the sleeve under the affected axilla.

- To button, line up the shirt fronts and match each button with the correct buttonhole, starting with the bottom button.

To remove the shirt, unbutton it and use the unaffected hand to throw the shirt back off the unaffected shoulder. Work the shirt sleeve off the unaffected arm, pressing the shirt cuff against the leg to pull the arm out. Lean forward. Use the unaffected hand to pull the shirt across the back. Take the shirt off of the affected arm.

SHIRT OR CARDIGAN GARMENT: OVERHEAD METHOD (BRETT, 1960)

The overhead method for putting on and removing front-opening tops may be less confusing for a patient with perceptual impairments. This method is not suitable for coats.

- Put the shirt on the lap, label facing up, and the collar next to the abdomen; drape the shirttail over the knees (Fig. 30-21A).
- Pick up the affected hand and put it into the sleeve (Fig. 30-21B).
- Pull the sleeve up over the elbow (Fig. 30-21C). If the sleeve is not pulled past the elbow, the hand will fall out when continuing.
- Put the unaffected hand into the armhole. Raise the arm and push it through the sleeve as far as possible (Fig. 30-21D).
- Gather the back of the shirt from tail to collar (Fig. 30-21E).

- Hold the gathered shirt up, lean forward, duck the head, and put the shirt over the head (Fig. 30-21F).

- To straighten the shirt, lean forward and work the shirt down over the shoulders. Often the shirt gets caught on the affected shoulder and must first be pushed back over the shoulder. Then reach back and pull the tail down (Fig. 30-21G).

- To button, line up the shirt fronts and match each button with the correct buttonhole, starting with the bottom button.

To remove the shirt, the patient unbuttons it, leans forward, and uses the unaffected hand to gather the shirt up in back of the neck. He or she ducks the head, pulls the shirt over the head, and then takes the shirt off the unaffected arm first.

PULLOVER GARMENT (BRETT, 1960)

The following steps are used for putting on a pullover garment.

- Position the garment on the lap, bottom toward chest and label facing down.
- Using the unaffected hand, roll up the bottom edge of the shirt back, all the way up to the sleeve on the affected side.
- Spread the armhole opening as large as possible. Using the unaffected hand, place the affected arm into the armhole and pull the sleeve up onto the arm past the elbow. Alternatively, the sleeve may be positioned between the legs, as described earlier for the cardigan over-the-shoulder method.

Figure 30-21 Patient with left hemiplegia putting on a shirt using the overhead method. **A.** Put shirt on the lap, with label facing up, collar next to abdomen, and shirrtail draped over knees. **B.** Pick up the affected arm and put it into the armhole. **C.** Pull the sleeve well over the elbow. **D.** Put the unaffected hand into the armhole and raise the arm to push it through the sleeve. **E.** Gather the back of the shirt from the tail to the collar. **F.** Hold the gathered shirt up. Lean forward and duck the head to put the shirt overhead. **G.** To straighten the shirt, lean forward and work the shirt over the shoulders. Reach back and pull the tail down and the front sides forward. Button it.

4. Insert the unaffected arm into the other sleeve.
5. Gather the shirt back from bottom edge to neck, lean forward, duck the head, and pass the shirt over the head.
6. Adjust the shirt on the involved side up and onto the shoulder and remove twists.

To remove, starting at top back, gather the shirt up, lean forward, duck the head, and pull the shirt forward over the head. Remove the unaffected arm and then the affected arm.

BRA (BRETT, 1960)

The bra is placed around the waist and hooked in front, where the patient can see what she is doing. One end can

be tucked into the waistband of panties or under the affected arm until the other end is brought around. It is fastened and rotated to the proper position; the affected arm is placed through the shoulder strap; and the unaffected arm is placed through the other shoulder strap. The bra is pulled up into place. It is removed by reversing the process.

A plump patient may need an adapted front-closing bra if she cannot approximate the two edges of the bra to fasten it. The bra is adapted with a D-ring on the side of the bra opening on the involved side and a pile Velcro strap on the opposite side. After the bra is around the waist, the strap is threaded through the D-ring and pulled to bring the two ends of the bra together. Hook Velcro must be stitched onto the bra so the strap can be fastened.

PANTS (BRETT, 1960)

The following steps describe how to put on pants. Modifications of the following method are used for men's and women's underclothing and pantyhose.

1. Sit. If a wheelchair is used, the brakes should be locked and the footrests should be up and/or swung out of the way. Move the unaffected leg beyond the midline of the body for balance.
2. Grasp the ankle or calf of the affected leg. Lift and cross the affected leg over the unaffected leg (Fig. 30-22, A & B). Alternatively, cup the affected knee in clasped hands to lift and cross the leg.
3. Pull the pants onto the affected leg up to but not above the knee (Fig. 30-22C).
4. Uncross the legs.
5. Put the unaffected leg into the other pant leg.
6. Remain sitting. Pull the pants up above the knees as far as possible (Fig. 30-22D).
7. To prevent the pants from dropping when standing, put the affected hand into the pant pocket or the thumb into a belt loop (Fig. 30-22E). Alternatively, use a pant clip to attach the pants to the shirt so they do not slide down (Ryan & Sullivan, 2004). Pants with

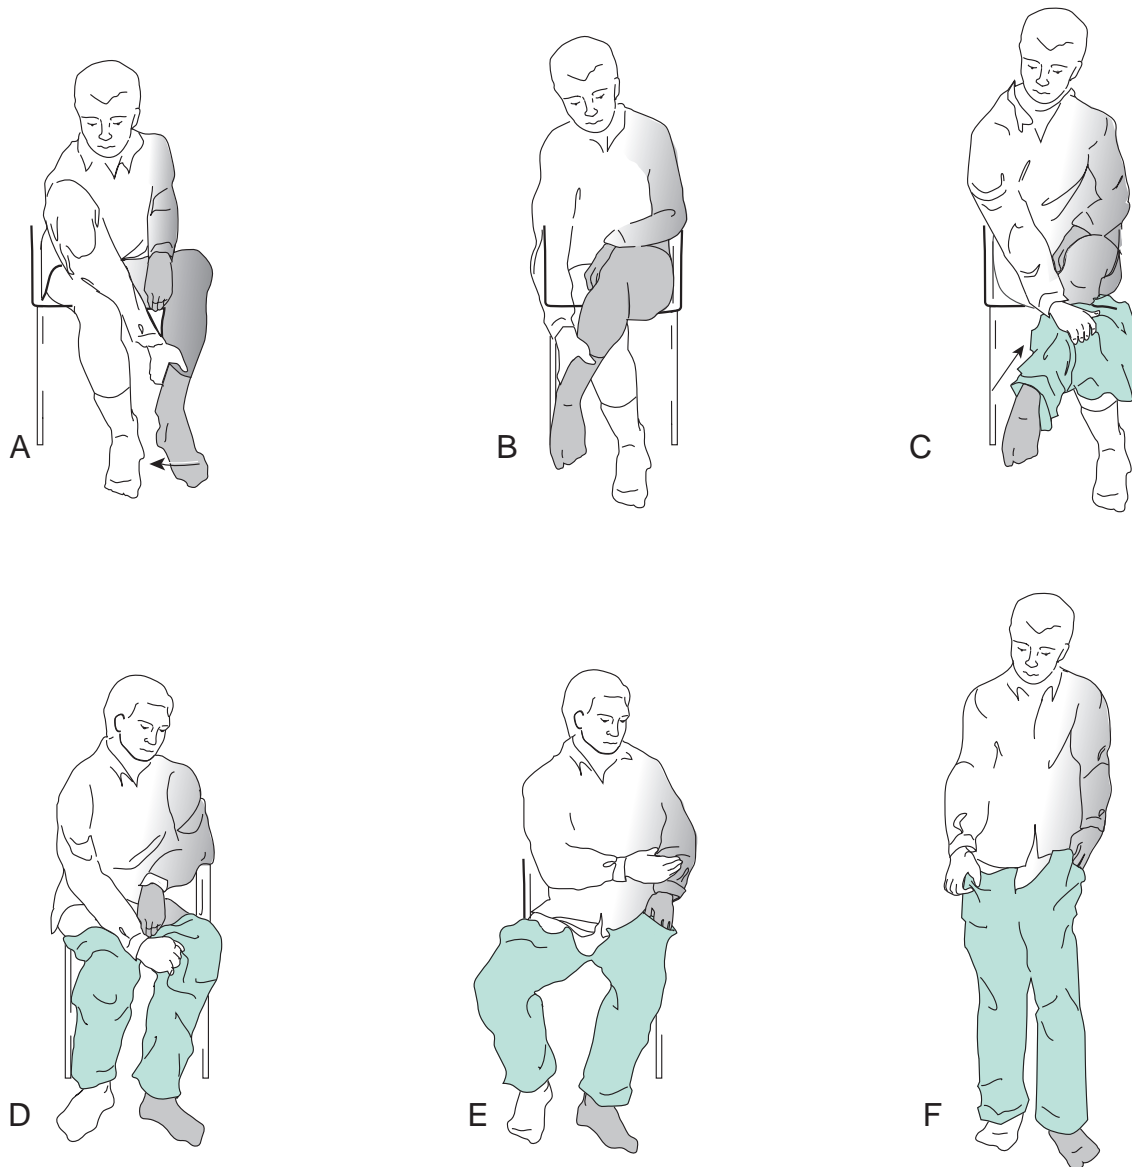

Figure 30-22 Patient with left hemiplegia putting on pants while sitting. **A.** With knees bent, move the unaffected foot across the midline of the body toward the unaffected side. **B.** Grasp the ankle of the affected leg, lift it, and cross it over the unaffected leg. **C.** Pull the pants onto the affected leg up to but not above the knee. **D.** Uncross the legs, put the unaffected leg into the pants, and pull them up above the knees. **E.** To prevent the pants from dropping when the person stands up, put the affected hand into the pocket. **F.** Stand up. Pull the pants over the hips and fasten, or sit to fasten if balance is not good enough to do it while standing.

elastic waistbands are also less likely to slide when standing up.

- Stand up. Pull the pants up over the hips (Fig. 30-22F); button and zip pants while standing. Persons with poor balance may remain seated and pull the pants up over the hips by shifting from side to side; they should button and zip the pants while seated.

To remove, unfasten the pants in sitting. Stand and let the pants drop past the knees or push down if wearing elastic waist garment. Sit. Remove the pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg. Uncross the legs.

People with poor balance should use the following method. Place locked wheelchair or chair against a wall. Sit. Unfasten the pants. Work the pants down on the hips as far as possible by shifting weight from side to side in the chair. Use the uninvolved arm to work the pants down past the hips. Remove the pants from the unaffected leg. Cross the affected leg over the unaffected leg. Remove the pants from the affected leg. Uncross the legs.

SOCKS OR STOCKINGS (BRETT, 1960)

The following method is used to put on socks or stockings.

- The affected leg is crossed over the unaffected leg as described earlier for donning pants. Or, if the patient has adequate flexibility, crossing the ankle over the thigh (like men sit) makes the foot easier to reach. The same process is used for the unaffected foot.
- The sock is opened by inserting the thumb and index finger into the top and spreading the fingers.
- The sock is put on the foot by slipping the toes into the opening made under the spread hand. The sock is then pulled into place, and wrinkles are smoothed.

Patients who cannot cross their legs can rest the heel on a small stool. Patients who cannot reach their feet may use a reacher to start the sock over the toes, but they will need to reach down to pull the sock over the heel. Although sock aids are effective for overcoming limited reach, getting the sock on most sock aids is difficult or impossible with one hand, so this device will not be helpful for most people with use of only one hand.

To remove, the leg is positioned as for putting the sock on. The sock is pushed off with the unaffected hand.

SHOES (BRETT, 1960)

A loafer is put on the affected foot with the shoe on the floor. The foot is started into the shoe, and a shoehorn is used to help ease the foot into the shoe. A tie shoe is put onto the affected foot after the leg is crossed over the unaffected one to bring the foot closer. If the laces have been thoroughly loosened, the person often can work the shoe on while the leg is crossed over by grasping the heel of the shoe with the unaffected hand and working it back and forth over the heel until it goes on completely. Sometimes it is necessary to insert

a shoehorn while the leg is crossed over and then carefully lower the foot with the shoe half on and shoehorn in the shoe and finish putting on the shoe by repeatedly pushing down on the knee and adjusting the shoehorn.

Tying the shoes is a problem. It is possible to tie a conventional bow one-handed, but it requires fine dexterity and normal perception. The patient with an amputation may prefer to do this or use loafers. The patient with hemiplegia can use adapted shoe closures or learn a simple, effective one-handed shoe tie as illustrated in Figure 30-23. Putting the lace through the last hole from the outside of the shoe toward the tongue lets the tension of the foot against the shoe hold the lace tight while the bow is being tied. One-hand shoe tying is difficult for patients with cognitive-perceptual deficits to learn.

ANKLE-FOOT ORTHOSIS

The posterior shell or molded ankle-foot orthosis (AFO) is usually easiest to don if placed in the shoe first (Ryan & Sullivan, 2004). The shoe laces should be quite loose to allow the maximum room possible for getting the foot into the orthosis and shoe. The orthosis acts like a shoehorn, as the foot slides into the shoe.

Sexual Activities

A helpful booklet, *Sex after Stroke* (American Heart Association, 2000), is available online (www.strokeassociation.org/presenter.jhtml?identifier=9065) or in print from the local affiliate of the American Heart Association/American Stroke Association. It discusses sexuality and body image, fears about resuming sex, specifics of sexual intimacy after stroke (bowel and bladder control, change of position to accommodate paralysis, birth control, pregnancy, and ways to make love other than intercourse) and contains a list of additional resources.

Suggestions for Selected IADLs

Writing

Persons with only one functional arm have to stabilize the paper when writing with the unaffected hand. The paper can be secured using masking tape, a clipboard, a weight, the affected extremity, or other similar means. If the dominant hand is the affected one, writing practice for the non-dominant hand, especially for the signature, is usually required. Alternatively, the patient can purchase a signature stamp.

Leisure Activities

Many devices for leisure activities are available for people who have lost the use of one hand, including devices for knitting, crocheting, embroidery, playing cards, and fishing. Resource 30-1 includes sources where devices can be explored and purchased.

Figure 30-23 One-handed shoe tie for a left hemiplegic patient. For a right hemiplegic patient, start the lace on the right side of the shoe so that the lace ends on the left side at the top.

Lower Extremity Amputation with Prosthesis

Persons with lower extremity amputations can benefit from many of the adaptations described for people with limited mobility due to weakness or decreased range of motion; however, lower body dressing for prosthetic users presents a unique challenge not previously addressed. Prior to dressing, patients should change the shoe and/or sock on the prosthesis to match the day's clothing. Patients with a transtibial (below knee) amputation with pants wide enough to pull up to the knee should dress while seated using the following steps:

1. Place pants over unaffected leg and amputated leg, pulling pants up as far as possible.
2. Patients who are stable standing on one leg can stand to pull the pants up and then sit down to don the residual limb stocking and prosthesis, exposing the area by sliding the pant leg up over the knee.
3. Patients who are not stable standing on one leg should remain seated and don the prosthesis before standing to pull up their pants so that they have the stability of

both lower extremities when standing to complete the task.

Patients with a transfemoral (above knee) amputation or those with a below knee amputation who wish to wear fitted pants that cannot be slid up over the knee should dress as follows:

1. Slide the end of the pant leg for the amputated limb down over the top of the prosthesis so that the prosthesis is dressed first. The shoe and limited ankle mobility will prevent the pants from being slid over the prosthetic foot.
2. Don the stocking and the prosthesis.
3. Place the unaffected leg into the pants.
4. Stand to pull up and fasten the pants.

Limited Vision (Procedures for Practice 30-3)

The suggestions listed here pertain to blindness (20/1250 to worse than 20/2500) and to low vision (20/80 to 20/1000) (Colenbrander & Fletcher, 1995). Organization

and consistency in the placement of objects is necessary for persons with visual impairment to locate things efficiently. General strategies to enhance visual performance include enlarging objects, magnification, increasing contrast through better lighting or use of color, and reducing glare in the environment (Lampert & Lapolice, 1995; Smith, 2001). Other modifications eliminate or reduce the need for vision by substituting with auditory or tactile information, such as a talking clock or locating dryer settings with a raised mark. The American Foundation for the Blind and Lighthouse International are major sources for obtaining information and assistive devices for persons who are blind or visually impaired (see Resources 30-1). For additional information, see Chapter 28. A number of high-tech solutions are available for persons with impaired vision, particularly for computer usage (see Chapter 19).

Suggestions for BADLs

Feeding

When possible, food should be set in a consistent pattern, using a clock method of description, such as “meat at 3 o’clock.” When this is not possible, a companion or server can tell the person where food is located on the plate. When pouring liquid, the correct amount can be determined by inserting a clean finger over the rim to feel when the liquid is near the top or by using a liquid level indicator, which is placed on the rim of the cup and gives an auditory signal when the cup is full. Food is cut by finding the edge of the food with the fork, moving the fork a bite-size amount onto the meat, and then cutting the food, keeping the knife in contact with the fork. For those with low vision, the plate, glass, and utensils should be a color that contrasts with both the table covering and the food.

Grooming

A major problem is identification of objects. This can be done through the use of taste, touch (size, shape, and texture), location, and Braille or bar code labels. The application of cosmetics or toiletries is another problem; fingers of the assistive hand can be guides, such as when shaving sideburns or applying eyebrow pencil. Aerosol sprays should be avoided because persons who have low vision cannot see the extent of the spray.

Dressing

Limited vision creates no difficulty with the physical aspects of dressing, but persons with impaired vision need a system to coordinate colors of clothes and compatibility of style. One system is to store clothes of like color together. Clothes should always be hung properly to prevent wrinkles. Wrinkle-free, stain-resistant, no-iron fabrics are desirable. Clothing selection can be done with the assistance of a sighted person who can describe colors and style. Tactile

or high-contrast identification tags can be placed on hangers to denote the color of clothes. Colorless wax polishes can be used to shine shoes.

Suggestions for Selected IADLs

Writing and Reading

Persons with visual impairment can use a signature or writing guide to stay within boundaries while writing in longhand. Using a black felt-tipped pen on white paper provides good contrast. Talking books and magazines can be used in place of written materials, and a variety of optical devices can enlarge print in newspapers, personal mail, etc. For those with moderately low vision, books, popular magazines, and *The New York Times* come in large-print versions. Many periodicals are available online and can be viewed with a screen magnifier, such as ZoomText (www.synapseadaptive.com/aisquared/zoomtext_9/zoomtext_9_magnifier.htm). Hand-held computerized devices (www.envisionamerica.com) that scan bar codes and identify products can be useful in the household and at work; other devices scan medicine bottles and inform the person of the medicine in the bottle and the dosage schedule.

Telephoning

People with very limited vision can memorize the position of numbers on the touch pad, and those with low vision can use phones with large buttons. A phone with one-button automatic dialing is very useful, as are voice-activated phones.

Time

The person can tell time using a Braille or talking watch or clock.

Shopping

Much shopping by persons with low vision can be done through catalogs, read by use of closed-circuit television (CCTV) or online with screen magnifiers. Portable CCTV that can be taken out and used in the community is becoming available.

Handling Money

Tactile discrimination enables the person to identify coins. Paper money is discriminated by the way it is folded after its denomination has been identified previously by someone else or viewed by magnification.

Playing Games

Braille versions of popular games, such as Monopoly, Bingo, and playing cards, are available. Large-numbered cards are also available for those with low vision.

Decreased Sensation (Procedures for Practice 30-3)

For additional information, see Chapter 27.

Suggestions for BADL

Problems of absent, decreased, or disturbed sensation affect performance of ADL whenever a possibly dangerous situation is encountered and because the automatic knowledge of limb movement and touch may be missing.

Bathing

With bathing, there is danger of scalding. When turning water on, the cold is turned on first, and then the hot is added gradually. Mixer valves should be installed to compensate when decreased sensation is a permanent condition. If the patient has intact areas of sensation, they can learn to test water temperature with those areas.

Dressing

Wrinkles, seams, or bands on clothing that are sufficient to cause tissue damage may not be felt by patients with impaired sensation and can cause decubitus ulcers within a short time. Clothing should be selected that is snug enough to prevent bunching but loose enough to avoid binding or excessive pressure. Persons with insensitive skin should inspect clothing visually or with an area of intact sensation to avoid wrinkles. They must dress warmly in cold weather to prevent frostbite.

Suggestions for Selected IADLs

Poor sensation does not allow graduated pinch and grip on tools and utensils to meet the demands of the task. The person grips with excessive pressure (Johansson & Westling, 1984). Prolonged, excessive grip or pinch can cause bruising and decubiti. Poor sensation also results in letting go, when the attention is directed away from the object being held. Devices discussed early for poor grip may help persons with impaired sensation for activities requiring sustained grip.

Activities that involve using hot objects, such as a riding mower or cooking at an outdoor barbecue, pose a threat because anesthetic lower extremities can be burned if allowed to rest against the hot engine cover or bottom of the barbecue. Objects should be insulated when possible, and patients should be trained to be extra vigilant in positioning themselves near hot items.

Cognitive-Perceptual Impairments (Procedures for Practice 30-3)

See Chapters 28 and 29 for information concerning methods to compensate for cognitive or perceptual impairments in activities of daily living.

Pain, Including Low Back Pain (Procedures for Practice 30-3)

See Chapters 32 and 41 for information concerning body mechanics to be used during occupational functioning for persons with low back pain.

Considerations in Bariatric Care

Occupational therapists are treating increasing numbers of patients who are exceptionally large. Obesity is associated with a number of health problems (Foti & Littrell, 2004). Additionally, persons who are exceptionally large often have movement limitations that result directly from their size, so these patients often require occupational therapy (Foti, 2005). Several considerations warrant discussion regarding adaptations for these individuals. Excessively large individuals with a medical condition may have more occupational performance deficits than are typically seen because of pre-existing limitations in strength relative to body mass, limited reach, and decreased endurance. A thorough functional assessment is needed to ensure all problems are identified (Foti & Littrell, 2004). Adaptive equipment must be carefully evaluated to make sure that it has been approved to handle the patient's weight and that it is sized appropriately to meet the patient's needs. For example, many tub seats are approved to handle up to 300 pounds and cannot be used safely by a heavier person. Traditional sock aids may be too small to accommodate the patient's foot or calf, and a soft variety may need to be used (Foti, 2005). The typical home environment may present a number of obstacles for persons of exceptional size, including narrow doorways or pathways that prevent the person from entering a room. Bathrooms are commonly too small to be functional for persons who are exceptionally large, and they may find themselves confined to one or two rooms in their homes (Foti & Littrell, 2004). Caregivers may be limited in the tasks they can assist a person with because of risk of physical injuries. Psychosocial issues may complicate the clinical picture.

Adaptive strategies described earlier for persons with weakness, limited reach, and/or endurance may all be effective in treating persons of exceptional size. A number of companies have equipment especially designed for the bariatric population that can help the therapist select appropriate and safe adaptations for these patients (see Resources 30-1; also, additional resources are included in the references by Foti, 2005 and Foti & Littrell, 2004).

Service Dogs: An Adaptation Option for a Range of Performance Limitations

Service dogs are specially trained to meet the needs of persons with limitations in mobility and/or ADL due to loss

of vision, hearing, and physical impairments. Service dogs are trained collaboratively with the owner so that they learn skills suited to meet the individual's unique needs. The training is extensive and, therefore, expensive, so service dogs are appropriate only for persons with permanent disabilities.

Service dogs can assist people with a variety of tasks. Dogs for people with visual impairment are primarily used for mobility by acting as a guide. Hearing dogs alert their owners to auditory stimuli that require a response, e.g., doorbells, alarm clocks, oven timers, and smoke detectors. Other physical disabilities vary significantly, and the range of activities that service dogs can assist with is very large. Dogs at Canine Companions for Independence (see Resources 30-1) learn about 40 commands, which can be adapted to individual circumstances. For instance, the tug command is normally used on doors and drawers but can be used to remove socks or other clothes (Fig. 30-24). The most common activities include help with wheelchair and floor transfers, mobility in home and community, carrying items, operating switches (e.g., lights, elevator buttons), retrieving and moving items, and opening doors, drawers, and cabinets (Allen & Blascovich, 1996; Fairman & Huebner, 2000).

Service dogs are an adaptive tool; however, they do not seem to carry the same stigma as assistive devices and may even support social participation. Service dog owners have reported increased interactions with friends and people out in public, increased confidence, and enhanced feelings of safety (Camp, 2001; Fairman & Huebner, 2000; Valentine, Kiddoo, & LeFleur, 1993). Allen and Blascovich (1996) conducted a randomized controlled study to examine the impact of service dogs on a number of variables, comparing an intervention group that received a service dog and a wait-list control group with no dog. The service dog group had higher scores on psychosocial variables (including self-esteem and community integration), in-

creased participation in school and work, and a decrease of 68% in both paid and unpaid assistance hours. The wait list group showed a similar pattern of improvement 18 months later when they received their dogs. Although the cost of training a service dog was estimated at \$10,000, the researchers estimated that savings in personal care attendants would reach \$60,000 after 8 years, the average working life of the dog (Allen & Blascovich, 1996).

EFFECTIVENESS OF THERAPY TO RESTORE THE ROLE OF INDEPENDENT PERSON

Evidence from meta-analyses and randomized controlled trials that demonstrate occupational therapy has a positive effect on client functional outcomes in BADLs and IADLs is summarized in Evidence Table 30-1. Additional studies, although less rigorous in design, also offer insight into occupational therapy intervention strategies aimed at increasing occupational performance in adults with physical disabilities through modifying the task and/or environment.

One study examined the effect of occupational therapy on BADL, IADL, and quality of life in 43 patients post stroke in an inpatient rehabilitation center in Australia. All patients received specific BADL training, and 79% received specific IADL training. Significant increases were seen in BADL, IADL, and quality of life. Improvement in BADL and IADL was the most common theme in a follow-up interview of participants who demonstrated an increase in quality of life from admission to discharge (Unsworth & Cunningham, 2002). Although this study lacked a control group, it identified an important link between ADL performance and quality of life that warrants further study.

A study of changes in patients' self-care ability following a 1-week rehabilitation stay was conducted with patients with multiple sclerosis (Mathiowetz & Matuska, 1998). Self-care ability was measured on admission, at discharge, and 6 weeks after discharge. Occupational therapy primarily used a compensatory approach, including adaptive equipment and techniques, as well as energy conservation strategies. Self-care ability for all BADL items from initial assessment to discharge increased significantly. Surprisingly, self-care ability continued to improve, and there were also significant improvements between discharge and 6 weeks later for all activities except feeding. This finding may suggest that participants learned to problem solve in the context of ADLs that enabled them to continue progress even after discharge, although other explanations exist, and this hypothesis should be studied further.

Assistive devices and adapted methods reduced the difficulty in doing daily activities by 42% among women aged 29–54 years who had rheumatoid arthritis (Nordenskiöld,

Figure 30-24 Service dog is given the “tug” command to help remove his owner’s sock (Courtesy of Canine Companions for Independence, Santa Rosa, CA.)

Evidence Table 30-1 Best Evidence for Occupational Therapy Practice Regarding ADL

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-specific practice of client-chosen BADL	Practice of specific tasks in a familiar context	403 stroke survivors (189 LCVA, 194 RCVA, 20 other). Mean age = 72.7 years.	Ranged from 1–15 visits over a period of 2 weeks to 5 months.	Meta-analysis of 4 studies.	Yes. The treated groups improved in BADL as measured by varied ADL assessments.	Mean weighted effect size was $r = 0.30$, equivalent to a 30% success rate over control treatment.	Trombly & Ma, 2002
Follow-up OT in the home after rehabilitation.	Home OT visits for review of assistive devices for bathing introduced in hospital.	53 adults with stroke who were discharged home with bathing equipment. Mean age = 72.1 years.	Control and treatment groups got inpatient instruction. Treatment group got 2–3 home visits.	Single-site randomized controlled trial. IB2a	Yes. The treated group improved more in BADL as measured by the <i>Functional Independence Measure (FIM)</i> than the control group.	$t(51) = 2.002$; $p = 0.051$; effect size, $r = 0.27$, equivalent to a 27% success rate over control treatment.	Chiu & Man, 2004
Home-based OT	In-home OT to clients with a diagnosis of stroke. “Home” included own home or residential or nursing homes.	965 stroke survivors. Mean age = 70.0 years.	Ranged from 10 sessions to up to 5 months of intervention.	Meta-analysis of 5 studies. Outcome measure focused on IADL.	Yes. The treated group showed small improvement on <i>Nottingham Extended ADL Scale</i> .	$Z = 2.97$; $p = 0.0003$; effect size, $r = 0.10$.	Walker et al., 2004
Home-based OT	Control: Conventional outpatient follow-up. Treatment: Conventional follow-up plus 6 weeks of home OT.	138 adults with stroke.	Client-centered intervention. Approximately 10 30- to 45-minute visits over 6 weeks.	Single-site randomized controlled trial. IA2a	Yes. Treated group reported higher performance scores on the <i>Canadian Occupational Performance Measure</i> .	Group differences measured with Mann-Whitney U , $p = 0.0006$; $Z = 3.25$; effect size, $r = 0.27$.	Gilbertson & Langhorne, 2000

continued

Evidence Table 30-1 (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Joint protection educational-behavioral program	Control: Standard program, including education on joint protection. Treatment: Joint protection including strategies to increase adherence.	127 adults with rheumatoid arthritis (<5 years since diagnosis).	Both programs included 4 2-hour weekly meetings.	Two-site randomized controlled trial. IA1a	Yes. At a 48-month follow-up, the treated group had significantly better ADL scores compared with the control group.	Group differences measured with Mann-Whitney <i>U</i> , $p = 0.04$; $Z = 1.75$; effect size, $r = 0.15$.	Hammond & Freeman, 2004
Assistive devices and environmental adaptations	Control: Usual care services. Treatment: Comprehensive assessment, prescription, training, and follow-up in assistive devices and home modifications.	104 home-based frail older adults. Mean age = 73 years.	Treatment group received, on average (means), 14.2 devices, 8.9 OT visits, and 2.4 home-modification technician.	Randomized controlled trial. IA2a	Yes. Although both groups had declined in BADL and IADL at the 18-month follow-up, the treatment group had declined significantly less than the control group in BADL. The difference in IADL was not significant ($p = 0.13$).	BADL, measured by the <i>FIM</i> : $F = 7.02$; $p = 0.01$; effect size, $r = 0.17$.	Mann et al., 1999
Service dog	Control: No dog (wait list for 13 months). Treatment: Received service dog 1 month into the study.	48 individuals with severe, chronic ambulatory disabilities requiring wheelchair use. Mean age = 25 years.	Dog training was 6–12 months. Training with participants was not specified.	Randomized controlled trial. IB1a	Yes. Self-reported biweekly hours of both paid and unpaid assistance were significantly less in the treatment group, suggesting more independence in ADL and IADL performance compared with the control group.	Effect of a service dog on assistance was very large: $r = 0.98$ for paid assistance and 0.96 for unpaid assistance.	Allen & Blascovich, 1996

EXAMPLE

A.C.: Adaptation and Training for Basic Activities of Daily Living

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

A.C. is a 50-year-old woman who was admitted to an inpatient rehabilitation unit 1 week after a decompression laminectomy with fusion of T5–T6 secondary to a metastatic spinal tumor with resulting paraparesis. The primary tumor was breast cancer, which was diagnosed and treated 3 years ago, and she was cancer free until the spinal tumor. The inpatient OT assessment revealed the following primary problems: (1) minimal to maximal assistance with bathing, dressing, toileting, bowel and bladder management, and transfers; (2) limited reach secondary to spinal orthosis (TLSO), which restricts trunk and hip flexion (worn whenever upright for 8 weeks post-operatively); (3) significant trunk and lower extremity weakness (2–/5), leading to poor sitting balance; (4) persistent pain in the mid-thoracic area; (5) fatigue; and (6) possible depression.

A.C. is in a stable and supportive marriage and has 2 teenage children living at home. She works as an elementary school nurse. Her husband works full time. She lives in a 2-story home. All bedrooms are on the second floor. There is a half-bath on the first floor and a full bath on the second. A.C. sought out both Western and complementary health care when treating her breast cancer, including acupuncture and yoga. Her immediate goal is to be able to return home without having to rely heavily on her family for assistance and to be able to cook for her family. Eventually, she wants to return to work.

Appreciate the context

“A.C. has an incomplete spinal cord injury, and it is hard to predict what her sensorimotor function will ultimately be. She will probably be discharged from inpatient rehabilitation within about 3 weeks, though, which means she will almost certainly still be relying on a wheelchair and will be wearing her brace for the first month she is home. Her home has some environmental barriers that will need to be looked at.”

“Being diagnosed with metastatic cancer after being cancer free for 3 years must be very difficult for A.C. It appears that she might have a reactive depression. I wonder if she is being treated for that. I wonder what her prognosis is. I should remember to look in her chart to find out the tumor grade and check my pathology books for a refresher on prognosis for metastatic cancer. Her active involvement in her prior treatment, such as using alternative treatments, suggests she might be anxious to work collaboratively in the rehab process.”

“I wonder how her kids and husband are responding to all this. A.C.’s goals suggest that she wants to return some level of ‘normalcy’ to their family routines as soon as possible.”

Develop intervention hypotheses

“I think that the things interfering most with A.C.’s ability to be independent in BADL are her limited reach (due to brace, lower extremity weakness, and impaired sitting balance), fatigue, and back pain. I am wondering if depression might be exacerbating her pain and fatigue. The home environment also presents some obstacles. A.C.’s background as a nurse will support the rehabilitation process. Her prior routines, which included healthy exercise and yoga, have left her with excellent upper extremity strength that she can use to compensate for her paraparesis. Her family is supportive, and her desire to return to roles as wife and mother seem to be powerful motivators for participation in treatment.”

Select an intervention approach

“At this point, I will primarily rely on an approach that **compensates** for A.C.’s deficits because her inpatient rehabilitation stay will be fairly short and it is important to her to minimize dependence on her family when she returns home. Additionally, it is likely she will be using a wheelchair at discharge, and her home is not currently accessible. **Modifying the physical environment** will require some time and should be started right away. Although fatigue can be approached with a **remediation** approach to increase the physical component, I think that the level of activity required for learning compensatory strategies will be enough to increase activity tolerance without using a rote exercise program.”

Reflect on competence

“I have worked with many patients who are limited by a back brace, but I haven’t worked with many who also have paraparesis. I’ll need to think more about how to combine methods to help A.C. reach her feet for dressing and bathing that will work with lower extremities that lack functional movement. I’m also not sure how to address the prognosis issue. Is she worried about her life expectancy? Should I invite her to talk about this, or would that be upsetting to her?”

Recommendations

The occupational therapist will see A.C. twice a day for 45-minute treatment sessions. The following long-term goals were established for A.C. to reach prior to her discharge home: (1) A.C. will be independent in all BADL except donning shoes and socks and washing feet; (2) A.C. will be independent in sliding board transfers, wheelchair to and from bed, upholstered chair, toilet, transfer tub seat, and car; (3) A.C. will be independent in planning and preparing simple, hot meals with a maximum of a 10 on the *Borg Rating of Perceived Exertion* at the completion of the task; (4) A.C. will be able to access necessary facilities in her home, including bed, toilet, shower, kitchen appliances, and electronics (telephone, computer, TV, etc.); and (5) A.C. will be independent in wheelchair mobility on smooth level surfaces and appropriately graded ramps.

Consider the patient’s appraisal of performance

“A.C. seems to have a realistic view of her abilities and limitations. If anything, she seems to underestimate what she can do, for example, she feels she can’t do anything herself, but she can feed herself, complete grooming, and bathe her face, arms, and thighs.”

Consider what will occur in therapy, how often, and for how long

“I’m going to bring up the issue of depression in the team meeting. I think she should be evaluated because, if she is clinically depressed, antidepressants might help with pain management and reduce fatigue, which would allow her to participate more actively in treatment. Right now, it is hard to make the most of the 90 minutes I have allotted for treatment each day. In the meantime, I need to make sure I use the right balance of physically challenging tasks and those that rely on more of her cognitive abilities, like making plans to improve the accessibility of her home. That way, I can utilize all the valuable treatment time without over-taxing her.”

Ascertain the patient’s endorsement of plan

“A.C. strongly agrees with the goals, although she seems to doubt whether all this can be accomplished in just 3 weeks. Her sense of self-efficacy seems pretty low right now and will need to be addressed in treatment. It might help to also involve her family in this aspect of care so they can help her see her progress, no matter how small the steps seem to be at first.”

Summary of Short-Term Goals and Progress

1. A.C. will require minimal assistance to don underwear and pants using adaptive equipment.

The therapist thought that donning the elastic stockings that A.C. is required to wear and donning shoes would be very difficult to master while the back brace had to be worn. The therapist explained the challenges these tasks presented, and A.C. agreed that it would be okay to have her husband help with shoes and socks until the brace was removed and she could reach her feet without adaptive equipment. A.C. positioned herself in long sitting, resting against the elevated hospital bed. She was able to use a dressing stick to get her pants over her feet with minimal assistance and verbal cues to increase her effectiveness with the dressing stick.

2. A.C. will be independent in self-catheterization.

A.C. couldn’t see her urinary meatus because the back brace prevents trunk flexion. She was given a leg abductor with a mirror that enabled her to see.

Assess the patient’s comprehension

“A.C. follows instructions well and remembers strategies that are taught to her (for example, the steps to doing a sliding board transfer), but she still requires help to initiate problem solving. For example, she needed prompting to come up with ways to apply energy conservation principles to a cooking task. Again, this might be related to depression. She was diagnosed with clinical depression and started on medication, but we can’t really expect to see a change for 3 weeks or so, and by that time, she’ll be home. So, I just continue to use treatment that I hope will be extra motivating. She loves to be able to transfer to the couch with her family where they can sit close on the couch and visit or watch TV without the wheelchair as a barrier between them. She said she was also glad to be able to make a snack for her kids ‘just like a mom!’”

Understand what the patient is doing

Compare actual to expected performance

Know the person

Appreciate the context

“A.C. is actually progressing a little faster than I expected with physical tasks such as transfers and lower body dressing. Maybe her experience with the difficult and controlled postures of yoga helps her adapt her movements to her “new” body. She also isn’t afraid to experiment with movement and that might be why she progressed so quickly with transfers and maneuvering the dressing stick for lower body dressing. Maybe I can push her a little more with the physical activities, as long as I watch her fatigue level.”

3. A.C. will require supervision for sliding board transfers from wheelchair to and from bed and level, firm, upholstered surfaces.

A.C. progressed quickly with sliding board transfers because her upper extremity strength was excellent and helped her both maintain her balance and move her body along the board. The therapist now just provides supervision in case A.C. loses her balance and pitches forward during the transfer. The therapist instructed A.C.'s husband and children how to “guard” A.C. during transfers, which enabled A.C. to transfer onto the couch in the lounge when her family visited.

4. A.C. will prepare brownies from a box mix with verbal cues and stand-by assistance with a maximum of 13 on the *Borg Rating of Perceived Exertion*.

A.C. was instructed in energy conservation techniques prior to the cooking task and identified 3 strategies she could use to reduce the energy demands of the task with 4 verbal cues from the therapist. She used reachers, a rolling cart, and long oven mitts to complete the task. She reported her perceived exertion was a 12. She shared her brownies with her family when they came in later to visit.

5. A.C.'s husband will bring in a layout of the first floor of their home with measurements, as requested by the OT in preparation for home modifications to increase wheelchair accessibility.

Initially, A.C. and her husband preferred to wait on the home modifications, hoping that A.C. might be able to walk with a walker upon discharge. When A.C. got into her second week, they realized that significant changes needed to be made at home, and the husband brought in the requested information. A.C. was especially upset to learn that the bathroom door was 1” narrower than her wheelchair.

“Funny, I didn’t really expect the resistance to bringing in home plans and measures. I guess those kinds of changes drive the reality of A.C.’s disability home for both her and her husband. A.C. seems especially upset about the bathroom. I wonder if her husband or a friend is handy enough to reframe the door so she can get to the toilet. We’re also going to have to address the issue of the bed. I think she’d be better off with a hospital bed until the brace is off because it helps with bed mobility and sitting balance for dressing, but this might be a ‘hard sell’ for both A.C. and her husband.”

Next Steps

- Continue to modify short term goals to progress patient toward BADL, mobility, and cooking using adaptive equipment and methods.
- Make preliminary recommendations for home assessment, collaborating with A.C. and her husband to determine the “best” solution and provide a home program to support follow through with recommendations (Fig. 30-25).
- Complete a home visit with A.C. and her husband to examine accessibility and make final recommendations.
- Provide training to husband and children (as appropriate—determined collaboratively with A.C.) in any areas that required assistance or supervision.
- Examine options for home-based occupational therapy and write a referral.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“I think A.C. will progress well with independence in occupational performance. I expect the home modifications will be a bigger challenge. She wants to be able to access the full bathroom and her bedroom upstairs, but this would require an expensive stairglide, which may be premature (and A.C. has also said she doesn’t want ‘such an eyesore’ in her house). Intellectually, I think A.C. understands the problems. Emotionally, the choices are hard. The temporary ‘fixes’ make her feel more disabled (changing the living room to her bedroom, replacing the bathroom door with a curtain so she can get to the toilet, etc.). This is an issue that she will continue to deal with after discharge.”

“I think home-based therapy would be best for A.C. after discharge. She certainly has a lot of skilled occupational therapy needs because we had little time to address a host of IADLs, as well as work and leisure tasks. She would qualify for home OT because she is home bound. Additionally, it would be helpful to work with her in her actual environment where she might feel more comfortable problem solving. Once she is out of the brace, she’ll become more mobile and should switch to outpatient therapy, which might include a driving evaluation and treatment and possibly return to work training.”

Figure 30-25 Home Program for A.C.: Modifications to maximize independence in the home upon discharge.

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Interdisciplinary Treatment in Rehabilitation

During A.C.'s inpatient rehabilitation, the occupational therapist worked as a member of an interdisciplinary team. How would the occupational therapist interact with the following disciplines to facilitate A.C.'s care?

- Physical therapy
- Social work
- Nursing
- Psychology
- Medicine

What avenues of communication might the occupational therapist use?

Grimby, & Dahlin-Ivanoff, 1998). The researchers found that eating, cooking, and toileting were most improved by assistive devices or methods, and dressing, clothes care, cleaning, outdoor mobility, and shopping were least improved. This study suggests that occupational therapists should pay special attention to those ADL least improved by devices when working with patients with rheumatoid arthritis to make sure that their needs are being met.

Shillam, Beeman, and Loshin (1983) used a pre-test/post-test design and found that subjects who participated in occupational therapy, including task-specific training and prescription of assistive devices, had a significant improvement in bathing ability. The greatest barrier to full independence for those who failed to reach independence was the wheelchair to tub transfer. Washing and drying the feet and legs were also problems for many due to limited sitting balance. Additional modifications or practice in transfers and bathing the feet and legs may help to improve outcomes in bathing.

A pre-test/post-test study addressed an occupational therapy program of 12 weeks in which 33 patients in 16 occupational therapy departments were taught strategies to compensate for apraxia during ADL. After statistically controlling for the apraxia score, motor functioning score, and spontaneous recovery, the results indicated large improvements in ADL. Effect sizes were large: $r = 0.75$ for the *Barthel Index*; $r = 0.80$ for ADL observation, and $r = 0.77$ on ADL questionnaire (patient perception) (van Heugten et al., 1998).

In a randomized crossover design, 15 subjects who had trouble dressing at home for 6 months after discharge from hospital post stroke received 3 months of dressing training in the home followed by 3 months of no treatment. Another 15 similar subjects first received no treatment and then received dressing training. Both groups showed significant improvement during the treatment phase, but neither group improved during the no-treatment phase. The group that received treatment during the first 3 months main-

tained their gains (Walker, Drummond, & Lincoln, 1996). This study is important because it suggests that gains in ADL post stroke can be made many months after the typical rehabilitation period is over.

Consideration of the findings of this research may help occupational therapists develop more effective intervention and provides preliminary evidence that should be studied through more rigorous clinical research.

SUMMARY REVIEW QUESTIONS

1. How is occupation-as-end used to improve occupational functioning?
2. Define and contrast IADL and BADL.
3. What conditions interfere with the patient's ability to learn ADL methods?
4. What principle of compensation is implemented when a patient with limited or restricted range of motion uses a sock aid?
5. What device can enable use of utensils when a patient lacks grasp?
6. What modifications may be necessary to enable a person with C6 tetraplegia to complete the tasks required of a college student majoring in journalism?
7. What principles of compensation are used for problems of incoordination?
8. State the steps a stroke patient can use to put on and remove a cardigan-type garment.
9. Name five energy conservation techniques and give an example of each that could be used by a patient with cardiac disease.
10. Describe how a person with low vision can decorate and arrange the bathroom to facilitate efficient independence.

LEARNING OBJECTIVES

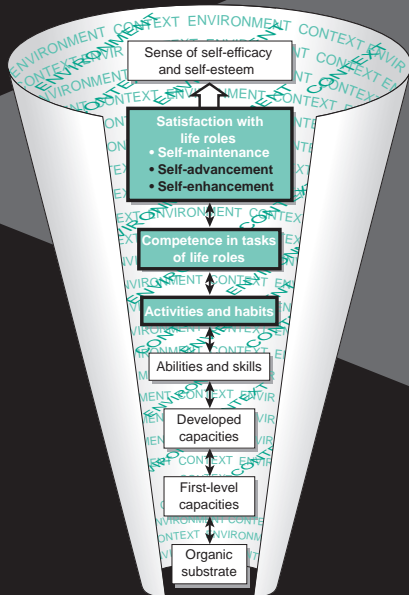

After studying this chapter, the reader will be able to do the following:

1. Define the terms functional mobility and community mobility and identify issues in each area of mobility that an occupational therapy intervention plan should include.
2. Identify aids and devices used to restore mobility.
3. State the hierarchy of mobility skills used to plan intervention.
4. Describe various transfer techniques and strategies for achieving mobility for persons with physical dysfunction.
5. Describe the roles of the occupational therapy generalist and occupational therapy driver rehabilitation therapist in assisting with community mobility goals.

CHAPTER 31

Restoring Mobility

Susan Lanier Pierce

Glossary

Glossary

Community mobility—“Moving self in the community and using public or private transportation, such as driving, or accessing busses, taxi cabs, or other public transportation systems” (AOTA, 2002, p. 620).

Driver rehabilitation therapist—Allied health professional with advanced knowledge and specialized training, skills, and experience in driver rehabilitation services, including the evaluation and training of persons with disabilities in driving or safe transportation.

Ecological validity—Treatment that reflects a person’s actual home and living environment.

Functional mobility—“Moving from one position or place to another (during performance of everyday activities), such as in-bed mobility, wheelchair mobility, transfers (wheelchair, bed, car, tub, toilet, tub/shower, chair, floor). Performing functional ambulation and transporting objects” (AOTA, 2002, p. 620).

Hemiwalker—A one-handed walker with four legs and a wider base than a quad cane. It is held by the strong upper extremity. This device gets its name because it looks like half a walker and is typically used by persons with one-sided weakness, such as those with hemiplegia.

In-home assessment—Objective evaluation of a patient’s living environment that takes place at the home. The size of the rooms and doorways, placement of the furniture, and so on are observed and measured (see Chapter 11).

Leg lifter—Device usually made of soft material that a person can use to lift a leg from one place to another or from one

surface to another; usually has a large loop on one end that can be placed around one foot or thigh and a loop or handle on the other end.

Mobility—The ability to move about in the home and community.

Quad cane—Straight cane with four short legs in a wide base for stability.

Rope ladder—Ladder device with two long parallel pieces of strapping connected by “rungs.” One end of the rope ladder is attached to the foot of the bed. A person pulls up gradually to a sitting position by pulling on the rungs in progression.

Transfer—Movement of one’s body from one surface to an adjacent surface. A transfer may be performed independently or with the assistance of one or two persons.

Transfer belt—Wide belt with handles that is wrapped snugly around a client’s waist to provide a handhold for another person to pull the client to a standing position and/or to assist the client’s balance during transfers or walking.

Transfer board—Device made of hard material, such as wood or fiberglass; placed under the buttocks to bridge the space between two surfaces during transfer.

Wheelchair and occupant restraint system—A crash-tested restraint system for a vehicle that secures a wheelchair and the occupant separately and appropriately for safe transportation.

Wheelchair wheelie—Maneuvering a manual wheelchair onto its rear tires and balancing in this position in order to raise the front casters off the ground.

A person’s skill in **mobility** in the home and community can be a key component to the ability to be independent and/or functional in basic and instrumental activities of daily living; therefore, restoring competence in mobility is a key intervention goal for occupational therapy. For persons to participate in the activities and tasks of their life roles, they must be able to move about in their surroundings. This may entail moving around in bed to dress or moving out of bed to go into the bathroom to use the sink or toilet or moving about the community to a workplace, grocery store, theater, or church. During the initial occupational therapy evaluation, the therapist assesses clients’ occupational functioning while understanding their occupational role(s) and contextual factors. Initial intervention goals will include mobility in immediate space such as movement in bed, transferring out of bed, and moving onto a treatment mat or onto a toilet. As successful outcomes are obtained in these areas of basic mobility, the intervention plan is reassessed to include more complex mobility skills that enhance basic and instrumental activities of daily living such as moving about the kitchen for cooking or bathroom for

personal hygiene and tasks. The occupational therapist may use assistive devices, assistive technology, or compensatory strategies to assist clients to restore their mobility and occupational functioning.

MOBILITY INTERVENTION PRINCIPLES

Mobility affects all basic and instrumental activities of daily living and, as such, mobility skills must be evaluated and treated throughout the continuum of care by occupational therapy. Guidelines related to mobility intervention include:

- Consider intervention planning for all aspects of mobility that influence a particular patient’s occupational functioning
- Improve a client’s mobility skills during activities of daily living training by following a hierarchy of skill building

- Understand how performance in mobility is influenced by a client’s contextual factors
- Be knowledgeable about adaptations and compensatory strategies to enhance mobility skills
- Co-plan with other disciplines or specialists in the total care plan for successful outcomes for individual mobility goals.

Definitions of Mobility

The Occupational Therapy Practice Framework defines two areas of mobility: **Functional Mobility** and **Community Mobility**. Functional mobility is “moving from one position or place to another (during performance of everyday activities), such as in-bed mobility, wheelchair mobility, transfers (wheelchair, bed, car, tub, toilet, tub/shower, chair, floor), performing functional ambulation and transporting objects” (AOTA, 2002, p. 620). Community mobility is “moving self in the community and using public or private transportation, such as driving, or accessing buses, taxi cabs, or other public transportation systems” (AOTA, 2002, p. 620) Both aspects of mobility must be addressed by occupational therapy throughout the evaluation and intervention process.

Each area of mobility requires a certain skill level. Accomplishment in each area of mobility builds a foundation of skills for the next higher level of mobility; therefore, a hierarchy of skills guides the order in which each area of mobility is addressed. Mobility needed in basic activities of daily living (BADL) is followed by mobility needed in instrumental activities of daily living (IADL) (Fig. 31-1). Occupational therapy goals for performance skills and for mobility must be achieved prior to intervention training in BADL. For example, the person with quadriplegia must be able to maneuver his or her body in bed for changing postures and/or sitting up before learning to dress in bed. A person learns to sit on a hard surface without support, such as a mat, before sitting on a soft surface, such as a bed, in order to learn to transfer to and from the bed.

Transfers to bed must be mastered before transfers to a car. A car transfer is more difficult because the wheelchair seat height is different from the car seat height and there is a space gap between the two seats. The client must handle his legs through the cramped space of a car door. Since the task demands for driving are higher than for any other IADL, driving should be the last IADL addressed; however, training and practice in mat, bed, and toilet transfers prepares the person for car transfers.

Every mobility task requires a certain amount of strength, coordination, and range of motion, as well as visual and cognitive abilities. A patient may have more than one area of deficit in occupational functioning that may hinder mobility functioning. A person with rheumatoid arthritis may have range of motion deficits as well as

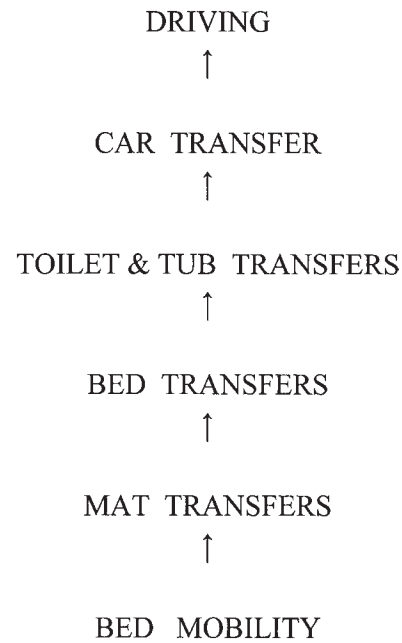

Figure 31-1 Hierarchy of mobility skills illustrates the order of accomplishing mobility skills.

weakness and problems with fatigue. A person with a spinal cord injury may have decreased sensation as well as paralysis or weakness. A person who has had a stroke or traumatic brain injury may have physical as well as visual and cognitive deficits that must be carefully considered in the more complex areas of mobility needed for instrumental activities of daily living.

Mobility Intervention Is Individualized

Each patient has unique methods of doing activities of daily living (ADL); therefore, customization of techniques and equipment is necessary. With a patient- or client-centered approach, the person must have input into the intervention plan for the outcomes in mobility to be successful. The therapist must be an active listener to the patient’s thoughts and opinions and be willing to modify techniques and strategies as needed.

Occupational performance skill deficits may affect mobility differently in particular environments of the individual, so the therapist must consider the patient’s mobility skills and activities in all relevant environments. For example, one person who has had a stroke may require a wheelchair outside the home but be able to get around at home with the assistance of an orthotic device such as a cane, whereas another requires the wheelchair both in and out of the house.

Strive for Ecological Validity

The first phase of training in functional mobility takes place in the accessible environment of the therapy clinic.

The second phase addresses functional mobility in the patient's home, and the third phase addresses community mobility in the patient's own environment. The occupational therapist should strive for **ecological validity** throughout the intervention process, which means that the intervention and final outcome take into consideration the actual environment to which the patient will be returning. The environment includes the home, yard, and community where the person lives, shops, works, plays, and/or goes to school or other public places.

Assessment of patients' personal environments must be made so that realistic training in the second phase can take place. The training can first use the mock environment of the therapy clinic or simulated environments. Once the therapist is familiar with the client's home and community, they can seek environments in or around the treatment facility that best simulate these environments. A comprehensive **in-home assessment** is crucial for discharge planning (see Chapter 11). The patient's real world may not consist of the level floors, low-pile carpet, easy curb cuts, or nicely ramped entrances of rehabilitation facilities. The outdoor terrain may be soft dirt, sand, or bumpy grass. Wheelchair maneuverability in the home may be through narrow hallways and doorways. The patient may have to transfer onto a waterbed or soft mattress rather than the adjustable-height surface of a firm hospital bed. There may not be a roll-in shower, so the patient may have to learn to use a regular tub with a tub bench. Even if the patient will be discharged to an assisted-living environment, maximum independence in mobility for that environment should be sought. Whether the patient can walk or use a wheelchair and has an ideal situation or not, it is crucial to know the real-world environment for that person so the intervention plan for mobility and the final outcomes will be of real value and meaning to the patient.

Because inpatient rehabilitation is so brief, the level of mobility an inpatient achieves on discharge may not be the same level that the person can achieve 6 or 8 months post discharge. The inpatient therapist should plan long-term post-discharge goals for mobility with the patient and the family so that he or she can work on continued goals for maximum independence and mobility after discharge as an inpatient. Independence in community mobility will more than likely be achieved during or even after outpatient rehabilitation and intervention. Educating the client and family of this fact will prevent the client from becoming discouraged and empower the family to assist in transportation until the client is ready to tackle the goal of returning to driving.

Interdisciplinary Team Approach

Teamwork between occupational therapy and physical therapy is important for intervention planning in mobility

so that the two disciplines can share a vision of how each other's treatment relates to planning for future goals in functional and community mobility. Communication between team members eliminates unnecessary duplication and promotes carryover of skills. The direction the occupational therapist takes in pursuing BADL should be influenced by the patient's achievements in physical therapy with lower extremity functioning and ambulation. Conversely, independence in bed mobility achieved in occupational therapy may influence balance and transfer training in physical therapy.

Achievement of physical therapy goals that are precursor skills for mobility training may take several weeks, so during this time, the occupational therapist works on BADL that do not demand a high level of lower extremity strength, trunk balance, and endurance. For example, a patient who will walk first learns to brush her teeth and wash dishes sitting down. When the patient has achieved standing tolerance and balance in physical therapy, the occupational therapist can incorporate standing in activities such as brushing teeth and washing dishes while standing at a sink. When it is determined that the patient will be using a wheelchair, the occupational therapist works on propelling a wheelchair and performing activities from the chair, such as dressing and cooking. If the patient will be a functional but limited walker with an orthotic device, the occupational therapist must incorporate the device into the BADL and IADL intervention goals, including functional and community mobility. For example, a person who uses a cane has to learn to maneuver in the kitchen with this device while cooking.

Intervention planning for community mobility requires the occupational therapist to seek the expertise of a **driver rehabilitation therapist** in order to complete the final outcome for community mobility goals. These experts have advanced knowledge and skill in driving and community mobility, have an allied health background to understand diagnosis and implications, and are able to provide specific evaluation and intervention services for driver evaluation, driver rehabilitation, driver training, assessment for use of community mobility alternatives, and safe transportation. These experts may be on staff in the inpatient or outpatient facility or may be found in private practice.

FUNCTIONAL MOBILITY INTERVENTION PLANNING AND TREATMENT

This section will discuss areas of functional mobility and describe strategies, methods, and adaptive equipment suggested by therapists and former patients that can be used in restoring functional mobility for persons with a variety of performance skill deficits. The occupational

therapist would assess and develop an intervention plan for the following areas of functional mobility:

- Bed mobility
- Wheelchair mobility including wheelchair propulsion
- Transfer methods for the person who is ambulatory, has limited ambulation, or is non-ambulatory
- Functional ambulation with or without orthotic devices

Bed Mobility

Bed mobility is the ability to roll from side to side, to roll over from supine to prone position, to sit up in bed, and to handle the upper and lower extremities during these maneuvers. These skills are necessary for dressing in bed, transferring in and out of bed, or changing positions for sleep. Gillen and Burkhardt (1998) suggest that one of the most common movement strategies in rolling from supine to prone is a lift and reach pattern. To begin rolling over, the person throws the arms in the direction he or she wants the body to go. Because of momentum, the upper trunk, hips, and legs follow.

A person with paralysis in the lower extremities and trunk may need a device to pull on in order to turn over. Examples are a **rope ladder**, an overhead trapeze, a bed rail, or a wheelchair positioned near the bedside. The first three devices mentioned are designed specifically to give a person something to grasp with the hand(s) or forearm(s) to assist in pulling to a seated position in a long- or short-leg position in bed (Fig. 31-2). Good scapular, shoulder, and elbow strength is the minimum requirement for using these devices. Wrist flexion and extension and hand grasping capability are helpful in using these devices.

The rope ladder (Fig. 31-2A) is two long parallel pieces of strapping connected by “rungs.” One end of the ladder is attached to the foot of the bed. The person pulls up gradually using each rung in progression until he is at the desired sitting level. The overhead trapeze bar can assist a person in rolling over or in coming to a long-leg seated position. The various configurations of bedrails can assist a person in rolling over, in getting positioned for sleep or in coming to a short-legged seated position on the side of the bed. A person can also use a wheelchair by grasping the armrest or push handles to pull against if the wheelchair is close to the bed with the brakes locked. A person with weak grasp can use the same devices by hooking the forearm or extended wrist around the device handle or a part of the wheelchair.

For rolling, the person first holds the bedrail or wheelchair part with the arm closest to the side of the bed toward which he is rolling. The momentum for rolling the upper trunk is gained by flinging the other arm across the body and grasping the device or wheelchair part with that extremity. Pulling with both arms should now turn the hips and legs. If not, the person can use an extended wrist

or hand to push the knee or thigh to get the leg moving. A **leg lifter** is a device for moving one leg at a time. This device has a large loop at one end that can be placed around the foot or thigh and a smaller loop or handle at the other end that a person can grasp to pull or lift a leg with (Fig. 31-2B). The leg lifter works well for persons who have hip flexion limitations that limit their ability to reach their legs or persons who have balance difficulties when in a long-leg sitting position and must maintain their balance by using one upper extremity. A hospital bed with powered head and knee controls can also assist a person with bed mobility and can be helpful for lower extremity dressing in bed. By raising the head and upper trunk, both hands are freed from holding one’s balance to perform the task at hand. Internal contextual factors may influence this choice because not every patient can afford a hospital bed or chooses to use a hospital bed once home.

Figure 31-3 illustrates the sequence a person with C7 quadriplegia uses for bed mobility without the use of orthotic devices. Good strength in the deltoid, pectoralis major and minor, biceps, wrist extensors, and scapula muscles is key, so strengthening these muscle groups in therapy is preparatory to learning this technique. Even without trunk muscles, a sense of balance is important and must be developed prior to performing this technique.

A person who cannot perform bed mobility tasks requires one or two persons to assist with rolling the upper and lower body in the proper sequence or using a log roll technique that moves the entire body at once. Figure 31-4 shows a person with incomplete quadriplegia and proximal weakness in the shoulders and hips performing bed mobility tasks with the assistance of his wife. Figure 31-5 shows mechanical and powered devices that assist the caregiver in moving a dependent person into or out of bed. The mechanical and hydraulic lifts can be on a movable frame, on a freestanding frame that hangs over the bed, or on a moving track that runs on the ceiling. Some lift systems can move the person from one room to another.

The occupational therapist must assess sitting balance for bed mobility and activities of daily living. Balance in long- and short-leg sitting should be assessed. Long-leg sitting is the posture in which the legs are extended straight out in front of the person on a flat surface and the hips are flexed to at least 90°. A position beyond 90° of hip flexion must be achieved to maintain balance in a long-leg sitting position when trunk and hip musculature are weak. Short-leg sitting is the posture in which a person sits with the hips flexed at least to 90° and the knees are flexed over the edge of the surface. The feet may or may not touch the floor, but stability is aided if they do.

Achieving sitting balance on a flat, hard mat precedes working on balance on a soft bed mattress. Upper extremity activities, such as throwing and catching a large ball, can be used to challenge the patient’s balance. Balance improves either because weak trunk muscles get stronger or because

Figure 31-2 Devices that assist with bed mobility. **A.** Bed ladder pull-up. **B.** Leg lifter. **C.** Overhead trapeze bar. **D.** Bed rail assist. (Courtesy of Sammons Preston, Bolingbrook, IL.)

the patient learns to balance by lowering the center of gravity and using the neck muscles to right the body. *While the person is working on improving balance on the mat or in bed, the therapist must maintain close supervision and contact and be ready to catch the person if balance is lost in any direction.*

A person who has good trunk balance may wish to dress while sitting on the edge of the bed. If the lower extremities are paralyzed, the person must manually move the legs over the side of the bed. For the dependent person, another individual swings the person's legs off the edge of the bed.

Figure 31-3 A person with C7 quadriplegia illustrates the steps for coming to a sitting position in bed without the use of assistive devices. **A.** The woman uses shoulder and scapula muscles to move to resting on elbows. **B.** She uses the triceps in one arm to lift her upper trunk while balancing on the other bent elbow. Using the triceps in the bent arm, she pushes the whole trunk upright until she is in the long-leg sitting position. **C.** She can hold her balance with one arm behind her while using the other arm to reposition the legs as needed. **D.** Once she is close to the edge of the bed, she can lean on one arm, which is pressing into the wheelchair seat, to hold her balance while she moves the outside leg off the side of the bed. **E.** She then moves the inside leg off the side of the bed. **F.** Now, in a short-legged sitting position, she can prepare for a sliding transfer into her wheelchair.

Performing Activities of Daily Living in Bed

Persons with lower extremity or trunk paralysis may need to perform dressing, skin inspection, self-catheterization, and/or a bowel program while in bed. While dressing in bed, it is necessary to reach one's feet by flexing the hips and knees so that the feet are closer to the hands for preparing to don pants, socks, and/or shoes. Independence in rolling from side to side and reaching one's buttocks are important

for performing manual bowel stimulation and clean up or using a long-handled mirror for inspecting potential pressure sore areas.

Wheelchair Mobility

For a person who cannot walk or has limited walking ability, a wheelchair can assist with necessary mobility in and

Figure 31-5 Powered and mechanical lifting systems. **A.** Mechanical unit attached to the wall. **B.** Ceiling-mounted powered track to carry a person from room to room. (Courtesy of SureHands Lift & Care Systems, Pine Island, NY.)

outside the home. A manual wheelchair is appropriate for a person who can propel the wheelchair using two arms, one arm, the feet, or a foot and an arm together. A powered wheelchair or motorized scooter is appropriate for the person who does not have the physical capability to propel a manual chair or has limited walking due to low physical endurance or lower extremity weakness. The scooter is popular with individuals with multiple sclerosis or cerebral palsy or the well elderly who have limited capacity for long-distance walking. Personal requirements for a scooter are the ability to transfer, good trunk balance, and an ability to maintain an upright posture with little support. There are persons who are totally dependent and unable to operate a power wheelchair who will require a manual wheelchair that will be propelled by another person. There are many models and styles of wheelchairs and

scooters with a variety of standard and optional features from which to choose (see Chapter 18).

The patient's home and community must be considered when assisting him or her in choosing the most appropriate wheelchair. For example, a person who lives in a rural environment with sandy or grassy terrain may require a four-wheel scooter or a more powerful motor on a powered wheelchair. Of great importance in wheelchair selection is the client's means of vehicle transportation. If the person can transfer or will be dependently transferred into a vehicle, then the wheelchair or scooter must break down and fit into the vehicle or onto an appropriate carrier. If the person will use the wheelchair or scooter to ride on while entering a vehicle on a lift or ramp, then it must be determined whether the person can transfer onto another vehicle seat while being transported. Most manual or power wheel-

Figure 31-4 A wife assists her husband in bed mobility. **A.** Using proper body mechanics, the wife assists her husband to roll over by first pulling his left shoulder toward her. **B.** The husband can assist by using his hip and knee flexors and pulling against the half bed rail. **C.** The wife swings his legs off the bed and lowers his feet to the floor while the husband uses the stronger left arm to push against the bed to hold his balance in a half-sitting position. **D.** Again, using proper body mechanics and allowing her legs and arms to do the work, the wife helps her husband come to a full sitting position.

chairs can be properly restrained for an occupant during transportation; however, a scooter cannot. The occupant of a scooter must transfer into a vehicle seat for safe transportation. If the client will sit in the wheelchair to drive, then it is important that the correct seat height has been achieved for good driver visibility and for maneuvering under the steering wheel. The rehabilitation team that is prescribing a wheelchair or scooter for any patient or client should *always* consult a driver rehabilitation therapist to ensure that the chair is suitable for the person's vehicle and driving or transportation needs. "Wheelchairs promote mobility for many people who are physically challenged. But in attempting to interface that same wheelchair with a vehicle to enable the person to drive, the wheelchair can become a stumbling block" (Pierce, 1992, p. 20). To prevent this, communication between the prescribing therapist and the driver rehabilitation therapist is paramount.

Intervention for Wheelchair Mobility

Environmental and/or architectural barriers will most likely affect a person's wheelchair mobility at some point, and he or she should be taught to deal with such barriers. When a patient receives a new wheelchair, indoor and outdoor mobility training is important so that he or she learns to handle and maneuver the chair in whatever circumstances he or she may encounter, such as tight spaces, a curb or ramp, and rough and uneven terrain. A program graded toward independent mobility should be a team effort among the physical, occupational, and recreational therapists, with the practice of skills incorporated into all rehabilitation activities. For example, the occupational therapist may take the person to the grocery store to shop for food in preparation for cooking a meal during therapy. This experience gives the person an opportunity to explore wheelchair mobility in this environment while also carrying items or pushing a shopping cart.

The initial stages of wheelchair training take place inside the rehabilitation facility. In the first phase, the patient learns how to propel the wheelchair on a smooth, uncluttered surface. The patient learns to manipulate the wheelchair and all of the removable parts as well as how to transfer in and out of the wheelchair. The second phase is learning to use the wheelchair outside. The patient learns to maneuver on various terrains, such as uneven sidewalks, gravel, and sand. Then the patient learns to negotiate obstacles such as curbs and steps. Once the patient can traverse outdoor surfaces, public buildings, such as grocery stores and shopping malls, can be used to teach the person to handle the wheelchair in crowded, narrow spaces.

Negotiating Ramps

A ramp enables a person using a wheelchair to overcome steps or a height discrepancy in a doorway or entrance. Ramps come in many shapes, sizes, and dimensions.

Ramps can be custom built or purchased and assembled from a kit. Factors that influence how well a wheelchair user negotiates a ramp include:

- The user's upper extremity strength and coordination, including grip strength
- The user's trunk balance
- The length and slope of the ramp
- The surface of the ramp (non-slip vs. slippery)
- The stability of the wheelchair (may require anti-tipping wheels)
- The need for hillclimbers or grade-aids on the wheelchair to prevent the chair from rolling backwards

Federal guidelines specify how ramps in public places should be constructed in terms of length, slope, texture, and so on. For example, for every inch of rise, the ramp must have 12 inches of length (1:12 slope). To overcome a 4-inch step, the ramp must be 48 inches long. A ramp in a public place must have a surface with a detectable texture for persons with visual impairments. It must have sides that are not vertical but slope at 1:10 maximum. There must be 4 feet of level landing at the top of the ramp (Americans with Disabilities Act [ADA], 1990). For private construction, a ramp that is longer and therefore has less slope (1:20) is more satisfactory for a person who uses a manual wheelchair and has upper extremity weakness because it is easier for that person to propel up or down the ramp.

The popular minivan conversions for wheelchair users with the 10-inch lowered floor modifications have ramps measuring 53 inches long by 29 inches wide for entering and exiting the vehicle. Before a person in a manual wheelchair purchases this type of vehicle, particularly for independent driving, his or her ability to ascend and descend the ramp safely should be evaluated (Fig. 31-6). This task is much more difficult than it first

Figure 31-6 A person with quadriplegia in a manual wheelchair attempts to push up the ramp into a minivan whose floor has been lowered 10 inches. This task is easy in a powered wheelchair but difficult in a manual wheelchair.

Figure 31-7 A therapist demonstrates how a person with good arm and trunk strength can safely negotiate a steep ramp by moving backward down the ramp. Leaning forward to shift the center of gravity prevents the chair from tipping backwards.

may appear because of the short ramp length and the steep slope. Upper extremity strength, good hand power, and trunk mobility and balance are necessary for safety of a manual wheelchair user while descending or ascending a minivan ramp.

One safe technique to use in descending any steep ramp is to orient the chair backward and lean forward to place most of the weight over the front caster wheels as the chair slowly descends the ramp (Fig. 31-7). If the wheelchair has a tendency to tip backward easily, a helper should stand behind the wheelchair and walk with the person to catch the chair should it begin to tip backward.

Wheelchair Wheelie

An advanced manual wheelchair skill called a **wheelchair wheelie** can be used to elevate the caster wheels so that objects on the floor, sidewalk, or ground can be cleared or a curb or step can be managed (Pierson, 1999). For this complex task, a person must have the following:

- Good basic wheelchair skills
- Upper extremity strength
- Good hand function with a strong grip
- Bilateral upper extremity coordination
- Understanding of the steps to perform the task and the safety issues involved
- Ability to maintain dynamic balance while performing this task

The patient must practice the wheelchair wheelie many times on level surfaces before attempting curbs and steps. In the clinic, a mat can be placed behind the wheelchair or the therapist can stand behind the chair ready to catch the

wheelchair should it tip too far backward. *Because of the danger of losing balance and falling backward, the therapist must be attentive and within close proximity of the wheelchair when the patient is practicing this advanced skill.* A length of rope attached to the push handles and running through a ceiling pulley can also be used to protect the person from falling and allow him or her to practice without a person behind him (Nixon, 1985).

The first step in performing a wheelie is to grasp the front portion of the wheel rims and quickly pull back equally on both hand rims. This places the hands in a rearward position on the hand rims. Another quick forward thrust on the wheels and then an abrupt stop rotates the chair frame backward with the rear axle acting as a fulcrum. The caster wheels rise, and the wheelchair balances on the rear wheels only. Small movements of the rear wheels control the balance of the chair (Deusterhaus-Minor & Deusterhaus-Minor, 1999).

Negotiating Curbs

In today's world and particularly since passage of the ADA in 1990, curbs on sidewalks at street intersections are becoming less of a problem as curb cuts proliferate. At times, however, the wheelchair user still has to negotiate a curb. Although some power wheelchairs can negotiate curbs well, ascending and descending a curb or step in a manual wheelchair will require good wheelchair skills. Usually the person who can perform a wheelchair wheelie independently can use that same technique for jumping over a curb or step. First the person approaches the curb or step, facing it. Once the wheelie position has been obtained, the casters are placed on the curb. The person leans forward to balance the chair and redistribute the weight and propels the large rear wheels up the curb or step with a hearty push. A person must have good balance and hand function to perform this maneuver.

To go down a curb or a step, the person approaches it backward, leans forward in the chair, and rolls the rear wheels over the step or curb. An alternative method for going down a curb is to approach the curb facing it, move into the wheelie position, and roll off the curb using the back wheels. The person must have an excellent sense of balance and control to perform this technique safely.

If a wheelchair user cannot move up or down a curb or step or roll through grass or over uneven surfaces, another person can provide assistance. In an assisted wheelchair wheelie, the helper pushes the wheelchair once the wheelchair is in the wheelie position (Fig. 31-8).

Negotiating Steps

Ascending or descending multiple steps in a scooter or power wheelchair is impossible except for a newly designed power wheelchair that is designed specifically for climbing stairs. A strong manual wheelchair user may be

Figure 31-8 **A.** A therapist performs an assisted wheelchair wheelie so the wheelchair can easily be moved through grass and uneven terrain. **B.** An assisted wheelie is also used to move a person in a manual wheelchair up a step or curb.

able to descend a couple of steps safely by performing a wheelie while moving down the steps. A person who can perform a wheelchair-to-floor transfer may be able to get out of the wheelchair in an emergency and “bump” up or down the steps while pulling the chair along. Skin protection during this task must be understood and practiced. *Training to do this should occur before an emergency arises.*

Moving a manual wheelchair and its dependent occupant up and down steps safely requires the assistance of two people. The back of the wheelchair should be positioned against the steps with one person standing behind the chair and the other person in front of it. The chair is tipped backward, with one person holding the push handles and the other person holding the front of the chair by its frame or leg rests. While the person in front maintains balance of the chair, the person behind pulls the chair up step by step. That person should take care to keep his or her back straight and use leg strength to move the chair. To take a person down the steps, approach the steps forward with the wheelchair tipped and balanced. The procedure is reversed, with the person in front of the chair holding onto the chair

Figure 31-9 A battery-powered stair lift makes going up and down stairs easy.

while guiding and controlling the speed of the chair down each step. Moving a power wheelchair in this manner is impossible and not safe due to the weight of the chair.

For individuals who must negotiate multiple steps in a home, there are various configurations of stair lifts that can be installed on a staircase for straight or curved stairs (Fig. 31-9). The person must be able to transfer onto the seating device and balance himself on the seat while the seat moves up or down the staircase. If the person has no ambulation ability, a second wheelchair must be available at the top of the staircase for the person to transfer into. Another viable but expensive option is a small elevator that can be installed in a commercial or private building that meets the space and structural requirements for installation.

Intervention Planning for Transfers

A **transfer** is the means by which a person moves one’s body from one surface to an adjacent surface. The method can be simple or complex depending upon the performance skill level of the person performing the transfers. There are various techniques and methods for safely performing a transfer, and the occupational therapist working in conjunction with the physical therapist must determine the best method for each client. The technique chosen depends upon the patient’s disability, upper and lower extremity strength, physical endurance, trunk balance, body type, orthotic devices, and/or wheelchair style (Definition 31-1). A graded training program for transfers

DEFINITION 31-1 *definition*

Various Levels of Transfers

Dependent Transfer

Person requires maximum assistance of one or more persons using a special technique or device to assist in moving from one surface to another.

Sliding Board Transfer

Person cannot bridge the gap between two surfaces without the use of a sliding board.

Standing Pivot Transfer

Person can stand up, then pivot the feet and turn the trunk, and then sit down on the transferring surface.

Independent Transfer

Person can perform all steps of a transfer with no physical assistance of another person. A device may or may not be used.

is necessary as a patient progresses through the rehabilitation process. A dependent transfer may be necessary until the person can begin learning assisted or independent transfers. The level of the transfer that is ultimately determined to be appropriate for the patient must reflect his or her physical and functional status.

The occupational therapy intervention should include family training so that the family member learns to perform each step of a transfer. The family member should practice with the therapist and patient in a protected, supervised environment. Proper body mechanics must be taught and practiced throughout any transfer to protect the helper as well as the person being transferred. To prevent back injury, the helper should keep the back and spine straight so that the physical lift or rotation of the transfer is done using the stronger muscles of the arms and legs.

Dependent Transfer

A person who is too weak to move requires another person or persons to lift or move him or her in a dependent transfer. A one-person technique entails standing in front of the patient and placing him or her in a forward flexed position with the chest lying on the thighs. This method cannot be used for the patient with limited hip flexion, for example, those with a hip fracture, post-hip replacement surgery, or heterotopic ossifications. This position shifts the patient's body weight over the knees and ankles rather than on the buttocks, which allows the buttocks

to be picked up and moved more easily. This method has proven worthy to teach family members because it enables the helper to control the movement of the patient's body while lessening the probability of hurting his or her own back (Fig. 31-10).

For the patient with limited hip flexion, this technique can be modified to sliding the buttocks toward the edge of the wheelchair and placing the patient's knees between the assistant's knees. Using proper body mechanics, the assistant squeezes the knees of the patient with his or her own knees while rocking the patient forward slightly and simultaneously pulling on the patient's pants or belt and rotating the hips to the surface being moved to.

For a two-person dependent transfer using a similar method, the second person stands behind the patient and moves the buttocks to the transfer surface while the first person moves the legs. A **transfer board**, sometimes called a sliding board, can be used to bridge the gap if the buttocks cannot easily be picked up. A dependent transfer can be performed by one or two helpers using a mechanical-hydraulic or powered body lifter (Fig. 31-5).

Sliding Board Transfers

A person who cannot stand but can perform a sliding board transfer can use the transfer board to slide the buttocks and bridge the gap between the two transfer surfaces. There are a wide variety of shapes, lengths, weights, and styles of transfer boards available from various manufacturers (Fig. 31-11). A long transfer board may be needed to bridge the large gap between a wheelchair and a car seat, but a smaller board can be used for transfer to the toilet or bed as the gap is smaller. A cutout on one end of the board may be needed to allow someone with a weak grasp to pick up the board. An angled or notched board may be best for maneuvering around the rear wheel of the wheelchair while transferring. A board made of high-density polished polyethylene plastic provides a slippery surface for bare skin, and a board with a moving center disc may allow easy sliding of the body. Off-the-shelf boards do not always meet specific needs of clients. Figure 31-12 shows a variety of custom transfer boards made by an occupational therapist to meet a specific client's needs when off-the-shelf boards were not useful. The client required various lengths, widths, and shapes of transfer boards to accommodate all of the different transfers that this person was able to perform.

Most transfer boards are positioned with one end under the patient's buttocks and thighs and the other end on the surface to which the person is transferring. Level surfaces greatly aid in the transfer, although one can use gravity to assist when sliding to a lower surface. For an independent transfer, the patient performs shoulder depression with the elbows extended and locked to raise and/or slide the buttocks along the surface of the board (Fig. 31-13). The person must also be able to handle his or her own legs to put them

Figure 31-10 A therapist demonstrates one type of dependent wheelchair to bed transfer that can be performed by one person. **A.** The therapist readies the patient by sliding the buttocks forward in the seat to avoid bumping into the rear wheel during the transfer. **B.** The patient is leaned forward onto the therapist's right thigh. If able, the patient can assist with the left hand on the wheelchair tire. The therapist has her legs around the patient's legs and readies herself with proper body alignment. **C.** The therapist uses the strength in her arms and legs to rock the client forward, lift the patient's buttocks, and rotate the patient to the bed. **D.** Since the patient's weight is shifted forward, there is little weight to pick up.

Figure 31-11 Two styles and shapes of transfer boards available through suppliers. **A.** Transfer board with hand holes and notches allows transfers from either side. **B.** Offset transfer board fits around the wheel of the wheelchair when the armrest is removed. (Courtesy of Sammons Preston, Bolingbrook, IL.)

Figure 31-12 An occupational therapist designed and built these specialized transfer boards to meet various clients' needs.

Figure 31-13 Independent sliding board depression transfer.

in place during or after the transfer. Factors that can impede this type of transfer include:

- Poor trunk balance
- Spasticity
- Excessive body weight or large, heavy legs
- Inadequate upper extremity strength
- Inability to lock elbows into extension
- Joint contractures or tightness in the elbows or wrists that prevent full elbow extension and/or full wrist extension
- A low ratio of arm length to trunk length

The same principles apply to tub, shower, and toilet transfers. Equipment, such as grab bars, a raised toilet seat, and tub bench, can make these transfers easier and safer. Car transfers are difficult because of the large gap between the car seat and wheelchair as well as the seat height discrepancy. A person may require a transfer board for this transfer but not for other transfers in the home (Fig. 31-14).

Stand-Pivot Transfer

A person with lower extremity deficits, who can support his or her weight on one or both legs, may be able to perform an independent or assisted stand-pivot transfer. An assisted stand-pivot transfer is performed with the helper standing in front of the patient and the transfer surface as close as possible. Generally it is best to transfer the patient toward his or her stronger side. The patient should first be slid toward the edge of the surface from which the transfer is taking place, with care to protect the person from slipping off the edge completely, especially if there is lower

extremity or trunk spasticity. The patient is assisted to a standing position (Fig. 31-15). The helper places his or her knees in front of one or both of the knees of the patient to prevent the patient's knees from buckling upon standing. The patient wraps his or her arms around the helper's body or neck, but only for support, not to pull up. The helper bends his or her knees, keeps the back straight, and grabs the waist or belt of the patient's pants or a **transfer belt**. This belt with handles is wrapped snugly around the patient's waist and provides a handhold for the helper. The helper rocks the person back and forth several times and then, using momentum, pulls the person to a standing position. A patient who can assist uses leg strength to stand or can use upper body strength to push off a wheelchair or chair armrest or bed rail to come to standing. By pressing against the weak knee or knees, the helper assists the patient to swivel or slide the heels toward the transfer surface while standing. The helper can then guide the patient's hips over and down to the transfer surface.

Independent Transfers

Patients with adequate strength to push up and move the trunk and to handle the lower extremities can transfer without assistive equipment. Figure 31-16 illustrates an independent transfer from wheelchair to bed by a person with C7 quadriplegia. This individual desired to live alone and not to have a hospital bed. She accomplished independence in this difficult transfer after discharge as an outpatient from therapy while working with an occupational therapist in her home. A special soft-surfaced transfer aid was custom built for her to bridge the gap between the wheelchair and bed yet protect her skin by preventing her buttocks from sliding over the wheelchair wheel or getting stuck in this gap (Fig. 31-16, B and C).

Orthotic Devices and Aids for Walking and Standing

A person with balance difficulties or weakness in one or both lower extremities may require some type of orthotic mobility device for stability and support while walking. Canes and walkers come in various styles and shapes (Fig. 31-17). The type of cane chosen by the physical therapist depends on the person's balance and gripping ability, with personal preference considered. A straight cane is selected for a person with good strength, coordination, and balance who nevertheless requires a device for support. The four-prong or **quad cane** is chosen for a person who is weak on one or both sides, has increased muscle tone or ataxia, and needs a wider, more stable base than a straight cane provides. The **hemi-walker**, so called because it is often used by persons with hemiplegia, provides the greatest stability for a one-handed orthotic device and can also serve to assist with standing (Fig. 31-17B).

Figure 31-14 Steps for transfer from wheelchair to car (A–D) and an independent transfer from wheelchair to van driver’s seat (E–H). **A.** The person leans to the outside of the wheelchair while the helper places the transfer board under the person’s buttocks and on the car seat. The sliding board is necessary to bridge the large gap between the wheelchair and the car seat. **B.** The person slides onto the board by pushing off the wheelchair and maintains balance by leaning against the dashboard of the car. The legs remain outside the car until the person is situated on the car seat. **C, D.** The legs are separately lifted into the car, and the sliding board is removed. **E.** The person rolls into the van backward and aligns her wheelchair with the van seat. **F.** She prepares to do a depression transfer. **G.** She lifts her body to the driver’s seat. **H.** She positions her legs. The seat is then swivelled and moved under the steering wheel.

Some patients have the strength and balance to stand without these devices while performing light ADL. Patients who do not have the standing balance or strength to stand at a work surface and use both hands may have to sit or perform ADL with one hand while standing. These individuals have limited ability to carry things while walking, so small carrying bags can be strapped to their assistive device for

carrying lightweight items. A stable pushcart can substitute nicely for a cane or walker for carrying items (Fig. 31-18).

A full size walker gives the person bilateral support for balance and stability while walking (Fig. 31-19A). A full-size or rolling walker requires the partial use of both upper extremities. A rolling walker with four small plastic wheels is effective for individuals with an ataxic gait, such as is

Figure 31-15 A patient with left hemiplegia is assisted in a sit-to-stand position. **A.** The patient places her unaffected hand on the therapist's shoulder for support. The therapist supports the patient's weak left knee by placing her knee against the patient's knee. **B.** The patient leans forward to move the center of gravity forward. **C.** The patient uses the strength of the unaffected side, with the help of the therapist, to stand. (Reprinted with permission from Gillen, G., & Burkhardt, A. [Eds.]. [1998]. *Stroke rehabilitation: A function-based approach* [p. 231]. St. Louis: Mosby.)

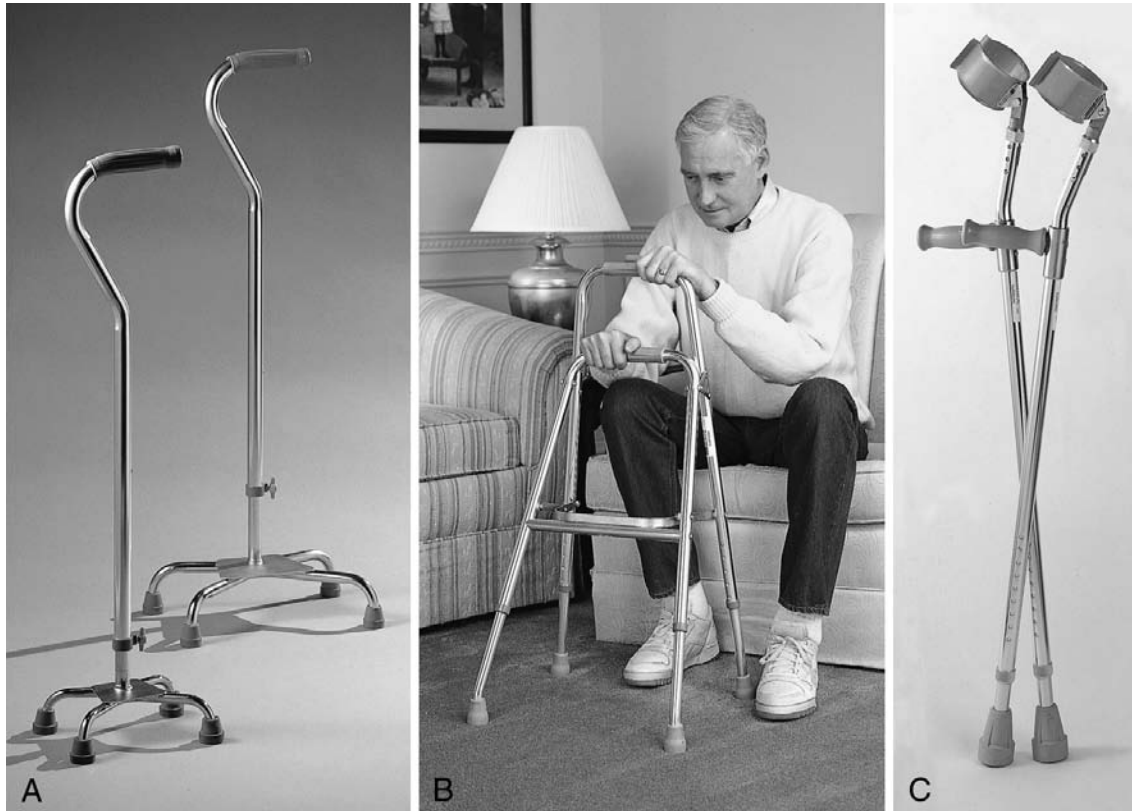

Figure 31-17 Various orthotic devices for walking. **A.** Quad cane has wide base with four points of contact to the ground to provide stability. **B.** Sidestepper cane/walker is typically used by a person with hemiplegia who requires more stability than the quad cane supplies. **C.** Forearm crutches allow a wide base of support for those who have leg weakness but good balance. (Courtesy of Sammons Preston, Bolingbrook, IL.)

seen in cerebral palsy or Frederick's ataxia, since it is easier to push the walker while walking rather than to pick it up for each step. It can be difficult for the person using a rolling walker to pivot to turn corners or prepare to sit down. With the full-size walker, the user can simply rotate around the axis of the body and carry the walker during the turn. Some walkers can be fitted with a fold-down seat for resting or a pouch or basket for carrying items. Folding-frame walkers are easy to store in a car's back seat or trunk or on the back of a scooter. Also, a lightweight, rotating handle can be installed on the walker for a person to push down on when standing from a bed, chair, or a car (Fig. 31-19B). The handle rotates 180° and locks onto the walker frame when not in use.

A three-wheel walker has the advantage of larger pneumatic wheels for a more stable base and hand brakes for safety (Fig. 31-19C). This type of walker can carry heavier items and can have a fold-down seat for individuals who fatigue easily, such as those with multiple sclerosis or arthritis. This type of walker is not indicated for a person who leans on the walker for support. The width and turning radius of these walkers is greater than those of standard walkers and may affect the user's maneuverability where space is limited. Loading the device into a vehicle must be solved if it is to be used in the community.

Patients who can walk only short distances with or without an orthotic device may also require the use of a

Figure 31-16 Steps for an independent transfer from wheelchair to bed by a person with lower extremity paralysis. **A.** The patient positions the wheelchair close to the side of the bed and removes the left armrest. **B.** A custom-made transfer board between the wheelchair and bed fills the gap and prevents skin damage by bumping the wheel. **C.** Shoulder, triceps, and wrist extensor muscles allow the client to lean on her left arm for balance. She pushes off with the right arm, using her triceps and latissimus dorsi, to move her buttocks from the wheelchair to the bed. **D.** She steadies her balance once on the edge of the bed. **E.** Having moved her right hand to the wheelchair seat for balance, she picks up the left leg with her left arm. **F.** The left leg is placed on the bed. **G.** She straightens the leg. **H.** She repeats the process to move the other leg up onto the bed. Maintaining balance is the key to performing this move independently and without assistive devices.

Figure 31-18 Carrying items on orthotic walking devices. **A.** Rolling cart with push handles for carrying many or heavy items. **B.** Tray for walker. **C.** Basket attached to walker. (Courtesy of Sammons Preston, Bolingbrook, IL.)

Figure 31-19 Walkers. **A.** Standard walker for child or adult. Small roller wheels can be provided on the front legs to assist with moving the walker. **B.** Easy-Up™ handle for walkers provides leverage for persons who can rise unassisted. The lightweight handle folds into the walker frame when not in use. **C.** Rolling three- or four-wheel walker can be used by child or adult who needs support to walk but has good balance. The large wheels travel over outdoor terrain easily. Hand brakes allow for safe slowing. A pack can be added to transport things. (Courtesy of Sammons Preston, Bolingbrook, IL.)

Figure 31-20 Use of a powered vertical up/down seat on a powered wheelchair to allow near approach to the sink for grooming.

manual wheelchair or scooter for longer distances. Using the wheelchair may be a more practical solution to enable performing tasks that require two hands, balance, and/or stability. By sitting in a wheelchair, the person frees up both hands for activities. A person who has good trunk balance may be able to use a stool for working at counter surfaces. Some persons can use a powered up/down seat on a wheelchair or scooter to reach high work surfaces or tall cabinets (Fig. 31-20).

Various mechanical and electric devices are available to assist a person in standing up or rotating and swiveling preparatory to standing. The powered lift wheelchair or the powered lift lounge chair (Fig. 31-21) is popular for persons with a variety of disabilities because the chair raises the person totally supported to a partial standing position. Also, some devices, such as the swivel disk or lift seat, can be placed in a regular chair or vehicle seat to help the person move his or her legs or start the momentum for standing upright. Electric seats for vans and cars similarly assist a person but tend to be expensive and have strict vehicle requirements (Fig. 31-22).

Standing can improve circulation and renal and bowel functions, reduce lower extremity spasticity, and prevent effects of prolonged immobilization. If a person has a job that requires standing, such as a beautician or a schoolteacher, there are various styles of wheelchairs available to assist this person in coming to a supported standing position or to increase her seated height. There is a stand-up manual wheelchair, a stand-up powered wheelchair, or a powered wheelchair with a powered up/down seat. These wheelchairs can provide a great means of mobility as well as meet the task demands of the person's job, including freeing both hands. The person using a powered chair that has this capability can move around in a standing or elevated seated position (Fig. 31-23). The manual wheelchairs with this capability are heavier than standard manual wheelchairs and not conducive to outdoor mobility so an active person may need a second lighter-weight wheelchair to use away from work.

COMMUNITY MOBILITY

Occupational therapy is involved with instrumental activities of daily living (IADLs), which are defined as “activities that are oriented toward interacting with the environment and that are often complex—generally optional in nature” (AOTA, 2002, p. 620). Community mobility is listed as one of the instrumental activities of daily living. Occupational therapy supports “engagement in occupations and in activities that allow desired or needed participation in home, school, workplace, and community life situations” (AOTA, 2002, p. 611). In other words, community mobility allows one to engage in life outside the home and, as an IADL, should be addressed in occupational therapy.

Occupational therapy must consider community mobility as an occupation that has value and meaning for each person. The topic should be treated as important and unique for each person and should be viewed in its entirety. The occupational therapist should understand how each client values community mobility, including driving, and be knowledgeable about how external and internal contextual factors will influence participation in this occupation. Today most people go into the community for almost everything they need. Although the internet and mail order provide extensive resources for persons to purchase drugs, supplies, and clothes without store shopping, these resources are inaccessible to some and can be unsatisfying in terms of social interaction. Therefore, community mobility is an important goal for most patients in occupational therapy. The feasibility, safety, and personal control of mobility are affected by (1) the socioeconomic status of the person (income may limit the type of transportation available), (2) physical characteristics of the site, and (3) transportation technology (Carp, 1988).

Figure 31-21 Mechanical devices to assist in standing up. **A.** Hydraulic action in this portable seat lift assists the person in rising. **B.** Car swivel seat. **C.** Cushioned seat that swivels 360°. **D.** Braun Companion seat. Figure 31-23 Permobil wheelchair options allow for many adjustable sitting and standing positions for activities and tasks at work and at home. (Courtesy of Permobil Company, Woburn, MA.)

Driving Is an Instrumental Activity of Daily Living

Driving a personal vehicle is the main form of transportation for most persons in our society today. Independence in driving can be key for a person to feel a sense of personal well-being and satisfaction through leisure, play, or work activities. Every occupational therapist, no matter the setting, should be addressing driving as an IADL. However, because of its complexity, driving should be one of the last ADLs resumed during rehabilitation (Pierce, 1996). Driving is the most complex IADL for most persons because it requires good physical, visual, perceptual, psychological, and cognitive skills and an integration of these skills. Consequently, most patients are not ready for a driving evaluation before discharge from the inpatient facility. Procedures for Practice 31-1 provides guidelines to determine when a person with a disability is ready for a driving evaluation.

If the patient is driving before he or she is ready, the therapist has an obligation to protect the public welfare by reporting the person to the appropriate licensing authority in the manner dictated by the state of residency. In 2003, the American Medical Association published *The Physician's Guide to Assessing and Counseling Older Drivers* (Wang et al., 2003). The role of the physician in addressing

PROCEDURES FOR PRACTICE 31-1

Guidelines to Determine When a Person with a Disability Is Ready for a Driving Evaluation

A patient or client who has all of the following can be referred for a driving evaluation:

- Maximum independence in basic activities of daily living
- Independent ambulation or wheelchair mobility
- Good strength, sensation, and coordination in at least one or, ideally, two extremities
- 20/40 visual acuity in at least one eye*
- 140° of total field of vision with both eyes*
- No double vision with or without compensation*
- No seizures for 6 months*
- Spasticity under control with or without medication
- Good visual-perceptual functioning, such as depth and figure ground perception
- Good cognitive functioning; short-term memory can be minimally to moderately affected
- Valid driver's license or learner's permit

* Requirements vary among states.

driver safety and the legal and ethical responsibilities of the physician are discussed, and there are also chapters describing the role of the driver rehabilitation specialist. Every occupational therapist should have a copy of this publication, which is available free in hard copy or CD-ROM at www.nhtsa.dot.gov or www.ama-assn.org/go/older-drivers. Although it is written with older drivers in mind, the material can apply to all age and disability groups.

Every occupational therapist should know the procedure for reporting impaired drivers in his or her state and which functions a therapist is authorized, obligated, or responsible to perform (Kaplan, 1999). A listing of individual state Medical Advisory Board regulations for reporting can be found at www.aamva.org. The occupational therapist should also know the driver rehabilitation therapists in their community or state, to whom patients can be referred when this service is needed. A list of driver rehabilitation specialists nationwide can be found on the website of the Association of Driver Rehabilitation Specialists (ADED) at www.aded.net or on the American Occupational Therapy Association's older driver microsite at www.aota.org/olderdriver. When looking for a driver rehabilitation therapist to assist your patient, consider the diagnosis of the patient and the background and experience of the specialist. A commercial driving school instructor who is also a driver rehabilitation specialist may not have the necessary medical background to understand your client's deficits and their implications for the driving task. If you are referring the client to a driving school instructor, a driver rehabilitation therapist should still be performing an occupational profile and performance skill assessment prior to the person having the road test with the driving school instructor (Pierce, 1993).

During the inpatient stay, the client may be allowed home visits on the weekends in preparation for discharge. It is important to work on community mobility while the person is still in rehabilitation so that feelings of isolation will not develop during these visits or after discharge. Transportation needs, particularly for the wheelchair user, may have to be addressed long before driving because the person may not be ready for a driving evaluation until 8–12 months after discharge. A referral to the driver rehabilitation therapist for “determination of transportation needs only” may be appropriate before discharge so that the patient, family, and funding source can be guided toward the appropriate vehicle and modifications. If the driver rehabilitation therapist can determine that the patient may be able to drive later, vehicle selection and modifications for transportation can be made with future driving needs taken into consideration.

A Driver Rehabilitation Therapist

Driver rehabilitation or driver evaluation programs throughout the United States are housed in hospitals, rehabilitation facilities, private practices, and state agencies.

PROCEDURES FOR PRACTICE 31-2

Steps for a Driver Evaluation by an Occupational Therapy Driver Rehabilitation Therapist

The following areas should be evaluated:

1. Occupational profile
2. Performance skills and client factors
3. Client's vehicle and how the client fits in the vehicle
4. Adaptive driving equipment needs
5. In-traffic performance
6. Inspection and fitting of the vehicle with equipment installed

A driver rehabilitation therapist is an allied health professional, such as an occupational therapist, with advanced knowledge and skill in the specialized areas of driver evaluation, driver education, and driver rehabilitation for persons with disabilities. An occupational therapy **driver rehabilitation therapist** can develop an occupational profile and perform a formal clinical evaluation of a person's physical, visual, perceptual, cognitive, and psychological functioning as it relates to driving (Procedures for Practice 31-2).

Developing an Occupational Profile and Performance Skill Assessment for Driving

The occupational therapy driver rehabilitation therapist will first develop an occupational profile to understand the meaning and requirements of the occupation of driving for each client and detail the internal and external contextual factors that may influence independence in driving. Examples of the relationship of driving to the person's roles are (1) working as a mailman, (2) living in a rural area but working in a city (commuter), or (3) the grandparent who is responsible for picking up a grandchild after school. The person's driving habits and routines are also considered, such as what type of traffic environment he drives in and what time of day he drives.

The second step is a clinical assessment to determine any client factors that may hinder safe driving ability and then to complete an evaluation of overall performance skills as they relate to driving and operating a motor vehicle. The evaluation and testing procedures are similar to those used to determine readiness for any other BADL or IADL with an emphasis on specific skills related to driving and are described in the early chapters of this textbook. For example, evaluation of a client's strength and range of motion may determine that special adaptive equipment will be needed to compensate for deficits. A visual performance deficit (nystagmus) or a cognitive deficit (impulsivity) will suggest possible problems to be anticipated

during the in-traffic assessment. Research indicated that the strongest independent predictors of crash-involved drivers was failure on the *Useful Field of Vision* test, which addresses several visual and cognitive processing domains, including visual sensory function, visual processing speed, and divided and selective attention (Sims et al., 1998). By understanding the client factors and specific deficits, the driver rehabilitation therapist can plan an evaluation road route that will challenge the known deficits during driving, thereby providing an accurate assessment of a person's capabilities and safety.

Vehicle Assessment

A driver rehabilitation therapist must evaluate the client's vehicle to assess its appropriateness. The client must be able to enter and exit the vehicle and store the wheelchair, scooter, or other orthotic device as needed (Fig. 31-24). The necessary adaptive equipment for driving must be compatible with the client's vehicle, or specific recommendations must be given regarding purchase of a more appropriate vehicle.

In past decades, the automobile industry produced many two-door cars from which disabled drivers could choose. The two-door cars allowed for easy loading of a folding-frame manual wheelchair behind the driver or passenger seat. Today few two-door cars exist that can accommodate loading the popular rigid-frame wheelchairs, but four-door cars, minivans, and trucks are now produced that allow easy loading of the rigid-frame wheelchair, either manually or electrically. Wheelchair-loading devices have particular vehicle and wheelchair requirements. The wheelchair measurements and weight must be taken to ensure that the loading device will accommodate the particular wheelchair or scooter. Likewise, the vehicle must be measured to determine that the particular vehicle model and make will accommodate not only the lifting device being recommended but also the wheelchair or scooter. It is a hand-in-glove process. The driver rehabilitation therapist evaluates the client, the wheelchair, and the vehicle for appropriateness, along with the client's ability to operate the loading device safely and efficiently.

A van can be set up for a person to drive from the wheelchair or to enable the person to make an independent transfer from the wheelchair to the driver's seat, as seen earlier in Figure 31-14. A van can be adapted with a device such as a wheelchair lift or a motorized ramp so that the person can ride the wheelchair into the vehicle. Structural modifications, such as a raised roof or lowered floor, are generally necessary to give the wheelchair user additional headroom, doorway clearance, and front windshield visibility. Full-size vans or minivans with structural modifications are very expensive (upward of \$40,000.00, not including the cost of the driving equipment).

Equipment Assessment

After a clinical assessment is completed and the therapist understands the client factors, performance skills, and contextual factors, the equipment assessment can be completed. This step should be an objective, methodical approach to determine exactly what adaptive equipment the person requires for safe operation of the vehicle.

Figure 31-24 A woman with rheumatoid arthritis illustrates how she uses a Braun Chair Topper, a mechanical device, to unload her manual wheelchair.

Development of driving technology over the past 25 years has allowed persons with a variety of disabilities to drive. If there is funding available, a person with a severe physical disability can drive. Driving technology can cost as little as \$85 for a steering device, \$300 for a left-foot gas pedal, and \$800 for simple mechanical hand controls, or as much as \$100,000 for a modified van with a sensitive steering, gas, and brake system (Fig. 31-25).

Persons with physical deficits or mobility challenges may require special driving devices or aids to assist them with particular driving tasks. Turning the ignition key can be difficult for a person with severe arthritis. Turning the head to check for cars prior to changing lanes can be impossible for persons with fused necks without adaptations. Dynamic balance in the driver's seat may be difficult for a person with quadriplegia or ataxia. The driver rehabilitation therapist analyzes each driving task for the person and determines the client's needs and desires and what specific aids are necessary for safe driving (Monga, Ostermann, & Kerrigan, 1997).

Various add-on assistive devices for primary and secondary vehicle controls are shown in Figure 31-26. To assist with steering, add-on devices for the steering wheel, called steering devices, can be used, including the spinner knob for one-handed steering and the tri-pin device for the person who lacks hand grip. Various levels of sensitized steering in combination with varying steering wheel diameter and placement are available to compensate for upper extremity range of motion and strength deficits. A person with right hemiplegia can operate the gas pedal with an easily installed left-foot gas pedal. A person with left hemiplegia may benefit from a turn signal crossover to allow safe operation of the turn signal with the right hand. Persons of short stature can use pedal extensions that

range in length from 1–10 inches, or a person with severe rheumatoid arthritis may require a key extension in order to turn the ignition key.

Electronic hand controls are available for a person with no use of the legs and limited range of motion and strength in the arms and hands. A handle on the control box moves 4–6 inches from full brake to full acceleration and operates with only 2 ounces of pressure. A person with muscular dystrophy or polio with proximal weakness but distal strength in the hands can use this control easily for gas and brake operation (Fig. 31-27). The driver rehabilitation therapist must consider the person's strength, range of motion, sensation, coordination, balance, and posture in determining which style of hand control is best for the individual. "Final determination of equipment needs should be confirmed in a moving assessment in an evaluation vehicle; however, the patient's own vehicle must be considered at some point" (Gillen & Burkhardt, 2004, p. 502).

In-Traffic Assessment

Following the pre-driving clinical assessment, an in-traffic assessment is necessary to make a final determination about a person's ability to drive. The person can be observed operating the vehicle and interacting in the traffic environment. An appropriate evaluation vehicle is used that is equipped with various adaptive equipment as well as dual controls for the instructor and other safety equipment. The purpose of the in-traffic assessment is to assess the person's driving knowledge, skills, and behaviors in the real driving environment on the road and in traffic. By knowing the deficits of the person, the driver rehabilitation therapist can plan a route to challenge them to determine whether the identified deficits interfere with safe driving. A structured

Figure 31-25 The Scott System allows many persons with polio, muscular dystrophy, C4–5 quadriplegia, and triplegia to drive independently. **A.** Person with C5 quadriplegia drives with the right hand in a tri-pin device. He pushes forward for gas and pulls back for braking, and supinates his forearm for turning right and pronates for turning left. **B.** One-handed steering with a small wheel by a person who uses his normal left extremity to push and pull the wheel for gas and brake; the wheel rotates 90° right or left for turning. (Courtesy of Driving Systems Inc., Van Nuys, CA.)

Figure 31-26 Various add-on assistive driving devices. **A.** Steering devices. **B.** Secondary control devices that cross over the functions of the gearshift (left), turn signal (middle), or gas pedal (right), which would be required by some persons after stroke.

Figure 31-27 Mechanical hand controls or more expensive electromechanical hand controls aid in safe operation of gas and brake. **A.** Push right-angle mechanical hand controls. Requires scapular stabilization and 4– (good minus) strength of shoulder flexion, internal rotation, and elbow extension. **B.** Electroserver hand control requires 3 (fair) strength within a 4-inch range. Can be operated by weak fingers or shoulder flexion and extension.

driving route may take into consideration the person's contextual factors, which include his or her driving patterns, habits, routines, and roles. For example, a particular route may be used to bring out the known deficits of the client, such as left visual neglect, to evaluate whether the deficits permit safe driving.

During the in-traffic assessment, a driver who requires adaptive driving equipment may require instruction and practice with the equipment prior to being evaluated for overall driving ability. Persons who have had a traumatic brain injury or stroke must first be evaluated for physical control of the vehicle and, secondly, for reaction time, judgment, attention, memory, dynamic visual skills, and higher executive functioning such as quick decision making, problem solving, and planning.

The therapist can break the driving task into component parts for the new driver. The occupational therapist's knowledge and skill in task analysis and performance skills is very effective in the evaluation car whether the client is an experienced driver or a new driver.

Driving simulators are available but expensive, and their contribution to the full assessment of a person's driving abilities is limited. A few simulators are relatively cost effective to a therapy program and are designed to give more pertinent information on the person with a disability. An example is the Elemental Driving Simulator by Life Sciences, which has face validity and provides feedback on more visual and cognitive skills than other typical driving simulators (Gianutsos, 1997).

Final Steps

After a comprehensive driver evaluation has been completed, a driving prescription can be written that specifies the client's vehicle and adaptive equipment needs. The therapist can then advise the client or funding source on how to find a mobility equipment dealer that can modify the vehicle properly. After the modifications are complete, the driver rehabilitation therapist will meet the client for a final vehicle inspection and fitting. The purpose of the inspection and fitting is:

1. To determine if all prescription items have been installed
2. To determine if all adaptive equipment or structural modifications have been installed and completed according to applicable industry and manufacture standards
3. To determine proper fit or adjustments needed to the added adaptive equipment to allow safe operation of all vehicle controls by the individual driver

Community Mobility Alternatives

"Most adults, with or without disabilities, drive cars as their primary mode of transportation. People age 65 and

older make more than 90% of their trips in cars, as either drivers or passengers" (American Association of Retired Persons, 2003, p. 87). When older adults are no longer able to drive, occupational functioning is jeopardized.

Driving Retirement

There are many persons seen by occupational therapy who are not candidates for learning to drive or are unable to drive for medical reasons or need to plan for driving retirement. When it is necessary to cease driving, the impact on lifestyle and independence may not be as difficult if pre-planning has occurred. Because these individuals still require community mobility for independent living, occupational therapy should address alternative transportation with clients. "Non-driving options can include public transportation such a fixed route rail, bus, paratransit, community transportation (e.g., community bus), demand-responsive transit (e.g., dial-a-ride), flex-route, Independent Transportation Networks, volunteer services, taxis, bicycles or tricycles, hitchhiking, and walking" (National Highway Traffic Safety Administration [NHTSA], 2006a, p. 10). In retirement states such as Florida, communities with golf cart paths are becoming very popular for older adults because the designated cart paths generally lead to shopping, social activity, and health care facilities.

Unfortunately, many older adults faced with driving retirement have made no plans for alternatives to driving. Some of those who have thought about alternatives expect to rely on friends and family for transportation rather than use other forms of transportation. Unfortunately, there are a higher number of persons who need a ride than the number who are available or willing to provide the ride (Yanochko, 2002).

Public Transportation

Many older adults perceive public transportation systems as unsafe, inconvenient, and inaccessible. Access to public buses can be hampered if the bus stops are not easy to get to, the sidewalks or paths to the bus stops are unsafe for pedestrians or wheelchairs, and there is poor lighting or difficult access to the entrance to the bus. Occupational therapists are perfect community partners to serve on city planning boards to assist in making transportation services more affordable and user-friendly. Environmental factors can play a critical role in either facilitating or undermining the ability for one to move about in the community. The occupational therapist is well suited to address both the personal and environmental factors that enable communities to support independence and safe transportation.

A person using a powered wheelchair who cannot drive a car generally needs a privately owned or public van or bus for transportation in the community. The van

must be equipped with a wheelchair lift as well as a **wheelchair and occupant restraint system**, also called a WORS (Fig. 31-28). A proper WORS is a crash-tested passive or active restraint device that secures a wheelchair and the occupant separately and appropriately

Figure 31-28 Wheelchair and occupant restraint system. **A.** Four points of attachment of tie-downs onto the wheelchair frame. **B.** An effective shoulder and lap belt restraint system requires proper belt angles. Incorrect belt placement can limit protection in a crash or load the occupant so as to cause injury. One end of the shoulder belt should be anchored higher than shoulder level. The lap belt should lie low across the bony structure of the pelvis.

DEFINITION 31-2

Basic Criteria for Proper Wheelchair Restraint

- There must be four points of attachment to the wheelchair.
- The attachment points must not be to any part of the wheelchair that is movable or removable, such as the armrests, footrests, or wheels.
- Proper strapping material and hardware must be used to withstand the forces generated by the wheelchair and the occupant in case of a collision.
- The occupant must be in a forward or rear-facing position, never a sideways or diagonal position.
- Occupant safety belts must be provided on the wheelchair.

Data from Bertocci, Hobson, & Digges, 2000; Schneider, 1981.

(Schneider, 1981). See information in Definition 31-2 for basic criteria for a proper wheelchair and occupant restraint system. As of 2000, wheelchair manufacturers must address the standards for restraining a wheelchair and the occupant in transit. The American National Standards Institute (ANSI) and the Rehabilitation Engineering Society of North America (RESNA) have contributed in an important way to the development of these standards (Bertocci, Hobson, & Digges, 2000).

Performance Skill Requirements for Community Mobility Options

Alternative modes of transportation, whether it be driving a golf cart or scooter or using a public bus or a subway, require different performance skills. The abilities of the person may determine what options they are able to use. In addition, they must have the finances to pay for services if needed. For example, a bus passenger must be able to understand a bus schedule and strategize a route and timing as well as have the fare and physically offer the fare, get to a bus stop, and then climb on and off the bus. The passenger must then recognize where they need to get off the bus and appropriately notify the bus driver.

Each alternative mode of transportation has its own physical, visual processing, and cognitive skills required for safe utilization. The occupational therapy practitioner must include, in a comprehensive evaluation of a client, a community assessment for the use of alternative modes of transportation. Considering the person's contextual factors is very important so that the evaluation includes all aspects of the person's community. Then the occupational therapy intervention to enable community mobility

should take place, if possible, near the person's home, on their chosen mode of transportation, and on the routes and paths that the person would be using.

Mobility as a Pedestrian

Walking should be encouraged as an alternate mode of transportation to motor vehicle travel. Walking is a form of transportation that also has the added benefit of being a healthy activity. Because walking is second nature to us, we forget that it is not only good exercise, but it also enables us to get where we need to go under our own steam, without having to rely on a vehicle. "Communities throughout the United States are mobilizing to promote walking and biking across the lifespan. Efforts include community design changes, health education, walking groups and media campaigns. . . regular, moderate physical activity can extend the lifespan and prevent or slow the development of chronic disease such as heart disease and diabetes, as well as decrease the likelihood of falls, arthritis pain and depression" (NHTSA, 2006b, p. 1).

A United States Department of Transportation report on active aging describes strategic planning for creating active communities, from identifying audiences, to assessing barriers and opportunities for physical activity, to developing strategies for increasing the number of older adult walkers and cyclists. The catalogue of strategies includes public policy changes, improved community design, and information and education approaches. All reports are published by Partnership for Prevention in collaboration with the United States Department of Transportation, National Highway Traffic Safety Administration and are available at www.prevent.org/activeaging.htm.

Pedestrian Safety

In 2004, 4,641 pedestrians were killed in traffic crashes in the United States—a decrease of 15 percent from the 5,489 pedestrians killed in 1994. There were 68,000 pedestrians injured in traffic crashes in 2004. Most pedestrian fatalities in 2004 occurred in urban areas (72%), at non-intersection locations (79%), in normal weather conditions (89%), and at night (66%) (National Highway Traffic Safety Administration, 2004).

Accident rates for elderly pedestrians resemble those for elderly drivers; that is, the rate is higher than for any other age group. Elderly pedestrians are often hit in crosswalks or when crossing intersections and are generally hit when they have almost finished crossing. They are usually observing the law and not behaving dangerously. Many do not see the vehicle that hit them, and when they do see the vehicle, they usually believe that the driver has seen them and will avoid them. It follows that persons with walking impairments and those in wheel-

chairs may encounter the same dangers at intersections or crosswalks as the elderly do. Education about pedestrian safety could save lives. Education of community planners and city leaders could encourage changes in traffic signal intersections, pedestrian walkways, and pedestrian warnings. The occupational therapy practitioner can include this information when training a person to be mobile in the community via a wheelchair, cane, scooter, golf cart, or public bus. The occupational therapy practitioner can help city planners be more sensitive to the needs of the well elderly or persons with disabilities of all ages.

The National Highway Traffic Safety Administration (NHTSA) pedestrian safety programs are directed toward reducing pedestrian injuries and fatalities for all ages. More information on these programs is available at <http://www.nhtsa.dot.gov/People/injury/Pedbimot/Ped>. An example of a program is called *Stepping Out* and was developed to fill the need for pedestrian safety materials for older adults aged 65 years and above. This booklet promotes safe walking and the benefits of walking and includes tips for staying safe at intersections, in parking lots, in non-sidewalk areas, and in bad weather. A copy of the program is available at www.nhtsa.dot.gov/people/injury/olddrive/SteppingOut/index.html.

Occupational Therapy Roles in Community Mobility and Driving

The American Occupational Therapy Association has defined two roles for occupational therapy practitioners in Community Mobility and Driving: the *Occupational Therapy Driving and Community Mobility Generalist* and the *Occupational Therapy Driving Rehabilitation Specialist*. All occupational therapists emerge from their professional education with the knowledge and skills to perform the role of the OT generalist in driving. The OT generalist begins the process by developing the occupational profile and asking questions to understand the value and meaning of driving to the client. The second step, the analysis of occupational performance, involves identification of the older adult's assets, problems, and potential problems related to the occupation of community mobility, including driving. The OT generalist can then plan intervention strategies to work on specific performance skills in preparation for a driver evaluation. Finally, the OT generalist must know the resources in the community so a timely referral can be made to the OT specialist. A fair and objective assessment by a professional is very welcome by families of older drivers or of persons with acquired or congenital disabilities. The OT generalist must often steer the family toward the need for a driver evaluation and the resources of the OT specialist in driving and community mobility (Hunt & Pierce, 2005) (Resources 31-1).

CASE

E X A M P L E

Mr. J.: Restoration of Mobility Following Stroke

Occupational Therapy Intervention Process

Patient Information

Mr. J. is a 67-year-old man with right hemiplegia and expressive aphasia from a left cerebral vascular accident (CVA). He was evaluated in an outpatient rehabilitation center, and the following problems were identified by the occupational therapist:

1. Client can roll over and sit up in bed but has difficulty moving his right leg off the bed in preparation for transferring and dressing.
2. Client cannot complete a stand-pivot transfer independently because he needs assistance coming to standing.
3. Client can propel his manual wheelchair with a one-arm drive on level surfaces but cannot negotiate a ramp or uneven terrain.
4. Client cannot perform bathroom activities at home because his bathroom is inaccessible to his wheelchair.
5. Client has not driven since the CVA but is very anxious to begin driving again. He is concerned about loading his wheelchair into a car by himself.

Clinical Reasoning Process

Objectives

Examples of Therapist's Internal Dialogue

Appreciate the context

M J. is still young with a good medical history except for the CVA. Most importantly, he is motivated to improve his mobility skills so that he can be less dependent upon his wife. His home environment and spousal and family support will enable him to reach higher goals for mobility and independence.

Develop intervention hypotheses

"Mr. J. has significant physical deficits that may be permanent, but with his young age and good health, I believe that his occupational performance could be enhanced greatly by improving his functional and community mobility skills."

Select an intervention approach

"I will develop an intervention plan that emphasizes functional mobility first and community mobility needs second. I know that there are precursor mobility skills that are required in the areas of bed mobility, transfers, and wheelchair mobility, so I will need to address these performance skill areas first before I address the specific tasks that he is weak in such as handling his legs in bed or propelling his wheelchair outdoors. It will enhance my intervention if I talk with physical therapy to see if they can work on improving his leg strength and his ability to stand up independently. I will need to explain to the client and his family that we will address his driving ability as a long-term goal after we have accomplished the short-term goals in functional mobility. I will explain how the skills in functional mobility will prepare him for the driver evaluation when the time is appropriate. I will let the family know that I can research community transportation alternatives available in their community that he may be able to use in the meantime or in case it is found that he is not able to return to driving in the future."

Reflect on competence

“I am concerned that I do not know all of my responsibilities as an OT generalist in driving and community mobility. I need to research this area before I begin addressing the topic of driving and community mobility. I also need to find resources in my state for an OT specialist in driving and community mobility so I can talk intelligently about the specialist’s services and purpose to the client and family.”

Recommendations

The occupational therapist recommended two treatment sessions per week for 8 weeks. In collaboration with the client and his wife, the occupational therapist established the following long-term treatment goals: (1) Mr. J. will be independent in bed mobility and sitting on the edge of the bed; (2) Mr. J. will be able to perform a stand-pivot transfer independently; (3) Mr. J. will improve his ability to negotiate outdoor terrain and ramps with his manual wheelchair and be advised on motorized scooters for use in independent long-distance mobility in the community; (4) in collaboration with physical therapy, Mr. J. will be instructed in using his hemi-walker to walk into the bathroom and perform sink activities while standing; and (5) Mr. J. will be referred to an OT specialist in driving and community mobility once he is able to transfer in and out of his car.

Consider the patient’s appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient’s endorsement of plan

“I do not believe that this client is aware of his potential for being more independent in functional mobility skills. Some of this may be related to his wife, who is unsure if he can drive again. I believe that he is motivated enough to be more independent and will have successful outcomes with an aggressive therapy program. I also believe that, when he sees that he can accomplish functional mobility goals and senses that his potential to drive again may be greater than he first thought, he will be highly motivated to work hard in occupational therapy. Mr. J. and his wife seem agreeable to the plan, and I hope that by including his wife that she will become more comfortable in letting him do more tasks for himself at home, which is very important to him.”

Summary of Short-Term Goals and Progress

1. Mr. J. will be able to move his weak leg off the edge of a bed and come to a seated position with or without orthotic devices.

The therapist ascertained after a week of occupational therapy that Mr. J. could move his weak leg off the bed using his stronger left leg by putting his left foot under the weak right foot and then moving both feet over the edge of the bed. She determined, however, that he would require a device to use to pull against to come to a short-leg sitting position on the edge of the bed. In the second week, various techniques and assistive devices were demonstrated to him, and it was determined that a portable half bed rail worked best. By the fourth week, Mr. J. could come to a short-leg sitting position on the side of the bed independently. He was also shown how to use the bed rail to help him stand up and ready himself for a stand-pivot transfer.

2. Mr. J. will become independent in sink activities in the bathroom.

The first week of therapy revealed that the client’s standing tolerance and balance were not sufficient to perform sink activities while standing even though he could walk short distances. In the second week, he was taught how to stand up from his wheelchair outside the bathroom door, walk into the bathroom using his hemi-walker and short leg brace, and sit on a tall-legged stool at the sink. The higher seat helped him come to standing when he pulled on the sink for assistance in standing up when ready to leave.

3. Mr. J. will be able to transfer into the passenger and driver side of his car independently.

By the third week, Mr. J. could handle his leg on and off the bed and could stand up independently. In the fourth week, Mr. J. was instructed in getting in and out of the passenger side of a car. After he could perform this transfer, he was taught how to transfer into the driver’s side of the car, maneuvering his legs under the steering wheel.

Assess the patient’s comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Initially it was hard to motivate Mr. J. to work on bed mobility tasks, such as rolling over, coming to sitting, and moving his legs over the edge of the bed, because he had become used to his wife helping him in bed mobility. As she began to support him doing more on his own, I saw a big leap in his motivation. Once he could accomplish the first task of handling his legs, he was then very eager to move onto learning to stand up and transfer on his own. I could see his eyes light up every session as he accomplished another goal because he could see how it would all come together in the end and make him less dependent upon his wife. Even though he was unable to do some tasks completely on his own, he recognized quickly that there is much assistive technology out there that can benefit him.”

“It has been very helpful for Mrs. J. to attend each of Mr. J.’s treatment sessions. As she has observed his weaknesses, she has been able to encourage him to complete his home therapy exercises and activities on days that he does not come to therapy. They have learned how to use the kitchen sink for support to let him work on standing tolerance 3–4 times a day. Mrs. J. has indicated that he will sometimes sit outside the bathroom and appear to long to just stand up and walk in. Mr. J. knows that they cannot afford to modify the bathroom doorway, so he understands that it is very important for him to have a good outcome with standing and this goal. He keeps asking me about a driving evaluation and is beginning to show some frustration in having to wait. Mrs. J. is very understanding of why this goal has been put off to later and has assured me that she will not let him drive before he is ready.”

In the sixth week, he was referred to an OT specialist in driving and community mobility that I found in the next town. He was instructed by this specialist to use a left-foot gas pedal and a spinner knob for driving, and the adaptive equipment was installed in his own car. In collaboration with the OT driving specialist, we both decided that Mr. J. could not be independent in loading his wheelchair into his four-door sedan. He did not have the standing balance to use a wheelchair loader that is bumper or trunk mounted. He could, however, use a car topper that will electrically pick up, fold, and load his manual wheelchair into a box on the top of his car all while he sits in the driver seat. By the time of his discharge, he had received all necessary in-vehicle training by the OT driving specialist and was beginning to drive around his own community.

“Mr. J. is accomplishing his goals quickly. I see him working very hard because he can tell that a driver evaluation is getting closer to becoming to reality for him. Through my contact with the OT driving specialist, I was able to discover that Mr. J. can use an adaptive equipment rebate from General Motors to help him purchase some of his driving equipment since his car was bought new 6 months ago. This will enable him to afford to buy the car topper as well as the devices he requires for driving. I introduced Mr. J. to another client of mine who also drives with adaptive equipment and went to the same OT driving specialist. This was very encouraging to Mr. J., and he actually went to see some driving equipment in this gentleman’s car. It was so great to see Mr. J. come into therapy after the first session of seeing the OT driving specialist. He was so excited and could finally see that he would be able to become much less dependent upon his family now. It was nice to hear him express his appreciation for my work, and he even admitted that he was glad I did not send him for a driving evaluation sooner.”

Next Steps: Revised short-term goals (1 month):

1. Mr. J. will become independent in toilet transfers and tub transfers but will likely require some assistive technology such as elevated toilet seat, grab bars, and a tub bench.
2. Mr. J. will become independent in long-distance ambulation by using a motorized scooter but will require assistance for loading and unloading the scooter.
3. Mr. J. will be independent in driving himself to and from therapy.

Anticipate present and future patient concerns

Analyze patient’s comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Mr. J. has made great progress over the past month. He does not seem as depressed as when I first saw him and is coming to therapy with more and more things that he would like to do. I have recommended that he obtain a referral for home health OT so that he can begin working in his own home environment. The home health OT can make sure he gets the right equipment in his bathroom and give him practice with his transfers in his own environment. He is totally agreeable to this plan. He is asking if he can drive now to and from his daughter’s house, which is about 45 minutes away in another small town. I have referred him back to the OT driving specialist to address this issue with him. Mr. J. and I decided that he no longer needs outpatient OT but can be followed for his other goals by the OT consultant.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

The Importance of a Client-Centered Approach

During the initial OT evaluation, Mr. J. appeared depressed and withdrawn. What observable signs did Mr. J. display during the evaluation from which the therapist might draw this conclusion? In what ways can the therapist investigate the cause of Mr. J.’s depression? What factors in the client’s contextual environment could cause these depressed feelings?

Evidence Table 31-1 Best Evidence for Occupational Therapy Practice Regarding Occupational Therapy to Improve Mobility

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Targeted occupational therapy at home to increase outdoor mobility	Intervention: Assessment of barriers to outdoor mobility, set mobility goals with the client, and delivered interventions to meet the goals. Control: One OT session of advice, encouragement, and provision of leaflets describing local mobility services.	168 community-dwelling adults diagnosed with stroke within 36 months; 86 randomly assigned to the intervention group and 82 assigned to the control group.	Up to 7 occupational therapy interventions for up to 3 months. Mean dosage = 4.7 visits for a mean total of 230 minutes.	Randomized controlled trial. IA1a	Yes. The occupational therapy intervention that targeted specific mobility goals was successful in increasing outdoor mobility in both the short (4 months) and long term (10 months). Those with the worst self-reported outdoor mobility at the start of treatment benefited most.	Out of the house as much as you would like?: 65% for intervention; 35% for controls. How many journeys outdoors in last month?: 37 for intervention vs. 14 for controls; $p < 0.01$. <i>Nottingham Extended Activities of Daily Living Scale</i> : No significant difference. <i>Nottingham Leisure Questionnaire</i> : No significant difference. <i>General Health Questionnaire</i> : No significant difference. Effect sizes could not be calculated from data provided.	Logan et al., 2004

<p>Transition from manual wheelchair to powered mobility device (PMD)</p>	<p>Prescribed (by a registered OT?) a PMD at point when no longer able to propel a manual wheelchair as primary mobility device.</p>	<p>Convenience sample of 8 community-living adults between ages 27 and 52 years, with static or progressive conditions, who had previously used a manual wheelchair before receiving a PMD between 6 and 24 months prior to the study (demarcation event).</p>	<p>Not applicable.</p>	<p>Retrospective study of behavior before and after the demarcation event of receiving a PMD (one group pre-/post-test design). IIIc2b</p>	<p>Yes. Results suggest that the transition to a PMD enhanced occupational performance, competence, adaptability, and self-esteem for persons with severe mobility impairments.</p>	<p><i>Occupational Performance History Interview (OPHI)</i>: significant improvement in role performance (Wilcoxon signed rank test, $t = 0, p = 0.001, r = 1.09$) after introduction of PMD. <i>Psychological Impact of Assistive Device Scale (PIADS)</i> (self-report): all participants rated adequacy, independence, quality of life, ability to adapt to ADL, and ability to take advantage of opportunities a score ≥ 2 (somewhat increased or better).</p>	<p>Buning, Angelo, & Schmeler, 2001</p>

SUMMARY REVIEW QUESTIONS

1. Define the two main areas of mobility for occupational therapy intervention and list three specific subareas under each main area of mobility.
2. Describe the hierarchy of intervention planning for mobility and identify two preparatory performance skills required for each area.
3. How can the principles of body mechanics be applied to training in transfer skills?
4. List the specific outdoor mobility skills that you should instruct a patient in who must now use a manual wheelchair.
5. List precursor abilities and skills that a patient with paraplegia must accomplish before learning to transfer into a wheelchair.
6. Describe the options available in teaching a patient how to negotiate a curb in a manual wheelchair.
7. Describe the different roles for evaluation and intervention planning for the OT generalist versus the OT driving and community mobility specialist.
8. List the performance skill factors to consider when determining whether your client or patient is appropriate to refer to an occupational therapy driver rehabilitation specialist for a driver evaluation.
9. For successful outcomes in mobility, identify specific areas of mobility intervention in which you will confer with an interdisciplinary team member and demonstrate your understanding of the interplay between the disciplines by defining each team member's responsibility for the areas you have identified.
10. Describe why planning for driving retirement is important and list the transportation alternatives that are available in some communities.

ACKNOWLEDGMENT

I thank Carol Blackburn, OTR/L, CDRS; Brenda Johnston, OTR; Daphne Cronin; Joan Bova; and Linda and Chuck Green for their assistance with the photography for this chapter.

CHAPTER 32

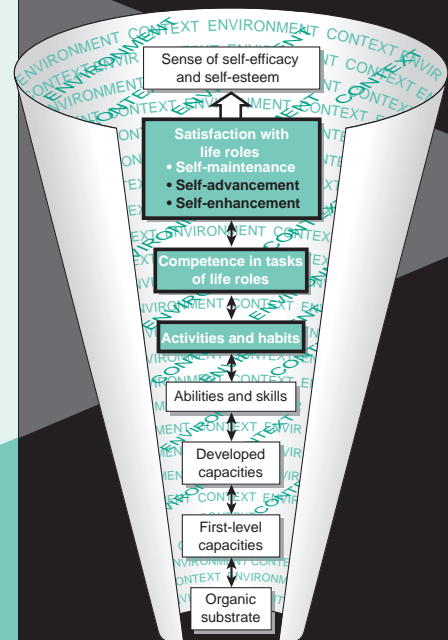

Restoring Competence for Homemaker and Parent Roles

Susan E. Fasoli

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. State the principles of compensation and adaptation.
2. State the principles of work simplification.
3. Identify adapted methods and equipment that enable persons with varied physical challenges and diagnoses to regain competence in homemaking roles.
4. Identify adapted methods and equipment that enable persons with varied physical challenges and diagnoses to regain competence in parenting roles.
5. Describe and teach proper body mechanics for homemaking and parenting tasks and activities.

Restoring competence in homemaker and parenting roles following a disabling event can greatly enhance one's sense of efficacy and feelings of self-esteem. Therapists typically address impaired performance of these life roles after a client has regained independence in basic activities of daily living (e.g., self-care). Home management and parenting tasks, however, can be incorporated into the rehabilitation process at any time, depending on the individual's own priorities and needs.

Homemaking and parenting tasks may be used as both occupation-as-means and occupation-as-end, depending on the client's rehabilitation potential and desired goals. This chapter focuses on the use of occupation-as-end to restore a client's competence and participation in homemaker and parent roles. This treatment approach allows for addressing significant impairments in occupational performance skills (e.g., incoordination or visual impairments) via the principles for compensation and adaptation highlighted in Procedures for Practice 32-1.

Principles of work simplification and energy conservation can be taught to clients with physical impairments who lack sufficient endurance to accomplish daily life tasks. Work simplification and energy conservation principles are commonsense ideas to improve task efficiency and reduce energy expenditure during all occupational tasks and roles, including those related to homemaking and parenting (Procedures for Practice 32-1).

HOMEMAKER ROLES AND TASKS: TREATMENT PRINCIPLES AND METHODS

An important role of the occupational therapist is to learn what life roles and tasks are particularly meaningful to the client (i.e., to explore his/her occupational identity) and to allow him/her the opportunity to grieve for what is lost or

PROCEDURES FOR PRACTICE 32-1

Principles of Adaptation to Compensate for Functional Limitations

Principles for Compensation and Adaptation

- Limited ROM: Increase the person's reach via extended handles and organize needed items within a compact work space.
- Weakness and low endurance: Use lightweight and/or powered equipment and allow gravity to assist. Employ work simplification and energy conservation techniques.
- Chronic pain: Reinforce use of proper body mechanics and pacing during physical tasks.
- Unilateral loss of motor control and limb function: Use affected limb to stabilize objects when possible. Use adapted methods and/or assistive equipment to perform bilateral activities with one hand.
- Incoordination: Stabilize at proximal joints (e.g., elbow) to reduce degrees of freedom necessary for control. Use weighted objects to minimize distal incoordination.
- Visual impairments: Use senses of smell, touch, and hearing to substitute for low vision. Enhance performance of visual tasks by improving lighting, reducing glare, or increasing contrast.
- Cognitive limitations: Employ visual and auditory aids to enhance memory and organization. Plan steps prior to beginning task. Work in familiar environment (e.g., home kitchen) to enhance cognitive performance during homemaking tasks.

Principles of Work Simplification and Energy Conservation

- Limit the amount of work. When possible, avoid over-fatigue by assigning heavy homemaking tasks (e.g.,

vacuuming, cleaning bathrooms) to family members or a housekeeper.

- Explore ways to reduce homemaking demands and expectations, such as using packaged mixes or frozen foods to decrease time and energy for meal preparation.
- Plan ahead. Schedule homemaking, child care tasks (e.g., changing bed linens, giving tub baths), and community outings (e.g., shopping, doctor visits) to distribute energy-demanding tasks throughout the week. Prioritize to complete important tasks before fatigue sets in.
- Use efficient methods. Organize work areas and store frequently used supplies in a convenient location. Avoid standing when it is possible to sit while doing the task (e.g., ironing). Slide objects across a counter or table rather than lift them. Identify needed items at the beginning of a task to avoid extra trips. Use a utility cart to transport items.
- Use correct equipment and techniques. Use assistive equipment (e.g., long-handled reachers) to decrease bending and stooping. Avoid prolonged holding by stabilizing items with non-skid mats. Adjust work height and use tools most appropriate for the job. When physical limitations are present, choose equipment that does not promote further deformity.
- Balance daily tasks with rest breaks. Clients should perform energy-demanding tasks early in the day, when they are most rested. Encourage self-pacing of tasks (don't rush!) to avoid fatigue. Frequent rest periods of 5–10 minutes can greatly enhance functional endurance during homemaking and parenting tasks.

changed (Unruh, 2004). Many factors, including psychosocial adjustment, cognitive or perceptual impairments, and physical limitations, can influence a client's ability to take part in homemaker roles and tasks.

Psychosocial Adjustment

When faced with the onset or progression of physical disability, a client and family may have a variety of psychological responses. These reactions may be characterized by lack of motivation and refusal to participate in therapy, expressed feelings of hopelessness or anger, and denial (American Occupational Therapy Association, 1997). For persons with chronic conditions, such as scleroderma or rheumatoid arthritis, the challenges encountered during household chores can strongly affect levels of life satisfaction and well-being (Sandqvist, Akesson, & Eklund, 2005). The family's expectations and reactions must also be considered when occupational therapists are setting intervention goals and establishing plans for treatment. These psychological reactions must be acknowledged and addressed by the occupational therapist if identified goals are to be achieved.

Barriers to Effectiveness

The occupational therapist must identify factors, in addition to psychosocial concerns, that can interfere with the effectiveness of intervention and inhibit performance during homemaking tasks. These factors include, but are not limited to, cognitive and perceptual impairments, poor vision, and environmental constraints including lack of family support.

Persons with cognitive impairments as a result of central nervous system disorders may have more difficulty learning compensatory techniques than persons with musculoskeletal or peripheral nervous system disorders. The client needs good memory, judgment, and problem-solving abilities to learn how an assistive device is used, when it is needed, and how it can safely enhance task performance (Moyers, 1999). Cognitive demands are increased when the adapted methods greatly alter the way the task is performed (e.g., ordering groceries online or learning to use a utility cart to transport items).

In the absence of intact cognitive abilities, clients may be able to learn new task methods, such as how to operate a microwave oven for meal preparation, if they can follow visual cues or instructions. The occupational therapist must ensure that the client can safely perform the task with the prescribed adaptations and meet unexpected challenges encountered during task performance.

Perceptual impairments, including poor figure-ground skills, poor spatial orientation, and visual neglect, can also interfere with one's ability to manage homemaking tasks

independently. Limitations in perceptual processing can interfere with one's ability to find needed items in the cupboard, decrease safety of pouring hot coffee into a cup, and increase the likelihood of falls when vacuuming or sweeping floors. In addition, poor visual processing, such as loss of central vision or decreased contrast sensitivity, can inhibit safety during homemaking tasks. Environmental changes, such as increasing available lighting throughout the home and enhancing contrast (e.g., pouring coffee into a light-colored mug), can improve performance (Lampert & Lapolice, 1995).

Support of family or friends can be instrumental for carrying out recommended adaptations, reinforcing the use of assistive devices, and identifying additional concerns in need of intervention. When family assistance is not available, other support services (e.g., homemaker, companion) may be employed to ensure safety in homemaking tasks.

Preventing Decline in Homemaker Role and Tasks

Occupational therapists are often involved with preventing disability in persons who are at risk for developing impairments, activity limitations, and restrictions in the performance of life tasks and roles (Moyers, 1999). Prevention programs for elderly persons include exercise classes to reduce physical limitations in balance, range of motion, and strength, in addition to group activities that exercise cognitive abilities, such as judgment and problem solving (Jackson et al., 1998). Homemakers may be instructed in home safety tips directed toward reducing clutter, removing loose rugs, and arranging furniture to clear walkways and allow access to electrical plugs and windows. Environmental modifications, such as the installation of grab bars and railings, can significantly decrease the occurrence of falls (Plautz et al., 1996).

Occupational therapists can be instrumental in identifying hazards in the home and providing ideas that may enhance a person's safety and continued independence. Many limitations encountered by well elderly persons during homemaking tasks may be prevented or alleviated by relatively simple and inexpensive solutions.

Homemaking: Techniques and Therapeutic Aids

Competence in the role of homemaker can be attained in either of two ways, depending on the client's level of physical and cognitive ability: by managing and directing others to perform homemaking tasks or by direct participation.

Although persons with severe physical disabilities may not be able to perform many homemaking tasks without assistance, they can be effective home managers. For instance, individuals with high-level spinal cord injuries can independently manage household tasks by directing

family members or paid housekeepers, managing finances, and overseeing shopping. Computerized banking systems and shopping services are accessible to those with Internet access and are relatively easy to use. Occupational therapy at this level may focus on organizing how household tasks may be scheduled, instructing the client in computer use, or identifying service resources in the community. Homemaker services, home health aides, and Meals on Wheels may provide the support necessary for a person with limited abilities to remain at home.

Persons who can physically participate in homemaking tasks can benefit from a variety of interventions that maximize role performance. The following sections discuss equipment and adapted methods for homemaking.

Equipment Considerations

A number of factors contribute to the selection and use of assistive devices and adapted equipment for homemaking. Simple modifications in the way a task is performed sometimes eliminate the need for an assistive device, and this is the preferable solution. When equipment is recommended, a primary concern is that the assistive device satisfies the needs of the client and enables the person to accomplish tasks that are otherwise impossible or difficult (Axtell & Yasuda, 1993). The person must be comfortable with the idea of using an assistive device and satisfied with its appearance.

When making equipment recommendations, the occupational therapist must consider both the immediate and long-term needs of the client. Individuals with a progressive disease, such as rheumatoid arthritis or multiple sclerosis, benefit from equipment that can enhance current

functional performance and provide for anticipated changes in physical status. In contrast, persons with non-progressive conditions, such as acquired brain injury or spinal cord injury, often use fewer assistive devices as they regain physical abilities or learn alternate ways to accomplish their tasks without equipment.

Generally, assistive devices should be simple to use and maintain, as lightweight as possible, and dependable (Axtell & Yasuda, 1993). If a client has mild cognitive impairments that interfere with equipment use, family members may be taught ways to enhance carryover at home. Insurance providers generally do not pay for assistive devices and adapted equipment. For those who cannot afford to purchase such items, loaner equipment may be available from local organizations, including disability support groups and senior citizen centers.

Meal Preparation, Service, and Cleanup

Efficient work areas, adapted techniques, and assistive devices can greatly enhance a client's safety and participation in meal preparation tasks.

Kitchen Storage and Work Area

Kitchens should be organized so that frequently used items are within easy reach of the place they are most often used. On average, persons who use a wheelchair can reach to retrieve items between 15 inches (low reach) and 48 inches (high reach) from the floor. Those who are ambulatory but have difficulty bending generally can reach 30 inches (low reach) to 60 inches (high reach) from the floor, depending on the person's height (Anderson, 1981).

Pull-out shelves and turntables in cabinets can compensate for limited reach and maximize usable storage space. Pans, dishes, and so on may be stored vertically to alleviate the need to move unwanted items to obtain the one underneath. Pegboards with hooks can be attached to the back of closet doors to hold pots, pans, and utensils for easy access. Shelves attached to the inside of cabinet doors are handy for holding assorted wraps, canned goods, and cleaning supplies. Items that are seldom used should be removed to eliminate unnecessary clutter.

Safety and independence in the kitchen can be enhanced by the availability of clear and accessible workspaces. For persons in wheelchairs, work counters should be 28–34 inches from the floor and have a depth clearance of 24 inches underneath to allow room for wheelchair leg rests. A work area that is at least 30 inches wide is recommended to provide sufficient space for needed items during meal preparation (ADA-ABA, 2004).

Gathering and Transporting Items

An important role of the occupational therapist is to help the client solve problems about gathering and transporting items at home by using work simplification principles and proper body mechanics (Procedures for Practice 32-1 and 32-2). Long-handled reachers can be helpful but should be used primarily for retrieving lightweight unbreakable items.

The wide range of assistive devices for transporting items around the home includes cup holders and walker or wheelchair bags. Homemakers who use a wheelchair may benefit from using a lap tray that easily slides on and off the wheelchair arms (Fig. 32-1). A variety of wire baskets and trays that attach to a standard walker are available for purchase, but many of these devices accommodate only a few things at a time, such as a sandwich and covered beverage. Individuals who perform homemaking tasks either from a wheelchair or ambulatory level may prefer to use a wheeled utility cart because of its larger carrying capacity. The therapist can help clients learn to maneuver the cart efficiently. Homemakers who use an assistive device or adapted methods to transport hot foods and beverages must follow strict safety precautions to avoid burns.

When limited income inhibits a client's ability to purchase assistive aids, the creative therapist can work with the client to identify inexpensive workable alternatives. No-cost solutions, such as attaching a plastic grocery bag or used bike basket to a walker, can add to independence in transporting certain items.

Food Preparation

The use of assistive devices and adapted equipment can make food preparation easier and more enjoyable. Homemakers who have lost the use of one arm following stroke or fracture find an adapted cutting board extremely useful

PROCEDURES FOR PRACTICE 32-2

Principles of Correct Body Mechanics

Principles of correct body mechanics that should be used during homemaking and parenting tasks (Melnik, 1994; Saunders, 1992) include:

- Keep the shoulders and hips parallel and facing the task. Do not twist the trunk when lifting.
- Maintain good balance by positioning the feet shoulder distance apart with one foot forward.
- When standing for long periods, reduce pressure on the lower back by placing one foot on a low stool and changing positions frequently.
- When sitting or standing, maintain a neutral position in the lower back by tilting the pelvis slightly forward to maintain the natural curve of the spine. Use this neutral back position when lifting as well.
- Use the strongest or largest muscles and joints when lifting (e.g., use legs rather than back, palms rather than fingers).
- Keep the back upright and bend at the hips and knees rather than bending forward at the waist when reaching for low items.
- Push before pulling and pull before lifting.
- While lifting or carrying, keep the object close to the body.
- Avoid rushing. Proper body mechanics are more effectively used when working at a comfortable pace.

when peeling or cutting vegetables, fruit, or meat. A raised edge along one corner of the board can stabilize a slice of bread for spreading butter or jam (Fig. 32-2).

The occupational therapist helps clients with physical limitations to solve problems such as the safest way to open cereal boxes and juice cartons. Some persons can open packaged food with one-handed techniques, while others prefer to use adapted scissors with a looped handle

Figure 32-1 Woman eating her lunch on a clear acrylic wheelchair lap tray that allows her to observe her lower body. (Photo by Robert Littlefield.)

Figure 32-2 Spiked cutting board with corner guards. (Photo courtesy of North Coast Medical, Inc., Morgan Hill, CA.)

(Fig. 32-3). Homemakers with weakness and impaired hand function may find it easier to open plastic milk jugs than cartons. Smaller containers are generally easier to manage than large ones. Non-slip mats or suction holders may be used under jars or bottles to hold them steady for opening with one hand and to reduce sliding or turning of bowls when mixing.

Knives, vegetable peelers, and other kitchen tools are available in many shapes and sizes. Clients with rheumatoid arthritis benefit from using utensils with ergonomically designed handles that require less hand strength and reduce ulnar drift (Fig. 32-4). Incoordination due to ataxia may be somewhat alleviated by the use of weighted utensils and tools. Freestanding or mounted jar openers can be helpful to persons with a variety of physical limitations. Homemakers can be taught adapted methods for cracking eggs (Fig. 32-5; Procedures for Practice 32-3).

Electric equipment, such as food processors, blenders, can openers, and electric knives, can conserve energy by reducing the physical demands and time needed for meal preparation. To be truly beneficial, this equipment must be easy to use and maintain and suited to the person's disability. For example, some one-handed cordless can

Figure 32-3 Looped scissors. (Photo by Robert Littlefield.)

Figure 32-4 Ergonomic right-angled knife. (Photo by Robert Littlefield.)

openers are available only in right-handed models and therefore are not convenient for persons with significant right hemiparesis after stroke.

Homemakers with limited mobility or reach find a side-by-side refrigerator more accessible than other models. Loops of webbing or rope can be attached to the door handles to enable clients with limited hand function to pull the doors open. Heavy items should be stored on a shelf that is level with a lapboard or wheeled cart so they can be moved in and out with minimal lifting.

Cooking

Most persons with physical impairments find lightweight non-stick pots and pans to be the easiest to handle and maintain. Ergonomically designed cookware with easy-to-grip handles can be ideal for persons with limited distal strength (Fig. 32-6). The use of double-handled casserole dishes, pots, and pans can enable joint protection by evenly distributing the weight of the pan between both hands.

Ambulatory clients with back or lower extremity pain or limited endurance can save energy by sitting whenever possible while preparing meals. Individuals who prepare food in a wheelchair can use a mirror mounted at an angle over the stove to keep an eye on cooking foods. Persons with hemiparesis may use a suction cup holder to stabilize pot handles while stirring. Homemakers can conserve energy when straining vegetables or pasta by placing a french-fry basket in the pot before cooking or by using a slotted spoon. This practice eliminates the need to carry

Figure 32-5 One-handed egg crack. (Photo by Robert Littlefield.)

PROCEDURES FOR PRACTICE 32-3

Methods for Breaking Eggs

Individuals with weak grasp can grossly hold the egg, throw it sharply into the bottom of an empty glass or metal bowl, where it will split in two, and then remove the shell.

Clients with functional use of only one hand may prefer to use the chef's method, as follows. Place the egg in the palm with one end held by the index and middle fingers and the other end held by the thumb to form a "C" around the egg. Sharply crack the egg on the side of a bowl, and then in one motion, pull the thumb down and the fingers up to pull the two halves apart (Fig. 32-5).

a hot pot to the sink to drain it. Those who can safely transport and drain hot foods at the sink can reduce the need for lifting and holding and enhance stability by resting the pot on the sink's edge when pouring. An adjustable strainer that clamps onto the top of a pot or pan can also be used.

A

B

Figure 32-6 Ergonomic cookware with easy-grip handles. (Photo provided by Sammons Preston.)

Figure 32-7 Oven push-pull stick. (Photo by Robert Littlefield.)

Homemakers who prepare meals from a wheelchair will find a self-cleaning stove with front-operated controls and a low wall oven (30–42 inches from the floor) to be the most practical to use and operate (Eberhardt, 1998).

Individuals with limited proximal arm strength or grasp should not remove hot items from a wall oven higher than waist level without supervision because of the potential for burns due to spilling or dropping. An oven push-pull stick may be used to manage oven racks or reposition hot dishes safely during baking (Fig. 32-7). If a client is planning to buy a new stove, the therapist may recommend a gas rather than electric range to reduce the risk of burns (Eberhardt, 1998) because the gas flames provide a visual cue that the burner is on.

Microwave ovens provide a cost-effective and safe alternative to conventional ovens and stoves. Elderly persons with arthritis, visual impairments, and limited endurance can be taught to use a microwave instead of a conventional stove to cook meals more easily and in less time (Kondo et al., 1997).

Dishwashing

Dishwashing can be made easier for individuals working in a wheelchair by placing a removable wooden rack in the bottom of a standard sink to reduce its depth to approximately 5 inches. The under-sink cabinet can be removed to allow persons in a wheelchair to face the sink head-on, with any exposed piping insulated to protect lower extremities from burns. A swing-away faucet with a single control lever can enhance the ability of a person with limited hand function to adjust water flow (Eberhardt, 1998). Installing this faucet beside rather than at the back of the sink further increases accessibility for persons in wheelchairs (Eberhardt, 1998).

Dishwashing in a double sink should be organized to allow the person to work from one direction to the other: dirty dishes, wash water, rinse water, and drying rack. Homemakers with hemiparesis may wash dishes with greater ease when the rinse water and dish rack are on their unaffected side. Suction bottlebrushes and scrub brushes can be attached to the sink to allow for cleaning glasses or silverware with one hand. A rubber mat at the bottom of the sink prevents plates from sliding when they

are washed and reduces breakage. Persons with limited grasp may prefer to use a terry cloth mitt or sponge mitt when washing dishes.

Work simplification includes air drying versus towel drying dishes and reusing them directly from the dish rack or dishwasher. Use of an electric dishwasher aids energy conservation, particularly when little pre-rinsing of soiled dishes is required.

Whenever possible, the homemaker can eliminate unnecessary cleaning by using oven-to-table ware or by serving directly from the pot. Pans can be lined with foil to reduce washing after baking or broiling. It is recommended that individuals clean as they prepare the meal and soak hard to clean dishes while eating to reduce the amount of cleanup required when the meal is over.

Grocery Shopping

Persons with physical impairments or limited endurance can more easily participate in grocery shopping with a few task modifications or assistive devices. When transportation is readily available, individuals may find that frequent visits to the market are more manageable because they can purchase and carry smaller quantities of food items at one time. Shopping at a small local market, although sometimes more expensive, can be easier and less energy consuming than shopping at a superstore. Grocery shopping can become a social event when done with a friend. Shopping together may provide an additional advantage if the friend can assist with reaching items on high and low shelves or carrying the bags.

Planning

A well-organized shopping list is necessary to make the most efficient use of time and to conserve energy at the store. Individuals should keep the list in a convenient location at home, so that needed items can easily be added between shopping trips. Store maps, available at the customer service desk of many large grocery stores, can be used to organize the list. The homemaker or occupational therapist can arrange the items on the list (e.g., produce, dairy, meats) according to the store layout, aisle by aisle. Copies of this list can be used between store visits to record the items needed under each category.

The person should plan ahead and shop during off-peak hours, when the store is not crowded. Once at the store, a client can use the grocery list and signs above the aisles to find needed items.

Carts

Ambulatory persons with mild balance impairments can use a standard grocery cart when shopping; however, they should not use it for support when bending to reach items on low shelves. Individuals who use a wheelchair may find that adapted shopping carts that attach to the wheelchair

are more convenient than a standard cart; although some have found that these attached carts interfere with their ability to reach items. When this is the case, homemakers who are independent with wheelchair mobility may prefer to leave a standard cart at the end of an aisle, gather needed items in a small lap basket, and transfer them into the cart before proceeding to the next aisle.

Large stores have motorized carts for shoppers with limited endurance and mobility. These carts are handy for getting around the store, but it may be necessary to call the store in advance to reserve one. The baskets on these carts are generally small, which may be problematic if the person is planning to purchase a large order. The client may need help to figure out the safest and most effective ways to obtain items from high or low shelves from a motorized cart.

Selecting and Retrieving Items

It is wise to shop for items that are easy to open and require little preparation. Persons with limited endurance can increase the ease of meal preparation by selecting frozen rather than fresh vegetables and skinless or boneless meats.

Individuals who have limited upper extremity range of motion or who use a wheelchair find it difficult or impossible to reach items on high shelves. A reacher can be used to retrieve lightweight unbreakable items, but assistance may be needed for heavier objects. Most stores provide an employee to assist with shopping if asked. Outgoing persons may prefer to ask people in the aisle for occasional help to increase opportunities for socialization.

Some individuals with traumatic brain injury or cerebrovascular accident have visual-perceptual problems that interfere with their ability to locate items (e.g., hemianopsia or impaired figure-ground skills). These persons can be taught to find objects more easily by scanning shelves in an organized manner, top to bottom and left to right. A person with severe visual impairments needs assistance to ensure safety and effectiveness while shopping.

Transporting Items Home

Generally, plastic grocery bags are easier to manage than paper. Foam tubing can be placed around the bag handles to reduce joint stress. At the checkout counter, the client should ask the clerk to keep grocery bags as light as possible and to bag refrigerated foods separately. Several half-filled bags are easier to manage than one or two full ones. Most stores provide assistance for transferring groceries into the car, but store workers should be instructed to place them within easy reach.

At home, a wheeled cart can be used to transport groceries into the house (Fig. 32-8). Persons with limited endurance can leave non-refrigerated items in the car until later, when the person has rested or a family member is available to bring them into the house.

Figure 32-8 Using wheeled cart to conserve energy when transporting items.

Computerized Shopping

Clients with physical limitations and limited endurance may find computer shopping to be a wonderful, energy-efficient alternative to conventional shopping. Persons with Internet access find that grocery orders can be easily placed online. Deliveries are made directly to the home, eliminating transportation and accessibility issues that may arise at the grocery store. The occupational therapist can help the client identify which method of shopping is most practical based on the individual's priorities, physical limitations, knowledge of computer use, and financial situation.

Clothing Care

When a homemaker identifies clothing care as an important goal, the occupational therapist can help the person modify the way laundry tasks are performed. Even persons with severe physical impairments can engage in some aspect of clothing care (e.g., sitting at table to fold clothes).

In-Home Appliances Versus Self-Service Commercial Laundries

Although top-loading washers decrease the amount of bending required to load and unload clothing for persons who are ambulatory, they provide an additional challenge for persons in a wheelchair. Front-loading laundry machines are easier for seated individuals to access, but

Figure 32-9 Kneeling to keep back straight when removing laundry from dryer.

persons who are ambulatory may need training in body mechanics, particularly when loading or unloading wet clothes. For example, it is recommended that ambulatory clients with low back pain kneel on one knee, bending at the hips and knees and keeping the back upright, when loading or removing clothes from a front-loading machine (Fig. 32-9) (Saunders, 1992). Homemakers with limited hand function due to spinal cord injury or rheumatoid arthritis find it easier to use knob turners to set machine dials (Fig. 32-10).

Individuals who use a self-service commercial laundry for clothing care should bring needed coins and pre-measured packages of soap for each load. Many such laundries have rolling carts available for carrying wet clothes from washer to dryer. If possible, persons with physical impair-

Figure 32-10 Knob turner. (Photo by Robert Littlefield.)

ments should choose a staffed laundry. These individuals can be called on for assistance if problems arise.

Collecting and Transporting Clothing

Ideally, the home laundry room should be on the same floor as the bedrooms to minimize the need to carry clothes up and down stairs. When this is not an option, family members can assist as needed to transport clothing to and from the laundry area.

Soiled clothing can be placed in a hamper lined with a plastic or cloth bag with handles. Seated individuals with good upper body strength can transport clothes to the washer by lifting the bag out of the hamper and either carrying it on their lap or hooking the drawstrings on the wheelchair handles. If the person is ambulatory but has difficulty bending, a clothes basket can be kept on a waist-high table or shelf to collect soiled laundry. A wheeled cart is handy for transporting clothes for persons at an ambulatory level.

Washing and Folding

Laundry detergents and bleaches should be kept within easy reach of the washing machine. Hand washing can be eliminated by laundering delicate clothing in a mesh laundry bag in the machine. Persons with visual impairments can fasten paired socks with pins when they are taken off so they don't have to be sorted when clean.

A person in a wheelchair can use a hand-held mirror and reacher to remove clothes from the bottom of a top-loading washer. Homemakers with very limited grasp due to spinal cord injury have found that stubborn items can be more easily removed from the washer tub after a wet towel or shirt is put back into the washer and the spin cycle is restarted. Movement of the wet towel inside the spinning washer can loosen clothes that are stuck to the tub.

Clothes can be folded while the person sits or stands at a table. An adjustable rod 42–60 inches high is convenient for hanging permanent-press items as they are removed from the dryer. Large items, like sheets and bath towels, can be reused immediately after cleaning so they don't have to be folded. Those who choose to fold sheets may find the task easier if they use the bed as a work surface.

Ironing

One challenging task for homemakers with physical impairments is to fold and unfold an ironing board. When possible, it is best to leave the ironing board set up in a convenient, out-of-the-way place. The board surface should be at waist level for persons who stand when ironing to reinforce good posture and body mechanics. Persons who iron while seated in a wheelchair will find a work surface of 28–34 inches high comfortable (ADA-ABA, 2004). A heat-resistant pad can be placed at the end of the ironing

board to eliminate the need to stand the iron up while arranging clothes on the board.

When buying a new iron, individuals should select a lightweight model with an automatic shut-off switch. A cord holder can reduce effort and keep the iron cord from getting in the way. Permanent-press clothing requires less care than cotton or linen fabrics and thus reduces ironing needs. Persons who iron only occasionally may prefer to use a small tabletop ironing board if they have sufficient upper body strength to store and retrieve it from a closet easily.

Sewing

Homemakers may enjoy sewing as a hobby or may only make occasional alterations or repairs. Persons who have hemiparesis after a stroke can still sew with an electric machine by using the unaffected leg to operate foot or knee controls. Persons who do not have use of their lower extremities can place the foot pedal of an electric sewing machine on the table and use one hand or elbow to depress it. Sewing is generally most successful when there is an adequate workspace and adapted methods to stabilize materials when cutting or stitching.

Persons with limited use of an affected arm can hand sew by using an embroidery hoop attached to the edge of a table or counter with a C-clamp (Fig. 32-11). To minimize sewing needs, sticky iron-on tape or fabric glue can be

Figure 32-11 Embroidery adapted with use of a hoop that fastens to the table; requires only one hand.

used for hems and small repairs. Rotary cutters, instead of scissors, make cutting fabric easier.

Indoor Household Maintenance

The occupational therapist helps clients identify effective ways to do household maintenance tasks, such as bed making and floor care. Adapted techniques and assistive devices can help the client to safely perform necessary chores without assistance.

Bed Making

Bed making can be simplified by straightening the sheets and blankets as much as possible before rising in the morning. Homemakers with limited mobility or impaired upper extremity function find it easier to make the bed by completing one corner at a time, starting with the head of the bed. If the individual is working from a wheelchair, the bed should be positioned so that both sides are accessible. Persons with chronic back pain must adhere to proper body mechanics when making beds, being careful to eliminate excessive forward bending.

When changing the sheets, a person can reduce extra work by carefully pulling blankets and spreads toward the foot of the bed, trying not to dislodge them from under the mattress. In this way, the person will not have to expend unnecessary energy to find and reposition the top edge of the blankets or bedspread. Although the bottom sheet should be fitted, it should also be loose enough to be easily applied.

If the client or a friend is handy at sewing, several adaptations can be made to standard sheets to increase the ease of bed making. Fitted sheets can be adapted by opening the two fitted corners at the bottom end and sewing Velcro straps onto each side. When fastened, these straps securely hold the bottom corners together. Another adaptation is sewing the bottom edge of a top sheet to the bottom edge of a fitted sheet. Although this large sheet is more difficult to launder, this can eliminate the need to lift the mattress to tuck under the top sheet. Persons with limited upper body strength or hemiparesis may find lightweight blankets and spreads and satin pillowcases easier to manage.

Dusting

Physically challenged homemakers can dust hard-to-reach places with assistive devices. Persons with limited upper extremity reach because of orthopedic or neurological changes can use a long-handled duster that is lightweight and easily extended to reach high places. Individuals with good hand strength may prefer to hold a dust cloth with a long-handled reacher or use a vacuum cleaner attachment to clean hard-to-reach places. Persons who cannot afford assistive devices may find that a dust cloth secured to the end of a yardstick or dowel with a rubber band meets their needs. Clients with limited grasp or fine motor control may

find that an adapted spray handle (see Fig. 30.7) attached to the furniture polish can and an old sock or duster mitten significantly enhance their independence in dusting.

Floor Care

Heavy homemaking tasks, such as floor care, are often the first activities that elderly persons or individuals with physical impairments find difficult because of the amount of strength and endurance required (Axtell & Yasuda, 1993). When the client's goal is independence in floor care, the occupational therapist must determine how this can be safely and efficiently accomplished.

Cleaning supplies can be conveniently stored and transported in a handled bin or canvas bag with a shoulder strap. When feasible, duplicate sets of equipment can be kept around the home to reduce the need to carry items. A number of lightweight, wet or dry floor cleaning tools are commercially available for quick cleanups. When a more thorough cleaning is needed, a dolly with large casters can reduce the physical demands of transporting heavy pails of water for mopping. Individuals should only partially fill cleaning pails to lessen their weight. A sponge mop with the squeeze lever on the handle minimizes bending and can be used with one hand. Individuals with limited hand function but adequate proximal arm strength can use a grasping cuff to help maintain a closed fist around mop or broom handles. Persons working from a wheelchair may find it best to start at the farthest corner and work backward out of the room. Furniture should be fitted with casters or Teflon slides if moved regularly.

Lightweight upright vacuums provide a good alternative to using heavier canister-style models because they work well and are easier to manage for both ambulatory and wheelchair-bound persons. A lightweight carpet sweeper is another good choice because it is maneuverable, is relatively inexpensive, and does not have to be plugged in to an electrical outlet. Although the carpet sweeper is easier to push, more repetitions are generally needed to clean the same area. Long-handled dustpans and brushes can ease cleanup because they eliminate the need for bending and stooping (Fig. 32-12). If the client has good hand function, cordless hand-held vacuum cleaners are handy for cleaning up small messes within easy reach.

Bathrooms

After a disabling event, a homemaker who cannot afford a housekeeper or does not have family members to assist may have to learn adapted ways to clean the bathroom. Cleaning needs can be reduced by rinsing the sink or tub immediately after use to wash away soap residue. Spray-on chemical products clean bathroom fixtures with little effort, substantially reducing physical demands. Toilet cleaning tablets can be dropped into the toilet tank to reduce the growth of bacteria between thorough cleanings.

Figure 32-12 Use of a long-handled brush with dustpan. (Photo by Robert Littlefield.)

A long-handled mop with a small head is useful for cleaning inaccessible areas behind the toilet.

Many homemakers with physical impairments find that cleaning the bathtub is difficult or impossible. These suggestions may make it possible. Persons with limited endurance or balance concerns should sit to clean the tub. Cleaning sprays and foams can be easily applied and rinsed off from a seated position, particularly if a long-handled shower hose is used. A long-handled bathroom cleaner with a non-scratch scrubbing sponge can enable persons with limited reach to clean tubs and shower enclosures without assistance (Fig. 32-13). Replacing sliding doors with a plastic shower curtain can make the bathtub more accessible for bathing and cleaning. The plastic curtain can be laundered in the washing machine or inexpensively replaced when it becomes soiled.

Hard to Manage Tasks

No matter how creative the occupational therapist and client are, some household tasks may be impossible for persons with physical impairments. However, a large number of assistive devices are available to ease the physical requirements of previously difficult tasks. Electric out-

Figure 32-13 Cleaning bathroom tile using a long-handled cleaner. (Photo by Robert Littlefield.)

let extensions can be plugged into existing baseboard outlets and secured to the wall to eliminate the need to bend when inserting or removing a plug. Devices that make it easier to replace hard to reach light bulbs are also available. The adaptive therapist is well able to analyze task demands and identify modifications or assistive devices that promote independence. When a client cannot accomplish household tasks despite adapted methods, the occupational therapist can initiate a referral to homemaker services.

Outdoor Household Maintenance

When a client's goal is to do outdoor household maintenance, such as yard work or gardening, the occupational therapist can offer suggestions to increase safety and independence.

Yard Maintenance

Persons with mild physical impairments can return to some level of outdoor home maintenance if desired. Individuals with good endurance can mow with a self-propelled lawn mower and accomplish small projects, such as maintaining a patio area. To reduce the risk of back injury when mowing, individuals should avoid stopping and turning the mower. For this reason, a lawn with rounded rather than angled corners is easier to mow (Yeomans, 1992). Rechargeable battery-operated edgers are more convenient than models that must be connected to an electric cord when operated. Numerous ergonomically designed products have been developed to reduce injury during outdoor work. For example, bent-handled shovels reduce excessive back strain and forward bending by altering the fulcrum of movement (Fig. 32-14).

Figure 32-14 Protecting the back while shoveling by using an ergonomically designed shovel with bent handle and lifting with the legs, not the back.

Gardening

Homemakers who are physically challenged need not give up the joy of gardening. Tools can be adapted, flower and vegetable beds can be raised, and wider walkways or wheelways can be created to increase a person's access to the garden. Container gardening is also feasible for persons with limited mobility.

Gardeners with limited hand function can adapt ordinary hand tools with inexpensive foam pipe insulation, which is available at most building supply stores (Yeomans, 1992). This foam, pre-split for easy application, can significantly enhance the comfort of grasping and holding the tool. In a randomized study, Tebben and Thomas (2004) reported that a garden trowel labeled as “ergonomic” did not elicit better wrist positions during use when compared to an ordinary trowel. This reinforces the need to carefully assess whether “ergonomic” garden tools truly enhance body mechanics and positioning for a given client.

Individuals who garden from a wheelchair can increase their reach by using long-handled spades, shovels, and pruners. Persons with limited trunk mobility or balance may increase their safety by sitting on a garden stool and using long-handled tools. Gardeners who are fairly mobile can use a kneeling bench, with handles that assist them in getting up and down. Tools can be transported around the yard in apron pockets, a backpack, or a child's wagon, depending on the person's needs and available options. Tools with brightly colored handles are easy to see and therefore not likely to be lost in the garden (Yeomans, 1992).

Homemakers who return to gardening need to take care of themselves while caring for their flowers. Stretching exercises before gardening can reduce muscle

stiffness and prevent injuries (Adil, 1994; Yeomans, 1992). Work simplification, energy conservation, and proper body mechanics are essential. Gardeners should keep themselves safe by using sun and insect protection, drinking plenty of fluids, and carrying a whistle around their neck in case they encounter unexpected problems when alone in the garden (Yeomans, 1992).

TASKS AND ACTIVITIES OF THE PARENTING ROLE: TREATMENT PRINCIPLES AND METHODS

The occupational therapist and client work closely to identify adapted methods and equipment that enhance participation and independence in parenting tasks. A holistic approach addresses parent and family needs within the home and community.

Psychosocial Adjustment

Parents whose physical limitations are due to an acute event, such as spinal cord injury or cerebrovascular accident, may initially lack a sense of competence, not only in their ability to care for themselves but also in their ability to care for their children. The occupational therapist must be sensitive to the client's psychosocial concerns. The impact of the client's impairments on family responsibilities and expectations must be considered when establishing a treatment plan. Restoration of parenting roles can be challenging for the client, the family, and the therapist.

Parents with diminished physical abilities following an acute event (e.g., spinal cord injury) are likely to have different intervention needs than parents with a chronic or progressive disease or disorder (e.g., rheumatoid arthritis or multiple sclerosis). Persons subjected to the acute onset of physical or cognitive impairments are confronted by sudden and sometimes drastic changes in the ways they can participate in important life roles and tasks. In contrast, individuals with progressive conditions and their families can gradually learn adapted ways to cope with changing abilities and levels of role participation over time.

During the evaluation, the occupational therapist should ask clients to identify which parenting tasks they highly value (e.g., play time, nursing, or bottle feeding) and which tasks are necessary for them to resume their parenting role. The client should then prioritize parenting goals in a way that addresses both valued and necessary tasks in a balanced way.

Barriers to Effectiveness

Barriers to a client's ability to return to parenting tasks and roles are similar to those for homemaker responsibil-

ities. A client's child care needs within home and community environments must be identified and addressed. Factors such as the child's age, activity level, and obedience greatly influence the challenges encountered by the parent with physical impairments. The occupational therapist works to identify the barriers that interfere with a client's ability to accomplish important parenting tasks, devises adapted methods that reduce or remove these constraints, and assists the individual in regaining competence in his or her parenting role.

Child Care: Techniques and Therapeutic Aids

Caring for young children under the age of 4 years is physically demanding and can contribute to musculoskeletal pain, even in parents without physical disabilities (Sanders & Morse, 2005). Parents with rheumatoid arthritis, spinal cord injury, and stroke have reported that child care tasks that require lifting and carrying are the most challenging, followed by tasks that demand fine motor dexterity and/or grip strength (Joe, 1997; Ostensen & Rugelsjoen, 1992). A national survey of parents with physical disabilities revealed that parenting tasks such as traveling outside the home with a child, recreational activities, and chasing and retrieving children require the greatest assistance from others (Barker & Maralani, 1997). Funding for adapted parenting equipment and personal assistance services to help with child care is extremely limited. Therefore, the parent and therapist must work together to identify adapted methods and inexpensive solutions that best address parenting needs.

Equipment Considerations

The occupational therapist and client should initially explore whether simple adaptations to the way child care tasks are performed can enhance performance. When these simple solutions do not work, the client and therapist should evaluate whether commercially available child care equipment can feasibly meet the needs of the parent and child. If not, more creative solutions and adaptations must be devised.

The occupational therapist must consider the cost of the adapted equipment and whether it is acceptable to the client in terms of appearance and ease of use. In addition, the therapist must understand that the appropriateness of any equipment changes over time as the child grows and develops (DeMoss et al., 1995; Vensand et al., 2000).

Bathing

Parents need to be sure that all necessary equipment and clothes have been gathered and are within easy reach before they begin bathing their infant or young child. A terry cloth apron worn during bathing can protect clothing and dry the baby after the bath.

Persons who are ambulatory may find that bathing the infant in a portable plastic tub in or near the kitchen sink is a good option because the height of the sink or counter minimizes bending and the tub can be easily filled and drained at the sink. Parents who use wheelchairs, however, may find this arrangement inconvenient because it is too high for safely lifting the baby in and out of the tub. Persons in wheelchairs also find it difficult to bathe the infant if the baby tub is in a regular bathtub because it is too low (DeMoss et al., 1995; Vensand et al., 2000). An alternative is to secure the baby bathtub to a sturdy table or serving cart near a sink. A portable dishwasher hose can be connected to the sink faucet for filling the tub, and a separate hose can be used to drain the bath water (DeMoss et al., 1995; Vensand et al., 2000). It may be easier for the parent to use this arrangement to bathe the older infant until the child is mobile enough to help with getting in and out of a regular bathtub. This diminishes the parent's need to lift a wet, slippery child from a low tub.

Diapering and Dressing

Commercially available changing tables are usually inaccessible for persons who use a wheelchair because the wheelchair does not fit under the table for diapering or dressing the child. In addition, the surface may be too high for a seated parent to lift and transfer the baby safely, particularly as the infant grows (DeMoss et al., 1995; Vensand et al., 2000). The client and therapist should work together to determine the changing surface that most effectively and safely meets the individual's needs.

Safety straps should always be used to secure the active baby to prevent falls. These straps are particularly helpful when the parent needs extra time to manipulate diaper or clothing fasteners because of diminished fine motor control. A mobile attached to the changing table and assorted toys can keep the baby distracted during changing.

Although adapted fasteners for diapers and baby clothing can require initial assistance from family or friends, they can greatly enhance one's independence in child care during the day. For example, loops made of packing tape can be attached to disposable diaper tabs to reduce fine motor demands (DeMoss et al., 1995; Vensand et al., 2000). Wraps that hold either cloth or disposable diapers can be adapted by attaching metal key rings to small holes made in the Velcro tabs (DeMoss et al., 1995; Vensand et al., 2000). Small pieces of Velcro can also be sewn onto a variety of infant and baby clothes. Ideally, clothing should have full-length openings with closures that the parent can manage. When a zipper pull is used, zippers are easier to manipulate than snaps.

Feeding

Mothers with physical challenges may choose to nurse or bottle-feed their baby. After an initial adjustment period, breast-feeding can be easier than bottle-feeding because it

eliminates formula preparation. If the mother is taking medications, it is important that she check with her physician before deciding to breast-feed to be sure that the medication will not harm the nursing infant. The mother should sit in a relaxed, comfortable position, using pillows to support the holding arm and baby while nursing. Pillows that are specifically designed to support the nursing infant are commercially available.

Some parents find bottle-feeding easier and more convenient with the older infant in a child seat, although others prefer to hold the child close to them when feeding (Fig. 32-15). Individuals with limited grasp may be able to hold a bottle and feed their infant after slipping their hand through a loop of webbing material attached to the bottle (DeMoss et al., 1995; Vensand et al., 2000). Lightweight plastic bottles with screw-on lids are recommended over glass bottles.

Older babies can be spoon-fed by a person with tetraplegia when the parent's wrist cock-up splint is adapted by attaching a Velcro loop to the palmar surface. The spoon is inserted into a utensil pocket made of Velcro hook and attached to the splint at the best angle for feeding (DeMoss et al., 1995; Vensand et al., 2000). An insulated baby dish can be used to keep food warm throughout the meal. Spoons should be rubber coated to protect the baby's gums and teeth if bumped while feeding.

Parents with impaired grasp and arm strength may not be able to attach or remove the tray on commercial high chairs (DeMoss et al., 1995; Vensand et al., 2000). In addition, it may be difficult for the parent to lift the child in and out of a standard high chair. Options to make high chairs more accessible for parents with physical limitations include altering the chair height, designing swing-away trays, and adding a climbing ladder to encourage the older infant to climb into the seat with supervision only (DeMoss et al., 1995; Vensand et al., 2000).

Lifting and Carrying

Adapted equipment that provides alternative ways of carrying the infant or young child or reduces the need for multiple transfers can greatly enhance the parent's satisfaction and ability to care for the child. Parents with distal weakness and pain, as seen with rheumatoid arthritis, benefit from wearing wrist supports to reduce joint stress when lifting and carrying their child (Nordenskiöld, Grimby, & Dahlin-Ivanhoff, 1998). Many clients prefer to practice lifting and carrying techniques with a weighted doll before trying to manage an active child.

A variety of cloth infant carriers and child front packs are available. Although these carriers allow the parent to transport a small child while leaving hands free, they may be contraindicated for persons with chronic back pain because the shoulders and back carry the weight of the

Figure 32-15 Alternative feeding position for mother with mild left hemiparesis following cerebrovascular accident.

child. Individuals who use wheelchairs may find child front packs handy for holding the infant while performing other homemaking tasks. Ease of use is important: adaptations may be needed to enable the parent with physical impairments to get the baby into and out of the infant carrier. The straps can be modified to reduce the parent's coordination needs (DeMoss et al., 1995; Vensand et al., 2000). Older babies with good neck and trunk control can safely ride on their parent's lap with only a safety belt attached to the wheelchair (Fig. 32-16).

Play

Parents with physical impairments may find that their ability to play with their young children is hindered because they cannot sit on the floor or bend to reach into standard playpens. Although infants can be entertained while they are sitting in a bouncy seat, older babies need a larger safe play area to develop gross motor skills. If cost is not an issue, a play care center, essentially a raised playpen that allows wheelchair access, can be built in the corner of a room (DeMoss et al., 1995; Vensand et al., 2000). If the center is equipped with swing-away doors, the parent can wheel up to the play center and easily reach into it to play with the

Figure 32-16 A mother confined to a wheelchair using a safety strap for an older baby while gathering items from the refrigerator.

baby. This play area can also be used for the child's naps during the day, eliminating extra transfers in and out of the crib (DeMoss et al., 1995; Vensand et al., 2000). Walking toddlers and their parents may find that a child's table approximately 18 inches high is a convenient place to play while the parent is sitting in a wheelchair or standard chair.

Cribs

Standard cribs are inaccessible for parents who use wheelchairs, and they require ambulatory parents to bend forward when putting the baby in or out of bed. A standard drop-side crib can be adapted in several ways, depending on the parent's physical needs.

Persons who are ambulatory but have difficulty bending because of chronic back pain can raise the crib by inserting leg extenders or blocks of wood under the crib legs. The crib mattress can also be raised to the highest setting but should not remain in this position once the baby is old enough to sit or to climb over the crib rail.

Parents who use a wheelchair find it easier to transfer the baby in and out of the crib if the rail is adapted. One modification is cutting the rail in half to form two gates. These gates are attached with hinges to the head and foot of the crib. Center latches that are inaccessible to the child secure the gate when the baby is sleeping (DeMoss et al., 1995; Vensand et al., 2000). Another option is to adapt the crib rail so that it slides along a horizontal channel (DeMoss et al., 1995; Vensand et al., 2000; Dunn, 1978) (Fig. 32-17). Whatever crib design is used, the release mechanism for the crib rail must be child resistant yet manageable for the parent to manipulate with one hand or with limited coordination and dexterity.

Figure 32-17 Crib with storage area, sliding gate side rails, and knee space to accommodate a wheelchair. (Designed by Lee Heintzman and Gordon Heintzman. Adapted from Dunn, V. M. [1978]. Tips on raising children from a wheelchair. *Accent on Living*, 22, 78–83.)

EFFICACY AND OUTCOMES RESEARCH

Although the number of studies on occupational therapy outcomes continues to grow, there is a lack of evidence concerning specific effects on homemaking and parenting abilities. In fact, no effectiveness studies on occupational therapy and parenting skills of persons with physical disabilities were found. Generally, occupational therapy outcomes are based on more global measures of ADL or IADL, such as the *Functional Independence Measure (FIM)* or the *Nottingham Extended Activities of Daily Living Scale* (Granger et al., 1993; Nouri & Lincoln, 1987). The effects of OT intervention on homemaking, meal preparation, or household management abilities are often embedded within these broader IADL scales, making it challenging, if not impossible, to discern specific changes in task performance. Furthermore, descriptions of OT interventions tend to be vague, making it difficult to interpret research findings or compare evidence of treatment effects across studies (Wilkins et al., 2003).

Research is needed to examine the degree to which adapted methods and equipment (i.e., occupation-as-end) contribute to one's satisfaction and competence in homemaker and parenting roles after a disabling event. Empirical support for the cost effectiveness of adapted equipment and supportive services may lead to improved reimbursement from third-party payers.

CASE

EXAMPLE

M.B.: Treatment to Improve Homemaking and Child Care Abilities

Occupational Therapy Intervention Process

Clinical Reasoning Processing

Objectives

Examples of Therapist's Internal Dialogue

Patient Information

M.B. is a 54-year-old widow referred for a home occupational therapy assessment following recent exacerbation of rheumatoid arthritis (RA). She lives alone in a ranch house and ordinarily cares for her 6-month-old granddaughter 3 days a week while her daughter works. Prior to her exacerbation, she was fairly active and able to manage all household and child care tasks independently with the exception of yard work. An avid gardener, she spent a good deal of time in her greenhouse prior to her exacerbation. She is able to use joint protection principles (e.g., avoiding positions of deformity, such as ulnar deviation) during functional tasks.

As a result of this exacerbation, she has decreased strength and dexterity in her hands and wrists, increased pain during activity, and a significant decrease in overall endurance. The occupational therapy evaluation identified the following problems: (1) moderately decreased ability to perform the household management tasks needed to maintain her independence at home, with fatigue after 30 minutes of activity; (2) moderate impairments in her ability to care for her granddaughter secondary to decreased strength and pain during resistive activities, such as opening baby food jars and attempting to lift the child; and (3) poor use of body mechanics and a tendency to rush through tasks when fatigued.

Appreciate the context

"M.B. is ordinarily a fairly active woman who has been caring for her 6-month-old granddaughter since she was a month old. She truly values the time she spends with the baby and is frustrated and somewhat depressed by her present limitations. Although her daughter has offered to find another child care provider while her mother recovers, this has been difficult to arrange in their small community. M.B.'s prior level of independence, combined with a strong desire to help her daughter and care for the infant, have motivated OT goals to optimize homemaking and child care abilities."

Develop intervention hypotheses

"I think that M.B.'s weakness, pain, and reduced endurance are the biggest barriers to her independence right now. Although she can tell me how to protect her joints during homemaking tasks, her pain and resulting fatigue are causing her not to use proper techniques. She tends to hurry through tasks so she can rest, and I'm concerned about her safety. I expect that, as her pain lessens, she'll do much better overall."

Select an intervention approach

"I will develop an intervention plan that emphasizes compensation for deficits; this will help to protect her from injury long term. By engaging her in important home and child care tasks, we will use occupation-as-means to improve her physical abilities as well."

Reflect on competence

"M.B. reminds me of a couple of other clients I've worked with in home care. It will be really important to involve her in problem solving of ways to best accomplish important tasks. This way she'll gain skills in handling unexpected situations outside of therapy."

Recommendations

The occupational therapist recommended three treatment sessions each week for 4 weeks. In collaboration with M.B. and her daughter, the therapist established the following long-term treatment goals: (1) M.B. will independently perform all indoor homemaking tasks, except floor care, with only occasional complaints of fatigue, using energy conservation and work simplification techniques; (2) M.B. will independently care for her granddaughter for 4-hour periods with only occasional complaints of pain, demonstrating appropriate use of assistive devices to protect joints during resistive activities; and (3) M.B. will use proper body mechanics when lifting and carrying her granddaughter and performing household tasks, such as meal preparation and laundry (see Home Program in Procedures for Practice 32-4).

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"I think that OT in the home will be the most effective means of addressing M.B.'s current needs, especially because she is highly motivated to make changes that will optimize her home and child care abilities. Her house is pretty accessible, and I think small changes will really help improve her independence and safety. We should be able to accomplish a lot in the next 4 weeks."

**PROCEDURES FOR PRACTICE 32-4****Home Program for Body Mechanics**

M.B., please focus on using proper body mechanics during all of your daily tasks! Below are specific ideas for you to incorporate every day:

- Be sure to have a broad base of support when lifting your granddaughter. Keep feet shoulder distance apart, and place one foot forward of the other to help with balance.
- Face the task you're doing, and don't twist your trunk when lifting!
- When doing tasks around the house that take a while (like feeding your granddaughter or re-potting small plants) sit versus standing to conserve energy. Sit up straight, and think about keeping a neutral position in your lower back by tilting the pelvis slightly forward.
- When doing laundry, use your rolling basket to help transport clothes. When you do need to lift clothes, use your strongest muscles (legs vs. back) and bend at your hips and knees to avoid straining your back.
- Don't rush! It's best to take rests before you feel tired, and it's much easier to use good body mechanics when working at a comfortable pace!

Summary of Short-Term Goals and Progress

1. M.B. will independently and safely prepare a light meal for herself without complaints of fatigue, using work simplification and energy conservation principles after initial instruction.

The therapist and M.B. first reviewed work simplification principles in the context of preparing a hot beverage, taking the opportunity to organize work areas in the kitchen so frequently used items were easily accessible. They identified ways M.B. could conserve energy during meal preparation, such as by retrieving all items needed at one location (e.g., refrigerator) before moving on to the next and sitting when possible to prepare foods. After instruction in self-pacing, M.B. was more willing to take brief rests during meal preparation before fatigue or pain began to worsen. After practicing proper body mechanics, she was better able to obtain and carry items safely around the kitchen without increasing pain. In addition, use of a jar opener significantly reduced the discomfort in her hands. To reduce preparation time and effort, M.B. decided to use frozen rather than fresh vegetables until her endurance improved. M.B. found that these strategies greatly reduced her level of fatigue during meal preparation, and she began to apply these techniques to other tasks around the house.

2. M.B. will safely and independently transfer her granddaughter from the infant seat to changing pad on the kitchen table with good body mechanics and safety and no complaints of discomfort.

M.B., her daughter, and the occupational therapist determined that the need for lifting and carrying the infant could be minimized by organizing essential child care materials, such as the infant seat, changing pad with straps, diapers, and toys, on one side of the oversized kitchen table and nearby hutch. M.B. found that bilateral wrist supports greatly reduced pain in her wrists when she lifted the baby.

Proper body mechanics were reinforced and practiced, such as standing close to the child with feet staggered and placed shoulder distance apart and using stronger muscles (legs rather than back) when lifting. M.B. progressed from requiring minimal assistance to lift and transfer the baby safely to performing the task independently. As she gained confidence in her abilities, her body mechanics improved and complaints of discomfort decreased.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"M.B. has cognitive strengths that I expect will help her to readily integrate new techniques with her current knowledge of joint protection."

"I was a bit concerned about her rushing through tasks when we first started therapy, but I think that was partly related to her desire to show us that she 'could do it.' I see that, as we gain rapport, she's becoming more comfortable with voicing her concerns about the long-term changes she is experiencing from her arthritis, and her fears about losing independence."

"M.B. is lucky to have such a supportive daughter; she has helped to identify creative ways for her mother to manage the baby's care. I sense that she is concerned about her mother's chronic rheumatoid arthritis and the physical changes that M.B. is facing now. I wonder what their long-term plans will be regarding living arrangement, etc."

Next Steps

Revised goals include the following: (1) M.B. will use work simplification techniques and proper body mechanics to do laundry independently; and (2) M.B. will safely and independently lift and transfer her granddaughter from a stroller to the infant seat with good body mechanics and will prepare and feed the child a warm meal without assistance.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"M.B. has been very responsive to therapy and has made great gains over the past couple of weeks. She is much more confident in her abilities, and her pain is being better managed through medication and the compensatory strategies she's learned to use. She's now ready to practice work simplification techniques during more physically challenging tasks. With a bit more therapy, she will be able to care for her granddaughter independently once again."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effects of Arthritic Changes in the Wrists and Hands and Impaired Endurance During Gardening Tasks

Although M.B. was diagnosed with rheumatoid arthritis 15 years prior to this OT assessment, she managed homemaking and gardening tasks with little adapted equipment until this exacerbation. While M.B. worked in her greenhouse, the occupational therapist observed her bending from the waist to pick up a bag of potting soil and watering can from the floor. In addition, M.B. complained of wrist and hand pain and fatigue while standing at her work counter to transplant seedlings and plants into larger pots. She was very frustrated by the challenges she faced when trying to replant the flower boxes on her deck, a place she enjoyed with family and friends on warm summer days.

How could the therapist help M.B. solve problems and use compensatory strategies and adapted equipment to decrease pain and improve her safety while gardening? How might the therapist reinforce use of proper body mechanics? What work simplification and energy conservation techniques might be useful in addressing her joint protection and endurance needs?

SUMMARY REVIEW QUESTIONS

1. Describe how work simplification and energy conservation techniques can help persons with low endurance and shortness of breath due to chronic obstructive pulmonary disease with meal preparation and household maintenance tasks.
2. Identify at least three principles of correct body mechanics that a person with chronic back pain should use when doing laundry and transporting groceries from the store.
3. Describe how a homemaker who has pain and weakness in her hands and wrists due to rheumatoid arthritis can use adapted methods or assistive equipment when preparing brownies from a mix.
4. Using the principles of compensation and adaptation, what recommendations would you make to a client with limited upper extremity coordination and strength due to multiple sclerosis when gathering the items needed to prepare breakfast from a wheelchair?
5. Give two examples of adaptations that may assist a paraplegic parent with spinal cord injury at T4 (see Chapter 43) to lift and carry an 11-month-old infant from the crib to the changing area.
6. Describe how a mother with upper extremity weakness and limited hand function in her right arm after a stroke can use one-handed techniques and assistive equipment to prepare a bottle and feed her 5-month-old infant.
7. How would you recommend that a parent set up a baby bathtub and needed supplies to bathe a 2-month-old infant from a wheelchair?

8. Discuss proper body mechanics for a person with general pain related to fibromyalgia who is playing with a 10-month-old baby and putting the baby to bed.

ACKNOWLEDGMENT

Many thanks to Robert Littlefield, photographer, and to Sammons Preston Rolyan for the assistive devices pictured in this chapter. Special thanks to the individuals who shared their ideas about adapted techniques with me, based on their personal experience with physical challenges.

LEARNING OBJECTIVES

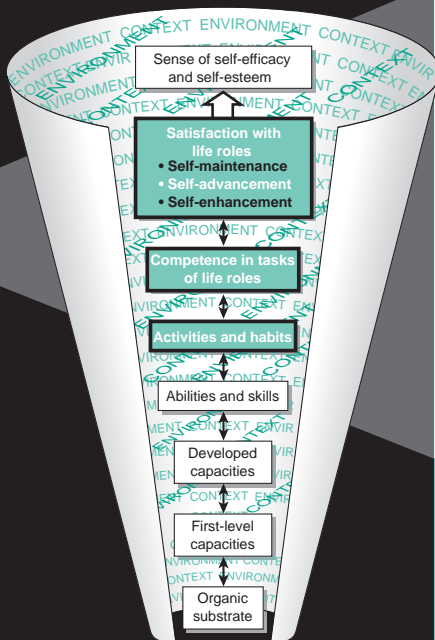

After studying this chapter, the reader will be able to do the following:

1. Understand and articulate the reasons people work.
2. Recognize and verbalize the unique role of occupational therapy in the return-to-work process.
3. Describe job analysis and how it is used in the return-to-work process, and identify other possible applications for the results of job analysis.
4. Describe functional capacity evaluations and considerations in selecting appropriate evaluations for clients.
5. Recognize how return-to-work evaluation tools can be used as treatment tools.

CHAPTER 33

Restoring Competence for the Worker Role

Valerie J. Rice and Stephen Luster

Glossary

Glossary

Functional capacity evaluation (FCE)—Systematic process designed to assess a client’s functional abilities. Functional abilities may include all physical and psychosocial abilities required in a work setting, such as musculoskeletal (strength, range of motion, etc.), cognitive, emotional, and communication abilities. The two performance categories include a general evaluation of physical abilities and an evaluation of job-specific capabilities.

Functional work assessment—Entire return-to-work evaluation process, including evaluations of (1) the individual client (occupational therapy and FCEs) and (2) the requirements of the job or potential jobs (job analysis).

Job analysis—Systematic evaluation of a job; a physical evaluation of the job site, observing workers performing their tasks, conducting a task analysis of the criterion tasks, measuring equipment and equipment placement, reviewing work-related documents such as job descriptions, and interviewing those who perform the job and their supervisors.

Task component testing, training—Functional capacity testing that identifies criterion tasks based on the most difficult, essential components of a job and develops specific evaluations or training programs based on those components. It is assumed that evaluating or training using task components critical to job success is a valid approach to determining work

performance, as the content requirements of the job are used to develop the evaluation or training.

Work conditioning—Treatment program focused on functional requirements of a job or employment setting; incorporates basic physical conditioning such as restoration of flexibility, strength, coordination, and endurance. Work conditioning is conducted after completion of acute care and before work hardening.

Work hardening—Multidisciplinary structured, graded return-to-work treatment program that progressively introduces greater rehabilitation requirements on the client-worker to achieve full capability of the worker to meet the demands of a job. Work hardening includes all aspects required for the client to return to full function in employment, such as psychosocial, communication, physical, and vocational needs, and typically incorporates work simulation as part of the treatment process.

Work-related musculoskeletal disorder (WRMD)—Wide range of health problems arising from repeated stress to the body encountered in the workplace; may affect the musculoskeletal, nervous, and neurovascular systems and include the various occupationally induced cumulative trauma disorders, cumulative stress injuries, and repetitive motion disorders.

Two people meet for the first time at a social event. After introducing themselves, the inevitable question is asked: “What do you do?”

The focus of this chapter is on returning a worker who has been incapacitated in some way to the workforce. The intervention begins after an individual has been identified as being unable to meet the requirements of his or her job. Thus, the primary roles for the clinician are *evaluating* the individual’s functional performance, strengths, and impairments as compared with the job requirements, *treating* the client, *matching* the client-worker with the job (enabling and integration process), and *reevaluation*. To understand the progression, it is first necessary to understand why people work, recognize how occupational therapists view work and their role in work rehabilitation, understand how the work role can be interrupted, and become acquainted with a few work-related assessments. An extensive explanation of the evaluation process is provided to enable a thorough understanding of the process and permit tailoring of the intervention to both the individual and the context in which the individual will work. With this knowledge, the occupational therapy process can be understood and implemented within the appropriate context.

WHAT IS WORK?

“He who complains against his work knoweth not life; work is an uplifting force by which all things may be moved. Repose is death, and work is life!”
(Jastrzebowski, 1857, p. 1)

Although we may not all agree with Jastrzebowski’s enthusiastic assertion that work is uplifting and *life itself*, there is some merit in his declaration. Used in the broadest sense of the term, everyone must work. It is part of life. Work, as seen in the first definition in Definition 33-1, consists of any physical or mental effort or activity directed toward the purposeful production or accomplishment of something. This means that work occurs in the home, in schools, as part of one’s employment, during volunteer work, and as part of one’s leisure. To work is *to do*, to accomplish. With this definition, returning the worker to work encompasses occupational therapy as a whole, as clinicians assist their clients to achieve their fullest capacity in all aspects of life. In this chapter, however, returning the worker to work refers to helping a client reenter the workforce, go to a place of employment

DEFINITION 33-1

definition

Work-Related Definitions

Work (noun)

1. Physical or mental effort or activity directed toward the purposeful production or accomplishment of something: labor. 2. Employment: job [out of work]. 3. The means by which one earns one's livelihood. 4. a. Something that one is doing, making, or performing, esp. as part of one's occupation: a duty or task. b. The amount of effort required or done.

Work (verb)

1. To exert one's efforts for the purpose of doing or making something: labor. 2. To be employed. 3. To perform a function or act: operate.

Work (synonyms)

Business, employment, job, occupation. Core meaning: what one does to earn a living. Work, the most general of these terms, can refer to the mere fact of employment or to a specific activity.

Career

1. Chosen profession or occupation. 2. The general progression of one's life, especially in one's profession.

Job

1. An action that needs to be done: task. 2. An activity performed regularly for payment, especially a trade, occupation, or profession. 3. A specific piece of work to be done for a set fee. 4. A position in which one is employed.

Occupation

Any activity or task with which one occupies oneself, usually specifically the productive activity, service, trade, or craft for which one is regularly paid.

Vocation

A regular occupation or profession, especially one for which an individual is particularly suited or qualified.

or job (including volunteer positions), and/or develop a means to earn a livelihood.

MOTIVATIONS FOR WORK

Why would an individual want to reenter the labor force? Why do people work in the first place? For most people, work is an economic necessity. In earlier times, people traded their wares and their abilities to attain the goods they needed. Although this practice still exists in some small communities, most residents of industrialized countries have distinct employment and pay for their goods and services with money earned at their jobs.

Self-Creation and Self-Identity through Work

We work to finance lives, homes, families, education, and fun. However, especially in industrial societies, we do not have to work from dawn to dusk to earn a living, and we are also not required to enter jobs dictated by our birth or heritage. For the most part, we have choices. We can choose our line of work according to our own values. Occupations are key, not just to being a person, but to being a particular person and to creating and maintaining an identity (Christiansen, 1999; Unruh, 2004). The use of one's time during the day provides a sense of purpose and structure, as well as building an identity. We create ourselves through our actions. Although we may define ourselves daily through our work, we may also fulfill other needs. Our values and the meaning of our lives arise from (and are seen in) our work and how we spend our leisure, home, self-care, and family time.

Work can fulfill our primary motivations (needs), as defined by some of the great psychologists and psychiatrists of our time. Work can fulfill the need to find meaning in life as asserted by Frankl's (1984) logotherapy. Work can fulfill the need to find pleasure, on which Freudian psychology is based. Work can also fulfill the need for power or striving for superiority stressed by Adlerian psychology (Stein, 2002). The point is that work can answer a number of needs. For some, work meets multiple needs of financial achievement, a sense of accomplishment and competence, socialization and status within society, pleasure and gratification, a sense of meaning and purpose, self-respect, and an identity. For others, work answers a singular need, leaving them to meet other needs elsewhere in their lives.

Matching Personal Values with Work Requirements

If our work forces us to behave in ways that directly conflict with our view of ourselves, we feel discomfort and are motivated to change our line of work. This is because people try to maintain positive views of themselves and refute or avoid feedback that is negative or disagrees with their ideal self (Swann, 1987; Swann & Hill, 1982). As an example, Enid DuBois worked as a telephone solicitor for a newspaper. Often, the solicitors were told to tell the potential customers that a portion of their money would go to a particular cause to encourage people to subscribe. "After a while, I didn't care. Surely I could have fast-talked people. Just to continually lie to them. But it just wasn't in me. The disgust was growing in me every minute. I would pray and pray to hold on a little longer" (Terkel, 1974, pp. 94–97).

We have seen a change in the desires of the workforce. Besides emphasis on pay and security, workers value and

expect their work to be psychologically meaningful. They expect to participate in decisions that affect their work lives (Hendrick, 1998). The current, better-educated workforce in industrialized nations seeks challenges, advancement, and a voice in their work lives.

Balance is particularly important to the younger generation entering today's workforce. Occupational balance refers to the integrating of one's work, home, and leisure activities (Backman, 2004). Other work-related values of younger persons in today's workforce include independence, autonomy, self-expression, recognition for their work, and continual learning (Chester, 2005). Younger workers need to feel valued and prefer work environments where they are mentored, treated with respect, and allowed to try some of their own ideas (even if they fail occasionally). More than past generations, they need to understand why things need to be done in a particular way, and they need to believe in and value the product, service, or mission they help to deliver (Chester, 2005). They value their social interactions at work, as well their own perception of the importance of the product created by their work (Polanyi & Tompa, 2004).

The importance of occupational involvement and the characteristics of work most valued differ according to one's culture (Hasan, 2004) and personal values. In fact, the importance of work within a single culture and perhaps within an individual can vary over time. For example, some researchers note that work alone is considered as a declining value, replaced by a high value of success in both personal and professional life (Deberdt, 2002). Similarly, people's values change over time, and their view of work can change accordingly. Thus, in rehabilitation, the therapist and the patient/client must explore the perceptions and values of the client, discover the client's occupational identity, and create an appropriate occupational balance intervention (Backman, 2004; Holmgren & Dahlin Ivanhoff, 2004).

INTERRUPTIONS IN THE ABILITY TO WORK

People's ability to work may be interrupted by changes in physical, psychosocial, or sociocultural status.

Physical Status

Mr. L. worked in a collision repair shop. His brother was fond of saying that he “banged on cars” for a living. The job required him to stand and manually remove the dents from car fenders using specialized tools. He was physically strong because his job demanded

it. He wasn't prepared for what happened after he broke his leg. It never seemed to heal correctly. He developed what they called reflex sympathetic dystrophy. The term didn't matter. All he knew was it hurt all the time and he couldn't stand or even sit for long periods. He received workers compensation and wondered if he'd ever work again (D. Rice, personal communication, 2000).

The direct result of injury or illness may be inability to resume work activities permanently or temporarily because the worker cannot fulfill the physical, cognitive, or emotional demands of the job. This mismatch between requirements and performance has been traditionally addressed by retraining the individual. The focus was on improving the deficits; thus the therapist worked to diminish individual shortfalls in strength, dexterity, coordination, range of motion, endurance, or memory. Whatever interrupted the client's ability to resume normal activities was addressed. More recently, the focus has broadened to include altering or redesigning the job to realign its requirements to the individual's residual abilities.*

Not all injuries or illnesses that disrupt the ability to work are the result of a sudden injury or illness. Non-traumatic injuries may also interfere with a person's ability to work. Non-traumatic injuries thought to be related to workplace demands include **work-related musculoskeletal disorders (WRMDs)**. These injuries are typically thought of as transient, although they can result in permanent disability. WRMDs include a wide range of health problems arising from repeated stress to the body encountered in the workplace. These health problems, which may affect the musculoskeletal, nervous, and neurovascular systems, include the various occupation-induced cumulative trauma disorders (CTDs), cumulative stress injuries, and repetitive motion disorders. Examples include damage to tendons and tendon sheaths and synovial lubrication of the tendon sheaths, bones, muscles, and nerves of the hands, wrists, elbows, shoulders, neck, back, and legs. Specific diagnoses include chronic back pain, carpal tunnel syndrome, de Quervain's disease, epicondylitis (tennis elbow), Raynaud's syndrome (white finger), synovitis, stenosing tenosynovitis crepitans (trigger finger), tendinitis, and tenosynovitis. (For a thorough review of WRMDs, see Kuorinka et al. [1995], Sanders [1997], Caryon, Smith, and Haims [1999], and Pransky et al. [1999].) Once again, the reason for not being able to return to work is the person's inability to fulfill the requirements of the job tasks, such as the administrative assistant with severe, chronic carpal tunnel symptoms who cannot use a keyboard without pain.

Traumatic injury, aging, or progressive disability may also alter self-perception and personal identity. When a person loses his or her sense of identity, life becomes less

* This same approach of designing the job or environment could enable older workers to continue working comfortably.

meaningful and can become meaningless (Debats, Drost, & Hansen, 1995; Moore, 1997; van Selm & Dittmann-Kohli, 1998), leading to depression so severe that it can interfere with a person's ability to carry out daily work. Thus, it is not always the initial injury that prevents a return to work; the resulting psychological adjustments can also interfere. Unless both the physical and psychological problems are addressed, the individual may not develop the skills needed to return to work.

Cognitive Status

People's cognitive abilities directly influence their ability to do a job and the type of job they can assume. For example, individuals who have had a brain injury (including mild to moderate traumatic brain injuries and strokes) can have difficulties with clear thinking, memory, concentration, decision making, and reasoning, as well as changes in their sensory processing and/or communication skills. After injury, they may suffer from depression, anxiety, or personality changes. All of these symptoms can interfere with their ability to return to work (National Institutes of Health [NIH], 2002).

Adults who have attention deficit disorder also experience thought and behavior patterns that differ from the "normal" population. These individuals are more likely to be fired and have difficulty keeping a job, yet 35% become self-employed (Barkley & Murphy, 1998 as cited in Adler and Cohen, 2002). A skilled therapist can help them recognize their strengths and the types of jobs or job structure that will take advantage of their skills and give them a good chance of success. For example, many adults with attention deficit hyperactivity disorder are innovative, energetic risk takers who can do well in jobs that permit multi-tasking, self-determination of scheduling, physical action, and out-sourcing of time-intensive detailed tasks.

Psychological and Behavioral Status

Psychosocial events may interrupt a person's ability to work, either temporarily or permanently. Divorce, severe illness, death of a family member, or change in job status sometimes triggers underlying psychopathology such as a mood or anxiety disorder. The disruption may be due not to underlying psychopathology but to the expression or manifestation of a normal reaction to a difficult situation.* Each individual reacts differently to life situations, and adaptation may come more quickly for some than for others. Examples of an individual's inability to meet work requirements include disruptions in the ability to concen-

* This is also the basic explanation for a combat stress reaction, which is a normal reaction to an abnormal situation, such as a traumatic stressful event. When it interrupts a person's ability, it is often referred to as an acute stress disorder, which is typically short term. Post-traumatic stress disorder is longer term and has more impact on daily function over time (Lifelines, 2006).

trate and follow complex directions, react quickly to emergencies (psychomotor retardation), attend to detail, or handle the pressures and anxieties associated with the work environment. Although there is less information on individuals returning to work after a psychological disorder compared with after physical injuries/illnesses, this is no less a problem than is a physical injury. In fact, it may be more difficult to return to work because of the attitudes and lack of knowledge and empathy of employers and coworkers, in addition to fears and concerns of the workers themselves.

Depression is predicted to be one of the fastest-growing maladies of the 21st century and is often associated with physical injury or loss of work. Although treatment for depression and other psychological and emotional disturbances has vastly improved, there are definite implications for the individual's ability to work. Work seems to mitigate the rate of mental health deterioration, with employment status being more important for men than women (Llena-Nozal, Lindeboom, & Portrait, 2004).†

Sociocultural Status

Fewer than 10 years ago, millions of disabled Americans were guaranteed the ability to keep their government-funded health coverage when they accepted a paying job (Ross, 1999). This was offered because it is believed that many disabled individuals do not seek employment for fear of losing Medicare and Medicaid benefits. In fact, in this country and others, fewer than 1% of those who receive government disability ever leave that system (Ahlgren et al., 2005). In addition, many long-term sick-listed individuals (46%) move from vocational rehabilitation to permanent pensions rather than returning to work, with almost none of those receiving a temporary disability pension ever returning to work (Ahlgren et al., 2005). This law should remove some of the fear, and up to 550,000 disabled persons will receive rehabilitation and training in preparation for return to the workforce (Ross, 1999). The impact of this U.S. law is not yet known.

Aging and age discrimination may also prevent workers from continuing to work or from returning to work following physical or psychological problems or following a downsizing. This problem may become more evident as the proportion of workers aged 45–54 years increases, which will be followed in the next 10 years by a substantial increase in the proportion of workers 55 years of age and older (Yelin, 1999).

† Although this chapter identifies some motivations for why people work, it is recognized that not all work exerts a positive influence on the worker. In fact, work-related stressors can contribute to psychological distress, occupational injury, or illness (Marchand, Demers, & Durand, 2005), thus influencing health, turnover, work attrition, and return to work. Certainly, therapists must ascertain whether these conditions exist for a client, an issue beyond the scope of this chapter.

WORK AND AGING

Society is challenged to consider three questions regarding older workers: (1) Can our nation “afford” older individuals who do not work? (2) Do older workers stand in the way of younger workers? (3) Are older workers less productive, slower, harder to supervise, less cognitively aware, and less physically able to do a job?

The workforce in 2012 will be more diverse and older, with a median expected age of 41.4 years and with 19% of workers aged 55 or older (Toosi, 2004). If all of these individuals did not work, there would be a severe shortage in multiple industries.

Yet barriers stand in the way of older individuals working. There is a concern about the safety of both the older worker and his colleagues among those hiring. A societal feeling of needing to “make room” for younger workers also exists. The attitude of retirement as a “public good” will have to change for older workers to get the jobs they seek. Perhaps it is happening, as there is a clear shift toward a longer work life in the United States (American Association of Retired Persons [AARP], 2006).

Who Are Our Older Workers and Why Do They Work?

The proportion of the population that works decreases with age (Tables 33-1 and 33-2). Not all older persons stop work as their own choice. Fifty-six percent of young retirees state that they were forced to retire, while 38% wanted to stop working (National Academy on an Aging Society, 2001). Those who work after age 60 tend to be male, educated, white, married, and in better health and better off monetarily than those who do not work (National Academy on an Aging Society, 2000). Older women who work feel more positive about growing older, report being in good physical health, and anticipate a better financial future than older women who are not working (National Center on Women and Aging, 2002).

Most older workers choose to work in order to remain active and productive, to do something fun, and for access to money and health care (AARP, 2006). Those who would

Table 33-2. Older Persons Who Work

Age (years)	Percentage Who Work Full Time	Percentage Who Work Part Time
40–59	80	
51–59	76	
60–69	61	36
70+	28	72

Data from National Academy on an Aging Society (2000).

like to work but cannot find a job report believing they lack necessary training or are experiencing age discrimination. Some of their fears may be founded as persons aged 55 and older are less likely to find a job than younger workers after displacement. Finding a job takes longer, wages are often lower when hired, and there are a number of age discrimination awards given by courts (Rix, 2005), even with U.S. anti-discrimination laws and European Union anti-discrimination directives on employment.

Three keys to successful aging are low probability of disease and disability, high mental and physical function, and active engagement with life (Rowe & Kahn, 1999). Active engagement with life includes having close personal relationships and pursuing activities that produce something of value (a product or service) (Rowe & Kahn, 1999). Thus, continuing to work (in the broad sense of the term) may lead to greater satisfaction with life and perhaps even a longer life of higher quality.

Paid Employment, Volunteer Work, and Occupation of Time

It is intuitive to expect that an individual’s occupational identity and the meeting of his or her needs and values (mentioned earlier) can be met through paid employment, volunteer work, or meaningful activities that occupy their time. Insufficient literature exists, however, to clearly substantiate this claim. Instead, we surmise that portions of this may be true based on findings. For example, individuals with mental illness who engaged in paid (competitive)

Table 33-1. The Aging U.S. Workforce

Age Group	Percentage of Work Force Expected in 2012	Percent Change		
		1982–1992	1992–2002	2002–2012
Youth (16–24 years old)	15	–12.2	3.7	9
Prime age worker (25–54 years old)	66	29.7	9.2	5.1
Older (55+ years old)	19.1	–0.2	34.4	49.3

Adapted from Toosi, 2004.

work reported being more satisfied with their daily occupations than those involved in seemingly meaningful work in a therapeutic setting and those with no regular daily activity, yet none of the three groups differed in terms of self-ratings of health and well-being (Eklund, Hansson, & Ahlqvist, 2004). Questions about life satisfaction were not included in the prior study, but satisfaction with life has been associated with working in asthmatics (Pirila et al., 2005), and people who are employed are more satisfied with their lives than those who are unemployed (this is true for the general population and those with schizophrenia or other forms of mental illness) (Priebe et al., 1998).

The switch from paid worker to volunteerism or other form of meaningful activity must be taken carefully because one does not automatically suffice for the other. Ibarra (2002) suggests that a change to another profession or career, attempting “bridge employment” in another area, or moving toward another occupation requires a person to “try on” the new identity through action and a “test-and-learn” model of change.

WORK AND OCCUPATIONAL THERAPY

Adolph Meyer advocated a “freer conception of work, a concept of free and pleasant and profitable occupation including recreation and any form of helpful enjoyment as the leading principle.” He said the “whole of human organization has its shape in a kind of rhythm,” and through structured use of time, people could achieve well-being (Meyer, 1922, pp. 1–2). By assisting the client to achieve a balanced lifestyle in work, play, rest, and sleep, early occupational therapists helped clients achieve a sense of homeostasis and health. Meyer broadly defined the term *occupation* as purposeful activity within the full spectrum of a person’s life.

Occupational therapy is soundly based on the concept of returning the injured worker to work, as it was founded on the belief that merely eliminating the disease or providing immediate treatment for traumatic injury was insufficient for full recovery and ability to assume life roles. Instead, a client should be guided through a strengthening and training process, both physically and mentally, to prepare him or her to resume occupational status in society (Committee on Installations and Advice, 1928; Rice, 1999a). Therapists used “crafts” in their treatment. What were once called crafts are today considered jobs. The term *craft* included activities such as carpentry, metal work, and bookbinding, all of which were full-time vocations. Initially, a wide variety of crafts or jobs were used in occupational therapy clinics. Occupational therapists realized, however, that carefully chosen occupa-

tion-based activities resulted in a transfer of training to almost any occupation the recovered client chose to pursue. This is opposite the current trend of work hardening, which simulates specific job tasks that will be required of the client upon return to work. The latter certainly has greater face validity, but to date, no published outcome research clearly supports one approach as superior to the other.

Occupational Therapists’ Unique Contributions

Occupational therapists, with their solid background in the full spectrum of human performance (physiological, biomechanical, psychosocial, and behavioral), are uniquely qualified to help clients return to work. A fundamental goal of occupational therapy is to facilitate the client’s highest level of functional status in all occupations and all contexts of life, including physical, emotional, social, cognitive, and communicative dimensions. Occupational therapists recognize that successful return to work is likely to depend on adequate function in many aspects of life, not solely task performance at a work site. For example, occupational therapists use their knowledge of human performance and the human mind to determine whether the impediments to returning to work are physical, psychosocial, or both. Therapists also use their knowledge of human psychology to discern possible motivations for the client to achieve well-being.

With some clients, the urge toward competence is obvious, and they work quickly to master their environment (White, 1971). Therapists can motivate others by having them visualize what they want to be able to do or the type of person they want to be and by working with them to achieve their *possible selves* (Markus & Nurius, 1986). Those who value work or for whom we can find the motivational factors in work are most inclined to participate fully in rehabilitation. They are also the most likely to return to the workforce. Providing small successes along the way does much to encourage the process, but without work that has intrinsic value for the individual, the return to work is likely to be unsuccessful. The application of the full spectrum of human performance elucidates the unique contributions of occupational therapists in returning the injured worker to the workforce.

Burwash Model

One model depicting the knowledge and intervention necessary for occupational therapists to evaluate and intervene in work practices is that presented by Burwash (1999), which is shown in Figure 33-1 and further described in Table 33-3. Returning to work is seen as one of the triangles representing concerns of clients. To

Figure 33-1 *Work Practice Model* (Burwash, 1999). The circular shape suggests many entry and exit points; intervention may progress in a linear fashion around the circle, or only one or two areas of concern may be addressed. The director's chair in the center is a reminder that focus is on the individual and his or her values, and the individual, rather than diagnosis or age, should be the director. The eight triangles represent concerns expressed by clients and are part of occupational therapy's professional heritage and within therapists' competencies. The pentagons suggest artists' palettes as a reminder that the intervention requires both art and science in dealing with productivity issues. The double-headed arrows represent environmental factors that influence and can be influenced by the client and therapist; they include social, cultural, and political factors, among others.

facilitate a return to work, however, the therapist may be involved in each of the eight areas. For example, the client may be leaving one line of work because of disease or disability and needs to reevaluate his or her values to explore and choose another career. While building the requisite physical and cognitive skills for the chosen job or career field, the client may also need to develop skills in searching for work along with the work habits needed to sustain a successful career.

The therapist must understand the client's value of work and self-perception as related to work (such as self-definition and self-esteem), so as to design the rehabilitation process and identify short-term goals and techniques to motivate the client. This client-centered approach to evaluation and treatment involves joint identification of goals and priorities by the therapist and the client (Law et al., 1994; Mattingly, 1991; Neistadt, 1995). For example, therapists can help clients ascertain whether they want their work to be a job rather than a career (see Definition 33-1) by examining where they fulfill their social, emotional, and achievement needs.

THE RETURN-TO-WORK PROCESS

Returning to work entails three main procedures: evaluation, intervention, and reevaluation.

Functional Work Assessments

Functional work assessments include evaluation of both the individual client and the work requirements the client will encounter. Individual evaluations incorporate the standard occupational therapy assessment, a delineation of the conditions preventing the client from returning to work, and a **functional capacity evaluation (FCE)**. The evaluation of the work requirements is often referred to as a **functional job analysis**, or simply job analysis.

Job Analysis

A job analysis is a systematic evaluation of the job that identifies its physical, cognitive, social, and psychological requirements. Conducting a job analysis entails going to

Table 33-3. Examples Using the *Burwash Model* (1999)

Model Segment	Client Concerns	Therapist Resources: Assessment Tools, Techniques, and Programs	Environmental Considerations
Valuing	“Why work?” “How does work fit into my life?” “What are my personal values and what types of work fit?” “Why am I not happy in this work?” “Is working worth it?”	Work Values Inventory, Life Roles Inventory, work values auction, spirituality of work questionnaire, Occupational Performance History Interview	Family and social group attitudes toward work; economic considerations for persons on disability pensions; religious beliefs about work; work and gender issues
Exploring	“I don’t know what I’m physically capable of.” “Are there any occupations that match my interests?” “What am I good at?”	Functional Capacity Evaluation, Self-Directed Search, work samples, computerized career exploration systems	Role definition of OT vs. other team members (career counselors, vocational rehabilitation counselor, teachers); family expectations
Keeping	“How is this health problem going to affect my work?” “I hurt so much after a day at work!” “I’m about to take stress leave; all of these changes are really getting to me.” “I can’t figure out how to get ahead at work; I’m really feeling stuck.”	Ergonomic interventions, stress management and relaxation techniques, energy conservation and work simplification techniques, goal setting, injury prevention and health promotion programs, advocacy	Family and friends’ expectations; public laws on disability and workplace ergonomic standards; employer, coworker, public attitudes toward persons with disabilities; client’s support system; funding issues; job market; physical accessibility; access to transportation
Returning	“Will I be able to work again?” “How do I prevent reinjury?” “How do I deal with coworkers’ comments about my illness?” “If I’m hurting at work, how do I cope with the pain?”	Work Environment Impact Scale, Worker Role Interview, graduated return-to-work programs, work hardening and chronic pain programs, assertiveness skills, Loma Linda Activity Sort, other resources in Exploring row above	Laws on injured workers and employers’ responsibilities to them, job market, funding for retraining, family responsibilities, possible financial settlements, advice from lawyers and others, employer–employee relations

the job site, observing workers performing their tasks, measuring equipment and equipment placement, and interviewing those who perform the job and their supervisors. Some of the tools employed in the job analysis are video cameras, tape measures, scales, goniometers, stopwatches, dynamometers, still cameras, and strain gauges. The results of a job analysis can be used in several ways, as seen in Procedures for Practice 33-1.

Basic Components of Job Analysis

Components of any job analysis include the job title, basic description or objectives of the job, number of employees performing the job, the work and break schedule, a description of any rotation or enrichment program, and output requirements for the workers. A description of the environment should include temperature, available space,

PROCEDURES FOR PRACTICE 33-1

Ways to Use Job Analysis Data

- Develop FCE
- Match injured workers’ capabilities to job task requirements
- Place workers on light duty
- Return previously injured workers to work
- Identify risk factors associated with work-related musculoskeletal disorders
- Develop pre-placement, post-job offer screenings
- Write job description (possibly using ADA terminology)
- Describe and advertise jobs

a list of fixed and movable equipment, personal protective equipment, and a sketch of the area. A sequential description of each task (essential function) and the component steps to complete it are also necessary. This should include measurements such as heights, weights, durations, distances, and so on.

Rationale for Conducting Job Analysis

The reason for conducting the job analysis dictates its questions and procedures. Purposes of conducting a job analysis include returning a person with a disability to work, identifying musculoskeletal risk factors, matching a rehabilitated or new worker with job demands, and developing assessments such as FCEs and pre-placement screening tests.

For example, if the results are to be used to return an individual classified as disabled according to the Americans with Disabilities Act (ADA) (Federal Register, 1991) to his or her work, the job must be described in terms of its essential functions (Definition 33-2). Therapists whose responsibilities include industrial rehabilitation and returning injured or disabled workers to the workforce or helping employers to advertise jobs should be well versed in Title I of the ADA. Several excellent book chapters for therapists are available (Bloswick et al., 1998; Isernhagen, 1995a; Kornblau, 1998a, 1998b), and therapists should also refer to the regulations and guides themselves (ADA Title I Regulations, 1991; Americans with Disabilities Act, 1990; Equal Employment Opportunity Commission, 1992).

If the reason for performing the job analysis is to identify risk factors that may predispose a person to musculoskeletal disorders, listing the essential functions is not compulsory. A job analysis primarily geared to injury prevention, such as work-related musculoskeletal disorders, should include descriptions of observed risk factors, such as repetitive motions, force, static postures, awkward postures, mechanical compressions, vibration, and the acceleration and velocity of dynamic motions, noted for each body part and quantified. For example, the duration of static hold using a pinch grip is noted in seconds. Literature on job analysis related to injury prevention can be found in several excellent sources (Alexander, 1999; Ellexson, 1997; Isernhagen, 1995b; Karwowski & Marras, 1999; Pular & Alexander, 1992; Rice, 1998; Rogers, 1983, 1992; Sanders, 1997).

For matching workers' capabilities with the job requirements, placing workers on light duty, or returning previously injured workers to work, tasks (i.e., essential functions) are broken into their component steps and quantitatively described in enough detail to permit them to be matched with the worker's residual capabilities (Procedures for Practice 33-2). The therapist who only occasionally participates in returning injured workers to the workforce may prepare a unique job analysis for each client; those who work full time in industrial rehabilitation generally keep a file of job descriptions that lets them quickly determine whether a client can return by comparing the results of the FCE with the job description (Isernhagen, 1995b). One benefit of having occupational therapists involved in job analysis is the ability to combine these purposes for conducting job analysis and developing a comprehensive database for an industry's use.

DEFINITION 33-2

Essential Functions

Fundamental, Not Marginal, Job Duties

Some considerations in determining whether a function is essential include:

- Whether the position exists to perform that function
- The number of other employees available to perform the function or among whom the function can be distributed
- The degree of expertise required
- Whether past and/or present employees in the job have performed the function
- The time spent performing the function
- The consequences of not performing the function

Reasonable Accommodations

Modifications of the work environment include job restructuring and providing adaptive or adaptable equipment and similar modifications to enable equal opportunities for employment by individuals with disabilities.

Use of Job Analysis in Developing and Selecting a Functional Capacity Evaluation

A job analysis should be conducted *prior to development or selection of an FCE*. An FCE consists of two parts: a general evaluation of physical abilities and a job-specific evaluation. Before one can decide whether to use solely the general evaluation versus the job-specific evaluation, the therapist must know whether the client intends to return to a specific job or type of job. If so, the information from the job analysis can be used to develop one of two types of FCE using criterion-referenced tasks. The first uses task components, while the second uses work simulations (both discussed later in the chapter). In both cases, the initial information is gathered during the job analysis.

Predicting Work Performance

The results of job analysis can also be used to predict performance. A review of 21 research studies designed to predict work performance, found static, dynamic, and combined strength tests and simulations predicted job

PROCEDURES FOR PRACTICE 33-2

Matching Job Analysis with Functional Capacity Evaluation

Job Title: Meat Grinder (ground beef, chicken, pork, turkey)

Job Analysis

Tasks

1. Load grinder
2. Grind and load meat tubs

Physical Requirements

Standing, walking, climbing stairs, carrying, lifting, stooping, handling, reaching, grasping

Steps for Task 1

Remove top from tub of meat	0.5 lb
Place top of tub to the side	Turn and place
Lift tub from stack	Lift 70 lb
Carry tub up stairs	Carry 70 lb 5 ft, climb 3 stairs

Empty meat from tub into grinder

Walk down stairs

Place empty tub on stack behind grinder

Steps for Task 2

Retrieve empty tub

Place tub beneath grinder spigot

Turn on grinder

Visually supervise grinding
Guide beef from spigot

Spread beef in tub

Turn off grinder

Lift tub

Carry tub either up the stairs to reload grinder (repeat steps 4–6 task 1) or to packaging area

Functional Capacity Evaluation Results

No limitations standing, walking, climbing, and descending stairs

Vision: 20/20 with glasses

Upper extremity reach and manual dexterity within normal limits as measured by Purdue pegboard

Grasp: 50 lb

Lifts

Single lift to 4-ft height 29 kg

Repetitive lift to 4-ft height

One lift every 8 min 20 kg

Stand

Use, handle large metal spoon

Use, handle large metal spoon

Turn handle, 0.8 lb resistance

Lift 5 tubs at 28 lb each

See steps 4–6

Carry 5 tubs at 28 lb each 15 ft

FCE Results Match Job Requirements

Yes

Yes

Yes

From Pentikis, personal communication, December 10, 1993.

performance. The most successful predictions, those that accounted for 60% of the variance or more, demonstrated several consistencies (Rice, 1999b). A major one was a well-constructed job analysis, with a breakdown of job tasks into component parts. (An example of component tests and a work simulation can be seen in Procedures for Practice 33-3.) Successful predictions also used multiple assessment techniques, such as interviews with ratings of key tasks for frequency, duration, and difficulty; direct observation; videotaping; measurements of masses moved and forces exerted; and identification of pace and frequency. The fidelity of the evaluative tool depends on use of the multiple constructs identified during the job analysis and accurately translating the description into the development of the FCE.

Job Analysis Conclusion

The ability to conduct a thorough job analysis is an essential skill for an occupational therapist working in an industrial setting. The prudent therapist conducts a similarly comprehensive analysis of the job of a homemaker, athlete, or child. The instruction received during entry-level

training for occupational therapy in task analysis provides an excellent basis for building expertise in job analysis. The one area of job analysis that neither is well-defined nor has a large number of case studies available for guidance is the cognitive, psychological, and social requirements of work.

One important concept is that, although the job analysis is part of the evaluation, the results are used to develop the treatment intervention and establish the end goals. In traditional occupational therapy, the treatment intervention and goals are based solely on the evaluation of the client and his or her desires, not on evaluation of the work site and the job demands.

Functional Capacity Assessments

A variety of assessments are available for evaluating work performance, with the majority coming under the classification of an FCE. An FCE is a systematic process designed to assess a client's physical capacities and functional abilities. Identification of an individual's capabilities also reveals his or her limitations. The FCE uses information available from traditional occupational therapy and medical evaluations along with performance-based evaluations.

PROCEDURES FOR PRACTICE 33-3

Example of Component Tests and Work Simulation for Military Medic Task: Stretcher Carrying

Job Title: Military Medic

Task

Carrying stretcher containing a wounded soldier to and from medical transport vehicles as part of a two-person team

Task Description

Maximal height a stretcher must be lifted is 135 cm, based on ground and air ambulance loading platform heights. Literature review revealed weight of 50th percentile male U.S. army soldier as 78.5 ± 11 kg (Gordon et al., 1989). The stretcher weighed 6.8 kg. When unloading air ambulances, patients must be carried to a ground ambulance, typically approximately 50 m.

Task Components for Functional Capacity Evaluation

1. Lift and lower a box approximately 71 kg to and from a 135-cm height.
2. Perform isometric grip strength test.
3. Run 1 mile in 10 minutes or perform aerobic treadmill testing.
4. Carry hand-held weights approximately 35.5 kg for 50 m.

Work Simulation for Functional Capacity Evaluation

Soldier walks or runs 50 m on treadmill carrying a stretcher holding an 88.6-kg mannequin. Soldier dismounts treadmill and walks or runs 5 m to a weight stack machine adjacent to treadmill and lifts weight equal to the patient's load to 135 cm to simulate loading patient into ground or air ambulance. Soldier gets back on treadmill and walks or runs 50 m to retrieve next patient. Treadmill speed is self-paced using toggle switch attached to stretcher handle.

The information gained from an FCE can be used to match the individual's residual capacities with the demands of a specific job as a basis for establishing work or work site modifications or accommodations, as evidence in the determination of disability or compensation status, and/or as a baseline for noting the physical capabilities of new employees. FCEs can be used in a variety of circumstances, including in industrial settings for pre-employment and post-offer screenings, in clinical settings for setting goal and treatment regimens, and for determining a worker's ability to resume his or her job duties. According to Crowe and Shannon (1997), an FCE can be an essential tool in determining whether a claimant is eligible for Social Security disability benefits.

Most FCEs include a review of the client's medical record, an interview that includes a work and educational history and sometimes a self-administered ques-

tionnaire, a basic musculoskeletal evaluation, performance evaluations, and a comparison of the findings with the job requirements (Isernhagen, 1995a). As mentioned previously, the two performance categories are a general evaluation of physical abilities and a set of job-specific evaluations. Some therapists include psychosocial aspects; however, this remains more of an exception than the rule unless the individual has specific mental health or neurological concerns. Both the psychosocial and cognitive aspects of FCEs are ripe for exploration, implementation, and research.

General Evaluation of Physical and Cognitive Abilities

Physical and cognitive abilities are evaluated to examine basic functional abilities thought to be common to a number of jobs. The evaluation is conducted to give baseline information and is a special concern when the job to which the individual will return is unknown. The general evaluation of physical abilities may include measures of flexibility, strength, balance, coordination, cardiovascular condition, and body mechanics. It should also include the individual's ability to sit, stand, walk, lift, carry, bend, squat, crawl, climb, reach, stoop, and kneel and any limitations with those activities. Work-related musculoskeletal disorders have become prevalent; therefore, the individual's ability to do particular types of repetitive motions should also be noted. Documentation should specify weight limits, duration of activity tolerance, unambiguous environmental restrictions, and exact side effects of medications. Subjective findings, such as reported degree and frequency of pain, along with any observations (grimacing), should be noted.

Job-Specific Evaluations

The second part of an FCE is job specific. This means that specific work tasks are designed to simulate the critical tasks associated with a specific job or set of jobs (described previously in the job analysis section as either task components or simulations). For example, the city of Calgary, Alberta, has developed a two-part FCE for its firefighters (Calgary Fire Department, 1999). The first portion is a physical fitness evaluation that includes cardiovascular respiratory fitness, muscular endurance, and flexibility. The second portion comprises job-specific tasks, including a tower rope pull, hose line extension, victim drag, ventilation exercise, equipment carry, smoke mask haze, and aerial ladder climb.

IDENTIFYING TASK COMPONENTS

Task component testing means that the most difficult and important functions of the job are identified and an evaluation or treatment plan is developed using the task components. An example of selecting the most difficult essential task is when a person must lift tools weighing 10

pounds and a 50-pound toolbox. The criterion task includes the more difficult of the two tasks on the assumption that a worker who can accomplish the more difficult task is also competent for the lesser one. The criterion tasks, in the form of task components or work simulations, are used because they are believed to predict job performance. It is assumed that testing applicants on single aspects of job performance that are critical to job success is a valid approach to determining work performance, as the content requirements are used (Wigdor & Green, 1991). An example of the development of criterion-referenced tasks using both the task component and work simulation techniques can be seen in Procedures for Practice 33-3.

WORK SIMULATIONS

Work simulations differ from task components in that they replicate essential series of tasks required on a job. For example, a firefighter's task of removing a hose, attaching it to a nozzle, and holding the hose during spraying is one task simulation. The same task series analyzed according to its task components might include only two portions, lifting an item that weighs the same as the hose and pushing a sled whose weight equals the amount of hose pressure. Work simulations frequently involve multiple constructs, such as strength, balance, and agility, and they have more face validity.

Psychosocial Behaviors

Some evaluations include the individual's psychosocial behaviors as they apply to work habits and motivation; however, this is not consistently part of the process. This part of the FCE should describe the client's limitations in comprehension, recall, and ability to follow instructions. Other psychosocial issues, such as ability to handle work pressures, respond to supervision, and relate to coworkers or customers, should also be noted.

Many FCEs use an evaluation called the detection of sincerity of effort, which is said to be an indication of a client's motivation to perform optimally during an FCE. The belief is that a client who is not sincere may have a less successful recovery or prolonged recovery, overuse treatment, have increased costs of care, and receive unwarranted disability payments (Lechner, Bradbury, & Bradley, 1998). In their excellent review article, Lechner, Bradbury, and Bradley reviewed several sincerity-of-effort evaluation methods for reliability and validity. They also examined the concept of using the coefficient of variation in muscle performance tests, the correlation between musculoskeletal evaluations and FCEs. They concluded, "to date, none of the previously discussed methods for detecting sincerity of effort have been adequately studied for its use with clients with LBP" (low back pain). They further state that "therapists also are advised to avoid reporting test results as 'valid' or 'invalid' based on perceived levels of coopera-

tion and to avoid using the terms 'symptom magnification' and 'exaggerated pain behavior' to describe client behavior" (Lechner, Bradbury, & Bradley, 1998, pp. 884-885).

Since alterations in mood and affect commonly coexist with and exacerbate physical problems, these issues should be included in the assessment. A brief screening tool can be used in conjunction with clinical observations to determine the influence of any psychosocial problems. The *Generalized Contentment Scale* is a quick 25-item paper and pencil measure of non-psychotic depression that is useful in determining the extent of mood alterations associated with loss of the work role (Hudson, 1982). If significant test results are obtained, assistance from psychological services may be indicated.

Selecting a Functional Capacity Evaluation

More than 55 FCEs are available, and selection of an appropriate one can be difficult. They differ in the physical and psychological factors they assess and the way the measures are administered. They also differ in the training required for competency in administration and interpretation. Some use a battery of tests that may or may not be based on a specific task analysis of the job in question. Such a battery may include strength, flexibility, and endurance tests. Others use actual simulations of the tasks required of the job. Few have undergone rigorous examination to determine whether the evaluation predicts actual job performance (Innes & Straker, 1999; Rice, 1999b). Although it may seem easy to select an FCE based on the availability of workshops and related products, the decision making process should be performed carefully. Some good review articles assist with selecting FCEs (Innes & Straker, 1999; King, Tuckwell, & Barrett, 1998) and pre-placement tests (Rice, 1999b). King, Tuckwell, and Barrett (1998) reviewed 10 FCEs for their years of availability, format, length of assessment and report, validity and reliability, availability of peer-reviewed published research, standardization of instruction, whether the FCE is norm or criterion referenced, and costs. Innes and Straker (1999) reviewed the test-retest, inter-rater, intra-test, and instrument precision reliability of 28 evaluations. Both articles contain charts that are well worth having as references for selection of evaluations. No single evaluation is likely to suffice in all cases for all clients. Therefore, clinicians should be familiar with various evaluations and select those most suitable for their setting and their clients.

Functional Work Assessments Conclusion

Knowledge of the two primary means of assessment in industrial rehabilitation, job analysis and functional capacity assessment, sets the stage for intervention. Individual clients' goals, work site design alterations, and bringing the capabilities of the worker closer into alignment with the demands of the job are all built on a well performed set

of assessments. The practitioner must integrate into the intervention process the detail the assessments provide, and the results of the FCE should be used to indicate a client's potential to work. This information should be clearly communicated to the employer and to the client. The bottom line is this: The best "evaluation" is one that is holistic; it examines the work, the work environment, and the workers needs, interests, desires (motivations), behaviors (habits and lifestyle), and personal characteristics.

Intervention

Intervention that is specific for returning the individual to the workforce builds upon traditional occupational therapy intervention, taking it a few steps further into the daily work requirements of the client. Throughout intervention, the therapist should maintain communication with the client's work supervisor and iteratively determine the potential for work site modification to match the levels of performance being discovered during the evaluation. These modifications may continue throughout the process, permitting the client to return to a work setting much earlier and encouraging personal identification as a contributing, competent worker.

Work Conditioning

Work conditioning generally follows acute care and precedes **work hardening**. Like traditional occupational therapy intervention, work conditioning focuses on remediation of underlying physical or cognitive deficits to improve function. The difference between traditional rehabilitation and work conditioning is that the intervention is focused on functional requirements of a job or employment setting rather than on life skills required at home or for recreational activities. Restoration of flexibility, strength, coordination, and endurance may be addressed. Work conditioning should increase physical abilities, engineer successful performance, and provide realistic feedback regarding the client's capabilities (Fig. 33-2). The client's day may include a regimen of warm-up exercises tailored to the activities planned for the day, conditioning exercises based on job requirements, and job-related tasks using work samples that replicate essential task components of a job. A program may begin with sessions of an hour or two and progress as the client-worker's condition improves to 8 hours per day.

Work Hardening

Work hardening is a multidisciplinary structured treatment designed to maximize a client's ability to return to employment. Work hardening includes all aspects required for the client to return to full employment function, such as psychosocial, communication, physical, and

Figure 33-2 Work conditioning using a simulated work task. This is an initial simulation, as the requirements for bending and stooping have not yet been added.

vocational needs. Although general physical abilities are addressed in work conditioning, work hardening is aimed more specifically at a particular job or classification of jobs, so it tends to use work simulation. Considerations added during work hardening include productivity (speed, accuracy, and efficiency), safety (ability to adhere to safety principles and use of safety equipment and algorithms), physical tolerances for specific tasks (endurance and ability to carry out the repetitive task requirements), organizational skills, and decision making. The key differences are the use of real or simulated work activities in a graded fashion, building to work over periods comparable with those in actual work settings; the full spectrum of work-related intervention; and the use of a multidisciplinary approach (Isernhagen, 1988). Disciplines included in a work hardening program can include occupational and physical therapy, psychology, vocational rehabilitation, social work, and social services. Other professionals who may participate full time or as needed include drug and alcohol counselors, nutritionists, and educators (special education or educational evaluators).

Work hardening environments should replicate the workplace as closely as possible. Sufficient space is needed for both traditional equipment for work conditioning and specialized equipment that may be brought from a job site. Also, the behaviors and interactions required of the clients should replicate a work setting, such as arriving and leaving on a set schedule, working with fixed breaks, having supervisors who give positive and negative feedback on performance, performance standards, and so on. Returning a client to a part-time or full-time light duty assignment during rehabilitation may help the client feel like part of the team. It may also assist employers by building their confidence in the process and by letting them observe first hand the capabilities of the client-worker.

All involved parties should be kept informed of the process. This includes employers, supervisors, insurance representatives, occupational health nurses, and the physician.

Reevaluation of the Client and Program Evaluation

Two types of intertwined evaluations should be conducted. Individual clients should be reevaluated, and the program as a whole should be evaluated. Monitoring clients' progress and annotating whether they have achieved functional goals should occur as in traditional occupational therapy during clinic-based treatment. Follow-up evaluations with the client and the client's supervisor are suggested so that, in case of a problem, the therapist can intervene before reinjury or exacerbation of the injury occurs. In addition, it is important to combine this information (having removed individual identifiers) with that of other clients to determine whether overall program goals are being met. It is important to know whether the program is meeting the needs of individual clients as well as those of the referral sources (employers). Tracking information such as the rate of successful return to work, the length of limited-duty time, and the subjective responses of past clients and their supervisors enables the therapist to improve the program. This information is important for showing the cost-benefit value of the services and should be available if reimbursement questions arise. The same information can be used in marketing strategies.

A CLINICAL IMPLEMENTATION OF THE RETURN-TO-WORK PROCESS

This chapter contains basic information about work-related assessment, intervention through work conditioning and work hardening, and reevaluation of both the individual and the program, along with background information on work motivation, interruption of work, and ways occupational therapists can intervene. Still, the application of this knowledge can be confusing without a framework. Therefore, this section describes a decision pathway and an example of an FCE (Fig. 33-3). The interventions identified in this decision pathway are closely aligned with the interventions articulated in the article "Occupational Therapy Practice Framework: Domain and Process" (American Occupational Therapy Association, 2002). These interventions are therapeutic use of self, education, consultation, and therapeutic use of occupations (occupation-based activity). These interventions are broad based, and it is probably beyond the scope of this chapter

to present a meaningful discussion of their merits or limitations.

The return-to-work decision pathway shown in Figure 33-4 presents work rehabilitation processes in the larger context of injury, medical management, and acute rehabilitation. As cost containment is a paramount issue in any health care organization, the decision pathway encourages a logical process to return the client to the workforce in a time-efficient manner. As can be seen in Figure 33-4, the decision pathway begins with an interruption of the work process, includes medical and rehabilitative intervention, incorporates the return-to-work process of evaluation and intervention, and offers several junctures at which the client may return to work.

The FCE in Figure 33-3 is composed of measures that are routinely available in most clinical settings (Resource 33-1). Additional tests can be added as available and desired. The many available off-the-shelf FCEs all have some limitations as well as merits, and therapists should be broad minded in their selection of tools for the FCE. It may be most efficacious for therapists first to develop an understanding of the return-to-work evaluation and intervention process and then to develop a structured evaluation system composed of available components that are specific to individual patients and the specific environmental context to which they must return.

The first page of information seen on the FCE (Fig. 33-3) contains the evaluation of the findings, an explanation of the discrepancies between the job requirements and work performance, and recommendations. This arrangement seems to put the end (the results) at the beginning before permitting the reader to follow and understand the evaluative process. The format is designed so the "bottom line" is immediately available for the employer and/or client to read. Background information in the form of the evaluative process is then provided as substantiation of the findings.

Each section of the decision pathway and FCE is explained in the next section. Also refer to the Case Example, which further demonstrates the use of the FCE.

Medical Management and Acute Rehabilitation

The return-to-work process begins as soon as a patient enters the medical system for treatment. Medical management (Fig. 33-4) concerns the use of medical and surgical treatment to control and remedy acute medical problems that have interrupted the work role. Acute rehabilitation naturally follows medical management when medical problems and their treatments have caused physical debilitation, muscle weakness, impaired joint motion, decreased flexibility and/or coordination, or other limita-

<input type="checkbox"/> Heavy—Infrequent lifting of 100 pounds; frequent lifting of 50 pound or less; slow-speed, 50-pound load carry/walking	<input type="checkbox"/>
<input type="checkbox"/> Very Heavy—Infrequent lifting in excess of 100 pounds; frequent lifting of 50 to 100 pounds; slow-speed, 50-pound load carry/walking	<input type="checkbox"/>

Factors Explaining Discrepancies between Job Requirements and Work Performance

- Suboptimal voluntary effort in testing
- Discrepancies between diagnosis and symptoms presented
- Discrepancies between client's perception of ability & actual ability
- Limited physical abilities
 - Joint motion/flexibility
 - Strength
 - Physical endurance
 - Sensation
 - Hand dexterity
- Limited psychosocial abilities
 - Mood/affect
 - Cognition
 - Pain tolerance/behavior

Figure 33-3 (continued)

tions. Acute rehabilitation for physical injuries can involve the use of physical agents, exercise, and education to restore abilities impaired by injury, illness, surgery, or enforced inactivity. Both medical management and acute rehabilitation entail evaluation, diagnosis, and procedures to remedy pathological conditions. At the end of each of these processes, a decision as to the potential for the client to return to work must be made. If the client is able and willing to return to work at these junctures, intervention is discontinued. Many clients with minimal residue of injury or illness and high internal motivation return to work without further intervention.

Work Rehabilitation

If medical management and acute rehabilitation do not result in a return-to-work status, efforts focus on the feasibility of returning the client to work. The method to determine return-to-work feasibility is the functional work assessment, which includes general medical information, a job analysis (if the job or type of job is known), an FCE, and an assessment of the client's perceptions of his or her abilities.

In addition to being evaluative, the functional work assessment forms the framework within which the therapist builds intervention strategies to bring about the return to work. The FCE used here can be carried out in seven steps.

Step 1: Pre-Evaluation Information

As indicated in Figure 33-3, information is recorded about the client's job, along with demographics and information regarding the client's medical condition and symptoms. Details about the job can be obtained through the client's self-report, a written job description, interviews with the employer, and/or an on-site job analysis.

Job Demands

The evaluator seeks to determine the specifics of the job in terms of physical, cognitive, and social demands. Careful review of the job description and interviews with client and supervisor allow the therapist to form a picture of the demands of the job. The therapist may also choose to conduct a job site analysis so that objective measurements and observations can further elucidate the demands. These job demands are key in setting up work samples later in the evaluation.

Medical History and Current Symptoms

In addition to a complete review of the medical record, the client is asked to describe his or her medical history, including medical treatment, surgery, rehabilitation, and time off work. Information about the client's current symptoms is gathered. The grid Current Symptoms Relating to Work Situation allows the client to describe symptoms and rate them on intensity. Clients are encouraged to state their desired resolutions to the current work/disability situation so

as to enable the therapist and client to establish goals jointly. Even though the evaluation is in the early stages, at this point, there is usually sufficient information to initiate treatment that can coincide with the continuing evaluation.

The therapist should determine whether the cluster of symptoms presented by the client matches those usually associated with the diagnosis or disorder. Significant variances between diagnosis and expected symptoms can be a sign of a client being overwhelmed by the situation or an early indication of symptom magnification. At this point in the FCE, the process may change from evaluation to intervention. The therapist may now choose to use a consultation intervention in which the client is assisted in explaining the discrepancies between conflicting findings. Although a disconnect between diagnosis and symptoms may not be at the client's conscious level, it should be addressed at once. During this intervention, it is appropriate to provide the client with additional information about the medical condition and its usual presentation and course in rehabilitation. It is important during this consultation to allow the client a face-saving way out, such as the opportunity to restate or discuss symptoms. The purpose of the consultation process is to help the client to either clarify information or adjust behavior according to new information presented by the therapist. Alignment of symptoms may also help to delineate those who have a well-defined WRMD versus those who may have signs and symptoms of overuse that are not yet at a stage of clinical diagnosis. This process may also assist the client to accept and understand his or her symptoms.

Step 2: Work Performance Measurement

In accordance with the job demands identified in step 1, the therapist determines which of the available work performance measures best simulates the demands of the current or target job. Although testing of ability components can be fairly general and applied to many jobs and tasks, if the job to which the client will return is known, the evaluation should be tailored to it. Figure 33-3 has a reporting format for selected work performance measures, including the following:

- Valpar 1: Small tools; fine motor dexterity

Figure 33-5 Valpar Work Sample 4. Upper extremity range-of-motion work sample.

- Valpar 4: Upper extremity range of motion; prolonged use of both hands in confined space with awkward angles (Fig. 33-5)
- Valpar 9: Whole-body range of motion; reaching, bending, and stooping while using hands
- Valpar 15: Electrical circuitry and print reading requiring attention, memory, new learning, and hand dexterity (Fig. 33-6)
- Valpar 19: Dynamic physical capacities; reaching, lifting, reading, decision making, and following directions (Fig. 33-7)

Methods Time Measurement (MTM) scoring criteria are used with all of these work performance measurements (Valpar International Corp., 1992). MTM compares work sample performance with an engineered standard that relates to competitive performance rather than to norma-

Figure 33-6 Valpar Work Sample 15. Electricity circuitry and print reading.

Figure 33-7 Valpar Work Sample 19. Work dynamic physical capacities.

tive data. The standards were developed by an engineering company and are designed to mimic the real pace of work rather than the burst activity common to testing. MTM grades performance in a percent rate of work from 0 to 150%. The percent rate of work is scaled against the following competitive work standards:

- Performance exceeding work standards
- Performance meeting work standards
- Performance below work standards with potential to meet standard
- Performance below work standard with minimal potential to reach standard

MTM can, at first, be confusing to clinicians accustomed to using only standard normative data, but it is essential for the therapist to understand it for proper analysis of work performance measurement data and to explain the results to the client and employer.

In the event that the client's work sample performance falls below competitive standards, steps 3 and 4 of the evaluation are used to discover the deficits responsible for the impaired work performance. Deficient work performance is generally the result of disconnects between job demands, internal motivation based on perception of abil-

ity, and/or performance and ability levels. If, however, demonstrated work performance on job-specific work samples meets the competitive standards, steps 3 and 4 can be omitted, and the therapist can proceed to data analysis and recommendations.

Step 3: Client's Perception of Ability to Work

Figure 33-3 shows two methods for gathering information regarding clients' perception of their abilities. The Employment Potential Improvement Corporation (EPIC) Hand Function Sort (HFS) and the Spinal Function Sort (SFS) (Fig. 33-8) are ratings of perceived capacity. These sorts require the client to view pictures of work situations (62 for the HFS and 50 for the SFC) and then sort them into four categories based on his or her perception of ability to perform the task within the situation. The categories include "able," "slightly restricted," "moderately restricted," and "unable."

The picture sort results can be analyzed in depth with the data compared with normative standards. The results can also be recorded in the format illustrated in Figure 33-3 as to the client's reported ability within each of the four physical demand characteristics categories of sedentary, light, medium, and heavy work. The second method of gaining the client's perception of ability is a self-rating of performance on a variety of common work tasks. Careful analysis of picture sort results and self-reports of ability give important information about the client's perception of his or her ability in relation to the diagnosis, presented symptoms, and the measures of ability that follow.

Step 4: Ability Measurement

Figure 33-3 incorporates tests and measures of ability, including body range of motion; static posture tolerance;

Figure 33-8 Patients sort cards based on their perceptions of ability to perform work tasks.

hand sensation and dexterity; extremity strength; lifting, pushing, and pulling strength; physical endurance; mood and affect; and cognitive problem solving. These are measures of performance skills and client factors that may affect an individual's capabilities at a number of jobs, rather than being tailored to any particular job or set of tasks. Examples include:

- Body range of motion, assessed by observing functional movements of the trunk and extremities to include reaching, touching hands to back of neck and middle of back, and bending or stooping toward the floor.
- Tolerance to the static postures of sitting and standing, observed and documented as the client performs other components of testing that require sitting or standing for extended periods.
- Physical strength, documented using both static strength and dynamic lift tests. A device such as the work simulator (Baltimore Therapeutic Equipment Co., 1999) can accomplish both static and dynamic lifting tests and allow comparison of strength between body sides and comparison against normative standards (Fig. 33-9).
- Physical endurance, using either a step test (Tuxworth & Shanawaz, 1977) or treadmill testing if available. *Before any strength or physical endurance testing, it is essential to ensure that the patient's medical record has been reviewed and the referring physician has given clearance for physical testing.*
- Hand dexterity and function, using any of a number of tests. The *Jebsen-Taylor Hand Function Test* is a standard in most clinical settings and can rapidly gather information on hand function using common objects rather than pegs or pins (Jebsen et al., 1969).

Figure 33-9 BTE Work Simulator used for dynamic strength testing.

- Mood and affect; alterations can exacerbate physical problems. This aspect of function should therefore be included in the assessment. A brief screening tool can be used in conjunction with clinical observations to determine any potential psychosocial problems. (See previous discussion of the *Generalized Contentment Scale*.) If significant findings are obtained, assistance from psychological services may be indicated.
- Cognition should be tested to determine whether difficulties with attention, memory, vision, reading skills, and problem solving are contributing to work deficits. The *Folstein Mini Mental Status Exam* (Folstein, Folstein, & McHugh, 1975) is a brief paper and pencil test that can give the clinician a quick look at the client's cognitive functioning. A score of less than 24 without obvious external confounding factors would strongly suggest the need for more formal cognitive testing before proceeding on in the evaluation. In addition, the *PSI Decision Making Test* is a 5-minute standardized paper-and-pencil test measuring attention, immediate memory, reading, and judgment (Ruch et al., 1981). Either or both of these tests can give the evaluator a general idea of cognitive function and help in determining whether further specialized testing is indicated.

Step 5: Summarize Test Data

The complexity of work demands and human behavior requires that therapists approach evaluation and intervention in a structured manner. If a structured approach is not used, there is a risk of being overwhelmed by the sheer amount of data or by the difficulties inherent in multifaceted behavioral interventions. To help manage information and use it as the basis for analysis, treatment, and recommendations, the sample FCE uses grids for summarizing and recording perception of ability, actual ability, and performance and work data. The evaluator summarizes observations from the tests and converts raw data to standard scores using either normative or MTM criteria. Completion of this section begins to paint a comprehensive picture of the patient's perceptions, abilities, and demonstrated performance in sample work situations. This information is the basis for the analysis in step 6.

Step 6: Analyze Findings

Under Assessment of Evaluation Findings, Figure 33-3 shows the variables to be considered in analyzing the results of test data. The first opinion relates to the quality of the FCE. Was this an incomplete or invalid evaluation, and if so, why did the therapist perceive it as such? The therapist annotates the client's demonstrated work performance to the job requirements on the Department of Labor Physical Demands of Work Level chart (United

States Employment Service Dictionary of Occupational Titles). If work performance in sample testing does not meet competitive standards of job requirements, the therapist explains the difference in terms of the client's abilities and/or motivation. In essence, this is a return-to-work equation involving several variables. The therapist must look for matches and disconnects in the data collected during the evaluation to present a meaningful analysis and recommendations.

1. The first match is between the diagnosis and symptoms. A given diagnosis usually results in a constellation of symptoms. The therapist must decide whether the symptoms match the diagnosis.
2. The next match is the agreement between the symptoms and the client's perception of his or her ability to work as expressed in the picture sort. An example of a disconnect is for the client to report hand paresthesias but not to indicate problems with precision tools on the card sort.
3. Next is assessment of the degree of agreement between the client's perception of ability to work and his or her demonstrated physical and cognitive abilities (potential to work). Examples of disconnects include the client who indicates inability to use heavy tools on the card sort but shows above-normal strength and endurance during physical testing.
4. The therapist compares the client's physical and cognitive abilities (potential to work) with actual work performance demonstrated during work simulations or task component testing to determine the level of agreement. Demonstrated physical and cognitive abilities should be close to those demonstrated during performance of work samples.

The analysis in this section is the basis for flowing the evaluation process seamlessly into treatment. Problems in incorrect perception can be addressed and reconciled through consultation and education about the pathophysiological aspects of the injury or disorder and expected course of recovery. Education in techniques such as joint protection, energy conservation, and body mechanics can increase the client's ability to deal with symptoms and limitations. Instruction in movement and stretching exercises can provide further skills for managing symptoms and limitations. Work conditioning can be initiated. Work conditioning using work samples can increase physical abilities, engineer successful performance, help the client to recognize his or her abilities, and assist the client to develop realistic goals.

Step 7: Recommendations

Figure 33-3 incorporates recommendation statements that can be supported from the information gathered in steps 1–4, summarized in step 5, and analyzed in step 6.

The first section of recommendations concerns the client who can return to either full duty or limited or light duty. The referring physician may well use evaluation recommendations to determine the parameters of light duty, so it is important to base the definition of the limits of light duty on the results of test data and to include what the individual can do as well as what he or she cannot do. The recommendations section also addresses clients who are not ready to return to work but who may be brought to work standards with interventions such as education or work conditioning and hardening. Finally, for clients who do not appear to have the potential to return to target-level work or the pre-injury job, the practitioner may recommend pre-vocational testing and vocational exploration of jobs within the client's physical demand capability.

SPECIALIZED OCCUPATIONAL THERAPY PRACTICE

Return-to-work evaluation and therapeutic intervention are complicated yet fascinating and rewarding. Work-oriented therapy, also known as industrial therapy, pushes the envelope of professional practice by demanding the blending of expert skill in assessment and data gathering with clinical reasoning and behavioral treatment. Applying occupational therapy skills and knowledge to the process is equally challenging because of the necessity of using physical and biomechanical knowledge along with cognitive and psychosocial knowledge. One particular benefit of practicing in the return-to-work field is being able to see the results of therapeutic efforts beyond those seen when practicing exclusively within the confines of a clinic.

Although the core of occupational therapy practice can be used as a basis for work rehabilitation and following step-by-step procedures should greatly increase the probability of seamlessly moving clients through the return-to-work process, this is considered to be a practice area that requires specialization. Therapists who specialize in return-to-work rehabilitation must develop observational and communication skills that are clearly understood by the client worker, the supervisor, the insurance representative, and medical professionals. They must become comfortable in the work settings of their clients, just as they are comfortable in clinic settings.

Occupational therapists specializing in this area have the potential to contribute to the growth of empirical evidence regarding outcomes of work-related interventions. The dynamic interplay between evaluation and intervention and the complexity of injured worker characteristics, in part, explain the relatively weak body of evidence regarding return-to-work rehabilitation at present.

Therefore, there is no Evidence Table specific to the Case Example in this chapter.

Return-to-work rehabilitation programs that use a comprehensive multidisciplinary approach provide an improved service to clients, guiding clients through the medical and rehabilitation processes without abandoning

them along the way to fend for themselves in their quest to return to meaningful employment. The needs of both client and employer are addressed, one by one, until the client is a client no more, having once again become a worker and a valued contributing member of the workforce and of society.

CASE EXAMPLE

Mr. B.: Return to Work After Hand Surgery

Occupational Therapy Intervention Process

Clinical Reasoning Process

Objectives

Examples of Therapists Internal Dialogue

Patient Information

Mr. B. is a 37-year-old married civil service employee. He works as an audiovisual support assistant and has a 2-year history of right dominant hand radial wrist pain. Mr. B. was intermittently treated for stenosing tenosynovitis of the first dorsal wrist compartment (de Quervain’s disease) during the previous year. Conservative treatment, including activity limitations, limiting wrist motion with a thermoplastic thumb spica-type splint, superficial heat and cold, deep heat using ultrasound, and trials of transcutaneous and percutaneous corticosteroid medication via phonophoresis, iontophoresis, and injection, did not relieve symptoms to a level allowing Mr. B. to work at full capacity. About 10 weeks prior to referral for FCE, Mr. B. underwent a surgical procedure to release the right first dorsal wrist compartment. The surgery and post-operative recovery period were unremarkable. By post-operative week 10, however, Mr. B. could not return to work because of continued pain in the radial wrist during job-specific tasks. His supervisor referred Mr. B. to occupational health services, and Mr. B. was subsequently referred to occupational therapy for FCE and recommendations for return to duty.

A review of Mr. B.’s medical record and results of an initial interview revealed that he was in reasonable health and, excluding de Quervain’s tendonitis, was without significant pathological medical history. Mr. B. had not been working for a total of 10 weeks, including the post-operative phase of his treatment. He was now back to work and on unofficial light duty status administered by the good graces of his supervisor.

Appreciate the context

“I believe that Mr. B. has received a reasonable standard of treatment for the diagnosed condition. He has progressed through an expected treatment regimen with invasive (surgical) treatment initiated only when conservative had failed.”

“Mr. B. seems to have a good working relationship with his supervisor as evidenced by the allowance of non-medically directed light duty.”

Description of Assessment

Mr. B. gave the therapist a specific listing of job tasks that included infrequent lifting and carrying of 50-pound items and fairly frequent lifting of approximately 25-pound objects. As part of his additional duties, Mr. B. was required to lift with one hand and carry a flagpole base weighing 17 pounds. The lift and carry were usually done with the right wrist slightly flexed and in radial deviation. Aspects of Mr. B.'s job description were verified by review of his written job description, an interview with his supervisor, and on-site observation.

Mr. B. stated that any use of his right hand caused wrist pain. He could perform all basic and instrumental activities of daily living but could not perform his job except for answering the phone and doing paperwork. He stated that it had taken “the doctors” 2 years to figure out his problem and the surgery had not fixed it. When asked about his desired outcome, he replied that he needed either to be trained for another kind of job or receive disability for this work-related injury.

Based on his job demands, the OT decided to use the Valpar 1 (small tools), Valpar 9 (whole-body range of motion), and Valpar 19 (dynamic physical capacity) to sample Mr. B.'s actual work performance. Mr. B. performed at the MTM rate of 95% on the Valpar 1, 90% on the Valpar 9, and 78% on the Valpar 19. Work performance on the Valpar 1 and 9 met competitive work standards; performance on the Valpar 19 was below competitive work standards.

The OT gathered subjective and objective data about Mr. B.'s abilities to examine the possible causes of the discrepancy between his abilities and the test and job demands. The EPIC Hand Functions Sort and the Spinal Function Sort allowed Mr. B. to express his perceptions of his ability to perform common work and leisure tasks. Results of these two sorts revealed that he perceived he could perform 80.5% of the tasks at normal or subnormal rates and intensity (categories A, B, and C); 19.5% of the tasks were rated as unable to perform in his present condition. Many of the tasks in both categories that were reported as not performable did not fall into the work domains usually associated with hand and wrist pain.

Measurement of physical abilities revealed body range of motion, ability to maintain static postures, and hand sensation as within normal range. Three of the seven subtests on the Jebsen-Taylor Hand Function Test were significantly below the mean. Static isometric strength testing using the BTE Work Simulator indicated that the right arm was below the first percentile, while the left arm showed average strength ratings at the 60th percentile. Lifting, pushing, and pulling ability of both arms using the BTE dynamic lift tests was below the first percentile. The general contentment scale score was 62. Cognitive performance under time pressure (decision making test) was at the 45th percentile. Physical endurance using the step test was three standard deviations below the mean for age group.

Planning the evaluation

“My task is to try to discover the reason this medical condition continued to limit Mr. B.'s successful return to work despite successful surgical treatment and hand rehabilitation. I will need to consider his medical history in light of the job demands and try to determine his motivations regarding recovery and return to work. I will need to assess his ability to perform work tasks to see if he is actually “work ready.” If he is not able to perform at job standards, then I will need to assess his physical, cognitive, and behavioral potentials to try to understand the ‘why’ of his work inability.”

Interpret observations

“The severity level of Mr. B.'s symptoms does not seem to match the expected response to surgical treatment and recovery for de Quervain's disease. Mr. B.'s perception of his performance ability does not match the severity of his reported symptoms either but does match measurement of physical and cognitive abilities. Work sample performance was greater than I expected from the evaluation of his physical abilities. Finally, I don't think that the sample work performance fully met target job requirements.”

“In general, I am seeing mismatches between diagnosis and symptoms, symptoms and abilities, and abilities and performance. I believe that this fits a pattern of psychological overlay that limits the application of ability to work performance. Combined with this situation, there is a general physical debilitation from several months of inactivity. The duration of his symptoms and perceived slow post-operative recovery are no doubt influencing symptom intensity and may be limiting his willingness to exert full effort during ability testing. At this time, he does not appear ready or willing to return to full duty.”

Develop intervention hypotheses

“At no time during the evaluation did Mr. B. appear to be exerting himself to the full extent of his ability, as would be evidenced in concentrated facial expression, sweating, or grimacing with effort. At no time did he express pain or appear to be in pain.”

Select an intervention approach

Recommendations

The OT interpreted Mr. B.'s potential for return to work as moderate and recommended that Mr. B. participate in a work rehabilitation program. Skillful application of physical and psychosocial therapeutic interventions would be required to meet the long-term goal of return to full-time work. Mr. B.'s perceptions regarding his ability and performance would probably have to change to restore Mr. B.'s work role competency.

Consider the patient's appraisal of performance

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"Before we started treatment, I thought it would be important to review the results of the test data with Mr. B. and encourage him to explore and explain the variances in the data. Selective retesting (requested by Mr. B. and agreed upon by the therapist) allowed Mr. B. to clarify conflicts in data and demonstrate higher performance levels."

Summary of Short-Term Goals and Progress

In 1 month, Mr. B. will be able to do the following:

1. Use principles of body mechanics, energy conservation, and work simplification to perform work simulations
2. Improve his endurance and work tolerance so that he can use his right hand and wrist during work activities
3. Problem solve with the therapist regarding necessary adaptations to work task and work area

Here is a summary of Mr. B.'s formal work rehabilitation. The therapist provided several lessons on anatomy, pathophysiology, and wound healing, which related to Mr. B.'s surgical procedure. A focal point was that wound healing is a multiple-month process and that some pain during that process is normal.

Based on recommendations from the FCE, the referring physician assigned Mr. B. to an official light-duty status that specified physical demand limitations, with Mr. B. participating in work in accordance with FCE results.

Mr. B. participated in daily 90-minute work conditioning treatment activities with emphasis on regaining physical endurance and progressive use of the right hand and wrist during work activities. A secondary purpose was to arrange for progressive successful work experiences, so Mr. B. would begin to habituate a positive work role.

Mr. B. was provided training in body mechanics, energy conservation, and work simplification, especially as they related to his FCE results and the demands of his job.

A formal work site and job analysis provided the work site supervisor with sufficient information to modify task and pace to match Mr. B.'s abilities.

The occupational therapist fabricated an ergonomic tool adaptation to correct the identified injury-producing task. This modification corrected the extreme hand posture of radial deviation, allowing a more neutral posture. The device was adopted shopwide in Mr. B.'s work area.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

"The plan and goals were devised in conjunction with Mr. B. so as to increase his compliance. The goals specifically avoided the psychosocial issues and focused on tangible items such as knowledge of the healing process, body mechanics, and increasing endurance. I wanted Mr. B. to have the opportunity to change his perceptions about his work ability by experiencing successful activity rather than psychological analysis."

"Analysis of the job tasks indicated that there were tasks that could cause a reoccurrence of wrist symptoms. I felt that it was important that Mr. B. know that the problem wasn't just related to his physical abilities but also to the job demands and that those job demands could be modified by changing the pace of work and by using adapted equipment."

Next Steps

Following 1 month of work conditioning, Mr. B. completed a partial FCE. Testing with the Valpar work samples indicated ability to work at target job standards. Mr. B. subsequently returned to full duty.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"I am pleased as to how Mr. B. responded to intervention. We succeed in helping, in part, because at no time during the evaluation or intervention phases of Mr. B.'s participation in the return-to-work process was there any attempt to confront, catch, or expose his psychological issues. I was careful to remain neutral and request only that he try to explain the variances in the data. Mr. B. was always given "wiggle room" and face-saving avenues in all interactions. Over the course of the rehabilitation, the combination of education, non-judgmental interactions, and successful repetitive work experience encouraged Mr. B. to choose to alter his perceptions of ability and performance and regain work role competency."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Work Rehabilitation

Wrist pain was the dominant feature in Mr. B.'s inability to return to work. At the time of the evaluation, Mr. B. was 10 weeks post surgery from a right first dorsal wrist compartment release and still complaining of significant wrist pain with work-related activities. At that time, Mr. B.'s surgical wound was most probably at the end of the second stage of healing (proliferation) or early in the third stage (scar maturation). Conventional wisdom regarding soft tissue wound healing holds that the third and last phase may continue for 9 months or longer.

How should the therapist interpret Mr. B.'s emphasis on wrist pain? Is it real or enhanced? Should Mr. B. have been given a longer period of protection from work stressors following the surgery? What is a possible consequence of an extended recuperation period?

SUMMARY REVIEW QUESTIONS

1. List four reasons people work and explain how each might affect their ability to return to work.
2. List four reasons older persons choose to work, along with four methods of attracting older workers to continue working.
3. Describe the unique contributions of occupational therapy to the return-to-work process.
4. Describe how job analysis is used in both the evaluation and treatment phases of the return-to-work process.
5. Describe other potential uses for the results gained from a job analysis.
6. Compare and contrast the two types of performance evaluation suggested in a FCE.
7. Using the job of grocery store clerk and scanning, keying, and bagging as the essential tasks, write a brief description of a treatment program based on task components and a description of a treatment program based on work simulation.
8. Use the return-to-work decision pathway to develop an evaluation plan for a 42-year-old diabetic who has intermittent retinal bleeding (loss of sight) and who has recently lost his job as a computer systems analyst.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define leisure in a conceptual and pragmatic fashion.
2. Evaluate the physiological and psychological benefits of engagement in active and quiet leisure.
3. Describe how leisure can be integrated into occupational therapy practice.
4. Identify various leisure assessments and describe how they are used.
5. Discuss barriers and challenges for clients and therapists engaging in leisure activities.

CHAPTER 34

Restoring Competence in Leisure Pursuits

Carolyn Hanson

Glossary

Chat room—Internet site where people communicate with each other in real time during a certain period on specific topics.

Electronic mail (E-mail)—Correspondence with people via the computer; sending a letter electronically.

Free time—Time other than that spent in work or self-care activities.

Horticulture therapy—Gardening as a therapeutic intervention.

Leisure—Freely chosen activity that requires control and commitment. Active leisure involves mental and physical exertion (e.g., wheelchair sports), whereas quiet leisure involves activities, such as reading and crafts, that require less physical effort. Socialization entails contact with others via telecommunication, computer, and/or in person.

Internet surfing—Using the Internet to access information.

Occupational imbalance—Excessive time spent in one area, usually work, at the expense of another, usually leisure. May aggravate health and quality of life.

Recreation—Time that is not spent in work or self-care and may or may not result in observable activity; similar to free time.

Therapeutic recreation—Professional use of recreational activities as primary form of treatment with patients; sometimes called recreational therapy.

Therapeutic recreation specialist—Trained professional who uses recreational activities as a therapeutic intervention with patients.

Activities of daily living (ADL), work, and play/**leisure** are core aspects of occupational therapy intervention that promote self-efficacy and self-esteem. Although information concerning the use of play/leisure in occupational therapy is scarce compared to ADL and work, play/leisure is incorporated into key models that inform practice. In the Occupational Functioning Model, engagement in play/leisure is categorized as a self-enhancement role under the control of and chosen by the individual (Trombly, 2002). Participation in social roles (including that of leisure) is a key concept in the International Classification of Functioning, Disability and Health (Brachtesende, 2005), and the Occupational Therapy Practice Framework (American Occupational Therapy Association [AOTA], 2002) endorses participation in leisure activities as a legitimate goal in occupational therapy treatment.

Terms such as play, leisure, and recreation are often used interchangeably in conversation. Leisure can be viewed as the adult version of play, as many similarities are present. Also, leisure is viewed as a more encompassing concept than play or recreation and is the term most frequently used in the occupational therapy literature. **Recreation** is often used to describe how we occupy time that is not devoted to work or self-care. **Therapeutic recreation specialists**, professionals who are trained to use recreational activities to improve the quality of life for patients, have played a major role in developing leisure programs in medical settings. The profession of **therapeutic recreation (TR)** gained prominence and became more formalized after World War II, as recreational activities were used in the treatment of disabled war veterans. The history of TR is similar to the history of occupational therapy because our profession was launched after working

with veterans from World War I. The distinguishing difference between the two professions is that treatment protocols for TR always use recreational activity as the primary form of treatment. Occupational therapists concentrate on the overall functioning of the individual, of which recreation is one component.

The purpose of this chapter is to review briefly the use of leisure with persons with disabilities; to highlight particular leisure assessments; to recommend the development of specific leisure programs and activities for adults with physical disabilities; to discuss barriers for both therapists and clients; to present a case study regarding the use of leisure in occupational therapy; and to provide leisure resources.

DEFINING LEISURE

A precise definition of leisure is elusive because our attitude toward a given activity shapes our perception of it as leisure or work. For example, sewing may be leisure for one person but considered work by another, which makes differentiation between the two complicated. Work and play are not always dichotomous experiences, however. Sometimes they become blended, and hopefully they are balanced, a central tenet of our profession (Primeau, 1996).

Balancing work and leisure is crucial for mental and physical health. Excessive time spent in work at the expense of leisure or vice versa may lead to **occupational imbalance** (Wilcock, 1998). Occupational imbalance may aggravate health and quality of life, resulting in injury or illness. Engagement in leisure activity is important to a balanced life and satisfaction with life. In fact, Kinney and Coyle

(1992) interviewed 790 adults with physical disabilities and found that leisure satisfaction was the most significant predictor of life satisfaction. To avoid occupational imbalance, leisure opportunities must be available and accessible to all people, including those with disabilities.

Recipients of occupational therapy services have a variety of leisure goals, which are shaped by the type of leisure preferred and the individual's cultural background. Here are some examples:

- Using **free time** in a meaningful way
- Developing or improving socialization skills
- Increasing physical components such as strength, range of motion, coordination, and endurance
- Facilitating emotional adjustment such as self-esteem, confidence, and relaxation
- Improving cognitive capacities such as maintaining attention and following instructions

Types of Leisure

Law et al. (1994) have partitioned leisure into three major categories: active leisure, which consists of recreational activities incorporating physical exertion such as wheelchair sports and travel; quiet leisure, which incorporates activities such as watching television, reading the newspaper, and crafts; and socialization, which consists of visiting and correspondence. Both quiet and active leisure activities appear to contribute to occupational balance, self-esteem, and wellness for persons with disabilities (Fig. 34-1).

Quiet Leisure

According to a British study surveying 54 OT fieldwork students in three practice settings, the most diverse and numerous activities used in treatment were from the leisure area as opposed to work or ADL areas. Using the *Canadian Occupational Performance Measure (COPM)* to

categorize these leisure activities, the students reported that quiet recreational activities were prescribed more than twice as much as active leisure. Examples mentioned by the students included crafts and board games (Drew & Rugg, 2000). Generally, adults with physical disabilities tend to engage in quiet and passive activities (Law, 2002), such as needlecrafts like knitting, crochet, and embroidery.

Another type of quiet leisure, **horticulture therapy (HT)**, refers to gardening for therapeutic reasons. Occupational therapists have traditionally used HT to facilitate leisure and occupational skills in diverse populations. Gardening assists in enhancing the emotional well-being of patients by affirming life and establishing a sense of peace in addition to improving range of motion and endurance (Harnish, 2001). Raised flower boxes enable wheelchair users to employ gardening skills while improving functional, emotional, cognitive, and physical skills. Various tools are designed to allow people with arthritis and upper extremity weakness to garden (Resources 34-1).

Active Leisure

People with chronic musculoskeletal diseases may be afraid to engage in activities that require physical exertion and believe that their leisure options are limited to quiet activities. Occupational therapists may inadvertently contribute to this misperception. Therapists may not be introducing active leisure to clients because exercise recommendation guidelines have not been fully developed for people with physical disabilities. Sports for those with disabilities, however, have been connected to rehabilitation efforts since the 1940s when archery was used as therapy for paraplegic war veterans. Wheelchair sports have continued to expand in variety to encompass wheelchair basketball, tennis, and quad rugby as a few of the better established popular sports (Fig. 34-2).

EFFICACY AND OUTCOMES RESEARCH SPECIFIC TO LEISURE

Figure 34-1 Recreational activity: billiards.

Insufficient physical activity has been identified as the major factor in the deteriorating health of people with disabilities (Coyle & Santiago, 1995). Despite the increased growth of wheelchair sports, many people with disabilities lead sedentary lives. Research data on the activity patterns of those with disabilities are scarce since insufficient evidence is available to determine exactly what activity is best for an adult with a physical disability based on safety, effectiveness, and outcome measures. Utilizing the research on the able-bodied, we know that a properly designed physical activity program includes aerobic, flexibility, and strength components (Durstine et al., 2000). Exercise dosage (intensity, frequency, and duration of the physical activity) needs to be modified for persons with disabilities

RESOURCE 34-1

Organizations, Information, and Equipment for Leisure Pursuits

Sport Organizations

- Disabled Sports USA— Provides sports opportunities to people with disabilities. Listing of summer and winter sports and equipment for these sports; methods to contact existing chapters. <http://www.dsusa.org>
- Adaptive Sports Association— Offers snow skiing instruction and summer sports options to physically and cognitively disabled persons of all ages. <http://www.frontier.net/~asa>
- Mesa Association for the Disabled— Non-profit organization providing sports and recreational opportunities to people with disabilities. Other links to sports organizations. <http://www.geocities.com/HotSprings/5896/>
- National Wheelchair Basketball Association— Provides rules, team registration, divisions of wheelchair basketball, and listing of basketball camps. Additional links. www.nwba.org
- Paralyzed Veterans of America— Research and education, sports and recreation, resources for professionals, publications, and products. Includes

Multiple Sclerosis Center of Excellence site.

<http://www.pva.org/>

- National Disability Sports Alliance— Player classification for sports; information for those with cerebral palsy, traumatic brain injury, and stroke as well as programming for people with muscular dystrophy and multiple sclerosis. <http://www.ndsaonline.org/>
- Wheelchair Sports USA— Qualifying standards and rules for sports. Links to various organizations and sporting events. <http://www.wsusa.org/>

Specific Leisure Activities and Sports/Sport Magazines

- American Horticulture Therapy Association— Membership information, conferences and educational opportunities, publications and information packets, and other HT sites. www.ahta.org/
- Chicago Botanic Gardens— Information on plants and flowers in the Midwest. Hosts a horticultural therapy certificate program. www.chicagobotanic.org
- World travel options focusing on accessible services and

transportation. Includes review of cruise ship accessibility. Excellent source of links to sports and other disability sources.

<http://www.accessable.com/>; <http://www.disabilitytravel.com/>

- Quad rugby home page— History of the sport, rules, U.S. teams, and classification of players. <http://www.quadrugby.com>
- Sled hockey rules and regulations (using a sled instead of ice skates to play hockey). <http://www.sledhockey.org/>
- GatorSport Adult Exploration Camp— Camp designed for adults with physical disabilities. Resources and organizations for a variety of sports and leisure activities. <http://www.gatorsport.net>
- Active Living magazine— Feature articles on living with a disability, health and fitness, listing of amputee support groups, and a variety of links. www.activeliving-magazine.com
- New Mobility magazine— Health, fitness and recreation for people with disabilities. www.newmobility.com

Equipment

- Cycles for the physically challenged: hand cycles, tandem tricycles, tandem bicycles, seats, backrests, footrests, and accessories. <http://www.haverich.com>
- TRS—Prosthetic hands for sports and other leisure activities, such as photography and playing musical instruments. Highlights adult, children, and infant technology. <http://www.oandp.com/trs>
- KY Enterprises— Adaptive recreational equipment and controllers for video games for those with limited use of their hands. <http://www.quadcontrol.com>
- Adaptive recreation and sporting equipment for people with disabilities and the aged. Leisure activities range from crafts and gardening to motorcycling and sailing and skiing. <http://www.achievableconcepts.com.au/>; <http://www.accessstr.com/>; <http://www.spokesnmotion.com> (various programs as well as equipment offered); <http://www.fhnbinc.org> (Fishing has no boundaries— gear and programs for everyone)

to maintain a training effect that does not cause abnormal clinical symptoms/signs or injury. For example, it is recommended that adults with physical disabilities lower the intensity of the exercise but increase the duration and the frequency of the activity (Durstine et al., 2000). Progress would be slower when these parameters are altered.

Persons with Spinal Cord Injury

Researchers surveyed 160 persons with spinal cord injury (SCI) regarding their post-discharge activities (Hoffmann et al., 1995). On the basis of their activity level, respondents

were placed in an active or an inactive group. Over a 1-year period, the active individuals spent, on average, 3.2 days in the hospital compared with 10.7 days for the inactive individuals. Inactive individuals were more than 2.5 times as likely to have pressure sores as the active ones. Results of this study underscore the cost-saving benefits of being physically active.

One hundred forty-three individuals with SCI from 18–55 years of age were surveyed regarding their engagement in physical activity before and after their injury (Wu & Williams, 2000). Individuals who participated in sports such as wheelchair basketball, rugby, and tennis were shown to have less depression, improved social

Figure 34-2 Active leisure: wheelchair basketball.

interaction, and less incidence of rehospitalization. The participants in this study reported that they engaged in sport because it was fun and provided a means to be fit and healthy and a means to interact with a variety of people. Peers with disabilities, as opposed to therapists, were invaluable in introducing newly injured people to wheelchair sports. Wu and Williams emphasized that therapists should take a more active role in educating clients about sports training and leisure activities (see the Case Example about K.J.).

Persons with Joint Replacements

Individuals with modern joint replacement can expect to have their joints last at least 10–15 years. This does not apply to people with hip and knee joint replacements who regularly jog or hike because this type of activity may endanger the integrity of the prosthetic components (Kuster, 2002). Since there are no prospective, randomized studies on physical activities post total joint replacement, the conservative opinions of orthopedic surgeons have guided current recommendations on suitable leisure activities. In general, speed, prior sport experience, and joint impact are factors when considering load or joint stress. High-impact activities requiring speed, such as football, soccer, and handball, are discouraged, whereas low-impact activities, such as swimming, cycling, and walking, are encouraged. Technically demanding sports (snow skiing, mountain biking) are not suggested for those individuals who have never engaged in these activities prior to their joint replacement. The rationale is that the learning curve for technical sports is too demanding on the replaced joints (Kuster, 2002).

Persons with Rheumatoid Arthritis

Minor and Lane (1996) noted that people with rheumatoid arthritis (RA) are prescribed rest and medication for their condition, which is appropriate for the acute condition but

CASE

EXAMPLE

K.J.: Resuming Leisure Activities After Stroke

Occupational Therapy Intervention Process

Patient Information

K.J. is a 42-year-old woman who sustained a left cerebrovascular accident (CVA) resulting in right-sided paresis. She had good return of right upper extremity muscles but lacks coordination. Muscles of right lower extremity are spastic, and K.J. cannot safely ambulate, so she is learning to use a wheelchair. K.J. feels sad and helpless at times, although she is making steady gains in feeding, dressing, and transferring. Previous leisure interests include playing basketball and driving her sports car.

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist's Internal Dialogue

"K.J.'s past lifestyle was active, and she valued mobility. I will bring up leisure adaptations when she is receptive. I'll want to encourage gains in self-care activities and help her see how this success can transfer over into engaging in leisure pursuits. It will be important for me to listen to K.J.'s concerns and fears. I will provide examples of disabled athletes and information on wheelchair sports. Maybe I'll show a video of wheelchair athletes playing basketball."

Patient Information (cont'd)

Develop intervention hypotheses

“I will address attitudinal barriers regarding belief in self by structuring successful ADL sessions. A visit with a wheelchair basketball player may motivate K.J. to work harder and feel better about the rehab process. I will find a car with hand controls since this may also facilitate interest in driving again.”

Select an intervention approach

“I will strengthen K.J.’s upper extremities by having her engage in ADL tasks as well as using light weights and resistive bands. It makes sense to work on gross and fine motor coordination tasks. I will introduce adaptive equipment and sports chairs for wheelchair basketball and discuss driver training programs. I will remediate skills when possible (strength and coordination) and compensate when necessary (wheelchair for mobility and hand controls for driving).”

Reflect on competence

“I will address ADL tasks and equipment, but I may need to refer K.J. to a wheelchair specialist to prescribe a custom chair. Local wheelchair sports camp (offering basketball and other sports) is available in the summer. I will provide contact info and web site addresses regarding sports chairs and the rules of wheelchair basketball. I will identify driver training programs in the area and refer her to a driving specialist.”

Recommendations

I will involve K.J. in treatment by making tasks relevant and meaningful. K.J. has begun to realize that basic ADL skills are needed to be able to leave the house. Leisure activities of playing basketball and driving a sports car may motivate her to make the most of her time in therapy. I will provide information on wheelchair basketball rules and sports chairs or refer to the Internet for specifics. I will contact an athlete with a disability (preferably a wheelchair basketball player) to demonstrate that K.J. can still be active even though she has had a stroke. This athlete (former patient) may most likely have a modified car or van if he is a wheelchair user. Having someone with a disability who is also an athlete will serve as an excellent role model for K.J., who is unsure about her abilities.

Consider the patient’s appraisal of performance

“When K.J. can dress and groom independently (with or without devices), transfer safely from a variety of surfaces, and obtain and maneuver wheelchair efficiently for 30 minutes, she will be able to physically begin playing basketball with a local group of wheelchair players who practice weekly at the community college. I believe that playing basketball will motivate K.J. to gain strength.

Consider what will occur in therapy, how often, and for how long

My therapy sessions will consist of grooming and dressing with adaptive equipment, increasing upper extremity strength by one muscle grade, increasing tolerance to activity, and practicing transfers from all surfaces and planes. I will expose K.J. to driving equipment and sports chairs. I’ll conduct daily therapy sessions for 30 minutes for 2–3 weeks. I want to arrange for a wheelchair basketball athlete to visit K.J. (who may also have car controls on a modified vehicle). Because K.J. is anxious to return to past activities, she is looking forward to meeting the wheelchair player and inspecting a car with hand controls. She is beginning to ask me for info on wheelchair basketball rules and specifics about team practices.”

Ascertain the patient’s endorsement of plan

Summary of Short-Term Goals and Progress

1. Dresses and grooms self independently and uses assistive devices for lower extremity dressing (long-handled shoe horn, sock aid, elastic shoe laces).
2. Upper extremity strength has improved by one grade (from 3/5 to 4/5 on MMT).
3. Transfers from a variety of surfaces and planes. Able to perform car transfers and is practicing placing wheelchair in back of driver’s seat independently.
4. Referred to a driving specialist. Appointment to be made when patient is ready.
5. Wheelchair athlete visited facility and played a one-on-one make-shift game with patient.

Assess the patient’s comprehension

“I want K.J. to understand the importance of doing daily self-care activities to be independent as well as use muscles on a continuous basis. She told me that she feels better about herself now that she can do more and depend less on others.”

Understand what she is doing

“I have seen K.J. improve dramatically; she has been less tearful and more motivated to try activities. The visit with the disabled athlete really helped in introducing her to life in a new but satisfying way. She established an easy rapport with him and shared some of her frustrations and fears. K.J. told her family that she is excited about playing basketball again even though she’s in a wheelchair.”

Summary of Short-Term Goals and Progress (cont'd)

Compare actual to expected performance	“K.J. has met and surpassed all my short-term goals. Although hesitant about using adaptive equipment, she has learned how to use devices well. I think that she’ll continue to work on perfecting her turning skills in a wheelchair (for tight turns in basketball practices). I have noticed that K.J. has had a brighter affect since the visit with the wheelchair athlete. I think she finally realizes that she can still engage in her pre-stroke preferred leisure activities. I know that K.J.’s motivation has made a big difference in her therapy outcomes. K.J. enjoyed her active lifestyle before her stroke and thought that it was all over for her after the CVA. With encouragement and support from the wheelchair athlete and me, she was able to see that life would be slightly different but she could still engage in these favorite activities.”
Know the person	
Appreciate the context	

Next Steps

1. Prepare patient for discharge by providing specifics on driver training programs (in area in case identified specialist is not available), sports equipment, and stroke info.
2. Make sure that patient has all equipment (self-care, customized wheelchair) or knows about what equipment would be most beneficial to obtain (e.g., basketball chair).
3. Encourage patient to contact therapist if any problems or questions arise.

Anticipate present and future patient concerns

“I want to make sure K.J. understands how to manage paralysis as well as signs of stroke. I will review stroke risk factors and how to prevent stroke as well as review info on driver training programs.”

Analyze patient’s comprehension

“I will ask K.J. to identify ways to minimize stroke. I will have her list strategies she will use at home to take care of daily tasks. Then I’ll evaluate her competence in using assistive devices.”

Decide if the patient should continue or discontinue therapy and/or return in the future

“When K.J. is able to take care of all self-care skills and can use her wheelchair effectively, she is ready for discharge. I will make sure that she has all the necessary resources so that she can obtain info or items if she hasn’t been issued them already.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Promotion of Leisure Exploration**

Before her stroke, Ms. K.J. found meaning in her life through engagement in leisure activities. In what ways did providing her with experiences to reengage in interests motivate her to participate in her rehabilitation more fully?

harmful in the chronic state. People with RA often stop engaging in leisure and recreational activities. Unfortunately, inactivity produces the same symptoms as the rheumatoid disease process: muscle weakness, decreased flexibility, fatigue, incoordination, depression, and lowered pain threshold. People with RA who do engage in aerobic exercise may experience a significant reduction in swelling, which is attributed to increased synovial blood flow. Minor and Lane emphasized that vigorous activity is only supported in people with no joint inflammation; otherwise, joint damage may ensue.

Based on clinical experience, Minor and Lane (1996) made the following recommendations for people with chronic arthritic conditions and no active inflammation:

- Warm up prior to vigorous activity.
- Include range-of-motion movement in any physical activity program.
- Engage in low-impact activities.
- Reduce load on joints by swimming, biking, or rowing.
- Wear shoes with good support and use orthotics, if needed biomechanically.

- Avoid overstretching as well as running and climbing stairs (of all locomotor activity, stair climbing produces most stress on hip joints).

Elders

In the Northern Manhattan Stroke study of 1000 elders, those who engaged in physically active leisure were found to have a decreased incidence of ischemic stroke (Sacco et al., 1998). Researchers of this study stressed that physically active leisure be emphasized in stroke prevention campaigns. In addition to a variety of sports, physically active leisure, such as walking, armchair or wheelchair aerobics (exercising the upper extremities while seated), swimming, and weight training (using light weights or machines; using resistive bands), is ideal for increasing endurance and tone in elders. As elders constitute more of our population, it behooves us to create and promote leisure and socialization opportunities in assisted-living facilities and retirement homes.

T'ai Chi is available for elders in many communities. Known as a soft martial art, T'ai Chi involves moving the body slowly and smoothly through its range of motion. Over the past 5 years, there has been an exponential increase in randomized controlled trials on the effects of practicing T'ai Chi. In a meta-analysis performed by Klein and Adams (2004), 17 clinical trial studies were critically reviewed with all showing statistical significance in at least one outcome measure. Typical outcome measures included the positive effects T'ai Chi had on quality of life and physical function. In addition, T'ai Chi was credited in improving pain management and balance. Although T'ai Chi appears to improve balance, it has not been correlated in preventing the incidence of falls in elders. Evidence is available, however, that strength training in elders with chronic conditions reduces the incidence of falls as well as improves ADL independence (Durstine et al., 2000).

Potential Contributions from Occupational Therapy

Occupational therapists value and understand the power of occupation, thus we can facilitate role change in people with physical disabilities and encourage adaptation to a new lifestyle through engagement in leisure (Fig. 34-3). To facilitate role change, we must be knowledgeable about leisure activities appropriate for our patients, discuss leisure interests, and provide opportunities for exploration. Proactively, occupational therapists can create sports programs or provide physically active leisure opportunities for people with disabilities and inform patients about active, quiet, and socialization activities

within their communities. Incorporating leisure activity into our assessment and treatment encourages the individual to take risks and be exposed to activities that they might not have attempted on their own.

ASSESSMENT TOOLS

Before recommending specific leisure activities or using leisure as an intervention, one should assess the patient's interest in leisure. The following are instruments that identify the types of activities that are meaningful to clients. Although this is not an exhaustive list of the leisure assessments available in the fields of occupational therapy and therapeutic recreation, the following sections present some of the better known instruments.

The Canadian Occupational Performance Measure

Designed by occupational therapists, the *Canadian Occupational Performance Measure (COPM)* detects self-perceived change in occupational performance over time (Law et al., 1994). The *COPM* contains three sections: self-care, productivity, and leisure. The leisure section is divided into quiet recreation, such as hobbies, crafts, and reading; active recreation, such as sports, outings, and travel; and socialization, such as visiting, phone calls, and correspondence. Individuals are requested to identify any problems in the three sections and to rate the importance of each activity on a scale of 1 to 10. Then five of the most important problems are identified, and individuals rate their performance and satisfaction with performance on these five problems (Table 34-1).

Figure 34-3 Large-print playing cards typify leisure adaptations available to elders. (Photo by Laurie Manuel.)

Table 34-1. Leisure Activity Chart

Activity Level	Paraplegia, Lower Extremity Amputation ^a	Tetraplegia ^b	Cerebrovascular Accident ^c	Traumatic Brain Injury ^d	Dementia ^e
Sedentary	Cards Board games Puzzles Painting, drawing Music listening Reading Computer activities Video games Needlecrafts Movies	Cards Board games Puzzles Painting, drawing Music listening Reading Computer activities Video games Movies	Cards Board games Puzzles Painting, drawing Music listening Mirror games Needlecrafts Computer activities Photo albums, scrapbooks Movies	Cards Board games Puzzles Painting, art, drawing Music listening Mirror games Needlecrafts Computer activities Photo albums, scrapbooks Movies	Matching games Sequencing games Sing alongs Show and tell
Mild	Archery Bowling Target shooting Billiards Flying Camping Fishing Photography Gardening Travel	Archery Target shooting Fishing Photography Gardening Travel	Paved nature walks Pet therapy Bowling Gardening	Paved nature walks Pet therapy Bowling Gardening	Putt putt Bowling Fishing Parties Gardening
Moderate	Sailing Swimming Weight training Horseback riding Scuba diving Golf Table tennis Dance	Sailing Swimming Weight training Creative movement, dance	Weight training Assisted swimming Creative movement, dance	Weight training Assisted swimming Creative movement, dance	Walking groups Creative movement, dance Weight training Swimming Table tennis
Vigorous	Wheelchair basketball Racing, track Tennis Softball Snow skiing Water skiing Rowing, kayaking Hand cycling Sled hockey	Quad rugby Racing Tennis	Stationary bicycle Rowing, kayaking Other activities depending on degree of paralysis or paresis	Stationary bicycle Rowing, kayaking Other activities depending on degree of paralysis or paresis	Speed walking, jogging Bicycling, tricycling Tennis Rowing

This table provides suggested activities for persons with disabilities. The appropriateness of any activity is greatly influenced by the individual's functional level. Specific adaptive equipment and special assistance may be required.

^a Treatment should emphasize activities that reinforce functional independence and physical fitness.

^b Specialized adaptive equipment is required for most activities. Functional independence is possible in many of these activities with proper planning and practice.

^c Treatment should emphasize visual-perceptual and one-handed activities. Activities that improve range of motion and visual field on the impaired side are valuable.

^d Activities should focus on cognitive challenges and games to strengthen fine and gross motor skills without complex rules or higher order thinking.

^e Activities to improve socialization, cognitive orientation, and recollection are important.

Interest Checklists

Occupational therapists have developed and used many interest checklists. The *Nottingham Leisure Questionnaire*, developed in England for stroke patients, is a 38-item list of activities ranging from watching television to doing sporting activities (Drummond & Walker, 1994). A 5-point scale is used to describe frequency of doing the activity, ranging from regularly (every day) to never. In obtaining test-retest reliability scores, 21 subjects completed the same questionnaire on two occasions within a 2-week period. Using Cohen's kappa coefficient, it was discovered that reliability was excellent (0.75–1.00) and good (0.60–0.74) for 23 of the 38 items and fair (0.40–0.59) for another six items. Inter-rater reliability was tested using the ratings of two occupational therapists and showed excellent agreement on 40 items and good agreement on one item; the total was more than 38 items due to write-ins of other activities not specified in the questionnaire (Drummond & Walker, 1994).

The *Interest Checklist* (Matsutsuyu, 1967) consists of 80 items grouped into the following categories: ADL, manual skills, cultural-educational, physical sports, and social recreation. The rating given to each item ranges from no interest to casual interest to strong interest.

Kautzmann (1984) developed an interest checklist for persons with arthritis that uses similar categories as well as games, organizational activities, and entertainment. This instrument consists of 64 items rated according to their importance, ranging from none to high, and their relevance to the person with arthritis (importance of activity and whether a priority for further development) (Kautzmann, 1984).

Finally, the *Lin Interest Check List (LICL)*, developed in 1991, contains 151 interests and activities within six categories: sports, physical activities, and nature; crafts; games; sociocultural and entertainment activities; community and education; and hobbies and miscellaneous. Level of interest, frequency, and history of participation are to be identified for each item. The *LICL* has high content validity and good test-retest reliability (Lin, 1991).

Occupational Therapy Assessment of Leisure Time

The *Occupational Therapy Assessment of Leisure Time (OTALT)* was based on a review of the leisure literature in occupational therapy and provides a frame of reference specifically for leisure (Soderback & Hammarlund, 1993). The purpose of the *OTALT* is to enable the client to use leisure time more effectively and to improve satisfaction with leisure activities. Using open-ended questions, the therapist interviews the client on the dimensional concepts

of time, intrinsic motivation, and free choice of leisure activity; capability; structure of social and cultural environment; engagement in leisure activity; pleasure for pleasure's sake; goal self-fulfillment, goal diversion, recreation, and relaxation; leisure role; leisure behavior; and influence on his or her leisure role and leisure behavior. Although multiple questions are provided for each dimension, therapists are encouraged to structure the interview the best way they see fit.

Leisure Questionnaires from Therapeutic Recreation

Beard and Ragheb (1980) have developed four leisure questionnaires that are commonly used by therapeutic recreation specialists in medical settings. The *Leisure Satisfaction Measure (LSM)* contains 51 statements about how patients perceive their needs being met through leisure. The *Leisure Attitude Measurement (LAM)* contains 36 items that quantify the patient's attitude in 3 areas: cognitive, affective, and behavioral (Ragheb & Beard, 1982). The *Leisure Interest Measure (LIM)* identifies patients' interest in the following eight domains: physical, outdoor, mechanical, artistic, service, social, cultural, and reading (Beard & Ragheb, 1990). The *Leisure Motivation Scale (LMS)* contains 48 items regarding motivation to engage in leisure activities and reflects four areas: intellectual, social, competence-mastery, and stimulus avoidance (Beard & Ragheb, 1983). As a whole, reliability and validity are good for these measures because items and domains have been analyzed extensively according to the test manuals for the four aforementioned assessments.

Physical Activity Scale for Individuals with Physical Disabilities

A relatively new assessment is the *Physical Activity Scale for Individuals with Physical Disabilities (PASIPD)*. *PASIPD* is recommended for use in studies of activity and health (Washburn et al., 2002). The brief scale consists of 13 items: six leisure time questions, six household questions, and one occupational activity question. Respondents indicate how many days and hours per session they engage in activity.

ARENAS FOR LEISURE INTERVENTION

Occupational therapists help clients resume pre-morbid leisure interests and explore new options. Table 34-1 describes leisure activities that persons with various diag-

noses are typically able to perform. The discussion that follows highlights two other broad areas of leisure intervention: information technology and sports camps.

Information Technology

Computers can provide leisure outlets, such as accessing information on activities and organizations and developing intellectual and creative abilities. Computer activities such as communicating with people in **chat rooms**, using **electronic mail (E-mail)**, **Internet surfing**, and playing video games are popular and accessible. If there is interest, therapists ensure a proper match between the person and the hardware and software. A structured training program is recommended to allow experimentation with appropriate equipment before purchase. With the right match, the computer can provide educational and social opportunities. Although distinctly having many advantages, computers may encourage individuals to be sedentary, remaining indoors and in one position for extended periods. As with any activity, moderation is the key. Frequent breaks and repositioning are crucial.

Sports Camps

Camps have been developed to introduce sports and leisure activities to people with disabilities and to facilitate engagement in physically active leisure and to promote health (Hanson, 1998). Focus may be on one particular sport, such as with wheelchair tennis camp, or an introduction to a variety of sports. Some camps are specialized for individuals with particular diagnoses; others include anyone with a mental or physical disability. Due to the focused nature of the camp and the time invested (camps may last from several days to several weeks), participants have the chance to socialize and learn specific sport skills. In addition, camp participants often learn techniques and obtain tips from each other on daily living skills such as transferring and catheterization. Affiliation with others is a strong motivating factor in promoting leisure activities.

Occupational therapists realize the many benefits of directing a camp, which range from raising the awareness of the able-bodied to providing the disabled with opportunities to explore sport. Additional benefits may include training for students and staff who serve as camp volunteers. Volunteers assist in monitoring participants for heat exhaustion and any untoward effects of exercise (Safety Note 34-1) and assist with coaching. It is possible to conduct research in camps, such as collecting outcome data on clients who are active and inactive and their functional abilities and incidence of secondary medical complications. A wide range of research projects

SAFETY NOTE 34-1

Safety Considerations During Active Leisure

Spinal Cord Injury

Individuals with spinal cord injury (lesion at T6 and above) are at risk for autonomic dysreflexia, which is brought on by being overheated or having an obstructed fecal mass, a kink in a catheter tube, or pain. Symptoms and signs include hypertension, pounding headache, profuse sweating, flushing, pupil constriction, and nasal congestion. **This is a medical emergency.** Obtain medical help while removing restrictive binders or clothing, elevating head, checking leg bag for obstruction, and monitoring blood pressure (Hollar, 1995).

Monitoring during Active Leisure Pursuits

The new participant requires supervision from a therapist, with subsequent monitoring by the participant. Environmental conditions with extreme heat (outdoor wheelchair racing in Florida in July) or cold (snow skiing in Colorado) should be cautiously considered and consistently evaluated for potential ill effects. Terminate activity if safety is questionable.

- Monitor body temperature.
- Monitor sweating and color of skin.
- Observe for signs of fatigue.
- Check for incontinence.
- Encourage skin inspection.
- Encourage fluid intake.
- Recommend pressure relief.
- Evaluate positioning, cushioning, and strapping during activity.
- Consider special training for activity.

will ultimately enable us to promote wellness and sports opportunities for individuals with disabilities. It is not enough to give anecdotal accounts of our successful interventions with clients; we must back up our statements with research data.

BARRIERS TO LEISURE ENGAGEMENT

A number of factors interfere with ensuring that persons with disabilities ultimately can engage in leisure activities that maintain a satisfactory occupational balance. Some factors stem from contemporary trends in occupational therapy; other interfering factors have to do with client access.

Barriers for Therapists

Occupational therapists often have limited time to work with clients and may feel they lack adequate knowledge about leisure activities and resources, but this is an important area for intervention. Asking about leisure interests and desires allows occupational therapists to provide exploratory experiences in a monitored and controlled setting and offer the “just right” challenge to their clients. Moreover, we can follow up by forging relationships with community and recreational centers to encourage continued participation upon discharge (Procedures for Practice 34-1).

Barriers for Clients

Access to recreational and leisure pursuits may be difficult for persons with disabilities. Personal, environmental, and societal factors may all limit leisure participation. Personal factors may include fatigue, pain, depression, comorbid illness, and medical condition.

Activity safety and weather conditions may impact participation as well (Mallinson et al., 2005). Environmental barriers due to poorly designed parking lots and sidewalks without curb cuts may prevent access. A recreational facility may have outdated, inaccessible bathrooms. Transportation to a facility or center may also pose problems, as may the financial requirements for specialized equipment such as wheelchairs designed for specific sports and adapted sports equipment. It may be difficult to find coaches and other personnel who understand the needs of those with disabilities. Despite these possible barriers, it is vital that people with disabilities have support and encouragement from their family and friends to participate in leisure activities that interest them and are within their capabilities.

Attitudinal barriers in our society are often more disabling than personal and environmental barriers. Individuals with disabilities such as tetraplegia and bilateral upper or lower extremity amputations may not believe that they are capable of participating in a variety of activities because of the attitudes of others. Advances in technology and changes in attitudes have allowed people with spinal cord injury and neuromuscular diseases to water ski using a sit ski; people with hand amputations can wind surf using sport-specific prostheses; wheelchair users can rock climb with special equipment; fishermen can fish (Fig. 34-4); and individuals with lower extremity amputations can play tennis (Fig. 34-5). Self-defense classes have been formed for community dwellers with visual impairments (Fig. 34-6). Wheelchairs designed specifically for use on the beach have been developed in addition to numerous models for various sports. With developing technology, opportunities to engage in numerous activities are possible if there is interest and motivation on the part of the therapist and the individual (Fig. 34-7).

In conclusion, human occupation is commonly taken for granted, and its health benefits are not acknowledged (Wilcock, 1998). This is even more pronounced in leisure. Engagement in leisure promotes health and decreases medical costs. Efforts to provide leisure opportunities for adults with disabilities are gradually increasing as we shift from hospital- to community-based treatment. Our renewed interest in community-based intervention supports our efforts to encourage leisure exploration and develop leisure programs for *all* people. Occupational therapists can become more aware of existing leisure opportunities and integrate leisure activities into assessment and treatment. By forming partnerships to develop and promote leisure options in new areas for people with disabilities, we can improve quality of life.

PROCEDURES FOR PRACTICE 34-1

Strategies to Promote Leisure

- Elicit enthusiasm and support from health professionals through in-service education that links leisure, health, and quality of life.
- Elicit support from family and friends.
- Identify interest and enjoyment in activity via leisure assessments and interviewing techniques.
- Evaluate for special needs and assist in choosing an appropriate activity based on current abilities.
- Provide exposure to activity and establish a schedule to learn.
- Set basic goals for activity that can be mastered early, and establish more challenging goals with progress.
- Follow up to evaluate success and to make possible adjustments.
- Create opportunities to reinforce engaging in activity that may be external or internal (longer lasting effect).

Figure 34-6 Self-defense training with the visually impaired.

Figure 34-5 Active leisure: wheelchair tennis.

Figure 34-7 Independent or group activity: hand-crank three-wheeled bicycle.

Evidence Table 34-1

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Leisure rehab vs. IADL treatment	Leisure group: Sports and games, gardening, entertainment. IADL group: Mobility, transfer training, dressing, cooking, bathing.	309 stroke survivors.	Median number of sessions = 10 duration of sessions = 55 minutes.	Randomized, controlled trial. IA1a	No difference between leisure rehab group and IADL group on outcome measures of leisure participation or functional training.	N/A No statistically significant differences.	Logan et al., 2003
Leisure activity, in-home treatment	Leisure activity training vs. leisure discussion about effects of stroke.	40 stroke survivors; mean age = 69.6 years.	60-minute sessions once a week for 5 weeks.	Experimental and control group. IB1a	No. Leisure activities training group did not have significantly increased scores on <i>Katz Adjustment Index</i> . Low dose of therapy is ineffective.	No significant differences between groups on activity level and satisfaction with free-time activity.	Jongbloed & Morgan, 1991

SUMMARY REVIEW QUESTIONS

1. How would you define leisure to a patient?
2. What are the benefits of engaging in quiet leisure? Active leisure? Socialization?
3. How might leisure goals be different for someone with a stroke? Spinal cord injury? Lower extremity amputation?
4. Describe specific ways that occupational therapists can integrate leisure into evaluation and treatment.
5. What kinds of barriers limit leisure introduction and exploration? How would you remove those barriers in your own practice?
6. Describe the ways in which leisure activities enhance health and wellness for all people, including individuals with disabilities.
7. Discuss the advantages and disadvantages of the various types of leisure assessments described in this chapter.
8. What leisure activities would you recommend for people with no lower extremity use? No use of one side of the body? Overall general weakness?

ACKNOWLEDGMENT

We thank Pat Dasler for her case study contribution and Laurie Manuel and Gary Rudolph for the photographs.

CHAPTER 35

Optimizing Personal and Social Adaptation

Jo M. Solet

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Integrate the psychosocial perspective in formulating a rehabilitation program.
2. Consider alternative practice models and value their application within the therapeutic relationship.
3. Place patients within life cycle and family contexts and recognize the implications of this placement for occupations and life roles.
4. Understand the impact of history and course of disability on psychosocial adaptation.
5. Appreciate existential issues raised by illness, injury, and disability; describe ways individuals construct meaning from these experiences.
6. Be alert for psychiatric complications and recognize indications for referral.

Glossary

Adaptation—Alteration or adjustment by which an individual or species improves its condition in relation to its situation or environment.

Attribution—Assigned cause or the process by which an individual assigns cause.

Continuity—The quality of persisting over time in an uninterrupted way.

Coping—Cognitive, emotional, and behavioral efforts individuals make to manage external and internal challenges that tax their ordinary resources.

Existential—Description of a perspective that emphasizes the human condition, including the felt necessity to create meaning in a universe that seems indifferent.

Pathography—Written personal story of illness or injury.

Post-Traumatic Stress Disorder (PTSD)—Lasting psychological response to witnessing or experiencing traumatic events, especially when helpless to prevent them.

Relaxation Response—Inborn human capacity to enter a special physiological state characterized by slowed brain waves, lowered heart and respiratory rates, and lowered blood pressure, which is believed to be health enhancing.

Retribution—That which is given or demanded as repayment or punishment for transgression; penance.

Termination—Period of closing a therapeutic relationship at the end of treatment.

“Man’s origin is dust and his end is dust. He spends his life earning bread. He is a clay vessel, easily broken, like withering grass, a fading flower, a passing shadow, a fugitive cloud, a fleeting breeze, a scattering dust, a vanishing dream.” —*Mazor for Rosh Hashanah and Yom Kippur: A Prayer Book for the Days of Awe* (1972)

The immediate change in physical functioning that an individual undergoes as a result of illness or injury is not alone a sufficient predictor of the capacity to benefit from treatment or of the future quality of life. Although the **adaptation** process may follow a general outline of stages, it is unique for each person and is influenced by the circumstances of onset and course, by the age and place in the life cycle, by the specific personality with characteristic ways of **coping** and finding meaning, and by the availability of family support. This chapter begins by introducing practice models and treatment structures that address the psychosocial perspective and then guides the reader through each of these life contexts, psychological, and social factors, which must be considered in individualizing occupational therapy treatment for physical disabilities (Procedures for Practice 35-1).

PRACTICE MODELS

Each practice model uses its own theoretical framework to interpret clinical observations, guide treatment planning, and promote recovery. Many occupational therapists use

components of more than one of these models; they find this can lead to rich, empathic, creative treatment and fruitful participation with the treatment team.

Psychodynamic Model

The psychodynamic practice model, which had its origin in Freud’s theories, emphasizes the relationship with the therapist as providing a safe, empathic, and consistent environment in which healing may take place (Rowe & MacIsaac, 1991). It considers patients’ internal experiences; conscious and unconscious longings for wholeness, love, and protection; and conflicts about dependency and helplessness. Motivation is conceived as the critical element for successful rehabilitation. The psychodynamic model both values the symbolic nature of activities and mandates that they be selected for intrinsic meaning and relevance for the patient. It advises special care in the ending of treatment, known as **termination**.

Cognitive-Behavioral Model

The cognitive-behavioral practice model focuses therapeutic efforts on the development of patterns of thinking and specific behaviors (Burns, 1990). Therapists who use a cognitive-behavioral model are careful observers and recorders who look for patients’ reactions to their environment and for interactions between their ways of thinking and ways of behaving. These therapists enhance motivation through planned rewarding of successive graded goals, called reinforcement; they shape thoughts and behaviors that indicate successful adaptation and

PROCEDURES FOR PRACTICE 35-1

Attending to Psychosocial Aspects of Physical Disabilities

In attending to the psychosocial aspects of physical disabilities, the occupational therapist works in partnership with patients to develop, reorganize, or restore occupational performance and life roles.

- The occupational therapist serves as a caring, consistent guide in patients' efforts to find meaning and as a resource for knowledge, skills, and competencies in personal, interpersonal, social, and vocational arenas.
- The occupational therapist, through both group and individual treatment, acknowledges and addresses patients' feelings, personal and social histories, and the contexts within which they live and work.
- The occupational therapist identifies strengths, assets, and possibilities with the goal of mobilizing patients' motivation and coping abilities and encouraging full participation in rehabilitation.
- The occupational therapist serves as an interface with patients' families.
- The occupational therapist directs the focus of the treatment team to the recognition and integration of the multiple dimensions of patients' life roles and relates the effect of altered capacities upon these life roles.

extinguish those that are maladaptive. For example, they reinforce treatment adherence and good self-care, such as wearing a splint or taking medication, and work to extinguish health-damaging habits, such as smoking, and socially isolating behaviors, such as aggressive outbursts. Skills for self-regulation, including the **relaxation response** and assertive communication, are also often components of cognitive-behavioral treatment (Basco, 1993).

Model of Human Occupation

Although the cognitive-behavioral and psychodynamic models are also applied by psychologists, social workers, and psychiatrists, the Model of Human Occupation (Kielhofner, 1992) evolved in the context of occupational therapy. This model focuses on engagement in purposeful activities and their central place in the experience of living. The client is recognized as “an occupational being for whom access and participation in meaningful and productive activities is central to health and well-being” (American Occupational Therapy Association [AOTA], 2002, p. 613). Human activities are defined

as multidimensional physical, social, spiritual, and symbolic and as embedded within each individual's specific physical, psychological, and cultural contexts. Evaluation in this model considers strengths and difficulties in occupational behaviors that are necessary to the fulfillment of life roles such as worker, parent, or friend. Treatment seeks to develop, remediate, or enhance performance. Success in occupational performance is inherently organizing to the personality and is importantly related to feelings of mastery, competence, group acceptance, and sense of identity (AOTA, 1995a, 1995b).

Wellness Model

Research over the past decade confirms that we function as integrated organisms, with changes in one bodily system felt throughout. Separation of the mind from the body is increasingly understood to be an academic exercise rather than a true reflection of the functioning of the human organism. For example, mainstream medicine now recognizes important relationships between immune functioning and psychological health first proposed in the early 1980s (Ader, 1981). Psychological states such as depression (Denollet, 1998) and anxiety (Kubzansky et al., 1998) are now routinely assessed as risk factors for heart disease, not just as reactions to it. In addition, the growing preventive perspective in health-care has begun to define the behaviors and habits related to sleep (Edinger & Erwin, 1992), nutrition (Buning, 1999), and exercise (Thoren et al., 1990) that, through multiple inter-connected channels, are likely to extend life and lead to greater physical and psychological well-being. Health behaviors may be difficult to address and psychological well-being may be difficult to achieve in the face of the stresses of physical disability; these often include pain and limited mobility, compromised social integration, and altered sleep and appetite. Specific health-promoting interventions support maintenance of function and reserve capacity of organ systems in those with chronic disabling conditions (Kemp, 2005; Stuifbergen et al., 2004). The occupational therapist works with other members of the clinical team to ensure that treatment addresses a foundation of these health-promoting behaviors that can be integrated into patient routines after discharge (Johnson, 1986).

PRACTICE STRUCTURES

Occupational therapists work with patients individually and in groups. Group participation is often an adjunct to or follow-up for individual treatment.

Individual Treatment

Individual treatment is framed by the therapeutic relationship, the alliance between a patient and therapist, which begins during the evaluation period. As the relationship develops, the occupational therapist learns not only about the physical capacities of the patient, such as strength and range of motion, but also about the type and degree of explanation the patient will find helpful during the course of treatment.

Patients who retain the capacity may wish to tell their story, describing to the occupational therapist how the illness or injury came to pass, their reactions to it, their losses, and their expectations of recovery. Listening attentively to patients' stories, even when their histories are available in some form in the charts, develops trust and tells patients that they are unique and their feelings and experiences are valued. Listening also supplies important information about interaction and communication ability, mood states such as depression or anxiety, ways of coping, and family and cultural contexts. All of these are critical to formulating social and psychological goals as part of intervention planning.

Group Treatment

Group treatment supplies a practice environment for patients' social participation, a therapeutic envelope or safe holding environment that is broader than that of individual treatment. Group treatment interrupts isolation and provides a context within which to identify and solve common problems (Ziegler, 1999). Groups may be organized to address goals related to specific disabilities, to promote mastery of skills, to practice leisure or creative activities, or to facilitate transitions. Although the primary focus of the group may not be to address psychological or social needs, treatment components influence patients' total well-being and provide a shared space for creating dignity, responsibility, meaning, and pleasure (Ziegler, 1999).

As groups evolve beyond parallel participation into interaction among members, patients support and learn from each other and begin to value themselves more highly. A group can also serve as a magnifying glass in which difficult behavior can be brought under the observation of others. When supportive confrontation is used to address and modify this behavior, it improves an individual's opportunities outside the treatment setting. When group discussions deepen, they provide for disclosure of grief and fears, for voicing **existential concerns**, for organizing personal narratives, and for engendering shared hopes (Alonso & Swiller, 1993; Weber, 1993). Occupational therapists include these social and psychological goals in all group planning, treatment, and documentation (Procedures for Practice 35-2).

PROCEDURES FOR PRACTICE 35-2

Planning Group Treatment

Choosing Goals for Group Participation

- Practicing social behaviors
- Following rules and recognizing group needs
- Identifying and solving common problems
- Learning specific skills and activities
- Accepting supportive confrontation and modifying behavior
- Disclosing feelings, existential concerns, and shared hopes
- Enhancing self-esteem through supporting others

Considerations for Choosing Group Members

- Cognitive and social capacities
- Readiness for broader interaction
- Congruence with other members
- Attention and memory
- Psychosis and dangerousness
- Communication ability
- Cultural background
- Energy limits

THE ADAPTATION PROCESS

The substantial variations in psychological and social adaptation to disability are related to the disability's onset and course, the patient's age and place in the life cycle, and individual differences in personality, ways of coping, and attributing meaning to experience.

Stage Theories

Viewing adaptation to disability as a natural course of stages such as shock, denial, anger, depression, and acceptance can be a useful way to conceptualize the psychological reorganization associated with an illness or injury (Miner, 1999). In reality, these stages may flow together and even be reexperienced as new challenges arise (Dewar & Lee, 2000). Clinicians may unconsciously protect themselves from recognizing the realities of living with a disability by assuming that all patients are passing through a natural series of stages that will eventually lead to a satisfying outcome; not all disabled individuals reach a stage of acceptance or well-being.

The four stages from acute injury through rehabilitation described by Morse and O'Brien (1995) constitute a template, summarized next, that may help therapists to recognize changing psychological states and anticipate the needs of their patients. The empirical study of traumatic injury and hospitalization upon which the stages are based demonstrates the special challenges of traumatic onset and offers illustrations of each stage using the language of patients' own recollections.

The first stage, "vigilance: becoming engulfed," encompasses the overwhelming physiological insult in which extraordinary cognitive efforts and heightened senses are recruited to preserve life. During this period immediately following traumatic injury, some patients in the study recalled detachment, a sense of being both observer and participant, as they began to direct the helpers who had arrived to care for them.

The second stage, "disruption: taking time out," begins when the individual relinquishes responsibility to caregivers or becomes unconscious. Patients remembered this part of their experience as a fog in which they were lost between nightmares and intolerable wakefulness. Patients in critical condition could not distinguish reality or focus beyond themselves. They were disoriented, heavily sedated, and not in control of their reactions. Patients at this stage sometimes perceived their caregivers as dangerous and the environment as hostile. Recognizing that during this stage many patients are afraid to be alone, the occupational therapist in the acute setting may facilitate the continuous presence of friends and family members, enlisting their help in orienting the patient.

The third stage, "enduring the self: confronting and regrouping," starts as the patient becomes more aware of his or her surroundings and begins to recognize the extent of the injuries. This is a time of focus on the present in which the conscious decision to carry on and rejoin the world must be made, even as growing awareness intensifies the psychological pain. Patients in the study described fear, panic over complete dependence, dread of painful treatments, and desperate efforts at control. During this stage, patients expressed shock at the loss of their former selves and began to anchor to staff and others for support and assistance. Some expressed an idealized view of their past selves as competent and attractive and their lives before the disablement as fully satisfying. Often they believed full recovery would occur in weeks or months, even with severe spinal cord injuries; the smallest gains were very important.

This is a time when the sensitivity of caregivers is critical for supporting hope. The occupational therapist is careful not to break the patient's denial prematurely because this defense serves as protection against psychologically overwhelming losses. The therapist should also avoid making promises about the expected degree of recovery, since it may later prove to be unattainable, compromising the therapeutic relationship and leaving the

patient feeling cheated, angry, resentful, and depressed (Davidhizer, 1997). An early intervention for certain patients during this stage is training in diaphragmatic breathing to induce the relaxation response. Breathing may provide the first avenue for perceived self-control. In addition, the relaxation response is associated with reduced pain and anxiety (Kabat-Zinn, 1991).

The last stage, "striving to regain the self: merging the old and new reality," is the period of physical and psychological challenge in which active rehabilitation takes place. The goals of active rehabilitation include making sense of the event, getting to know the altered body, and accepting the consequences of the experience, including the possibility of continued dependency. This is the stage at which patients may begin to revise and reformulate expectations. The occupational therapy treatment plan integrates these psychological demands and addresses them in concert with activities of daily living, strengthening, endurance, mobility, and prevocational training. As preparation for the social situations that may be encountered after discharge from the protective rehabilitation environment, treatment anticipates and addresses fears of inadequacy and of rejection by others (Gardner, 1999). Participation in group treatment, including role playing specific situations, such as facing direct questions about the disability or about altered appearance, may be a component of this social preparation.

Onset and Course

The circumstances of onset and the course of the specific disability are important factors influencing the adaptation process.

Early Acquisition

When an individual is born with a disability such as spina bifida or has an injury in early childhood, the sense of self develops continuously with the disability, typically within the framework of the family and often with the support of therapy mandated through school programs. The challenge for the individual born with a disability or disabled in early childhood is to grow into each life stage encountering new developmental challenges—physical, psychological, and social. A disability that does not have major effects in childhood may later become significant as cognitive, emotional, and behavioral demands change and expectations for independence increase (King et al., 1993; Simkins, 1999). A significant proportion of individuals with early disabilities later develop new medical, functional, and support needs as they reach their forties and fifties (Kemp, 2005). Through a series of interviews with adults disabled as children, King et al. (2003) identified three pathways—belonging, doing, and understanding—through which challenges were met at these life

“turning points.” Successful adaptation came through social support, described as feeling “believed in,” through determination and the conviction that challenges could be met, and through realization, by changing beliefs and expectations.

Degenerative Illness

When disability has a slow onset and course, as is the case with degenerative illnesses such as rheumatoid arthritis and multiple sclerosis, increasing disability is expected. Degenerative illnesses are not fully predictable; the course may be slow or rapid, complicating efforts to retain control over the life course. Each loss can feel like a reminder, a new insult. In multiple sclerosis, for example, there may be plateaus or even periods when symptoms remit but later recur (Mairs, 1996). Post-poliomyelitis syndrome (PPS) occurs in a different pattern. Seventy percent of individuals who had a primary polio infection years before, develop new symptoms, such as fatigue, pain, and atrophy, that require them to revisit struggles from their past (Jonsson, Moller, & Grimby, 1998; Kemp, 2005; Kemp & Krause, 1999). Some may stretch to the limits of their physical capacity in an effort to maintain occupations intrinsic to their life roles and to remain connected to valued peer groups. Ideally, as symptoms progress, processes of realization and reorganization bring with them adaptation and an acceptable compromise including altered patterns of daily occupations (Thoren-Jonsson, 2001). Maintenance of a hopeful attitude can be difficult when stabilization or recovery is not anticipated (Lynch, Kroencke, & Denney, 2001). The challenges of degenerative illness are to continually adapt to reorganized life roles, maintain internal resources, and evolve concrete supports in the face of impending decline (Boeije et al., 2002).

Traumatic Injury and Illness of Rapid Onset

Traumatic injuries, such as spinal cord injury, and disease processes with extremely rapid onset, such as Guillain-Barré syndrome, do not allow for psychological preparation. The dramatic nature of the onset may quickly exhaust the reserves of friends and family. Affected individuals may undergo not only an immediate change in ability to function but also a discontinuity in time and sense of self, a loss of personal identity, and a shift in confidence about the world as safe and just (Gardner, 1999; Morse & O’Brien, 1995). The individual is also at risk for development of post-traumatic stress disorder, characterized by hyperarousal and reexperience of the trauma (Herman, 1992). The occupational therapist considers each of these in evaluation and treatment planning.

Disability and the Life Cycle

The developmental tasks of each period of life are biologically, socially, and culturally determined, and they

build upon those that have preceded them (Franz & White, 1985). Therefore, the point in a person’s life at which he or she becomes disabled, together with the trajectory of the disability, help to determine what will be entailed in the long-term process of adaptation (Boeije et al., 2002). The occupational therapist must keep in mind the normal demands of patients’ period of life and consider ways these demands may be met within the context of disability.

Adolescence

Currently, 90% of those born in the United States with a disability live to at least age 20 (Shultz & Liptak, 1998). Along with the usual challenges of young adulthood, including transition from school to work and from parents and family to the broader community, those disabled at birth or in childhood must negotiate the change from child to adult healthcare. This can include losing long-term supportive relationships and taking increased responsibility for care coordination and decision making (Shultz & Liptak, 1998). When adolescents or young adults who have already acquired some independence from their parents become disabled, they may find being thrown back into childhood dependence especially painful. Psychological distress in adult rehabilitation inpatients has been reported to be greatest among these younger patients, decreasing with age (Laatsch & Shahani, 1996).

The emphasis on peer acceptance, athletic ability, physical appearance, and emerging sexuality at this time of life puts the disabled young adult at special risk for rejection and social isolation; development of social competence is an especially important contributor to successful adaptation (King et al., 1993). In addition, as they reach the age that society presumes coincides with independence, young adults no longer qualify for the mandated instruction and therapy available through many public schools. Each year 300,000 of the disabled students who depart the secondary schools in the United States do not go on to live independently; rather, they watch from the sidelines as their peers move on without them (Betz, 1998). Research confirms the need for community-based transition services to support adolescents with disabilities in “building bridges” to the adult world (Stewart et al., 2001).

Adulthood

The developmental tasks of adulthood may include confirming career choice, finding a partner, and parenting children. When an adult at this point in the life cycle becomes disabled, plans and conceptions about the future, which may already have been the focus of substantial effort, require reorganizing. Adapting to disability occurring at this stage may require altering vocational course,

finding different leisure activities, redesigning an intimate partnership, and rebalancing parenting roles, just when some sense of competence and direction has been won (Rena, Moshe, & Abraham, 1996).

Midlife

A disability that strikes in midlife may find the individual at the peak of his or her career mastery and earning capacity, sometimes with adolescent children or aging parents as dependents. Although a history of successful coping with multiple life roles may already exist, this may be a difficult time to accommodate change and reorganize responsibilities (Quigly, 1995). Available resources may be limited, especially when the disabled person is the head of the household. A person disabled at midlife may feel prematurely aged, deprived of the anticipated leisure activity of healthy retirement and the hard-earned relief that follows discharge of career and parenting duties. In addition, marriage or intimate partnership may be at risk, as some non-disabled partners choose to avoid additional demands or to seek a different mate.

Later Life

Disability in later life, even at a time when health decline may be anticipated, threatens the individual's ability to participate in the community in which he or she may have a long history and feel an important identification. Isolation is common. The elderly person may be realistically worried about losing his or her home or may already be institutionalized. He may be concerned about being a financial or care burden to an aging partner or to children who are stressed by their own responsibilities. Anticipated generative roles such as grandparent or mentor, with the opportunity to offer wisdom and nurturance, may be short-circuited. An elderly disabled person may already have lost his social cohort and main supporting relationships. When additional disability is imposed on an already frail system, accommodation can be extremely difficult. Interests and leisure activities developed over a lifetime may have to be abandoned and efforts made to find other satisfactions (Hasselkus, 1991). Furthermore, the devaluation of the elderly in our society, commonly combined with limited financial resources, can compromise care and undermine motivation (Kemp, 1993). The experience of overwhelming loss without hope for the future can lead to despair. Just as she does when working with younger patients, the occupational therapist models a problem-solving mindset with realistic expectations, reconciling capacities and marshalling patient strengths toward sense of fulfillment (Bontje et al., 2004). When remaining time before death is limited, some elderly people feel an urgent need to undertake a life review, drawing together the strands of meaning from their past. The occupational therapist recognizes the privilege of participating in this life review process.

Individual Differences

The occupational therapist will find it helpful to remember that patients come to treatment with formed personalities and ways of interacting with the world that may or may not have been healthy or effective even before the injury or illness. In addition, patients may regress during hospitalization when deprived of their usual occupations, relationships, and areas of control, which served as supports to their personal and cultural identities. Some must deal with lost bowel or bladder function or inability to walk, capacities that they developed as babies. Others may have brain damage, altering memory or the ability to make plans or follow directions. Some patients have been hospitalized following traumatizing events that compromise psychological functioning. Those hospitalized for medical problems are known to suffer more psychiatric illness than their healthy peers, especially depression (Joseph, 2005). Some patients seem easy to treat; others are recalcitrant, uncooperative, or resistant. Some become increasingly demanding, asking for special treatment, breaking rules, and exhausting all efforts (Main, 1957). Some appeal to the therapist's wish to rescue them; others, in their failure to improve, stir feelings of disappointment, shame, and helplessness in the therapist (Groves, 1978; Kahana & Bibring, 1964). It is some comfort for the new occupational therapist to recognize that these are all part of the normal experience of being a clinician. Collegial support and knowledgeable supervision help with the treatment of difficult patients and the management of the therapist's feelings.

Personality

Individual differences in personality, along with variations in cultural context and personal history, contribute to the uniqueness of responses to illness and injury. For example, it is often said about head injury that it is not just the injury but the head that matters. Serious stresses may intensify normal fears, longings, and relationship demands. Ongoing pain, with the attendant loss of sleep and degraded sense of mastery, can further alter functioning. Psychiatric illness and character problems can be exacerbated by threats to physical health and the integrity of the body (Zegans, 1991). Each individual must be treated as unique. The occupational therapist should be prepared to recognize and address distinctions among an array of personality styles (Kahana & Bibring, 1964) and ways of coping (Solet, 1991), some of which are summarized next.

Personality characteristics that have driven an individual's career choices and have helped define his or her relationships may be a mismatch for the requirements of hospitalization. Patients who are orderly, punctual, and conscientious may find that perceived loss of control distorts their self-esteem. They may react by becoming demanding, inflexible, and obstinate; if they become openly

angry, they may feel ashamed and conscience stricken (Kahana & Bibring, 1964). A clinical approach that is congenial, efficient, predictable, and routine and that includes explanations as well as inclusion in decision-making is most reassuring for these individuals. The occupational therapist takes special care in pacing and grading challenges to provide for periods of control and success.

Patients who have a history of loss, helplessness, abuse, or abandonment may react to illness or injury with fears that no one will take care of them. They may make intense, urgent demands, seem over-dependent, easily disappointed, occasionally impulsive, and insatiable in their need for reassurance. Some, feeling unlovable, may expect abandonment and may withdraw rather than cling (Kahana & Bibring, 1964). A successful clinical approach for these individuals includes readiness to give care and to show concern along with limit setting that is consistent and not punitive. Good coordination between team members is especially important for these patients, who sometimes compare team members or complain about one team member to another.

Some individuals act guarded or suspicious when hospitalized (Kahana & Bibring, 1964). These characteristics may be an intensified part of their usual personality but may also arise from the disorientation and lost **continuity** accompanying illness or injury. Neurological and sensory changes can make relatively ordinary events difficult for patients to interpret; a right-hemisphere lesion or even the loss of eyeglasses or a hearing aid may have important ramifications. The occupational therapist is alert to the variety of conditions and diagnoses that may relate to such behavior. Wary, suspicious patients may need continual orienting and often benefit from the reassurance and company of friends or family. The occupational therapist uses language patients can understand to acknowledge their worries, answer questions, and address complaints without arguing or reinforcing false observations. Especially if suspiciousness evolves or becomes more elaborate, the occupational therapist seeks neurological or psychiatric consultation.

Patients may react to their helpless state by asserting their importance, being smug or grandiose, or demanding that only the most esteemed clinicians be involved in their care. When they are deprived of the surroundings, belongings, and roles from which they derive status and identity, patients need confirmation that these are recognized. The occupational therapist uses history taking as a time to begin offering this recognition and acknowledgment. Repeatedly feeling forced to confront their impairments can provoke some patients to make compensatory claims of superiority. The therapist resists the urge to put these difficult patients in their place because such expressions of entitlement are often a sign of deep vulnerability (Groves, 1978). The occupational therapist is hopeful and points out areas of strength and strategies for ongoing effort (Keith, 1999).

Some patients seem to reject caregivers' efforts to reduce their suffering. They may appear self-sacrificing, have a history of bad luck, or even seem to revel in their misery (Kahana & Bibring, 1965). When patients do not seem to wish to recover, their symptoms may be serving a hidden purpose, such as penance or atonement. The occupational therapist may have to refer a patient who appears excessively guilt ridden for psychotherapy. Alternatively, illness or injury sometimes returns isolated or lonely people to a caring social environment from which they do not wish to be separated by recovery. Treatment planning should recognize needs for social stimulation and companionship. In collaboration with the patient, the occupational therapist organizes in advance for appropriate social contact after discharge.

Ways of Coping

Coping can be defined broadly as the cognitive, emotional, and behavioral efforts individuals make to manage external and internal challenges that tax their ordinary resources. Coping includes what people think, feel, and do in response to stress. Ways of coping can be understood as organized between three sets of poles: seeking versus withdrawing from social connections; seeking versus avoiding information and control; and expressing or repressing emotional reactions. Coping efforts contribute to health because they help define capacity for perceiving and reporting symptoms, for decision making, for complying with treatment demands, and for accepting comforting and support, all of which affect physiological processes and the sense of well-being (Stone & Porter, 1995).

Although individuals may have characteristic ways of coping that align with their personalities, the demands of any particular situation, including the length of time the challenge has lasted, are also important in determining ways of coping. For example, the period before surgery that provides the opportunity for active coping by seeking information and making decisions is very different from the post-surgical period, in which little control can be exercised and detachment or distraction may be most useful. In parallel fashion, coping with an acute health crisis may draw on different coping capacities from a patient and family than those required by an ongoing disability. As coping requirements change or awareness increases, the patient and family may reappraise their situation, recognizing new possibilities and drawing on additional resources.

In the clinical setting, ways of coping are assessed by self-report questionnaires, clinical observation checklists, and interviewing (Lazarus & Folkman, 1984; Solet, 1991; Nochi, 2000). As part of evaluation, the occupational therapist asks the patient and family members about prior challenges or crises and the coping efforts that were made. Treatment then draws on successful coping such as securing arrangements for continued religious participation during

hospitalization when this has proven to be an important source of strength in the past (Larson & Milano, 1995). Treatment may also include active teaching to enlarge the patient's universe of coping alternatives. Examples include keeping a journal to encourage emotional expression (Pennebaker, 1995); participating in a specialized group to enhance social connection (Weber, 1993); gaining companionship, comfort, or direct help from a pet or animal assistant (Gal, 1999); practicing the relaxation response to decrease perceived pain and anxiety (Kabat-Zinn, 1991); and learning assertive communication to feel more confident asking questions, identifying goals, and collaborating in treatment decisions.

No particular way of coping is in itself good or bad; it must suit the individual in his specific circumstances. For example, coping by wishful thinking, denial, and withdrawal may serve important protective purposes early after an injury, when recognition of the extent of losses could overwhelm the individual. Recognizing that successful adaptation can involve cycles of approach and avoidance, the occupational therapist is cautious about fracturing patients' protective ways of coping; she is aware of possible reactions including anxiety, shame, and resentment (Martz, 2004; Thoren-Jonsson, 2001). An avoidant coping strategy when it lasts over an extended period can prevent full participation in treatment and limit needed emotional expression, knowledge acquisition, and social reintegration. Lasting avoidance, denial, or withdrawal may indicate overwhelming fears, guilt, or self-loathing or signal cognitive impairments and is cause for seeking psychiatric or neurological consultation.

THE SEARCH FOR MEANING

Occupational therapists are confronted daily with illness and injury. We grapple with ways to continually affirm our profession and to make sense of the suffering we witness (Peloquin, 2002). Our patients, facing these same questions of meaning, look to us not just for help in physical recovery but for our vision to guide them in interpreting their experiences. Their confrontation with the fragile nature of life may bring their deepest longings to the surface; they wish for vanished loved ones, protection, belonging, vigor, significance, and relief.

Existential Questions

“What is really important for a life to be worth living? What is it others will say about me when I die? What will my life say? Those are the kinds of questions my brain was filled with after the accident. It's no wonder I couldn't focus on details when the questions of life were asking to be answered.” (Lowenstein, 1999)

Our patients ask us to recognize and acknowledge these questions and longings. They offer us the privilege of helping them to reclaim personal continuity and to create meaningful life narratives, which integrate their experiences of illness or injury with changing self-concepts (Boeije et al., 2002; Helfrich, Kielhofner, & Mattingly, 1994; Nochi, 2000). They challenge us to seek and reinforce their motivation to heal and to nurture their well-being at critical turning points and in the face of what for some will be lasting physical compromise (Brendel et al., 2001; King et al., 2003). They need us to join with them in celebrating the presence of interior life, personal connection, and the mystery of existence despite ambiguity, painful loss, and the final certainty of death (Fig. 35-1).

Attributions

Meaning and belief systems are fundamentally woven into the human mind and society. The way we make sense of experience not only describes but actually affects our reality (Kleinman, 1988; Peloquin, 2002). Most people with an illness, injury, or traumatic life event eventually ask “Why

Figure 35-1 The Self in danger. (Pen and ink by Margaret Rusciano Tolksdorf, Pelham, NY.) See www.virtualeasel.com.

Table 35-1. Patient Attributions

Type of Attribution	Description of Individual and Situation	Quotation Showing Explanation for Illness or Injury
Retribution	Salesman drinking and driving, now a paraplegic following an accident	“I don’t believe God could be persuaded to forgive me for killing a child in the accident.”
Faith	Computer expert, mother, hit by an electronic garage door when dropping off her car for repair	“I have learned to live one level higher. Life requires a leap of faith when you no longer understand or validate in the same way. The intuitive comes to the forefront; before it stood behind.”
Personal responsibility	Poet, mother, rode as a passenger on an icy day in a car she knew to be in poor repair	“I never thought about what I was doing then, but since my injury I think about that choice all the time.”
Victimization	College student, former swim champ, attacked when skinny dipping by hoods offended by his exposure in front of their girlfriends	“I am afraid the possibilities for my future are diminished. It is so hard to see friends and younger sibs going through school, finishing, moving on with their lives. I am NOT an evil guy; what is this for? When this happened, I was sure I had died and gone to purgatory.”
Acceptance	Biochemist hit by a bus crossing the street	“Is there any reason the owl eats the bunny and not the other way around? Injury and death are part of all nature. I am different now: I have lost my arrogance.”
Chance	Engaged woman following an accident that disabled her and killed her boyfriend	“People like to take credit for the good things and blame others for the bad things, but really, an awful lot happens by chance. The important thing is to be ready for the good things—and I am ready.”

me?” and try to make an **attribution** about or create an explanation for their experience. Clinical research has demonstrated the range and character of these attributions (Solet, 1991) (Table 35-1). Dangoor and Florian (1994) have established sense of coherence, a measure of ability to construct meaning from experience, as more important than actual degree of disability in contributing to well-being among chronically disabled women.

Retribution

Some individuals see their illness or injury as a punishment, penance, or **retribution**. As children we are taught that when we break rules, we will be punished; thus, it may be natural on some deep level to believe that a painful event indicates badness or unworthiness deserving punishment. In actuality, no realistic connection may be present between patients’ behavior and their injuries, or they may be accurate in describing a connection, such as a history of drunk driving or unsafe sexual practices. In either case, attributions of retribution can render individuals immobilized by guilt and shame, unable to seek information or emotional support or to participate actively in their own recovery (Solet, 1991). They may require support to forgive themselves; some also need to focus on altering their dangerous behaviors. The opportunity to be heard and the reality of being accepted by the occupational therapist can help them begin to value

themselves, feel worthy of treatment, and invest in the future.

Victimization

Again, either through a realistic analysis or based on deep feelings alone, some patients see themselves as victims. Especially when facts support the construction, such as in an assault or an accident from a faulty product, the occupational therapist validates the attribution and acknowledges the loss of trust that accompanies such an experience. The risk for patients who make attributions of victimization is that they may take on the role of victim more broadly as a lasting self-characterization. They may be unable, because of fear, anger, or sense of helplessness, to see the world as a place that is safe to rejoin. The occupational therapist helps by showing the realistic boundaries of these beliefs and by being a reliable and trustworthy caregiver.

Chance

Chance or luck is sometimes invoked by patients to explain illness or injury. Such an arbitrary universe as these patients perceive may be seen as dangerous and out of control, a form of impersonal victimization. Alternatively, an arbitrary universe may be benign and open to individual willingness to accept not just loss but opportunity. The occupational therapist encourages patients who endorse chance to see hopeful possibilities.

Faith

Many patients demonstrate faith that their experience of illness or injury will, in the end, have meaning and purpose. These attributions based on faith need not exist only within the context of formal religion to engender optimism and encourage adaptation (Benson, 1995). They may convey a deep conviction that there is a plan for the universe in which good will ultimately prevail, a plan beyond ordinary human understanding (Rankin, 1985). Attributions of faith may be especially poignant for those who are isolated and have few relationships because of their disability, allowing them to feel deeply valued beyond their difficult individual circumstances (Solet, 1991). Recent research points to the healing nature of deep self-disclosure such as may take place in prayer (Pennebaker, 1995). Occupational therapists are open to hearing about patients' spiritual lives and practices as elements of culture and daily life that can support healing.

Narratives and Metaphors

Patients want to tell their stories, and they need to be heard. The process of constructing and sharing a narrative of illness or injury organizes experience, shapes continuing perceptions, and breaks isolation. Through narrative, patients connect the present to the past, forming continuity in their lives and identities (Spencer et al., 1995; Boeije et al., 2002).

Increasingly patients are turning to the Internet, especially to disease- or disability-specific chat groups to exchange narratives of their experiences and to offer support and treatment information. Recent analyses of some of these virtual communities has shown the information offered can be surprisingly accurate and sophisticated, with patients helping each other and family members to be more aware of treatment possibilities and more ready to be active partners in decision making (Hoch & Ferguson, 2005). Occupational therapists may help patients identify virtual communities connected to reputable sources and may serve as translators and interpreters when relevant material is complicated.

Occupational therapists use specific structures to collaborate with patients in interpreting their lives, including life charts, assisted autobiographies, and occupational storytelling (Frank, 1996). Through attentive listening, occupational therapists not only validate patients' experiences but also enhance their own clinical reasoning, tailoring empathic language and treatment activities to match patients' individual needs and motivations (Kautzman, 1992).

A common characteristic of these narratives is the use of certain metaphors that connect individuals' experiences to universal themes of culture and help to place their

suffering in meaningful contexts. Hawkins (1993) described five metaphors that frequently serve as frames for interpreting illness or injury; each can be understood as coordinating with role expectations for the therapist and with specific risks for patient adaptation (Solet, 1994).

Rebirth

The metaphor of rebirth is a central religious and mythological theme. Through it, illness, injury, and the closeness of death are seen as transformative and regenerative (Hawkins, 1993). It is common for patients to reevaluate their lives around their illness or injury and to describe a profound altering of values and priorities. The old self dies and a new and different self is born through suffering. The change brought about through this confrontation can be experienced like a religious conversion; wisdom and spiritual renewal can become the gift and compensation for suffering. Part of the role of the occupational therapist is to bear witness to these changes. Sometimes the illness is equated with a life of sinfulness: drugs, unsafe sex, smoking, bad diet, and aggressive treatment of others. The patient may wish the therapist to serve in a priest's role, to grant absolution and confirm worthiness for care. The risk to patients using this metaphor is its association with attributions of deserved punishment, described earlier. Patients may become passive in penance, feel underserving of health, and be unable to mobilize for the rigors of treatment (Solet, 1991).

Battle

The metaphor of battle is very common and is the most congruent with the Western system of medical care (Hawkins, 1993); it is frequently used by clinicians and politicians. We hear often of "the war on cancer" and "the war on drugs." In this metaphor, the patient becomes the hero doing battle with a monstrous foe; the therapist is the ally in "fighting disease." The illness or disease is seen as exogenous, from the outside, and a crusade is launched to attack it. This metaphor combines aggression with social optimism and dignifies the active, courageous stance known colloquially as "fighting spirit" (Walker, 1999). Although some patients may relate easily to this aggressive position, others, by personality or beliefs, are a poor match and find the metaphor disturbing. Furthermore, the battle metaphor of attack on the invader may not be fully suitable for some illnesses. Cancer cells are, in fact, not an external threat, like plague or tuberculosis, but parts of the self turned unruly. Pain can also be difficult to conceptualize as an invading adversary with which to do battle, since it may be experienced as from within by the patient. In treating rheumatoid arthritis and other autoimmune diseases, the goal is quite the contrary: to help the patient's body to stop fighting itself.

Athlete

Somewhat related to the battle metaphor is that of the athlete. The patient deals with illness as a game or sport in which the central issues are courage, stamina, and endurance (Hawkins, 1993). The therapist is the coach; the patient is in training; new skills are learned through practice. This is particularly effective for individuals who have a history of sports participation or are sports fans. The risk to patients with this metaphor is in its implications regarding performance. There is an audience in sports; there is competition for who is best; there are rules and standards that must be followed, and trespass may lead to shame, as if the game were lost. The requirement to be courageous and strong throughout the ordeal so as not to lose or disappoint may prevent real communion with others over the reality of suffering and the inevitability of death. It may be helpful to emphasize that patients, caregivers, and family are all part of the team.

Journey

Illness as journey is a common metaphor found in narratives in which the patient travels to the kingdom of the sick, returning with the gift of wisdom. Susan Sontag (1988), writing about cancer, describes the disease as granting “a more onerous citizenship” (p. 3). Within this metaphor, the therapist serves as a guide, having accompanied others in this same land. The journey of illness or injury may be a rite of passage involving degradation, humiliation, and depersonalization (Hawkins, 1993). This metaphor fits especially well with the loss of vision (Hull, 1990) or with traumatic brain injury and the period of rehabilitation (Keith, 1999; Lowenstein, 1999). The individual leaves the world of ordinary sensations and consciousness and finds that expectations must be redefined; roles and relationships are changed, and activities that were once taken for granted must be relearned or abandoned (Pasciewicz, 1987). One risk to patients with the journey metaphor is that it can lead to a perception of exile; injury, illness, and disability can be isolating, sometimes permanently. In a real sense, withdrawal from society may be the result when the individual cannot cope with alterations in appearance, personality, mastery, or ability to communicate. Historically, exile has been forced when behavior or appearances ranged far from society’s accepted norms or when the spread of infectious diseases threatened others, as with AIDS or leprosy. Group participation with other “travelers” may help limit isolation.

Nature

In contrast to the four metaphors described earlier, the New Age metaphor places faith in the healing powers of nature, especially the efficacy of positive emotions. This metaphor may be construed as a reaction to aspects of modern

medical care, which has been faulted for defining the patient as the passive focus of technology, subject to external treatment forces, rather than as a vessel filled with self-healing resources. The therapist’s role here is as caring partner. The disease or injury may be described as presenting an opportunity to alter values or to recognize and integrate hidden powers of the self. The risk to patients is the sense of bafflement, failure, and shame they may feel if conscientious efforts are not rewarded with health. This construction emphasizes the requirement to be “positive,” and individuals may develop guilt about their own normal feelings of grief, fear, or anger, believing that they are hindering their own recovery. They may be deprived of legitimate ownership of authentic feelings. This metaphor works best when the occupational therapist demonstrates belief in the goodness of the full spectrum of human feelings and in the whole cycle of nature, which includes not only spring but also winter.

Pathography

Occupational therapists may prepare themselves to respond with empathy to their patients’ narratives by exploring published accounts of illness or injury known as **pathographies** (see supplemental reading list). Authors have many motivations, including trying to find meaning in their own experiences, consolidating changed identities, breaking isolation, validating others, offering hope or counsel, exposing inhumane care, and giving specific information about treatment alternatives. Some pathographies are inspiring tales of recovery or of transcendence over pain or disability (Hull, 1990), even over imminent death (Bauby, 1997; Broyard, 1992). Some are offered by family members as a testimonial to a loved one or a journal of the shared ordeal (Wiltshire, 1994); others aim to elevate natural healing capacities and transform our health care system (Barasch, 1993). Numerous popular films also depict disabled characters and their struggles and ways of coping. Such films, even when their stories are fictional, help us understand views of disability in our culture. For some patients or their families, the occupational therapist selects readings or films as an educational component of treatment.

THE HEALING CONTEXT

Although health care policy-makers assume families will provide a healing context for their disabled members, very little formal structure is in place to support their efforts (Levine, 1999). As our population ages and as advances in medical technology extend lives, the burden on family members is expected to grow. Idealizing or romanticizing the position of disabled individuals and their families avoids confronting the real deprivations many suffer

and camouflages important ethical questions regarding responsibility for the allocation of societal resources (Saetersdal, 1997).

Family Care Giving

In the United States, more than 25 million unpaid informal caregivers provide an estimated \$196 billion worth of labor; the overwhelming majority of these caregivers are family members (Rolland, 1993). More than 400,000 children under 11 years old and more than 1 million U.S. adolescents provide care for an adult family member with a chronic illness (*Boston Globe*, 2005). Evidence as to stress on partners and family members suggests some carry a level of responsibility that can damage their own health and well-being.

Loss of disabled persons' income often places these families in financial jeopardy. Dangoor and Florian (1994) identify socioeconomic status as one of the criteria that are more important than actual degree of disability in contributing to adaptation among chronically disabled women. In 1997, one third of adults with disabilities lived in households with an annual income less than \$15,000, compared with only 12% of the non-disabled; Americans with disabilities spent four times as much on medical care, services, and equipment as their non-disabled counterparts (Kilborn, 1999).

Family Reorganization and Identity

In the United States, 6% of adults, 15.5 million people, are unable to perform a major life activity. Half a million adults with developmental disabilities are living with parents over age 65. Families with a newly disabled member or a disabled member who is losing functional capacity through the common pattern of accelerated aging, experience grief, increased demands, and changes in routines, roles, structures, and expectations, often on top of increased financial burdens (Lynch, Kaplan, & Shema, 1997; Kemp, 2005). Additional stresses may exacerbate preexisting marital discord or substance abuse. Such problems are reflected in the divorce rate, which is higher than normal among couples when one spouse is disabled, with men leaving their wives more frequently than the reverse (Kilborn, 1999). Adaptation requires learning and concrete planning as well as transformation within the family unit parallel to that of the disabled person. Partners and families struggle to construct ways of coping with specific problems and ways to forge new identities among themselves and within their communities.

Engaging with Family Members

The occupational therapist, often working in concert with a nurse or social worker, may be the major preparatory

interface with the formal health care system for a family planning to receive a disabled member at home. To initiate collaboration with the family, the occupational therapist assesses readiness and does not force premature instruction that could frighten, anger, or alienate the family (Levine, 1999). In all contacts with the family, the occupational therapist remains aware of and respects the rights and wishes of the patient with regard to privacy and confidentiality (Procedures for Practice 35-3).

Important differences between what occupational therapists and family members value as treatment and support are common (Humphrey, Gonzalez, & Taylor,

PROCEDURES FOR PRACTICE 35-3

Engaging with Family Members

Goals of Interaction with Patients' Families

- Seeking information about family medical and social history
- Offering specific information about disability and treatment
- Collaborating and fostering inclusion in decision making
- Validating feelings
- Acknowledging experiences
- Fostering hope and successful coping
- Guiding reconnection with patient
- Instructing in issues of patient care and safety, including home visits and use of assistive devices
- Facilitating use of community resources, including barrier-free opportunities and support groups

Considering the Family Context

Try to answer the following questions when assessing a patient's family context.

- Where is the patient in the life cycle, and what have been the patient's roles and responsibilities?
- How have the roles, responsibilities, and expectations of family members been altered?
- Is there lost income and/or added expense?
- What family problems may be exacerbated by this crisis?
- How has the family coped with crises in the past?
- How will the likely course of the disability affect the family?
- How is the family making sense of the experience? Do they have a specific cultural perspective or religious belief?
- To what communities do they belong that may be a source of help or strength?
- Do they need referral for family counseling?

1992). Hasselkus (1991, 1994) found that occupational therapists focused treatment planning on disabled individuals' level of independence; family members, however, were more likely to express concern that their returning member be safely cared for with a sense of maintained identity. Ongoing life satisfaction rather than level of self-care is becoming recognized as the most valuable measure of rehabilitation success and one that may be more congruent with patient and family needs and expectations (Levine, 1987).

If the patient is to be discharged home, the occupational therapist typically accompanies the patient on a pre-discharge visit to check for safety and to organize installation of assistive devices. This is a good time to facilitate social participation by helping the patient (and family) become aware of community resources and barrier-free opportunities. Community connection is especially important to those living independently with a disability. The occupational therapist also connects the patient and family with specific support and advocacy groups through which they may share problem-solving, feel a sense of camaraderie, and be empowered if they choose to work to improve the system for themselves and others.

Some patients are discharged to separate quarters or to institutional settings. Discharge of a family member to a long-term care facility involves wrenching decisions and can feel like abandonment, especially in families whose traditional culture and values include loyalty and strong bonds among members (Banks, 2003; Turner & Alston, 1994). This is true even when it seems clear to the clinical community that taking the individual home would seriously overtake the resources of the family. The occupational therapist acknowledges these feelings and helps organize ways to maintain family relationships even when the disabled member will not be living at home.

In certain cases, family stress may be extreme, communication difficult, and reactions overwhelming. Family members may disagree over what care is appropriate for individuals who are not legally competent to make decisions about their own care. This happened in the case of Terry Schiavo (Quill, 2005), in which national attention was drawn to the court battles between her husband and parents over whether this brain-damaged woman was responsive and whether her condition warranted continuing life-sustaining interventions.

In non-traditional family constructions and partnerships, additional stresses may result from lack of legal recognition of couple and parenting commitments with the associated rights to direct and oversee care and to health insurance coverage. Currently in the United States, only Massachusetts legally recognizes marriage between individuals of the same gender, with civil unions recognized in Vermont, New Hampshire, and Connecticut (October 1, 2005) and same-gender domestic partnership legal in California (www.glad.org; www.lamdalegal.org).

The laws here are evolving, with issues of cross recognition and transportability of rights across states still to be further defined. The 1996 Federal Defense of Marriage Act prevents same-gender couples from receiving certain Federal protections and tax benefits afforded traditional couples. Gay marriage is legally recognized throughout Canada.

Although most people fail to prepare legally for sudden illness or disability, when decline can be anticipated, as with degenerative illness, individual wishes can be discussed, powers of attorney can be organized, and health care proxies completed. Some hospitals make a practice of making forms and information available (Dr. Andrea Patenaude, personal communication, Dana-Farber Cancer Center, Boston, MA). Social workers, psychologists, and attorneys specifically trained for assisting couples and families may serve a critical role in marshaling resources, modeling expression and compassion, and guiding direction. When an illness has been shown to have possible genetic links, additional questions arise, including whether other family members should undertake testing and what the implications might be for pregnancy. Specially trained genetic counselors can clarify the ethics and science, supporting informed decision making (Patenaude, 2005). The occupational therapist is alert to the possible necessity of specialized referrals (Procedures for Practice 35-3).

Partnership and Sexuality

The unique role of occupational therapists in addressing both activity and meaning places them in an ideal position to include sexual well-being among treatment goals. Sexual well-being correlates with adjustment and satisfaction in other areas of life and is an important component of the partnership bond (Woods, 1984). As one of the activities of daily living, sexual activity merits an accepting, problem-solving focus.

To acknowledge and accept the sexual identity of their patients, occupational therapists become aware of their own beliefs and values and suspend judgment when these values differ from those of their patients. Even when the primary sexual counseling is done by another team member, such as a nurse, occupational therapists are prepared to recognize intimate needs within different stages of the life cycle and sexual orientations. They are prepared to initiate discussion of sexual activity, including birth control and safe practices, without being seductive or eroding clinically appropriate boundaries. Embarrassment or a sense of undesirability may prevent patients from raising sexual concerns themselves. The occupational therapist acquires sufficient medical and psychological background related to disabilities and sexuality to anticipate patients' needs and questions and to organize appropriate referrals.

Desire, sexual responsiveness, sensory channels, and mobility may be altered by disability (Basson, 1998; Hulter & Lundberg, 1995). The occupational therapist explicitly helps the disabled person by encouraging him or her to reconceptualize sexuality and sexual activity more broadly and to explore new possibilities for sexual expression. When the disabled individual has a consistent sexual partner, the therapist may offer the opportunity to include him or her in teaching or treatment sessions. A satisfying sexual relationship is learned; it is based on more than simple instinct or appetite and does not have to be unplanned or spontaneous to be fulfilling (Woods, 1984). The disabled person and his or her sexual partner may learn to adapt to periods of fatigue, continence timing, or requirements for special positioning.

Fears may contribute to the disabled person's hesitancy about sexual activity. Fear of rejection may be based on altered appearance or on perceptions of the social acceptance of the needs and desires of disabled people. These fears can discourage efforts to establish or maintain relationships. In some cases, especially when this coincides with depression or social isolation, referral for psychotherapy can be valuable. Patients with certain diagnoses may have been warned about the danger of overexertion and may harbor fears about heart attacks or strokes. Some patients fear being injured by sexual activity or anticipate increases in their pain. Here a physician knowledgeable in sexual medicine can be a critical resource. Informed and sensitive medical management, sometimes including medications, can help disabled individuals successfully address problems and claim their sexual selves.

In some settings, disabled individuals are vulnerable to sexual exploitation or abuse, especially when cognitive or verbal limitations prevent them from reporting their experiences or serving as reliable witnesses in a court of law. A significant fear of parents of disabled young adults relates to their children's vulnerability in this regard (Hallum & Krumholtz, 1993). Occupational therapists who work with such patients are aware and alert to these possibilities and meet legal and ethical requirements for reporting concerns.

COMPLICATING FACTORS

Substance abuse, pain, depression, and post-traumatic stress disorder are common complications of illness and injury that hinder adaptation and mandate specific treatments.

Substance Abuse

Illicit drug use in our society is highest among those who are marginalized and culturally or economically

disenfranchised (Li & Ford, 1998; Moore & Li, 1994), among whom are many disabled individuals. Social isolation, losses producing painful feeling states, and traumatic experiences related to injury confer special vulnerability and suggest reasons disabled individuals are at higher than normal risk for substance abuse. Consistent with this observation, disabled vocational rehabilitation clients were shown to have higher use of illicit drugs in all categories, including crack cocaine and heroin, than the general public (Moore & Li, 1998).

Alcohol and drug use have been implicated not just as reactions to but also as causative agents in disability, most notably in relation to auto accidents. Research evidence points to alcohol as having a role in a significant number of spinal cord injuries (Heinemann, Mamott, & Schnoll, 1990). Beyond health complications such as malnutrition and liver disease, which may affect all abusers, disabled abusers may be at increased risk for adverse drug interactions, falls due to balance or mobility impairments, and sores and gastrointestinal bleeding that may go undetected because of sensory losses (Heinemann, 1993; Yarkony, 1993).

In studying users' history of drug choice, Khantzian (1990), who posited a self-medication theory of substance abuse, found that many had experimented with various classes of drugs and settled on any that offered a particular type of needed relief. For example, individuals used stimulants to relieve depression and hyperactivity, opioids to mute psychologically disorganizing feelings such as rage and aggression, and alcohol to break emotional constriction and allow for release or connection. Primary motivations for substance abuse, he concluded, are difficulties in managing feelings, low self-esteem, lack of supporting relationships, and poor self-care, which are particularly common among individuals with abusive or traumatic histories or severely deprived circumstances. Other factors found to be associated with illicit drug use among those with disabilities include best friend's drug use and history of high risk-taking (Moore & Li, 1998).

Meyer (1999) studied not only the neurobiology of addiction but its sociology as well. He concluded that for some individuals, drug use becomes a "career." Drug seeking grows into a main source of activity and occupation, especially when no compelling or achievable alternative can be perceived. The addict's lifestyle then becomes a further barrier to other avenues of fulfillment.

As members of the treatment team, occupational therapists are alert to the possibility of substance abuse, prepared to make appropriate referrals, and able to participate in humane, respectful care (Procedures for Practice 35-4). Well-designed substance abuse treatment addresses appropriate stages of recovery; is sensitive to ethnic, cultural, and linguistic differences; and is responsive to patients' particular needs (Cambridge Health Alliance, 1995). Treatment addresses the factors that may have predisposed the individual

PROCEDURES FOR PRACTICE 35-4

Addressing Substance Abuse

Considering Substance Abuse

- Take an occupational history. Was the patient functioning in work or school? Was the patient maintaining relationships?
- Are any family members likely to be helpful in understanding the patient's history?
- Is there any evidence that substance abuse was a primary cause of the condition?
- Might the condition have provoked substance abuse?
- Are there predisposing factors such as depression, trauma, family history of substance abuse, or membership in a marginalized group?
- Does evidence support need for referral?

Treatment Goals for Substance Abuse

- Improve health habits and self-care.
- Develop skills in self-regulation and impulse control.
- Experience group participation; learn to communicate needs; learn to give and receive support.
- Prepare for constructive vocational role.
- Value a clean and sober identity.
- Connect with community resources to maintain change.

to substance abuse, not just the behavior itself. Suggested treatment goals for substance abuse are listed in Procedures for Practice 35-4.

Pain

Although pain is not a diagnosis in itself, it can accompany many illnesses, injuries, and disabilities including spinal cord injury, acquired amputation, cerebral palsy, multiple sclerosis, and post-polio syndrome (Ehde et al., 2003). Along with subjective assessment of independence and severity of disability, the existence of pain has been found to be directly related to well-being among those with severe motor impairments (Dudgeon et al., 2002). Dudgeon's subjects described their experiences of chronic pain as a "personal venture," as "mysterious" with "unclear causes and consequences" and with "little or dissatisfying communication" about it found to be possible. More than a simple sensation, pain is a perception that emerges at the intersection of body, mind, and culture. Pain is an ineffable private experience that each individual must learn to interpret, but it is also a universal phenomenon with broad influence on society at large. A major contributor to healthcare use and a significant

reason for lost work days and disability benefits, pain also adds significantly to family and marital discord (Grunebaum, 1996). An estimated 50 million Americans are partially or fully disabled by pain, with arthritis, headaches, and back pain among the largest contributors (Mayday Fund, 1998).

The Personal Experience of Pain

The daily reality of the individual in pain often includes sleeping difficulties, problems concentrating, and decreased mobility, which can limit all areas of occupational performance including work, recreation, and sexual expression. Altered moods, especially agitation or lethargy with depression, are common among those who have had pain over an extended period, multiple assessments without diagnosis, or multiple treatments without relief. Grief over lost mastery and diminished life roles with feelings of rage, helplessness, victimization, and defectiveness can result, leading to social withdrawal. Prompt and preemptive treatment of pain is a strong priority, ideally before roles, relationships, and even identity become irretrievably eroded (Bridle, 1999; Carr & Goudas, 1999; Harris, Morley, & Barton, 2003).

Pain Treatment

A full pain treatment program includes pharmacological, educational, physical, and psychological components and is administered through a team of clinicians that includes an occupational therapist. Group and individual treatments are often combined. Education presents a mind-body pain model that both gives recognition to the stress and distress that accompany pain and supports the efficacy of several avenues of treatment (Solet, 1995). Recognition and validation are necessary elements because pain patients sometimes feel that no one understands or cares about the extent of their suffering (Main & Spanswick, 1991).

The mind-body model encourages patients to view their pain not as a simple response to tissue damage but as a complex experience that can be affected by many factors, such as positioning for activities, ways of thinking, and emotional reactions (Fields, 1997). Diary keeping (self-monitoring) provides information about which specific factors affect an individual's pain experience; this is vital for collaboration in treatment planning. Diary keeping also documents evidence of improvement, which bolsters patients' motivation and supports treatment adherence (see Clinical Reasoning box, Cognitions Associated with Pain).

The physical components of a pain treatment program can include instruction in body mechanics, and stretching, strengthening, aerobic exercise, pacing, massage, and acupuncture. The psychological components can include the relaxation response, biofeedback, cognitive therapy (modification of thought patterns), affect management

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Cognitions Associated with Pain

Chronic pain is commonly associated with certain elements of self-narrative. As part of effective pain treatment, the individual must learn to become aware of and change thoughts or cognitions that are undermining function and self-esteem (Gallagher, 1997). The statements that follow might be uncovered through monitoring or in dialogue. Using Helplessness and Dependency as examples, write positive alternative statements for the other examples of Rumination and Retribution, Punishment in the spaces provided below.

Helplessness

- The pain prevents me from doing all the things I want to do.
- The pain makes me bad at everything I used to be good at.
- There is no point in trying.

Alternatives

- When I pace myself, I get things accomplished.
- It is harder to do some things, but I can still do many things well.

Dependency

- Everyone should take over for me because of the pain.
- I can't be expected to do anything when I feel like this.

Alternative

- Some things are harder to accomplish, but I can still do them. I will ask for help when I truly need it.

Rumination

- I have to attend to the pain every minute to be sure it is not getting worse.

Alternative

Retribution, Punishment

- I must have done something to deserve this.

Alternative

(control of emotional reactions), and training in assertive communication (Caudill, 1995; Gallagher, 1997). Each of these treatment components may contribute a degree of relief and help patients in managing their pain, even when complete relief is out of reach.

Depression

Theoretical debate and research over the etiology of depression continues, with exploration including reactions

to loss, neurobiological mechanisms, and genetic predispositions. These explanations need not be mutually exclusive since the brain is the substrate for interpretation of personal experience. The frontal lobes, which mediate executive functions such as goal-directed activity, have been implicated in the neurobiological processes associated with depression (Powell & Miklowitz, 1994). Clinicians sometimes mistakenly assume that depression is simply a stage or normal reaction to a disabling illness or injury and that it will remit if left untreated. With periods of hospitalization so short in the current environment, those with lasting depression can be lost to follow-up.

Among medically ill older adults, major depression is experienced by an estimated 20%, and minor depression is experienced by an additional 20–30% (Koenig & George, 1998). Personal or family histories of depression constitute special risk factors following the onset of illness or injury. In some cases, depression is part of a larger picture that includes swings in energy level and emotions, called bipolar disorder or manic depression. Depression, whatever the cause or pattern, can undermine all areas of functioning and, when severe, is life-threatening. Presence of depression mandates referral for assessment, including for risk of suicide. As many as 15% of those who suffer from depression or bipolar disorder commit suicide each year; suicide is the ninth leading cause of death in the United States (Nemeroff, 1998).

Diagnosis and Treatment of Depression

Patients whose motivation to participate in treatment is sapped by significant or unrelenting depression not only lose a critical opportunity to reorganize life skills and identity in a protected setting but also fare poorly if depression remains untreated after discharge. Evidence supporting this relationship of mood to physical health is increasingly clear. Research demonstrates that depression is a risk factor for future heart disease (Denollet, 1998) and that depression increases the risk of dying after a heart attack or stroke (Nemeroff, 1998).

Making a diagnosis of depression in cases of ill, injured, or disabled patients can be complicated; symptoms customarily associated with depression, such as sleep or appetite change, can be directly related to the primary conditions for which some disabled patients are seeking care. In addition, actual brain damage may alter neurobiology.

Since occupational therapists often have a close and continuous relationship with their patients, their observations of behaviors, feelings, and ways of thinking contribute important information to diagnosis. The occupational therapist looks not only for somatic or bodily symptoms but also for cognitive and emotional signs of depression. These include indecisiveness, inability to concentrate, diminished interest or loss of pleasure in formerly enjoyable activities, feelings of worthlessness or excessive guilt, and recurrent thoughts of death or suicide (Nemeroff, 1998).

Patients with bipolar disorder commonly receive diagnostic attention during a depressive phase, and the full scope of their psychiatric illness is not always clear. As the implications for treatment are different, especially in terms of medications, it is important when considering depression also to look for any personal or family history of mania; symptoms include very high energy, sleeplessness, pressured speech, grandiose thinking, unbridled spending, and even delusions (Ghaemi & Sachs, 1999). Patients' lack of insight into and inability to report their own psychological state during manic periods is the rule.

The occupational therapist documents concerns about depression or mania in the medical record, including supporting observations, and brings this information to the attention of the treating physician or team to facilitate referral for psychiatric evaluation (Safety Note 35-1). Assessment for antidepressant and/or mood-stabilizing medications and psychotherapy is a high priority. Components of occupational therapy treatment for depression include restoring self-care and appetites, improving feelings of mastery through meaningful goal-directed activities, reframing self-defeating cognitions, and encouraging social integration.

Post-Traumatic Stress Disorder

Individuals injured or disabled through war, natural disaster, accident, abuse, or violent crime are at special risk for the psychological symptom complex called **post-traumatic stress disorder (PTSD)**. Even those who have witnessed terror or extreme helplessness but are not themselves physically injured, which sometimes includes family members of the disabled person, may develop PTSD. Symptoms can include hyperarousal (vigilance), nervousness, fearfulness, nightmares, flashbacks (spontaneous re-experiencing), ruminations, and mental absence or dissociation (Herman, 1992). For some patients, the resulting disability may

SAFETY NOTE 35-1

Indications for Psychiatric Referral

- Inability or unwillingness to comply with treatment
- Substance abuse
- Uncontrolled pain
- Traumatic flashbacks or dissociation
- Depression with suicidal tendency
- Mania
- Hostility, agitation
- Paranoia, unwarranted fears
- Hearing voices, delusions
- Social isolation or withdrawal
- Extended denial
- Unresolved religious or existential crisis
- Overwhelming guilt
- Family upheaval

constitute life-long physical evidence of the traumatic experience, even serving as a proprioceptive cue or trigger for PTSD symptoms and continuing stress reactions. In addition, some disabilities, such as spinal cord injury, carry with them medical problems that can be life-threatening and serve as a further source of anxiety (Martz, 2004; Ville, 2001).

Individuals with symptoms of PTSD require immediate referral to be evaluated for specialized psychotherapy and medication. Coordination between caregivers is critical to a positive outcome for these patients, who need a safe, predictable environment in which they can make sense of their experiences. Listening to their narratives can be disturbing, so strong team support and supervision are important for all involved caregivers, including occupational therapists.

CASE EXAMPLE

Mr. D.: Adaptation Process after Stroke

*I felt a Cleaving in my Mind-
As if my Brain had split-
I tried to match it-Seam by Seam-
But could not make them fit-*

*The thought behind, I strove to join
Unto the thought before-
But Sequence unravelled out of Sound-
Like Balls-upon a Floor-*

Emily Dickinson (1830-1886)

Clinical Reasoning Process

Occupational Therapy Intervention Process

Patient Information

Mr. D. is a 53-year-old right-handed white man who suffered a severe right thalamic hemorrhage with rapid onset and steady improvement. His presenting problems at inpatient OT assessment included left hemiparesis; left homonymous hemianopsia; left neglect and anosognosia; disorientation to time and place; deficits in perception, attention, memory, and visuospatial processing; and complete dependence in activities of daily living. Mr. D. retained superior verbal ability, had an advanced education, strong family support, and adequate health insurance. He is a husband, father, and former university dean and public administrator and has been his family’s primary breadwinner.

Objectives

Examples of Therapist’s Internal Dialogue

Appreciate the context

“Mr. D. was obviously in the prime of his career at the time of his stroke; it must have come as such a shock to him and his family. His vocational background suggests that he is used to being highly respected and in charge. He has been directing others, not accepting direction. I imagine that it will be particularly difficult for him to adjust to a dependent role of any duration. I will want to think of as many ways that he can be in control as possible and support his family in recognizing his needs in this regard.”

“With high school–aged children and a spouse who has not been working outside the home, financial pressures may add to the stress. I wonder if his wife may need to seek employment and may not be available as a caregiver for him when he returns home.”

Develop intervention hypotheses

“Mr. D.’s denial of the severity of his disability is a major obstacle to recognizing the need for and committing to OT treatment.”

Select an intervention approach

“I know it will be important that I show respect for his history of life roles by prioritizing OT goals related to intellectual and social skills and beginning with activities that emphasize compensation through his most preserved areas of function. This strategy should help increase his motivation and sense of personal continuity.”

Reflect on competence

“Mr. D.’s preserved verbal strengths will help in building our therapeutic alliance.”

Recommendations Related to Personal and Social Adaptation

The following goals were set for inpatient treatment (5 days/wk for 3 months) and outpatient follow-up: (1) foster therapeutic alliance; (2) identify/enlist motivating strategies; (3) consider past occupational roles and future adaptation; (4) encourage partnership in setting priorities for goals; (5) develop sense of mastery and control through specific skill development and relearning: reading, self-care, and mobility; and (6) guide the search for meaning.

Consider the patient’s appraisal of performance

“Trust will be critical in countering neurologically based denial. I must help him to believe there are good reasons for what I am asking of him. As his denial begins to break, the increased awareness of his losses will be painful; questions of meaning are likely to arise. I will try to help him find his own best way of making sense of his experiences. I will have to examine my own feelings about what has happened to him, a robust and gifted man at the height of his career.”

Consider what will occur in therapy, how often, and for how long

Ascertain the patient’s endorsement of plan

“I think that it is important to integrate safety and self-care goals into treatment if he is to return home without requiring a full-time aide. Continued dialogue will be needed to negotiate for attention to these goals and to address issues of physical dependency, which at present do not appear relevant to him.”

Interventions Related to Personal and Social Adaptation

- Improve orientation to time and place.
- Solicit narrative of his experiences related to the stroke.
- Compensate for left visual field deficits and denial using cues from OT.
- Improve awareness/positioning and range of motion in left upper and lower extremities.

Assess the patient’s comprehension

Understand what he is doing

“I need to continually orient Mr. D. to his surrounding and circumstances and, later, to the OT role. Other staff and team members can be enlisted to help so that Mr. D. is getting a consistent message. Staff and team should be made aware of the effects of his neurological deficits on his reasoning and tendency to confabulate.”

This case study follows the structure introduced in this chapter for integrating psychosocial components in treatment planning. The internal dialogue in the Case Example emphasizes these aspects as related to ongoing physical rehabilitation. The patient described, Mr. D., was in active inpatient rehabilitation for 3 months, followed by periodic home visits for outpatient treatment. Medical complications contributed to his unusually long length of stay. During the period following his stroke and after a second stroke until his death, he continued to correspond with this author, his occupational therapist. He expressed the wish that his experiences be used to help others. He often quoted the Emily Dickinson poem above. The accompanying series of drawings demonstrate his growing awareness during his inpatient stay (Fig. 35-2).

Figure 35-2 Six serial self-portraits drawn by Mr. D. during months 3, 4, and 5 after right-hemisphere stroke.

Maneuver the wheelchair for short distances.
 Practice supervised self-care.
 Attempt reading and writing.
 Facilitate personal continuity through narrative and drawings.
 Address existential questions.
 Open lines of communication with family.

Compare actual to expected performance
 Know the person
 Appreciate the context

“Sometimes he sounds almost psychotic, but I appreciate that actually he is trying to make narrative sense of what he experiences through a limited field of vision and with a damaged perceptual framework normally supported by the right hemisphere.”

“With his denial breaking, I believe that it is crucial to avoid flooding Mr. D. with failures in these areas. Time must be given in OT to enjoy relative successes before new demands are added. With growing awareness of losses, periods of despair or depression may emerge.”

“I can see our alliance is deepened when I identify and name his feelings and reflect back what I have heard. Mr. D.’s drawings convey a great deal about his changing body image and sense of self.”

“His stories help me understand and guide the developing ways in which he is trying to make sense of what has happened to him.”

“I need to keep in mind how much Mr. D.’s life has changed. He was accustomed to giving orders, delegating authority, and having his decisions respected. How can I help him find some sense of mastery outside those roles that have been so much of his identity? What are his family members expecting? What additional relationships and institutional supports are in place that can help Mr. D.’s world work for him when he is discharged? Friends? Church?”

Next Steps

As an outpatient, Mr. D. will work toward being able to: (1) compensate for neglect and visual field deficits in the context of reading and writing tasks; (2) initiate social interaction including telephone management skills; (3) monitor moods; (4) walk short distances with an assistive device; (5) carry out exercises to maintain left arm range of motion; (6) continue drawings and narrative; (7) explore vocational requirements and expectations; and (8) participate in a home visit for assessment of safety and equipment.

Anticipate present and future patient concerns
 Analyze patient’s comprehension
 Decide if the patient should continue or discontinue therapy and/or return in the future

“As Mr. D. continues to adjust to what has happened to him, I anticipate that he will have concerns with his level of dependency. He was the bread winner; he is not likely to return to a high-paying position. He took care of his wife and family. Will they now have to take care of him? There is a risk of repeat stroke; ongoing medical management is critical. Does he have fears about this?”

“So far, no signs of a plateau in improvement have been seen. Mr. D. wants to continue OT after discharge, and I agree that he should. Coming home will be hard. He has been in a supportive environment with much interaction where his safety has been assured. His family has been attentive, but they have not had primary responsibility for his care. Outpatient therapy will maintain alliance during this critical transition and continue building competence. Family expectations must be explored; they will require transitional support as he returns home.”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Effect of Stroke-Related Deficits on the Adaptation Process

Mr. D.’s cognitive-behavioral deficits associated with right-hemisphere brain damage initially limited his ability to appreciate his circumstances and adjust to his condition. He retained the ability, however, to verbalize his concerns and comprehend verbal input from others. How might the therapist’s plans and goals specific to adaptation have changed if Mr. D. had impairments typically associated with left-hemisphere lesions (e.g., communication deficits)?

Evidence Table 35-1 Evidence for Occupational Therapy Practice That Incorporates Personal and Social Adaptation

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Client-centered, in-home ADL practice	In-home OT to achieve client-identified ADL or IADL goals plus routine services	138 stroke survivors (67 LCVAs, 71 RCVA); mean age = 71 years.	30–45 minutes per visit for 10 visits over 6 weeks.	Randomized controlled study. IA2b (lacked control for difference in attention between treated and other group who received routine services only).	Yes. The treated group showed small improvement on <i>Nottingham Extended ADL Scale</i> and <i>Barthel Index</i> vs. other group.	<i>Nottingham</i> : $p = 0.02$, $r = 0.17$. <i>Barthel</i> : $p = 0.06$, $r = 0.13$.	Gilbertson et al., 2000
Task-specific practice of client-chosen BADL	Practice of specific tasks in a familiar context.	323 acute stroke survivors (147 LCVAs, 156 RCVA); mean age, 72.5 years.	Ranged from 1–15 visits over a period of 6 weeks to 5 months.	Meta-analysis of 2 studies.	Yes. The treated groups improved in BADL as measured by the <i>Barthel Index</i> .	Mean weighted effect size was $r = 0.16$, equivalent to a 16% success rate over control treatment.	Trombly & Ma, 2002
Training neglect for enhancement of functional tasks	Tested association between neglect and function; study justifies therapeutic efforts at primary remediation of neglect.	40 right-handed adults with RCVA (19 with neglect, 21 without neglect).	Tested at 3 points: <i>LOTCA</i> , <i>FIM</i> , and <i>Rabideau Kitchen Evaluation</i> .	Longitudinal controlled study using consecutive admissions.	Neglect predicted lower performance on all areas of <i>LOTCA</i> /cognitive skills and <i>FIM</i> /daily functional tasks and longer hospitalization.	15.8% neglect group ADL independent vs. 81% non-neglect group; $\chi^2 = 4.27$; $p < 0.04$. Student's $t = 2.48$, $p < 0.02$.	Katz et al., 2000

(continued)

Evidence Table 35-1 Evidence for Occupational Therapy Practice That Incorporates Personal and Social Adaptation (continued)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Social support; family educational counseling; and leisure-focused therapy	Examined success of community reintegration efforts as reported in multiple studies.			Meta-analysis/literature review of 17 studies between 1970 and 2002: 4 on social support; 10 on family education; and 3 on leisure activities.	Social support: improves outcome. Family education: positive family impact. Leisure activities: no consensus.		Bhogal et al., 2003

Abbreviations: ADL, activities of daily living; IADL, instrumental activities of daily living; LCVA, left cerebrovascular accident; RCVA, right cerebrovascular accident; BADL, basic activities of daily living; LOTCA, Loewenstein Occupational Therapy Cognitive Assessment; FIM, Functional Independence Measure.

SUMMARY REVIEW QUESTIONS

1. Write a letter from the rehabilitation hospital to a close friend or family member describing your feelings and efforts to cope following a disabling accident.
2. Generate five short hypotheses through which to understand why a patient might seem unmotivated in treatment. Considering your hypotheses, what components would you expect interventions for pain and depression to have in common and why?
3. Present briefly the four stages from injury to rehabilitation as described by Morse and O'Brien. In what ways are stage theories helpful? What wrong assumptions can they produce?
4. What stresses might disabled patients' families or partners experience? What are three ways occupational therapists ease those stresses?
5. Explore an online chat room serving a virtual community of ill or disabled individuals. Give examples of support and information that you find being exchanged. What criteria would you use to evaluate the value of this chat room for its participants? In what ways might a chat room be like group treatment? In what ways might it be different?
6. Respond to this patient's question: "Why go on living with a severe disability?" What feelings or reactions in yourself over such a question would lead you to seek extra support or supervision?
7. List four indications that would cause you to seek psychiatric consultation or referral for the patient in Question 6.
8. View one or more of the films that portray a disabled person. What strategies for coping are depicted in the film(s)? What is demonstrated about the close relationships and occupations of disabled individuals? How might the film(s) influence the audience's understanding of living with a disability?

ACKNOWLEDGMENT

I would like to thank the patients who have been my teachers for the more than 30 years I have been an occupational therapist; Jenny Lee Olsen, Director of Library Services at Cambridge Health Alliance for her generous help and guidance in the literature search; Manu Thakral for thoughtful comments on the developing manuscript; and editors Mary Radomski and Catherine Trombly for their confidence in offering me the opportunity to contribute to this book.

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Understand the historical background of civil rights for people with disabilities, the social model of disability, the independent living movement, and the establishment of the Americans with Disabilities Act.
2. Understand key events and policies that affect accessibility of home, work, and communities.
3. Describe four intervention techniques for maximizing access to participation at home, in the workplace, and in communities.
4. Recognize examples of products, design features, and other contextual factors that interact with a client's ability to perform occupations.
5. Explore intervention plans that reduce demands and facilitate access to home, workplace, and community.
6. Outline evidence-based best practices for reducing environmental demands and maximizing performance patterns.

CHAPTER 36

Optimizing Access to Home, Community, and Work Environments

Dory B. Sabata, Shoshana Shamberg, and Michael Williams

Glossary

Age in place—The concept that as people age, they can continue to live and participate within their own homes and communities of choice.

Assistive technology—Any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities (Assistive Technology Act of 1998).

Electronic and information technology—Equipment or interconnected system or subsystem of equipment that is used in the creation, conversion, or duplication of data or information (Section 508 of the Rehabilitation Act).

Excess disability—Decreased ability to function beyond the functional impairment associated with a particular health condition.

Universal design—A design approach for creating products and spaces that addresses the need for access by all potential users.

Visitability—A movement started by Concrete Change that advocates that all homes have a no-step entrance, wide doorways, and access to a first floor bathroom for visitors.

Vocational rehabilitation—Therapeutic preparation for obtaining and participating in employment.

Workplace accommodation—Strategy to reduce barriers and maximize participation in employment for people with disabilities by changing the work environment, job task, or how the job is performed.

Occupational therapy intervention to optimize accessibility requires both knowledge of the process to implement changes in the physical environment and the product options available. This chapter highlights some of the historical events that have shaped this dimension of occupational therapy practice. Occupational therapists use four intervention strategies to optimize access to home, community, and work environments: universal design, environmental modifications, assistive technology, and task modification strategies. Application of strategies will be discussed for home, workplace, and community environments along with factors affecting the implementation of environmental modifications. Given the importance of evidence-based practice, some of the research that demonstrates efficacy for these types of interventions will be described in terms of client outcomes.

ACCESSIBILITY: AN HISTORICAL PERSPECTIVE OF ACCESS TO THE ENVIRONMENT FOR PEOPLE WITH DISABILITIES

Occupational therapists provide training and strategies to help people with disabilities to optimize participation in activities in a variety of contexts. One way this is accomplished is by promoting environments and attitudes that facilitate a person's right to decide how and where he or she will live, work, and socially participate. Political advocacy, legislation protecting civil rights, and changing demographics of the population are all influential in shaping current occupational therapy practices for optimizing environmental access.

Independent Living Movement

Services to increase quality of life for people with disabilities were established in accordance with the Comprehensive Rehabilitation Services Amendment of the Rehabilitation Act of 1973. This initiated the Independent Living Movement (ILM), which models itself on the Civil Rights Movement. The ILM stems from grassroots activists who promoted an alternative to the medical model perspective of disability. The ILM differs from the medical model in that it is consumer oriented and directed (American Occupational Therapy Association [AOTA], 1993).

Independent living is defined as control over one's life based on the choice of acceptable options that minimize physical and psychological reliance on others in making decisions and performing everyday activities (Frieden & Cole, 1985). With this movement and supporting legislation, Centers for Independent Living (CILs) were established to provide referral and direct services in housing, attendant care, transportation, recreation, housing, and social and vocational counseling. These centers are important because they provide a support system to consumers, often educating the family support network or compensating for the lack of one. CILs are unique community-based non-profit nonresidential programs that are substantially controlled by consumers with disabilities (Johnson, 1986).

With this client-centered method of service delivery, the client and caregivers define what they want and need, and the occupational therapists help them meet their goals. The role of the occupational therapy practitioner varies with the setting and/or the needs of the consumer. The practitioner may act as consultant, advocate, case manager, and, often, provider of both non-medical and traditional occupational therapy services in the home or community.

Legislation and Governmental Regulation of Accessibility

Over the past 50 years, a number of key legislative initiatives paved the way for fully ensuring that all citizens, including people with disabilities, have access to community, job, and residential environments. Federal legislation addressing accessibility issues began in 1954 with the Hill Burton Act (PL 83-565) to correct construction and design problems in federally funded hospitals. The Architectural Barriers Act of 1968 (PL 90-480) created the United States Architectural and Transportation Barriers Compliance Board (ATBCB), which was authorized to study architectural design and develop standards for the construction of accessible buildings. Their findings are reported in the Minimum Guidelines for Accessible Design (MGRAD). The Rehabilitation Act of 1973 (PL 93-112) expanded the powers of the ATBCB or Access Board, which was then authorized to enforce federal accessibility requirements in federally funded buildings, federally funded programs, subsidized and public housing, and transportation facilities. These standards, called the Uniform Federal Accessibility Standards (UFAS), are based on MGRAD and guidelines of the American National Standards Institute (ANSI).

The Fair Housing Amendments Act (FHAA) of 1988 established the Fair Housing Act Accessibility Guidelines (FHAAG) for multifamily housing of four units or more and civil rights housing protection for people with disabilities. The FHAA mandates accessibility compliance and civil rights protection in private housing. People with disabilities are provided equal access to housing and a mechanism for filing complaints when their civil rights are violated. According to this law, the resident cannot be denied the opportunity to modify the rented home to meet individual needs for accessibility. The cost of the modification, however, is the responsibility of the renter. The landlord may require that the work be done by an approved professional, and an escrow account may be established in which the tenant must place funds for returning the residence to its original state. Modifications that may be easily used by other tenants and do not change the nature of the residence are not required to be returned to the original state. Such modifications include widened doorways, levered handles, grab bar solid blocking, and the like. A ramp may have to be removed, cabinets under counters may have to be reinstalled, and the tub may have to be returned to the bathroom from which it was removed to create an accessible shower stall (Procedures for Practice 36-1).

In 1990, with Congressional approval of the Americans with Disabilities Act (ADA), 43 million Americans with disabilities were awarded civil rights protection by extension of equal rights protection established by the Civil Rights Act of 1964. The ADA is an attempt to correct the many loopholes of earlier legislation aimed at providing services and rights for people with disabilities and a

PROCEDURES FOR PRACTICE 36-1

Guidelines, Standards, and Regulations of Accessible Design

Occupational therapists who work with contractors and designers familiarize themselves with the following standards, guidelines, and legislation that affect accessibility and the physical environment.

- American National Standards Institute (ANSI)
- Minimum Guidelines for Accessible Design (MGRAD)
- Section 504 of The Rehabilitation Act 1973
- Architectural and Transportation Barriers Compliance Board (ATBCB)
- Uniform Federal Accessibility Standards (UFAS)
- Fair Housing Amendments Act of 1988 (FHAA)
- The Fair Housing Act Accessibility Guidelines (FHAAG)
- Americans with Disabilities Act of 1990 (ADA)
- Americans with Disabilities Act Accessibility Guidelines (ADAAG)

method of enforcing specialized regulations through the courts. Part of the ADA stipulates that state and local accessibility regulations must be considered in the design or modification of public spaces including businesses, schools, parks and other recreational facilities, state and local government buildings, and public transportation. The ATBCB used both the Uniform Federal Accessibility Standards (UFAS) and FHAAG standards to create the Americans with Disabilities Act Accessibility Guidelines (ADAAG) (Table 36-1).

In addition to the federal policies and standards that affect the built environment, state and local governments also have established building codes and safety codes. These codes can affect the location, design, and layout of public and private spaces. Most building design is based on the functional abilities and physical stature of an average person. The ADAAG was developed to propose some specifications for designing more accessible public spaces. The ADAAG was based primarily on the needs of younger adults with disabilities, and today, these implemented environmental features are not designed to meet the needs of older adults (Sanford, 2001). Guidelines can serve as a starting point to creating accessible public places but should not be the only consideration.

AGING

In addition to trends related to governmental oversight of accessibility, changing demographics also influence occupational therapy intervention to optimize access to home,

Table 36-1. Sample of ADAAG Specifications^a

Measure	Specification
Toilet height	17 in to 19 in
Grab bar diameter	1 1/4 in to 1 1/2 in
Space between wall and grab bar (see Fig. 36-6)	1 1/2 in
Length of grab bar behind the water close	36 in
Clear space for wheelchair for 180° turn (see Fig. 36-7)	60 in
Maximum high forward reach allowed	48 in
Minimum low forward reach	15 in
Minimum clear width of an accessible route	36 in
Curb ramp minimum width	36 in
Maximum slope of a ramp in new construction	1:12
Preferred ramp slopes (see Fig. 36-5)	Between 1:16 and 1:20
Minimum landing length	60 in
Minimum landing size if ramps change direction at landings	60 in × 60 in
Maximum threshold for exterior sliding doors	3/4 in
Maximum threshold for other doors	1/2 in

^a This table does not include requirements for children's use, nor were these measurements and specifications intended for homes.

work, and community. Overall, the population is aging, and those with chronic disabilities are living longer. By 2020, an estimated 54 million people in the United States will be aged 65 and older (United States Census Bureau, 2004). Over one fifth of those aged 45–54 have a disability, and about 14% of these people are severely disabled. Numbers increase sharply for people aged 65–69, of whom nearly 45% have some type of disability and 30.7% have severe disabilities; for those aged 80 and older, the numbers are nearly 74% and 58%, respectively (McNeil, 2001). Even with increasing disability with increasing age, older adults are active members of communities. The majority of older adults continue to reside in a home rather than in institutions (Greenwald and Associates, Inc., 2003). Older adults are participating longer in the workplace as well (Toossi, 2004).

When environmental demands exceed a person's abilities, **excess disability** results, which greatly limits participation in activities at home, in the workplace, or in the community. The current housing stock is often not accessible, and it is not designed for people to **age in place**. Workplaces have not been designed with aging workers in mind either. Communities have experienced increasing urban sprawl, and zoning has often distanced housing from commercial services such as stores and social and medical services.

Aging in Place

Older adults indicate a strong preference to continue living in their own homes. Homes have not been designed for

aging in place. Although older adults are increasingly recognizing the need for home modifications, often their homes still lack the needed accessibility features (Bayer & Harper, 2000).

Aging in the Workplace

The American Association of Retired Persons (Bayer & Harper, 2000) reports that 80% of boomers believe they will continue to work during retirement. From 2000 to 2015, the annual growth rate of people ages 55 and over in the U.S. labor force will be nearly four times that of the overall labor force (Toossi, 2004). The phenomenon of aging in the workplace will present many new challenges to accessibility. New skills will be required for older adults to engage in an ever-increasing technological environment. Computer technology and interfaces will need to be designed to adapt to changes in vision, hearing, sensation, motor skills, and cognition that may be experienced by aging workers.

Elder-Friendly Communities

The increasing number of aging adults need environments to be adapted, modified, and designed to meet the needs of increasing disability and age-related changes. Livable or elder-friendly communities that facilitate participation incorporate affordable, accessible housing, supportive service, and transportation options (Kochera, Straight, &

Guterbock, 2005). ADAAG was not designed with older adults in mind, and community environments will need to include alternative accessibility options beyond the ADAAG to maximize community participation for older adults.

ROLE OF OCCUPATIONAL THERAPY

Occupational therapists analyze the physical environment as it relates to human performance, determine specific functional and environmental problems, and negotiate intervention options in collaboration with the client and support network. The generalist practitioner understands that the environment can be changed to decrease demands or to maximize abilities to facilitate performance. Specialists in accessibility and environmental modifications understand the range of possibilities and are conversant in the language needed to communicate effectively with building professionals as well as with clients. Other specialist competencies have been identified by the American Occupational Therapy Association (AOTA) for the Specialty Certification in Environmental Modifications.

Decades of regulation to eliminate discriminatory practices have led to the Americans with Disabilities Act (ADA) of 1990. Occupational therapy practitioners who are knowledgeable about these changes in policies and demographics provide valuable consultation and information to help facilitate social participation and performance of occupations that are meaningful and purposeful. A client-centered approach to service delivery empowers the client to advocate for his or her own needs with knowledge and a wide array of resources.

OVERARCHING STRATEGIES TO OPTIMIZE HOME, WORK, AND COMMUNITY ACCESSIBILITY

Any effort to optimize accessibility is always informed by an understanding of how environmental changes fit into the broader context of a client's requirements and preferences. Environmental press theory and concepts related to meaning associated with personal space shed light on these issues (Resources 36-1).

Environmental Press Theory

A conceptual framework called the docility hypothesis or environmental press theory (Lawton & Nahemow, 1973) is often used to describe a “just-right fit” between the

demands of the environment and the abilities of the person. Occupational performance is dependent on this person–environment fit. Occupational therapy practitioners understand the importance of occupations to their clients and can help to implement environmental interventions to promote safety and reduce activity demands.

Meaning Associated with a Person's Space

When entering the home, workplace, or even community of a client, occupational therapists recognize that the physical space is meaningful to the client. Some people may feel trapped or have negative feelings about their environment, while others find a particular environment nurturing and comforting (Marcus, 1995). Think about your own environments in which you perform occupations. For example, do you sit in a particular seat in class? One's choice may depend on where one's friends sit, the relationship with the instructor, being in the habit of sitting there, or a number of other reasons. Regardless of what the reasons are, meaning has been established with that place.

Objects can become symbolic of goals and affect the identity of the people who use them (Csikszentmihalyi & Rochberg-Halton, 1981). Occupational therapists recognize that removing objects can be interpreted as a loss to some clients. Some objects may not seem functional, but they do have meaning and purpose. When making changes to a particular environment, introducing new tools, or removing objects, be aware of their meaning to the client. The occupational therapy practitioner needs to be sensitive to the meaning of the context and recognize how that may affect compliance to recommended interventions.

Occupational therapists evaluate the occupational functioning of their clients in the physical context and make recommendations for changes to the environment to optimize accessibility. Practitioners, however, often become frustrated when clients do not follow recommendations. The Consumer Decision Model (Ohta & Ohta, 1997) proposes that people need to perceive a high threat and severe consequences to their current environment, as well as high efficacy and low cost to making changes to the environment. Often clients will not make changes until a crisis arises.

Intervention Strategies to Optimize Accessibility

Through activity analysis, occupational therapists can identify the barriers in technology and the environment that may contribute to further disabling a person with functional limitations. Regardless of whether

interventions are targeted at participation in the home, workplace, or community, the four strategies discussed in this section can be applied.

1. Universal design and other accessible design
2. Environmental modifications
3. Assistive technology
4. Task modification strategies

Universal Design and Other Accessible Design

Occupational therapists' understanding of occupational performance can offer valuable knowledge to an interdisciplinary team that implements universal design to help maximize occupational performance for all potential users. By understanding the needs of people with a variety of health conditions, occupational therapists can contribute to increasing accessibility of spaces and products that are used by many people (Definition 36-1; Procedures for Practice 36-2).

Products that are designed for use by everyone should use universal design principles. One example is the use of an automatic door opener. Automatic doors decrease the need for strength, motor skills, and cognitive skills. In addition to being useful to people with these types of functional limitations, automatic doors can be helpful to any worker who is carrying packages through the doorway. Figures 36-1, 36-2, and 36-3 illustrate some design features of both home and workplace that apply universal design to a bathroom, kitchen, and office space.

Environmental Modifications and Assistive Technology

Most environments have not been built with universal design features in mind, and therefore, environmental modifications are needed to increase accessibility. Environmental modifications are changes made to the

current physical environment. Occupational therapy practitioners collaborate with the client and with other team members, such as design, construction, and other building professionals, to develop a plan for reducing environmental barriers.

A typical home bathroom does not contain the same features noted in the universal design bathroom (Fig. 36-1). Therefore, homes may need to be retrofitted to include them. For instance, someone who has a bathtub may need to replace it with a curbless shower to facilitate bathing in a wheelchair. Public Law 100-407 (1998) defines **assistive technology** as “any item, piece of equipment, or product system, whether acquired commercially off the shelf, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities.” Assistive technology can be added to the environment.

Task Modification Strategies

Design features, modifications, and assistive technology are used to decrease environmental demands and to reduce barriers. Task modifications are changes in how or where a task is performed. Occupational therapists provide training to clients who need to learn how to do a task in a different way.

One way in which a task can be modified is by teaching a client to perform a task from a different position, such as seated rather than standing, or using a non-dominant hand. Another type of task modification is performing a task in a different location (such as bathing in a shower rather than a tub or sleeping in the living room instead of the bedroom). Changing the time of day in which an activity is performed is another strategy used by people who fatigue and need to allocate their energy to their most important activities of the day. Objects in the environment can be grouped for a similar task, or the

DEFINITION 36-1

de·fin·i·tion

Types of Accessible Design

When providing consultation to designers, contractors, families, and patients, occupational therapists appreciate the breadth of access and functional performance strategies and aids that may be available to consumers. The following terms help to clarify the various ways that accessible environments can be created and labeled. This assists in communication with other professionals on the implementation team, especially the designers and building contractors.

- “**Universal design** is the design of products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design” (Mace, 1997). Environments created using the elements of universal design are accessible, adaptable, aesthetically pleasing (non-medical appearance), and often cost effective. Universal design is intended to eliminate barriers and the need for major structural modifications, and to provide features that can be used by people with a wide range of abilities and needs across the life span. This design approach minimizes the need for major costly structural modifications to accommodate a functional impairment or age-related decline (American Association for Retired People, 1996). Universal design features address the natural effects of aging, which may result in physical, sensory, and/or cognitive decline (ABLEDATA, 1995). Ideally, this type of design should address the general needs of people with a wide range of functional abilities and limitations.
- An accessible environment may be used, approached, and entered easily, especially by people with disabilities. It is not necessarily designed to address a specific functional limitation.
- An adaptable environment is one that is built or modified so that adaptation for individual and changing needs can be accomplished over time without major structural changes.
- Lifespan design incorporates accessible and adaptable features for use as occupants grow older to accommodate changes in functional ability (Shamberg, 1993).
- A barrier-free environment is built or altered to remove obstacles and maximize accessibility. It is usually designed to address the specific needs of individuals with functional limitations. An example of barrier-free design is a wide, flat entryway to accommodate wheelchairs. By modifying physical space, equipment, tasks, and behavior, a person can compensate for age-related changes or disability and maximize comfort, safety, and independence. Often the environment produces greater barriers to a person’s functional performance than the actual disabling condition (Center for Universal Design, 1997).

PROCEDURES FOR PRACTICE 36-2

Principles of Universal Design

When designing a space or product to be used by all potential users, the following principles should be applied.

Equitable Use

The design is useful and marketable to people with diverse abilities.

Guidelines

- Provide the same means of use for all users: identical whenever possible; equivalent when not.
- Avoid segregating or stigmatizing any users.
- Provisions for privacy, security, and safety should be equally available to all users.
- Make the design appealing to all users.

Flexible in Use

The design accommodates a wide range of individual preferences and abilities.

Guidelines

- Provide choice in methods of use.
- Accommodate right- or left-handed access and use.

- Facilitate the user’s accuracy and precision.
- Provide adaptability to the user’s pace.

Simple and Intuitive

Use of the design is easy to understand, regardless of the user’s experience, knowledge, language skills, or current concentration level.

Guidelines

- Eliminate unnecessary complexity.
- Be consistent with user expectations and intuition.
- Accommodate a wide range of literacy and language skills.
- Arrange information consistent with its importance.
- Provide effective prompting and feedback during and after task completion.

Perceptible Information

The design communicates necessary information effectively to the user, regardless of ambient conditions or the user’s sensory abilities.

(continued)

PROCEDURES FOR PRACTICE 36-2 (continued)

Guidelines

- Use different modes (pictorial, verbal, tactile) for redundant presentation of essential information.
- Provide adequate contrast between essential information and its surroundings.
- Maximize “legibility” of essential information.
- Differentiate elements in ways that can be described (i.e., make it easy to give instructions or directions).
- Provide compatibility with a variety of techniques or devices used by people with sensory limitations.

Tolerance for Error

The design minimizes hazards and the adverse consequences of accidental or unintended actions.

Guidelines

- Arrange elements to minimize hazards and errors: most used elements should be most accessible; hazardous elements should be eliminated, isolated, or shielded.
- Provide warnings of hazards and errors.
- Provide fail-safe features.
- Discourage unconscious action in tasks that require vigilance.

Low Physical Effort

The design can be used efficiently and comfortably and with a minimum of fatigue.

Guidelines

- Allow user to maintain a neutral body position.
- Use reasonable operating forces.
- Minimize repetitive actions.
- Minimize sustained physical effort.

Size and Space for Approach and Use

Appropriate size and space is provided for approach, reach, manipulation, and use regardless of user’s body size, posture, or mobility.

Guidelines

- Provide a clear line of sight to important elements for any seated or standing user.
- Make reach to all components comfortable for any seated or standing user.
- Accommodate variations in hand and grip size.
- Provide adequate space for the use of assistive devices or personal assistance.

PROCEDURES FOR PRACTICE 36-3

Therapeutic Intervention to Promote Safety and Independence: Principles of Work Simplification

- Use both hands to work with symmetrical motions when possible.
- Lay out work areas within normal reach. Work where the areas of both hands overlap and arrange supplies in a semicircle within easy reach. Plan storage within normal reaching ranges in the working area. Arrange storage at first point of use; have extras of the things you need at more than one work center, for example, measuring cups, spoons, knives, and so on. Create fixed workstations where there is a designated location for each job so that supplies and equipment can always be kept there ready for immediate use.
- Slide heavy objects rather than lifting and carrying. For example, slide pots from sink to range. Use a wheeled cart if counters are not contiguous.
- Avoid holding and grasping; instead, use utensils that rest firmly or suction cups or clamps, so both hands are free to work.
- Let gravity work for you by using a laundry chute, refuse chute, gravity-fed flour and sugar bins, or a pan below the level of a cutting board.
- Store small tools so that they are in the proper position to grasp and start working immediately. Store the egg-beater so its handle can be grasped in the left hand without shifting.
- Create efficient storage by using a pegboard on the wall with hooks for hanging, magnetic racks for knives and utensil storage, step shelves to maximize tight spaces with less reaching, and vertical storage racks.
- Have machine controls and switches within easy reach. Change the location and position of switches by using extension cords and minimize unplugging and plugging by using a multiplug outlet or extension cord with a single on-off switch.
- Whenever possible, sit to work in a comfortable chair and adjust the work surface or chair height for upright posture and forearm support. When you are seated, place feet flat on the floor or use a footrest. Use a chair with back support, especially in the lower back. Use a support cushion where needed, and slope the seat slightly to the back so that you do not slide forward. Ensure enough knee room to allow you to face the job to be done.
- Use the height appropriate for you, the worker, as well as the job. Jobs requiring hand activity need a higher work surface than those requiring arm motion or pressure. Since body proportions differ, use individualized measurements when possible. The arms and shoulders of a seated or standing person should be relaxed without raising hands above the level of elbows. A work surface a few inches lower than the elbows allows a person to work without hunching the shoulders and enables proper leverage for the work to be done.
- Create pleasant working conditions with a minimum of stress and strain. Natural lighting, halogen lighting, adequate ventilation, comfortable clothing, pleasing colors and music, windows looking onto natural settings, and organization of the environment facilitate this goal.

steps to completing an activity can be simplified (Procedures for Practice 36-3).

SPECIFIC INTERVENTIONS FOR ACCESS TO THE HOME ENVIRONMENT

When helping clients optimize access to their home environments, occupational therapists evaluate performance of activities of daily living (ADLs) and other activities that are currently performed in the home. Therapists assess the environment for hazards such as clutter, poor lighting, and broken steps. They also assess the person's behavior within the environment such as balance and strength when transferring, problem-solving skills in emergency

situations, and sensory/perception such as for detecting temperature changes when cooking and bathing. (See Chapter 11 for a full discussion of assessing accessibility.)

The three most challenging areas of the home are the entrance, inside stairs, and the bathroom (Housing and Urban Development, 2001).

Entrance and Stairs

The front door may not be easily accessible by someone using a wheelchair or even a walker. Steps can provide a challenge when entering the home. For people who are ambulatory but unsteady, a solution may be adding secure handrails to support the body. Handrails may be a low-cost modification initially used to support an older person as they are trying to use the steps. People who use mobility devices (e.g., walkers and wheelchairs) may need

more extensive modifications to the environment such as a ramp or lift.

Ramps are a lower cost option to creating a no-step entrance. The slope of a ramp needs to minimize the steepness without making too long of an entrance. Some alternatives for ramp configurations can be found in Figure 36-4. Often, there is a tradeoff between strength and

endurance in relation to the slope of the ramp. Figure 36-5 demonstrates the rise to run ratio or ramp slope. When the entrance to a home is very steep or the yard space required to build a ramp is insufficient, lifts may be another alternative. An often aesthetically pleasing option is to use soil and ground covering to create a gradual sloping feature called an earth berm.

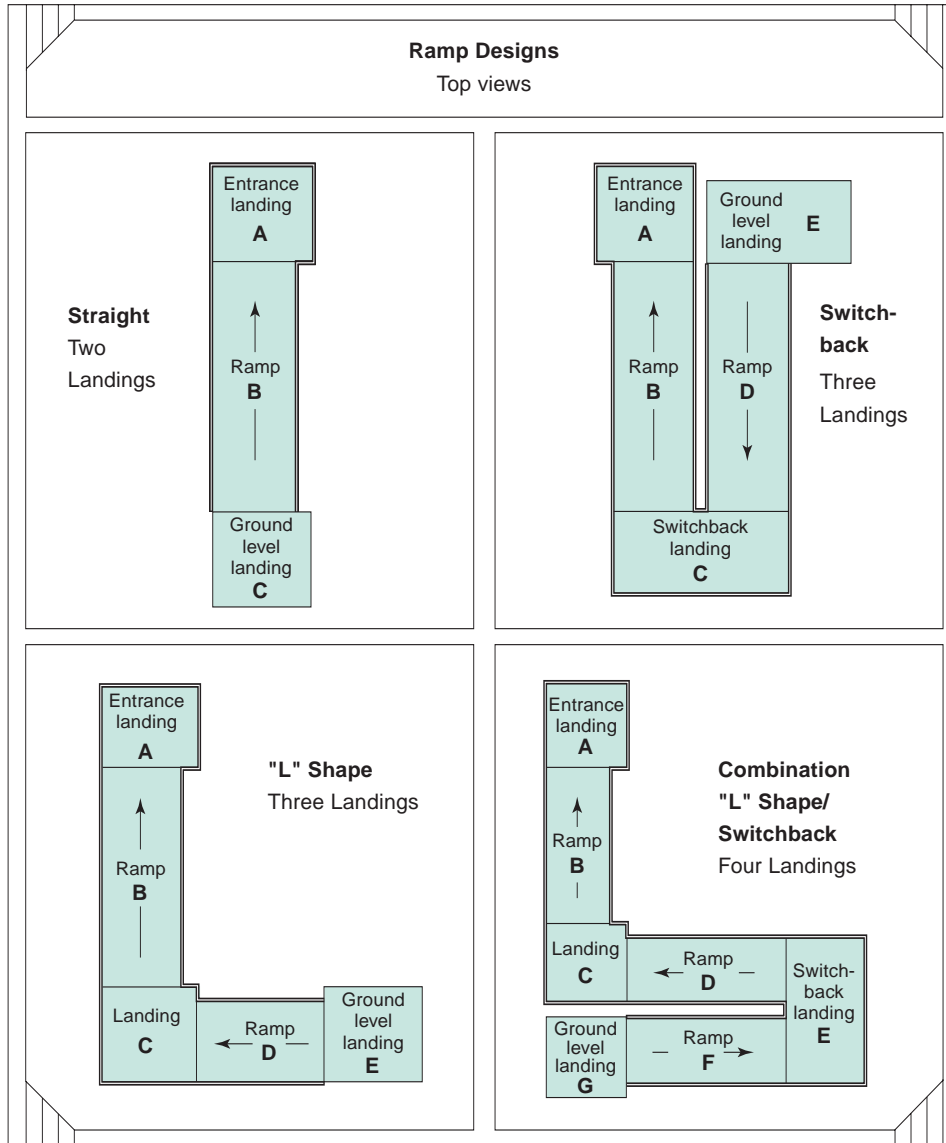

Figure 36-4 Typical ramp specifications. For an outdoor uncovered ramp, the ratio of height to length is 1:20 (for every inch of height, 20 inches of length). For a covered outdoor or indoor ramp, the ratio is typically 1:12. Landings are needed wherever the ramp changes direction and at 30-foot intervals on long ramps. The landing at the top of the ramp should be 5 × 5 feet for adequate maneuvering. The bottom of the ramp must have at least 5 feet of level area at the termination point. Recommended widths of ramps range from 36 to 48 inches with handrail grasping surface 30 to 34 inches high. (Reprinted from Henson J. [1988]. *Building a ramp* [p. 7]. Little Rock, AR: Arkansas Department of Human Services, Division of Rehabilitation Services.)

Maximum Ramp Slopes Between Landings

Figure 36-5 Sample ramp slope specifications.

Bathrooms

Bathing, grooming, and toileting are typically performed in the bathroom. When bathrooms are not accessible, people may perform these activities in other locations. Older adults may use a bedside commode to toilet in a bedroom or living room. People who cannot access their second-floor bathroom may sponge bathe in the kitchen sink. Figure 36-1 shows some features that offer different options for creating a more accessible bathroom.

INTERVENTIONS FOR ACCESS TO WORK ENVIRONMENT

Although the ADA does not apply to home modifications, Title I of the ADA ensures that workers with disabilities have access to accommodations that enable them to perform the tasks required for their job (see Chapter 33). Entering and exiting the workplace, moving around the workplace, and completing essential job tasks may be difficult if environmental barriers exist. Workplace accommodations can be used to reduce activity demands and therefore maximize occupational functioning at work. For example, heavy doors can be challenging to open. Guidelines indicate that doors should open with 5 pounds or less of pressure or with electronic controls. Other examples of common workplace accommodations include computer adaptations, such as voice input and output software, large-print screens, adapted keyboards, accessible workstations and bathrooms, adapted telephones, telecommunications display device (TDD) or text telephone, Braille and large print materials, sign language interpreter, and adapted controls on equipment (Fig. 36-3). In addition to accessing workstations, environmental barriers can also exist in accessing the restrooms and break rooms; this aspect of social participation is also the purview of the occupational therapist working to optimize access for clients.

As is clear from the previous discussion, occupational therapists can help clients optimize access to home and work in many ways. The interaction of the person's abilities and the environment is key in determining which interventions will best facilitate occupational performance.

Procedures for Practice 36-4 details a wide array of modifications for various functional limitations.

INTERVENTIONS FOR ACCESS TO THE BROADER COMMUNITY

Homes and workplaces are part of communities. Schools, parks and recreational facilities, retail stores, and places for health and social services are also part of the community environment. These public spaces are subject to some of the established guidelines. Guidelines, such as the Fair Housing Act Accessibility Guidelines (FHAAG) and the Uniform Federal Accessibility Standards (UFAS), provide recommendations for design of architectural features, installation of equipment, and space planning, including height, width, type, and configuration of elements and fixtures (Architectural Transportation Barriers Compliance Board or Access Board, 1991). The FHAAG regulates the design of private multifamily housing, such as apartments. The ADAAG applies to public spaces, particularly the workplace and community. To further explain some of the specifications outlined in ADAAG, see Figure 36-6 for installing grab bars and Figure 36-7 for the turning radius for wheelchair users (Procedures for Practice 36-5).

Access to visiting one's neighbors is another issue around community accessibility. The concept of **visitability**, as discussed by Eleanor Smith of Concrete Change (Atlanta, Georgia), suggests that all home environments be designed so that people can visit one another. Visitability includes three basic features for access to homes, including a no-step entrance, wide doorways (32 inches) on the first floor of the home, and access to a first floor bathroom with an accessible toilet, sink, and light switch. For the most part, private homes are not required to be accessible. Recommendations can be made, however, to include basic features of access in the design of a home to meet future needs, eliminating the need for major and often costly modifications later (Concrete Change, 2001).

Access to the community goes far beyond just meeting set standards or adhering strictly to guidelines. Specialists who thoroughly understand the minimum accessibility features can advocate not only for implementation of these features, but also for exceeding them to further optimize accessibility.

FACTORS AFFECTING EFFECTIVENESS OF INTERVENTION STRATEGIES

The goal of environmental interventions is to improve accessibility to facilitate occupational functioning. To opti-

PROCEDURES FOR PRACTICE 36-4

Examples of Suggested Environmental Interventions for Specific Functional Limitations

The following are examples of environmental interventions for people with visual impairments:

- Adequate lighting with high lumens. Use non-glare lighting with sconces or shades. Halogen lighting is recommended for close work and task lighting in work areas for extra lighting when needed. Use switches that can provide adjustable light intensity for different tasks.
- Window treatments that allow for light filtering and adjustment and awnings on the outside of windows when direct sunlight is the most intense.
- Contrasting colors of surfaces to define objects and spaces, especially background and foreground, such as light switch covers contrasting with walls, chair seat contrasting with floor, wall contrasting with floor, countertops contrasting with sink, dark food on light-colored cutting board and the reverse, and step edges contrasting with step surface.
- Tactile indicators, raised letters, or voice output on controls and signs. Use large print with high contrast from the background. Vary textures to provide cues for directionality and dangerous situations.
- Elimination of busy and confusing patterns on such surfaces as rugs, upholstery, and wallpaper.
- Elimination of clutter and obstacles from access routes throughout the environment and removal of low-profile furniture or moving it against walls out of access routes.
- Visual aides such as closed-circuit television, magnifiers, large-print computer screens with high contrast, and talking devices.
- Illuminated switches for appliances and lights. Large knobs and handles that contrast in color and have a non-slip surface.
- Bathroom grab bar system that contrasts with the wall and that has a 1.5-inch diameter and a non-slip surface. Colored tape may be wrapped around the bar to create a pattern.

The following are common environmental interventions to address the needs of people with hearing impairments:

- Use of TDDs for telephone communication. Use of fax machine and telephone relay system.
- Handy access to paper and writing implement for communication.
- Vibrating or visual signal devices, such as alarm clocks, smoke alarms, telephones, doorbells, and baby monitors to place under pillow or bed when sleeping.
- Closed caption features on television and videos. Use of closed-loop or amplification devices for use in group settings or large spaces.

- Access to oral and sign language interpreters when needed.
- Amplification devices to eliminate background noises and increase volume of desired noise.
- Arrange furniture so people sit facing each other and ensure that there is adequate lighting so the person can use visual cues when conversing.

The following suggestions address the needs of people with mobility impairments:

- Ranch-style houses with at least one no-step entrance. The house should be on a flat lot with continuous sidewalks and street access from house to house and block to block. The house should be in an area with accessible public spaces like banks, shopping centers, library, post office, medical offices, parks, and recreation centers.
- Open, unobstructed spaces in each room with adequate turning radius for the wheelchair.
- Bathroom off the master bedroom with a wheel-in shower, transfer space on at least one side of the toilet, pull-down grab bars to use when needed.
- Open-bottom sink with counter space and a ground fault circuit interrupt (GFI) outlet within easy reach.
- Either a built-in transfer bench or portable one in the shower. Barrier-free shower doors or a shower curtain. Hand-held showerhead on an adjustable-height track.
- Wheelchair stair lift providing access to the finished basement.
- Patio or deck off the back door and master bedroom with access to a garden area.
- Environmental control system (ECU) to regulate the thermostat, lighting, television, stereo, and so on from one portable control unit.
- Wheelchair-accessible home office with computer station.
- Adjustable-height countertops, cabinets, and sinks.
- Wall oven and microwave at accessible heights.
- Stovetop with staggered burners and front or side controls.
- Angled mirror over the stove to show contents of pots for a seated person.
- Accessible switches for exhaust ventilation and fire extinguisher.
- Low-maintenance lawn covering and landscaping. Raised, vertical, or container beds for gardening from a wheelchair.
- Garbage can on wheels.
- Wheelchair-accessible table tennis, pool table, swimming pool with a lift.

PROCEDURES FOR PRACTICE 36-4 (continued)

The following recommendations address the needs of people with mild dementia living in their own homes:

- Environmental cues and assistive devices to address safety and memory deficits and communication deficits.
- Personal emergency response system with medication management. Training in use of devices and monitoring of ability to learn.
- Automatic medication management system that is set up weekly by a home care nurse.
- Burglar alarm and posted fire escape plan. Client instructed in emergency response and escape, with periodic reinforcement to ensure carryover of learning. Smoke alarms that are hard-wired with battery backup.
- Emergency lighting in case of power failure.
- Daily call to monitor self-care ability.
- Meals on Wheels and use of microwave with electric hot water pot. Electric range or microwave oven rather than gas stove. Step-by-step instructions for each appliance and any safety precautions on or next to the device. Ongoing monitoring for safety awareness and proper use.
- Pre-programmed telephone numbers used most for one-button speed calling.
- Well-organized environment to compensate for any problem-solving or memory deficits. Labeled cabinets or doors removed in the kitchen for viewing the cabinet contents.

imize client acceptance of accessibility recommendations, the occupational therapist tries to address client awareness of resources, funding issues, and interdisciplinary communication.

Awareness of Resources

Occupational therapy practitioners work with clients to make them aware of their options regarding ways in which environmental demands can be reduced. Clients can often identify the occupational areas that are difficult for them,

but they may not realize that the environment presents barriers to their occupational functioning. People continue to believe that something is “wrong” with them rather than with their environment when they have difficulty performing their occupations. Occupational therapy practitioners identify the demands and barriers presented in the environment and help clients address these accessibility issues in treatment plans.

Additionally, when clients do identify the need for environmental interventions, they may not know who can make the modifications, where to go to get services, and how to pay for them (Bayer & Harper, 2000). Occupational therapy practitioners can help families identify needed home modifications and access services. Home modifications are often pieced together through a variety of service providers. Area Agencies on Aging and Centers for

PROCEDURES FOR PRACTICE 36-5

Community Access: Accessible Design of Architectural Elements of Public Spaces and Multifamily Homes

The occupational therapy practitioner considers the following major elements of the environment when consulting about public spaces and multifamily homes, as specified in FHAAG and ADAAG:

- **Accessible route.** An accessible site must have a continuous unobstructed path connecting all elements and spaces of a building or facility, such as route from parking space to the entrance.
- **Signage.** ADAAG specifies the proportion, size, location, symbol usage, and level of contrast for character signage. Letters must contrast with background and must be raised and have Braille markings. Raised letters or numbers used to mark buildings, rooms, or offices must be placed on the right or left of the door 54–66 inches off ground or floor level.
- **Parking spaces.** Accessible parking spaces are required in every parking lot that services employees or visitors. The parking spaces must be convenient and marked for use for people with disabilities. Accessible spaces must have a minimum width of 12 feet, 5 feet of which serves as a drop-off zone and must be connected by an accessible route to an accessible entrance.
- **Approaches.** Paths must be a minimum of 36 inches wide. Pathways should be constructed of firm, smooth, non-slip continuous surfaces. Ramps must have handrails, curb guards, and non-slip surfaces. Landings must be provided at the base and top of each ramp. These landings must be no more than 30 feet apart.
- **Doors and doorways.** A doorway must have a clear opening of 36 inches (32 inches with door open) and must be operable by a single effort. Doorway entrances must be level at grade (0.5 inch or lower threshold). Fire doors are exempt from accessibility guidelines. Turnstile or revolving entrances are not accessible to those who use wheelchairs, and an alternative must be provided.
- **Stairs.** Stairs must be designed to have consistent tread and riser dimensions, be equipped with handrails, drain properly, and have adequate lighting and non-slip surfaces.
- **Elevators.** Elevators should be automatically operated and should have a cab door at least 32 inches wide, protective door and reopening devices, door and signal timing for hall calls, a door delay for cab calls, and an area large enough for wheelchair accessibility.
- **Controls.** Switches and controls for light, heat, ventilation, windows, curtains, fire alarms, and all similar controls must be placed within reach of people in wheelchairs, preferably approximately 42 inches off the floor.
- **Warning signals.** Warning signals must be both visual and audible in nature and located at appropriate accessible heights as designated by ADAAG. Fire or exit signage must be at least 7 feet from the floor.
- **Lighting.** Adequate non-glare lighting should be provided, and electrical outlets and rocker-style or pressure-sensitive switches must be located at accessible heights.
- **Public telephones and water fountains.** A public telephone must be placed so that the coin slot, dial, and headset are reachable from a wheelchair. Phones for people with hearing impairments should be labeled as such, with clear visual operating instructions. Coin slots should not be more than 54 inches off the floor. Similarly, water fountains should be fully accessible. The fountain should not be recessed. Its controls should be on the front of the unit. A wall-mounted unit should not be more than 36 inches off the floor. An accessible cup dispenser and a telephone amplification device are examples of reasonable accommodations.
- **Bathrooms.** Toilet stalls should have grab bars. Toilet partitions should be rearranged and widened to increase maneuverability. Clearance under sinks and counters is necessary. Insulation on hot water pipes under sinks is important. Lowering paper dispensers, raising toilet seats, providing an accessible flushing lever, and lower mirrors or full-length mirrors are appropriate.
- **Automated teller machines.** ATMs must be usable for people with disabilities. Accommodations may be as simple as the installation of an angled mirror to enable a person in a wheelchair to see the screen or may run to major redesign and retrofitting. Tactile cues, Braille, and/or voice prompts must be provided for people with visual impairments.

Independent Living are federally supported social service organizations that vary by location as to whether they offer home modification services. Rebuilding Together is a national non-profit provider of home modifications and home repair with local chapters across the country. The variability across geographic locations can be challenging in finding service providers who assist with creating accessible home environments.

Vocational rehabilitation services often assist with **workplace accommodations** for people with disabilities. Some workplaces have ergonomic consultants or departments that help create workplace environments that reduce the risk of injuries while optimizing work productivity. The needs of aging workers will be a new challenge for many workplaces to begin to address.

Accessibility of public spaces is somewhat regulated with regard to the ADA. Many buildings and spaces, however, were built prior to 1990 (when the ADA took effect). Older buildings continue to contain many accessibility barriers. New construction is subject to meeting ADAAG. Occupational therapists can serve not only as consultants to projects aimed at increasing community accessibility, but also as advocates raising awareness of the barriers to community participation.

Community coalitions, local building codes, and local services available can all affect community accessibility. Interested individuals and organizations may form local coalitions to promote changes in building codes or to better coordinate the delivery of services. Since the information age, virtual communities also exist through the Internet. Occupational therapy practitioners can assist with gaining access to **electronic and information technology** for people with disabilities. This can be achieved by understanding the various formats, software programs, and interfaces with the technology needed by people with disabilities.

Funding Issues

One of the major barriers to home, workplace, and community access is finding funding for the changes. Universal design is a relatively recent concept and is not yet a standard practice in the design of new building and construction of homes, workplaces, and communities. New construction with accessibility features costs less than retrofitting existing structures.

Funding must be pieced together from a variety of sources. Individuals pay out of pocket. Employers may assist with funding workplace accommodations. Some insurance companies may pay for home and/or workplace accommodations. Community organizations with grant funds may pay for services that improve community ac-

cessibility and home accessibility. Funding options vary greatly by location, organization, and reason for the intervention.

Communication and the Interdisciplinary Team

As in other areas of practice, occupational therapy practitioners work in collaboration with other professionals who have different perspectives and terminology. Building professionals, such as contractors, designers, architects, and building code officials, are not part of a typical health care team but can be part of the team providing environmental interventions to promote accessibility. Professionals of multidisciplinary teams need to develop a method of communication that promotes collaborative problem solving. Occupational therapy recommendations that address client's occupational functioning are made in collaboration with the contractor who understands structural and construction issues. As with any type of team, all members need to have a similar understanding of the goal to effectively achieve the desired outcome.

EFFICACY AND OUTCOMES

The desired outcomes when optimizing accessibility are to maximize occupational functioning and social participation. People with disabilities, older adults, caregivers, personal assistants, and potentially anyone who is part of a particular environment can all benefit from the outcomes of environmental interventions. As a person ages, changes with aging may be modulated by reducing participation in activities rather than in changing the environment. Unknowingly, by limiting activities, the older person may contribute to further declines in physical functioning. Research in the area of fall risk reduction has demonstrated that occupational therapy visits with home modification recommendations can be an effective approach to reducing fall risk among older adults with a history of falling (Cumming, Thomas, & Szonyi, 1999). Researchers also have found the use of home modifications and assistive technology to be a cost-effective alternative to institutional care (Mann et al., 1999).

Not only do people with disabilities benefit from environmental accessibility, but also all potential users of a particular space or setting benefit. In a study of people with dementia and their caregivers, the caregivers were better able to cope with difficult behaviors of the person with dementia following home-modification interventions (Gitlin et al, 2001).

Evidence Table 36-1 Best Evidence for Occupational Therapy Practice Regarding Home Modification Interventions

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Assistive technology (AT) and environmental interventions (EI) will result in greater ADL performance and reduced overall cost of health-related services	OT visit with recommendations, implementation of AT and EI.	Older adults in New York (N = 104; treatment, n = 52; controls, n = 52).	For treatment group, mean AT devices received, n = 15; mean EI interventions, n = 1.44; mean visits from OT = 8.9; and mean visits from technician, n = 2.4.	Randomized, controlled study; level I evidence. IA2a	Significant difference in number of AT devices received. Significant difference in number of EIs received. Cost-effective alternative to long-term care.	AT devices: t = 6.57, p < 0.001, r = 0.297 EIs received: t = 4.1, p < 0.001, r = 0.14. Cost effectiveness compared with long-term care: d = 0.56, r = 0.243.	Mann et al., 1999
Home modifications for caregivers (CGs) of persons with dementia	Home visits by OT with educational strategies and home modifications to manage ADL and IADL dependency and difficult behaviors of persons with dementia.	Family CGs in Philadelphia area caring for family member with dementia. N = 171 (treatment, n = 93; controls, n = 78).	Five 90-minute home visits by OT.	Randomized, controlled study, stratified by race and gender; level I evidence. IA2a	Intervention group compared with controls reported: less decline in IADL performance of person with dementia; spousal CGs were less upset by behaviors of person with dementia; female CGs were able to better manage behaviors; and female and minority CGs showed improved management of functional dependency.	Decline in IADL performance: p = 0.030, t = 2.24, r = 0.017. Spousal CGs less upset by behaviors of person with dementia: p = 0.049, t = 1.97, r = 0.15. Female CGs better able to manage behaviors: p = 0.037, t = 1.97, r = 0.16.	Gitlin et al., 2001

<p>Home modification intervention to reduce falls in older adults</p>	<p>Standardized assessment of home hazards, recommendations, and supervised implementation by OT, follow-up visit.</p>	<p>530 community-dwelling older adults in Sydney, Australia, prior to being discharged from inpatient hospitalization. (controls, n = 266; intervention, n = 264); mean age = 77 years.</p>	<p>1-hour home visit, with additional visits as needed and follow-up.</p>	<p>Randomized, controlled study with block design; level I evidence. IA1b</p>	<p>Intervention group demonstrated a 19% reduction in falls compared with control group. Those with prior history of falls showed a 36% reduction in fall rates in the intervention group compared with controls.</p>	<p>Reduction in falls: $p = 0.05$, $t = 1.96$, $r = 0.15$. Reduction in falls in those with a prior history of falls: $p = 0.001$, $t = 2.54$, $r = 0.19$.</p>	<p>Cumming, Thomas, & Szonyi, 1999</p>	<p>Improved management of functional dependency by female and minority CGs: $p = 0.049$, $r = 0.15$; and $p = 0.037$, $r = 0.16$, respectively.</p>
<p>Bathroom modifications to maximize self-care performance</p>	<p>OT recommendations for bathroom modifications</p>	<p>Pre-test, n = 34; post-test n = 20.</p>	<p>Two home visits from OT: initial evaluation and recommendations and follow-up reevaluation. ADL performance: $t = 3.01$, $p < 0.01$, $r = .322$. Transfers: $t = 5.08$, $p < .000$, $r = .576$</p>	<p>Gitlin, Miller, & Boyce, 1999</p>	

CASE

EXAMPLE

Mrs. P.: Implementing Environmental Interventions to Optimize Occupational Performance

Occupational Therapy Intervention Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>Mrs. P. is an 85-year-old woman who sustained a right-sided cerebrovascular accident (CVA) 2 months ago, resulting in left-sided hemiparesis. She was recently discharged from the rehabilitation center to an apartment that she has shared with her husband for more than 30 years. Mr. P. would like to hire an attendant to work a few hours a day to assist with Mrs. P.'s personal care and to help with the housekeeping, but financial constraints do not allow for this. Both Mr. P. and their daughter carry out most of the household tasks and have reported becoming increasingly frustrated and fatigued. They both say that they don't believe that they can leave Mrs. P. alone because of their concerns about her safety and independence. Prior to her stroke, Mrs. P. prided herself on her ability to care for her husband and her home. Mrs. P. has been referred to the community occupational therapist to address concerns about her independence and safety in her home environment.</p>	Appreciate the context	<p>(See related assessment chapter, Chapter 11, for description of the assessment process and patient's background.)</p> <p>"I know that Mrs. P. is returning home where she lives with her husband. She needs assistance with personal care and housekeeping. Her husband wants help but cannot financially afford to hire an assistant for his wife. Their daughter lives nearby and helps when she can. Her workplace does not like her to take off time during the day though. She needs to take her mother to doctor appointments and tries to schedule them around her lunchtime."</p>
	Develop intervention hypotheses	<p>"I anticipate that Mrs. P. will be able to safely engage in some self-care and housekeeping activities. I may be able to help her delay further decline or even delay institutionalization by implementing environmental interventions and helping her acquire assistive technology that promotes accessibility and optimizes her occupational performance."</p>
	Select an intervention approach	<p>"Since I am unsure of Mrs. P.'s readiness to change, I will apply the Consumer Decision Model and further assess her perceived threat and consequences of her situation and cost and efficacy of interventions. I will also approach the intervention plan by addressing components of the Person-Environment-Occupation Model and determine how to decrease demands in the home environment to increase occupational performance."</p>
	Reflect on competence	<p>"I have worked with several clients with unilateral hemiparesis resulting from a stroke who were discharged home. I am knowledgeable about various tools and databases (such as LifeEASE, ABLEDATA, and eCASPAR) and am confident that I will be able to offer some options of products that may be useful to the needs of my client. I will work with another therapist who is knowledgeable in other techniques for stroke recovery that focus more on remediation such as constraint-induced movement. I will also make referrals to social work for assistance with finding funding sources and locating caregiver support for the family members."</p>

Recommendations

The occupational therapist recommended 3–5 visits to negotiate environmental modifications and assistive technology. In collaboration with Mrs. P., her husband, and her daughter, the occupational therapist established the following long-term treatment goals: (1) following bathroom modifications, Mrs. P. will safely complete bathing activities with minimal supervision and prompting; (2) after instruction on task modification, Mrs. P. will engage in light housekeeping tasks with minimal assistance from family; (3) Mrs. P. will complete dressing and grooming tasks with the use of assistive devices and verbal prompting; and (4) Mrs. P. will participate in activities at a senior center 2–3 times a week.

Consider the patient’s appraisal of performance

“Mrs. P. lacks of awareness of safety risks. I suspect that she may have attention deficits or executive function disorder, and further assessment is needed. This might explain why she does not demonstrate any memory deficit but does seem to have difficulty with initiation and sequencing. She is aware of changes in her abilities to perform meaningful activities.”

Consider what will occur in therapy, how often, and for how long

“Mrs. P. will have home modifications made to her bathroom including replacing the tub with a shower, placing non-skid strips on the shower floor, and installing grab bars. Here is how I plan to approach Mrs. P.’s other needs: provide Mrs. P. and her family members training on safety issues and how to protect and care for her paralyzed side, which is likely to be neglected; use task modification strategies to engage Mrs. P. in meaningful housekeeping tasks; provide visual and verbal cues to encourage visual scanning to the affected side and to avoid injury; and provide assistive devices to assist with dressing, grooming, and meal preparation activities.”

Ascertain the patient’s endorsement of plan

“Mrs. P. is motivated to engage in housekeeping tasks, which are important to her. She is agreeable to the plan and understands that her family will feel more secure if she follows through with the recommended safety features.”

Summary of Short-Term Goals and Progress

1. Mrs. P. will complete dressing and grooming tasks daily with the use of assistive devices.
2. Mrs. P. will complete at least two IADLs with task modification strategies, assistive devices, and set-up from family.

The occupational therapist introduced task modification strategies and assistive devices that facilitate access to participation in self-care and household activities. The therapist recognized that Mrs. P. was motivated to contribute to her family and her household.

The occupational therapist recognized that Mrs. P. liked gadgets and that she was open to trying assistive devices that reduced physical barriers. The therapist assisted Mrs. P. and her family in selecting several assistive devices to increase ADL and IADL performance and then trained Mrs. P. to use them. Mrs. P.’s family reported that Mrs. P. was less dependent on them for self-care activities.

Assess the patient’s comprehension

“I could see that Mrs. P. became frustrated with learning to use a button hook for dressing. We discussed other alternatives, and eventually, she preferred to have Velcro fasteners on her clothes to replace buttons.”

Understand what he is doing

Compare actual to expected performance

“Mrs. P. was able to use a spiked cutting board while seated at the kitchen table. Her family assisted with set-up, but otherwise, she was able to complete most meal preparation.”

Know the person

Appreciate the context

“I anticipated that Mrs. P. would improve her participation in activities with the strategies and devices. She was highly motivated. We did have to try some different strategies to get the expected outcome. An additional outcome was that her family caregivers felt less burdened.”

Next Steps

Revised short-term goals (1 month):
Following bathroom modifications and training with assistive devices, Mrs. P. will complete bathing with minimal supervision 2 times per week.

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"Mrs. P. does not want to be dependent on her husband to assist her with bathing. She is waiting for assistance from Rebuilding Together to provide a roll-in shower in place of her tub."

"I am concerned about Mrs. P.'s visual left neglect. She doesn't seem to be aware of the deficit, and she is resistant to strategies for visual scanning to the left. Also, she has fallen a couple times in the past month. Her visual and sensory perception is impaired, and she has difficulty when getting up from a chair. I wonder if she is experiencing orthostatic hypotension, which is contributing to her fall risk. I have referred her to a physical therapist. Following her bathroom modifications, I will visit her again and provide training."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Interventions to Decrease Environmental Demands

The demands in Mrs. P.'s home environment did not match with her current abilities and resulted in decreased performance of meaningful self-care and housework activities. Describe at least two different intervention strategies used by the therapist to help Mrs. P. progress toward resuming self-care and homemaker roles.

SUMMARY REVIEW QUESTIONS

1. What historical events affect current practices and trends in accessibility of homes, workplaces, and communities? Why is knowledge of these important to the occupational therapy practitioner who consults on accessibility?
2. How do the evaluation results influence decisions about interventions used to optimize accessibility in the home, workplace, and community?
3. What are some of the design and product solutions that help to reduce activity demands within the home environment?
4. How can universal design principles be applied to the design of communities, homes, and workplaces to maximize occupational functioning and social participation?

CHAPTER 37

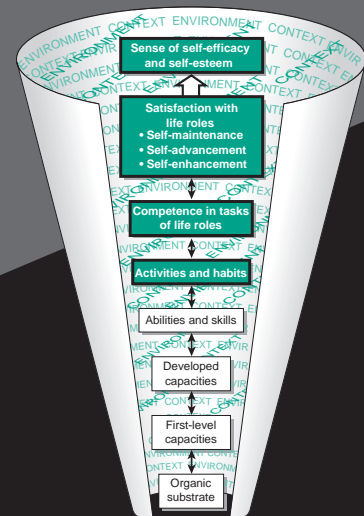

Preventing Occupational Dysfunction Secondary to Aging

Glenn Goodman and Bette R. Bonder

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe normal age-related changes as they relate to areas of occupation, performance skills, performance patterns, and client factors (body functions and body structures).
2. Discuss activity patterns of older adults as related to activities of daily living, instrumental activities of daily living, education, work, play, leisure, and social participation.
3. Describe considerations in assessing the function of older adults.
4. Discuss interventions through which occupational therapists can facilitate function in older adults.
5. Describe the factors that make intervention following illness or injury for older adults different from that for younger adults.

Glossary

Crystallized intelligence—Ability to use stored or previously learned information.

Dementia—Symptom caused by a number of conditions and characterized by loss of memory, language functions, ability to think abstractly, and ability to care for oneself.

Fluid intelligence—Ability to use new information.

Presbycusis—Age-related sensorineural hearing loss, especially for high-frequency sounds.

Presbyopia—Age-related vision change caused by loss of flexibility of the lens, which leads to poor near vision.

Productivity—Activities that make an economic contribution to society, including but not limited to paid employment, volunteer work, child care, and homemaking.

From 1950 to 2000, the total resident population of the United States increased from 150 million to 281 million, representing an average annual growth rate of 1% (Administration on Aging, 2004; Federal Interagency Forum on Aging Related Statistics [FIFARS], 2004). During the same period, the population 65 years of age and over grew almost twice as rapidly and increased from 12 to 35 million people. The population 75 years of age and over grew almost three times as quickly as the total population, increasing from 4 to 17 million people. Projections indicate that the rate of population growth during the next 50 years will be somewhat slower for all age groups and older age groups will continue to grow more than twice as rapidly as the total population. From 2000 to 2050, it is anticipated that the percentage of the population 65 years and over will increase substantially. Between 2000 and 2050, the percentage of the population 65 to 74 years of age will increase from 7% to 9%, and the population 75 years and over will increase from 6% to 12%. By 2040, the population 75 years and over will exceed the population 65 to 74 years of age. The aging of the population has important consequences for the health care system (Administration on Aging, 2004; FIFARS, 2004). As the older fraction of the population increases, more services will be required for the treatment and management of chronic and acute health conditions. Providing health care services needed by Americans of all ages will be a major challenge in the 21st century (Administration on Aging, 2004, p. 21).

These figures have considerable import for health care providers, particularly occupational therapists, who are concerned with assisting individuals to maintain or regain ability to perform valued daily activities. Enhancing functional performance of older adults can have economic, social, and personal benefits for these individuals, their families, and society as a whole.

The emphasis in this chapter is on the normal aging process. Older adults are, of course, subject to all of the illnesses and injuries that affect younger people, as well as some that are far more likely to occur in older individuals,

such as cerebrovascular accidents, dementing illnesses, and cancer. Other chapters in this volume address mechanisms by which therapists can provide effective intervention for these conditions. When illness or injury occurs, however, the therapist must put the consequences in the context of the individual's life stage, which makes understanding normal aging essential. Special considerations in intervening with older adults are also discussed in this chapter.

NORMAL AGING

Changes that accompany normal aging occur in every sphere, both internal to the individual, including the cognitive-neuromuscular substrate, first-level capacities, and developed capacities, and external to the individual, as in social situations and responses to the physical environment. It is essential to remember, however, the wide range of variation among individuals. All of us know individuals who, at age 55, have stooped shoulders, shuffling gait, and poor vision and hearing and whose favorite activity is napping. We also know individuals who, at age 80, have a vigorous stride and engage in activities that would exhaust many a younger person. The existence of a physical change does not necessarily lead to a commensurate decrement in function. This section considers typical cognitive-neuromuscular, first-level, and developmental changes that accompany normal aging. These changes occur to varying degrees among older adults, with varying effects on performance.

COGNITIVE-NEUROMUSCULAR SUBSTRATE

Without question, genetic factors influence the aging process (Jones, Bland, & Quinn, 2003). Perhaps most

important from the perspective of aging is the contribution of genetics to predisposition to illness and disability, including type II diabetes, some cancers, and high blood pressure (Jones, Bland, & Quinn, 2003). The interaction of genetic predisposition with personal behaviors and environmental circumstances leads to expression of genetic tendencies. Thus it may be possible to reduce risk of most genetic disorders by half or more through modification of behaviors (Rowe & Kahn, 1998). For example, exercise can reduce risk of high blood pressure and heart disease even in individuals with a strong genetic risk (Kell, Bell, & Quinney, 2001).

FIRST-LEVEL CAPACITIES

This section summarizes age-related changes in the following systems and capacities that allow for reflex-based responses: sensory, neuromuscular, cardiovascular, and cognitive. These first-level capacities are client factors as described in the Occupational Therapy Practice Framework (American Occupational Therapy Association [AOTA], 2002).

Sensory Changes

Some sensory changes normally occur with aging; others result from disease processes common among older adults (Hooper, 2001). One role of the occupational therapist is to evaluate the level of dysfunction caused by change in client factors such as sensation and process skills that allow individuals to interpret sensory input. Therapists then can determine strategies to compensate for problems that interfere with abilities, activities, tasks, and life roles in performance areas of occupation.

Changes typically occur in all sensory spheres, including vision, hearing, gustation, olfaction, touch, and vestibular sensation. Changes in multiple sensory channels require careful intervention to optimize function. Furthermore, decrements may occur at the level of reception or of interpretation or integration, that is, either peripherally or centrally in the nervous system (Bottomly & Lewis, 2003). Sensory loss can severely impair the older person's ability to communicate with other humans; the psychosocial consequences can be devastating (Heine & Browning, 2002).

Vision

In 2002, 18% of non-institutionalized people 65 years of age and older were visually impaired, which is defined as full or partial blindness or other trouble seeing. The prevalence of visual impairment increases with age, from 14% of people 65 to 74 years of age to 33% of people 85

years of age and over. Cataracts, glaucoma, and macular degeneration are primary causes of visual impairment among the older population (FIFARS, 2004).

Deterioration of near vision, called **presbyopia**, begins to affect most people when they are about age 40 (Boyce, 2003). The lens loses its elasticity and becomes less able to focus because of weakness in the ciliary body (Lewis, 2003). Presbyopia is easily accommodated through the use of a well-known assistive device: eyeglasses.

Another common change is development of degenerative opacities (cataracts) of the lenses, which lead to decreased sensitivity to colors, increased sensitivity to glare, and diminished acuity (Boyce, 2003).

Several diseases, including diabetic retinopathy and retinitis pigmentosa, can affect the retina at any age. The effects of these diseases, both of which may lead to total blindness, are most pronounced in the elderly population because both are progressive degenerative diseases (Boyce, 2003). Macular degeneration, a disorder causing loss of central vision as the macula deteriorates, is most common among older individuals. Most older individuals with macular degeneration retain sufficient peripheral vision to assist in mobility but not enough for activities such as reading or watching television (Boyce, 2003).

Musculature that controls eye movement tends to lose strength and tone (Tideiksaar, 2002). Tear secretion may be reduced and degenerative changes may occur in the sclera, pupil, and iris (Bottomly & Lewis, 2003). Such changes can result in excessive dryness, loss of light/dark accommodation, and poor night vision. Finally, decreased color vision and changes in the vitreous body that affect retinal function occur with aging (Bottomly & Lewis, 2003).

Hearing

Approximately 47% of men and 30% of women over 65 years old have severe hearing loss, especially for high frequencies (FIFARS, 2004). Conductive hearing loss may be the result of problems in the external or middle ear, such as wax buildup, Eustachian tube blockage, or stiffness of the ossicles and membranes (Lewis, 2003). Age-related sensorineural hearing loss, known as **presbycusis**, results from dysfunction of the sensory hair cells of the cochlea, neural connections from the cochlea to the cerebral cortex and brainstem, or vascular changes in the auditory system (Lewis, 2003). Functional consequences of these changes include difficulty hearing high-frequency sounds, distinguishing consonants during conversation, and filtering background noise during conversation, and challenges to balance due to inner ear changes (Tideiksaar, 2002).

Taste and Smell

Thresholds for taste and smell increase with age (Rawson, 2003). This has several functional implications. First, the

ability to appreciate food flavor is closely related to olfaction (Lewis, 2003). Inability to detect aromas may cause food to seem tasteless, possibly resulting in secondary nutritional disorders. Safety may become a concern, as individuals may not be able to detect harmful odors such as natural gas, spoiled food, or smoke (Aldwin & Gilmer, 2003). Smoking or environmental exposures may exacerbate age-related changes in taste and olfaction (Bottomly & Lewis, 2003).

Tactile Changes

Tactile changes can occur due to normal aging, but there is more evidence to suggest tactile changes occur more frequently due to pathological conditions of the skin and nervous system (Aldwin & Gilmer, 2003; Bottomly & Lewis, 2003; Ebersole & Hess, 1998). Changes in the number and sensitivity of touch and pressure receptors have been reported, but studies showing definitive loss of pain and temperature sense are not yet conclusive (Aldwin & Gilmer, 2004; Ebersole & Hess, 1998; Lewis, 2003).

Proprioceptive and Kinesthetic Changes

Documentation of changes in proprioception or kinesthesia that are purely related to aging is scant. Some studies, however, have reported a decline in lower extremity proprioception among elderly patients that was not found when the upper extremities were tested (Bottomly & Lewis, 2003). Changes in proprioception secondary to loss of vision, peripheral vascular disease, arthritis, cardiovascular disorders, stroke, disorders of the inner ear, and diabetes have also been reported (Bottomly & Lewis, 2003; Ebersole & Hess, 1998).

Vestibular Function

Vestibular changes are particularly significant because of the importance of falls as a health risk for older adults. Approximately 33% of older adults fall each year (Balogun & Katz, 2002), and 15% of these individuals are subjected to serious health consequences, such as broken hips (Tideiksaar, 2002). The mortality rate following hip fracture approaches 50% (Kell, Bell, & Quinney, 2001).

Older adults have more postural sway than younger adults (Waddington & Adams, 2004), a condition that is exacerbated when vision is impaired. Vestibular righting response diminishes with age, which can lead to problems in maintaining balance. Age-related changes in static balance, dynamic balance, and gait appear to increase the probability of falls (Aldwin & Gilmer, 2003; Bottomly & Lewis, 2003; Ebersole & Hess, 1998; Lewis, 2003; Tideiksaar, 2002).

Central Nervous System

With age, the cerebrum atrophies (Bottomly & Lewis, 2003; Ebersole & Hess, 1998), and cerebrospinal fluid space increases. Neurons are lost or atrophy, particularly in the precentral gyrus, postcentral gyrus, superior temporal gyrus, and Purkinje cells of the cerebellum (Bottomly & Lewis, 2003). The number of synapses falls, and neurotransmitter systems change. In addition, plaques, fibrillary tangles, and other cellular abnormalities have been found in the brains of functionally normal older adults (Lewis, 2003). Responses to stimuli as measured by electroencephalogram also slow down. Neurotransmission can be impaired by aging, leading to behavioral abnormalities (Strong, 1998).

Peripheral Nervous System

Among the changes in the peripheral nervous system seen in aging are loss of both myelinated and unmyelinated nerve fibers, axonal atrophy, and nerve conduction velocity (Verdu et al., 2000). Some sources, however, indicate that the manifestations of nervous system deterioration (reduced sensibility, coordination, cognitive abilities, and reaction time) observed with aging do not correspond to the relatively small physical changes seen at the cellular level (Bottomly & Lewis, 2003). In addition, variation between individuals makes functional and structural generalizations problematic.

Musculoskeletal System

The musculoskeletal system is affected by the aging process. The effects of normal change can have consequences for mobility and function. The following sections describe the normal aging process as it affects muscles and bone, as well as the impact of various diseases on the musculoskeletal system.

Muscles

The number and size of muscle fibers decrease with age (Kell, Bell, & Quinney, 2001). Increase in fatty and connective tissue, decreased strength, and loss of type II fast-twitch anaerobic muscle fibers that are responsible for phasic movement have been reported, as have decreases in muscle flexibility and endurance.

Joints

Joint function declines steadily after age 20. Ligaments and tendons become less resilient and more prone to injury (Bottomly & Lewis, 2003). The quantity and viscosity of synovial fluid decrease with aging. Cartilage becomes opaque, with an increase in cracks and fraying

(Bottomly & Lewis, 2003). The effects of weight bearing and stress on joints and the effects of diseases, such as the various kinds of arthritis, make the rate and nature of cartilage deterioration highly variable. Once cartilage is destroyed or damaged, it does not regenerate. This has special significance to the elderly, who must rely on prevention or corrective surgery to manage the potentially disabling effects of loss of cartilage (Bottomly & Lewis, 2003; Lewis, 2003).

Bones

The progressive loss of bone mineral content with aging results in loss of bone mass and density. The rate of these changes is affected by diet, exercise, and gender (Kell, Bell, & Quinney, 2001). Osteoporosis has been studied extensively. Women after age 39 have a rate of bone loss double that of men. Post-menopausal women are affected most. By age 65, at least 50% of women have developed some form of osteoporosis. The rate of degeneration slows by age 70 (Lewis, 2003).

Effect of Disease on the Musculoskeletal System

Arthritis, osteoporosis, connective tissue diseases, orthopedic injuries from falls and trauma, and repetitive motion disorders are most prevalent in elderly individuals (Tideiksaar, 2001). Almost 50% of men and women have some form of arthritis by age 65 (FIFARS, 2004). In 1996, hip fractures alone were responsible for more than 300,000 hospitalizations among people 65 years of age and older, of whom 80% were women. Among people 85 years of age and older, 90% of women and 54% of men had measurably reduced hipbone density.

Cardiovascular Changes

The cardiovascular system loses efficiency with age, which is the result of changes in the frequency and regularity of the conduction system (Dean, 2001), a reduction in pacemaker cells (Bottomly & Lewis, 2003), alterations in blood pressure (Newman, 1995), changes in the elasticity, length, and thickness of the arteries (Bottomly & Lewis, 2003), a decrease in heart rate and stroke volume (Dean, 2001), and a general thickening of specific heart tissues, such as the atria and valves (Bottomly & Lewis, 2003).

Aging affects every component of the cardiopulmonary system (Dean, 2001; Kell, Bell, & Quinney, 2001). Elastic tissues decrease and fibrous tissues increase. This especially affects the medium and small airways constructed of smooth muscle. The joints of the chest wall stiffen, the muscles of the diaphragm flatten, and the chest wall becomes more barrel shaped and less compliant (Dean, 2001). Approximately 50% of individuals over

age 65 have blood pressure greater than 140/90 (Ebersole & Hess, 1998).

New research suggests that the effects of aging on the cardiovascular system once thought to be irreversible and consistent are highly variable among individuals (Chodzko-Zajko, 2001) and cultures (Ebersole & Hess, 1998) and reversible with exercise and dietary and behavioral changes (Blair et al., 1996; Chodzko-Zajko, 2001).

Cognitive Changes

As it is difficult to differentiate between first-level and developed capacities in cognition, the following discussion combines these two aspects of age-related changes. Age-related changes occur in some aspects of intelligence, problem solving, abstract reasoning, memory, memory processing, and attention. In all of these functions, changes are most noticeable after age 70, although gradual decline occurs when individuals reach the age of 30 (Anstey & Low, 2004).

As measured by the *Wechsler Adult Intelligence Scale*, intelligence quotient decreases with advancing age, largely the result of decreases in the performance rather than verbal subscales (Riley, 2001). Performance subscales may depend on **fluid intelligence** (the ability to use new information), whereas verbal subscales may use **crystallized intelligence** (recall of stored memories) (Anstey & Low, 2004). In particular, flexibility in reasoning tasks seems to decline (Riley, 2001), although older adults show wide individual variation in these cognitive tasks. Problem-solving skills also seem to become less efficient (Anstey & Low, 2004).

To remember, one must attend to the matter to be recalled and be able to receive information through sensory channels. The information must be processed (interpreted) and stored. Initial storage may be relatively short term. Overall, well older adults do not have memory loss in processing and short-term storage of information, although some have difficulty encoding large amounts of information at once (Anstey & Low, 2004).

Decrements in long-term memory and encoding are noticeable (Anstey & Low, 2004). Older adults have more trouble recalling information than do younger ones, although retrieval difficulty is not as noticeable for recognition. For example, on seeing a name, an older person may remember the face and personality of an acquaintance but, on seeing the person, have difficulty retrieving the name. This difficulty is much less pronounced when the information has practical significance. Remote or very long-term memory appears not to decline. This finding, however, is more anecdotal than data based and must be viewed with caution (Riley, 2001).

Another common phenomenon is increased difficulty with word finding, accompanied by subtle deficits in short-term memory, such as difficulty remembering names or

where one put an object. Dubbed mild cognitive impairment, this irritating but not disabling condition seems to begin in late middle age (Royall et al., 2005). In most instances, the individual remembers the information later. For some individuals, memory training has helped minimize associated functional decrements (Riley, 2001).

One challenge in examining cognitive change in older adults is the clear association between sensory decline and cognition (Valentin et al., 2005). Visual or hearing deficits may reduce the individual's ability to respond accurately to questions or to follow instructions, creating the illusion of greater cognitive problems than may actually be present.

CASE

EXAMPLE # 1

Mrs. P.: Optimizing Occupational Function Despite Limitations Associated with Aging

Occupational Therapy Intervention Process	Clinical Reasoning Process	
	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>Mrs. P. is a 73-year-old woman who lives alone in a ranch-style house in a small town. Her grown daughter visits about four times a year; her son visits once a year. Mrs. P. was divorced 12 years ago and never remarried. Mrs. P. worked as a nurse for more than 20 years at a large university hospital. Now she works 2 days a week at a nursing home three blocks from her house, where she reviews charts for quality assurance. Mrs. P. has always enjoyed work and feels that the staff are close friends. Other than her income from the job, Mrs. P.'s only source of funds is Social Security.</p> <p>Throughout her adult life, Mrs. P. has been in a sorority consisting of about a dozen women who have been friends since they were young women. They live nearby. For many years, she was a member of a women's group that raised funds for the ballet in the nearby city. When she is at home, Mrs. P. enjoys working on a dollhouse that she built.</p> <p>Mrs. P. has a long history of health problems. She survived breast cancer when she was in her 40s, and 3 years ago, she had surgery to remove a cancerous tumor from her colon. She has high blood pressure, which is controlled with medication. She also has a significant hearing loss that is gradually worsening.</p>	<p>Appreciate the context</p>	<p>"Mrs. P. strikes me as a very independent woman, someone who is used to calling the shots. I will want to be very careful to respect that in her throughout this process."</p> <p>"Clearly, Mrs. P. has a strong social network. It impresses me that she has maintained strong connections with both her friends from work and her sorority sisters. I wonder if she would consider allowing these life-long friends to help her out now."</p>
<p>Reason for Referral to Occupational Therapy</p> <p>Recently Mrs. P.'s sorority sisters noted changes in her social behavior (missing meetings, not answering her phone, refusing social invitations) and contacted her son with their concerns. He urged his mother to make an appointment with her family physician, her primary care provider for the past 30 years. During the visit, the physician discovered that her high blood pressure has worsened, as has her hearing. She also reported being very tired and having difficulty managing around the house. The physician ordered a series of medical tests and asked a home health agency to send an occupational therapist to evaluate the home and Mrs. P.'s function. He assured her that her son agreed to pay for this evaluation.</p>		<p>"It's important for me to get a sense of how Mrs. P. is functioning in her own environment, and I am pleased that a home visit was ordered. She will likely be the most comfortable here, and I'll be able to get a clearer sense of what the barriers are to her occupational functioning."</p>

Results of Occupational Therapy Assessment

Mrs. P. agreed to a home visit by the occupational therapist. The therapist decided to evaluate Mrs. P.'s home and her performance of basic self-care and instrumental activities of daily living. The therapist used the *Check It Out Check-List* (Pynoos & Cohen, 1990), the *Interest Checklist*, and the *Self Assessment of Occupational Functioning*. She also asked Mrs. P. to give her a tour of the house and to describe problems encountered in daily tasks.

"I decided to use these instruments because they will help identify areas of occupation that are most important to Mrs. P as we collaborate to develop an intervention plan, and they apply a theoretical model of practice—the Model of Human Occupation."

Develop intervention hypotheses

"I have a number of core hypotheses as I approach this consultation: (1) return to work is feasible and valued by employer and client; (2) consultation with physical therapy, physician, audiology, and social work is feasible; (3) client's reasons for social withdrawal need further assessment; (4) client continues to have interests in current occupations; and (5) client may be interested in alternative occupations to replace current work and leisure activities if these are not feasible."

Select an intervention approach

"Consultative, adaptive, collaborative, client-centered, and rehabilitative approaches could all possibly be implemented."

Reflect on competence

"I have knowledge and skills that I believe can help Mrs. P. Occupational therapy has strengths in energy conservation, adaptation of work and home for safety, meaningful occupations, and social skills. Physical therapy, audiology, physician, and social work could provide assistance with hearing, hypertension, financial, and social problems."

Recommendations

1. Develop an intervention plan in consultation with client, family, employer, and sorority sisters if appropriate.
2. Recommend consultation with physical therapy, social work, physician, and audiology.
3. Prioritize goals with interventions that are financially and functionally feasible in consultation with all stakeholders.

Consider the patient's appraisal of performance

"Mrs. P. seems to want help to improve her functioning, but I do feel that I am somewhat limited as to how much I can do for her in just one session. I will want to make sure that I am addressing her priorities and, if she is interested, am willing to work with her to explore availability of alternative resources to fund care."

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

"I find myself wondering about whether or not other stakeholders are invested in the client over the long term? What are they willing and able to provide in support?"

Problem List and Solutions

The therapist and Mrs. P. discussed these concerns and worked jointly toward identifying potential solutions. Since the therapist was asked to do an evaluation, not to provide long-term intervention, she must provide Mrs. P. with sufficient information to address her concerns.

Assess the patient's comprehension

"Mrs. P. was very forthright about her concerns and could readily agree with some of my observations about the potential safety hazards related to all of her clutter. I can't tell whether her reluctance to get rid of things reflected difficulty with decision

Problem List and Solutions (cont'd)

Home safety

Mrs. P. acknowledged that the house was cluttered with old papers, knickknacks, and clothes. She was reluctant to throw anything away but agreed to have her daughter store some of the items for her. Mrs. P. also indicated that she had no funds to replace the worn carpet, although both agree that worn spots and loose edges contribute to falls. She and the therapist identified several possible sources of funds and discussed the possibility of taking the carpet up entirely.

Physical deconditioning

Mrs. P. indicated that she had much less energy than she used to and quickly becomes short of breath when walking around the house. She agreed to begin a gradual plan of physical activity, starting with a stroll around the block each day.

Social isolation

Mrs. P.'s hearing loss was quite noticeable. The therapist encouraged her to see an audiologist to have her hearing evaluated. Mrs. P. expressed concern about paying for a hearing aid but agreed to ask her son for help.

Mrs. P. indicated that her friends were all in poor health and "no fun" anymore. She also said she was worried about falling at work. She was unwilling to discuss any alternatives for maintaining ties with her friends but agreed that she could discuss her concerns about work with her supervisor.

Understand what she is doing

making or, perhaps, her overall fatigue and deconditioning."

Compare actual to expected performance

"Mrs. P. is remarkably insightful. She realizes that falling at home or at work could have serious health consequences, but she may be self-limiting her activities more than is necessary. She seemed very receptive to my suggestions regarding how she could safely increase her activity level."

Know the person

Appreciate the context

Next Steps

1. Client will consult with physician to address hypertension and fatigue.
2. Client will consult with physical therapy to address lack of endurance.
3. Client will consult with audiologist to address hearing loss.
4. Client will return to work.
5. Client will employ methods of energy conservation to work, self-care, and home maintenance tasks and will report ability to complete these tasks with fewer incidence and severity of fatigue symptoms.
6. Client will address safety hazards in the home, such as clutter and unsafe flooring, by removing these dangerous barriers.
7. Client will engage in activities with sorority sisters twice a week.

Mrs. P. and her occupational therapist developed a time line for Mrs. P. to call her doctor, her daughter, her son, and her boss, and Mrs. P. and her therapist agreed that the therapist will make a follow-up call to check on her progress in 2 weeks. On follow-up, the therapist learned that Mrs. P. had accomplished a great deal. Mrs. P.'s physician determined that she had pernicious anemia and instituted monthly injections of vitamin B12. Mrs. P. reported that she already felt more energetic.

Mrs. P. started walking around her yard twice a day. Her daughter came to visit and helped her organize the house. Her son sent a check for a new hearing aid. Mrs. P. had not yet talked with her boss and was worried about doing it. She and the therapist practiced the conversation to provide Mrs. P. with a strategy. A week later, Mrs. P. called the therapist to tell her she was back at work.

Anticipate present and future patient concerns

"I wonder if the employer is satisfied with Mrs. P.'s work performance. Is Mrs. P. enjoying her work? "

Analyze patient's comprehension

"I should ask Mrs. P. about her interactions with the sorority sisters and her family. Are there more frequent interactions? What is the quality of those interactions?"

"Is Mrs. P. falling at home or at work and, if so, how frequently? How could I best evaluate for this? How about incidence of shortness of breath? I should consider these factors before deciding to discontinue intervention. Is the client able to manage daily activities including work without a worsening of hypertension or fatigue?"

"If I am only able to intervene in one session, how could I most effectively address these complex issues using consultation, advocacy, and ethical/professional behavior? Can communication with the physician, the family, and other professionals involved address this concern adequately?"

Analysis of Reasoning

The therapist's initial task was to gather the information needed to clearly identify the problem. As the therapist secured information, it became evident that both Mrs. P. and her family needed to be consulted. Goals were identified based on their input. In this case, the occupational therapist provided an assessment and recommendations but left implementation of the plan to this capable client and family.

Decide if the patient should continue or discontinue therapy and/or return in the future

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Intervention to Prevent Performance Decrements**

The occupational therapist focused on screening and prevention in this consultative intervention. How might the therapist's assessment and intervention approaches have been different if Mrs. P.'s function had deteriorated to the extent that she was placed in a long-term care facility?

A Special Note about Dementia

Dementing illnesses are extremely common among older adults. **Dementia**, which is characterized by forgetfulness, difficulty finding words, and other cognitive loss, is not a normal condition of aging. Rather, it is a symptom of any of several disease processes (Corcoran, 2001). Some, such as depression, sensory deprivation syndrome, malnutrition, and drug toxicity, are reversible; others are not. Alzheimer's disease, the most common form of dementia, is a progressive disorder that eventually leads to total disability and death.

It is beyond the scope of this chapter to deal with the methods for intervening with individuals with dementing disorders. A few suggested intervention strategies are included in Procedures for Practice 37-1 and in Chapter 29 of this book. Health care professionals should be familiar with the early symptoms of cognitive disorder, such as difficulty finding words, forgetfulness about everyday events and procedures, and lack of recollection of familiar individuals. When noted, these symptoms should be carefully evaluated by a geriatrician, a physician trained to work with older individuals. Reversible causes may be treated relatively easily. If the individual has an irreversible dementing illness, a variety of management strategies can help informal and formal caregivers to cope with resulting problems. This enhances quality of life for both the ill person and the caregivers. One excellent source of information about management is *The 36-Hour Day: A Family Guide to Caring for Persons with Alzheimer Disease, Related Dementing Illnesses, and Memory Loss in Later Life* (Mace, Rabins, & McHugh, 1999).

**DEVELOPED CAPACITIES: CHANGES IN VOLUNTARY RESPONSES**

Changes in organic substrates and first-level capacities may impair such voluntary responses as rising from a chair and gait speed (Fiatarone et al., 1990). Weakness in ankle dorsiflexion and knee extension has been correlated with falls in older individuals (Tideiksaar, 2001).

**PROCEDURES FOR PRACTICE 37-1****Strategies for Working with Individuals with Dementia**

- Place items used frequently in visible locations.
- Use simple, one-step instructions.
- Maintain habitual activities as much as possible; simplify as needed.
- Obtain a bracelet identifying the person as memory impaired in case of wandering.
- Encourage physical activity during the day to improve nighttime sleep.
- Provide activities that stimulate memory (for example, baking or music that the person used to enjoy).
- Avoid excessively crowded or unfamiliar surroundings that might lead to catastrophic reactions.
- Contact the local Alzheimer's association for resource lists and support groups.

Loss of dexterity and coordination with aging is well-documented (Desrosiers et al., 1995). Scores on the *Jebsen Hand Function Test* (Jebsen et al., 1969), the *Nine-Hole Peg Test* (Mathiowetz, Weber et al., 1985), and the *Box and Block Test of Manual Dexterity* (Mathiowetz, Volland et al., 1985) all decline with age. The result can be increased difficulty in activities requiring such skill.

ABILITIES AND SKILLS: PHYSICAL CAPACITY

The following changes in physical capacity typify skills and abilities that are affected by normal aging: postural alignment, sway, and instability with postural changes

(Tideiksaar, 2001); gross motor coordination (Bottomly & Lewis, 2003); fine motor coordination and dexterity (Desrosiers et al., 1995); strength and endurance (Bottomly & Lewis, 2003); walking speed, step length, and step height (Bottomly & Lewis, 2003; Tideiksaar, 2001); and reaction time (Bottomly & Lewis, 2003).

ACTIVITIES AND HABITS

Activities and habits are prominently discussed in the Practice Framework (AOTA, 2002). The category labeled performance patterns considers habits, routines, and roles. As with physiological change, activity patterns are highly individual (Bonder & Martin, 2000). In fact, older adults have great freedom of choice in our culture. Some older

CASE EXAMPLE # 2

Mrs. S.: Optimizing Occupational Function for a Senior in a Nursing Home Setting

Occupational Therapy Intervention Process

Patient Information

Mrs. S., an 80-year-old nursing home resident, has five children. Four of them live within 50 miles. Mrs. S. worked as the personal secretary for the provost of a small college for 20 years. She had a variety of interests, including reading, cooking, and baking; participating in church and local theater; and gardening.

Mrs. S. faced a number of challenges in her life, including the early death of her father, the Great Depression, her husband's absence for 3 years of service in World War II, raising a child with schizophrenia, the early and sudden death of her husband (she was 51 when he died), and adjusting to a move from her home to an apartment and now to a nursing home.

Mrs. S.'s medical history is fairly typical for a person her age. She developed osteoarthritis in both knees, resulting in several microscopic surgeries and two total knee replacements. She was hospitalized for a brief bout of depression secondary to menopause. She has presbyopia with resulting losses of both near and far vision that are well corrected with eyeglasses. She has severe hearing loss in both ears that is partially corrected with hearing aids.

Mrs. S. also had a series of strokes that began when she was 70. The strokes left her with mild spasticity, about 50% of proximal upper extremity active range of motion, and only a

Clinical Reasoning Process

Objectives

Appreciate the context

Examples of Therapist's Internal Dialogue

"I should focus on past and current occupations and performance in areas of occupation. I want to take note of the current status of body functions and structures and how these may influence performance in the areas of occupation. It's important that I identify performance patterns, habits, and routines and try to make sense of all that relative to the cultural, spiritual, physical, social, personal, temporal, and virtual contexts of Mrs. S.'s past and current environment. For example, I wonder how possible changes in these factors have influenced her occupations and what areas of occupation may be compromised by these changes."

Patient Information (cont'd)

mass grasp in her left hand. She had full use of lower extremities except for a loss of about 15° of right active knee flexion and mild spasticity and weakness in the left lower extremity. She lost approximately 25% of the visual field on the left side to hemianopsia but can accommodate for this by turning her head. Mrs. S. also had mild dysarthria and dysphagia. She dribbled urine because of changes in bladder function and weak sphincter musculature. She wore a small protective pad and took medication to control this. She was hospitalized a year ago for an attempted suicide and major depression as a result of the breaking of her knee replacement and difficulty adjusting to the idea of another major surgery. She received psychiatric services and a long rehabilitation stay after she agreed to have the knee replacement. Her recovery from the knee replacement was very good except for her complaint of chronic pain in the knee that has not responded to medication.

Prior to the failure of her first knee replacement, Mrs. S. was totally independent in all basic activities of daily living. After her knee replacement and rehabilitation stay, a trial in her assisted-living facility became problematic because of her declining ability to walk and transfer to the bathroom and inability to do her own personal care. She and her family decided that Mrs. S. should be admitted to a nursing home, where she would receive closer supervision and assistance for her personal care.

Reason for Referral to Occupational Therapy

The nursing home staff was concerned about Mrs. S.'s safety and social withdrawal. Mrs. S. was still using a wheeled walker but found placing her left hand on the walker handle difficult. She was able to move from her bed to the bathroom independently but had several recent falls. She dressed independently if her clothes were placed on a chair beside her bed. However, she displayed poor judgment in activities such as bending too far over the edge of the bed and dangerously reaching for things she dropped on the floor. She also tripped over things while walking. She used a wheelchair on outings with her family and with the activities program at the nursing home. Mrs. S. rarely smiled, and nursing staff reported difficulty getting her to participate in group activities or outings, even though she was physically able to do so. Her family was supportive. Her oldest daughter had power of attorney and durable medical power of attorney. Mrs. S. paid privately for nursing home care and had funds remaining to cover about 2 more months of care. She was willing to pay privately for brief occupational therapy intervention.

“Are there standardized or non-standardized assessments that could be used to address functional mobility, ADL, depression?”

Results of Occupational Therapy Assessment

After reviewing the medical records, the occupational therapist evaluated Mrs. S.'s life roles, tasks, activities, skills, abilities, and developed capacities. Mrs. S. was interviewed along with her oldest daughter and primary nurse. Some of the critical questions raised during the interviews were:

- What safety issues are you most concerned about?
- What is your level of satisfaction with life right now? What do you think could be done to improve it?
- What things do you like to do right now? What things irritate you?
- If you could change five things around here to make things better for yourself, what would you change?
- What worries you most? What makes you happiest?
- Do you have any goals to improve yourself, your environment, or your living situation?

Results of Occupational Therapy Assessment (cont'd)

Develop intervention hypotheses

“I have a number of core hypotheses as I approach intervention planning: (1) the client is motivated to improve; (2) the caregivers are motivated to collaborate on the established goals; (3) the family is supportive and motivated to assist in achieving the goals; (4) direct intervention as well as consultation and collaboration are necessary to achieve the goals; (5) the client has the potential to achieve the goals; (6) the other stakeholders have the resources to collaborate in accomplishing the agreed upon goals; and (7) it is financially possible to consult other professionals such as physical therapy, urology, orthopedic surgery, pain management specialist, audiology, and social work.”

Select an intervention approach

“Rehabilitative, client-centered, consultative, adaptive, and collaborative approaches may all apply to this client.”

Reflect on competence

“Skills from other professionals will be needed to address many of the issues. OT has strengths in the areas of safety, urinary incontinence, meaningful occupations, functional mobility, ADLs, and psychosocial issues.”

Recommendations

1. Interview client, family, caregivers, and nurses to identify problems that are of highest priority for each stakeholder.
2. Further assess safety and performance of ADLs.
3. Recommend consultation with physical therapy, social work, audiology, psychiatry, and urology.
4. Develop a plan of care in consultation with all stakeholders.

Consider the patient's appraisal of performance

“I need to address issues that are most important to the client, the family, and the caregivers. I wonder if there is consensus among all stakeholders about these issues and their relative importance. I will need to consider what can be done in the way of consultation, direct OT intervention, and collaboration with others considering the client's strengths and weaknesses, the motivation of all stakeholders, and the context. Who will be responsible for goal achievement using which model of team intervention?”

Consider what will occur in therapy, how often, and for how long

Ascertain the patient's endorsement of plan

Summary of Short-Term Goals and Progress

The interviews and evaluation revealed the following problems:

1. Mrs. S. tends to get upset and take things into her own hands when she has to wait for assistance. This results in unsafe or dangerous behavior and activities.
2. Mrs. S. gets depressed and does not feel like socializing with others, especially residents with problems similar to hers or worse.
3. Mrs. S. needs some meaningful activities to replace the wide variety of activities that formerly gave her pleasure.
4. Mrs. S. needs some modifications to her environment to increase safety and orientation to reality and current events.
5. Mrs. S. is easily embarrassed and has difficulty asking for personal assistance, especially with urination and personal hygiene.
6. Mrs. S. would like more interaction and visits from her family.

Assess the patient's comprehension

“How can I and the team best monitor falls, frequency of urinary incontinence, quality and quantity of participation in mandatory or optional leisure activities, and the list of positive and negative feelings?”

Understand what she is doing

“What can be done to assess motivation of client, staff, and family in monitoring follow-through with recommendations, and do I need to adjust instructions and goals depending upon progress or lack of progress achieved?”

Compare actual to expected performance

Know the person

Appreciate the context

“I should consider standardized assessments of depression, occupational function, cognition/judgment, and ADL function.”

Occupational Therapy Goals

The following goals were agreed upon by Mrs. S., her family, and the nursing staff:

1. Mrs. S. will request and wait for assistance or supervision for trips to the bathroom or will use a female urinal at bedside.
2. Mrs. S. will call for assistance should she drop any item on the floor that is not within easy reach of her long-handled reacher. Otherwise, she will continue to dress herself independently with setup at bed or chair level.
3. Mrs. S. will attend at least two outings per week with family or with the nursing home activities program. She will provide constructive criticism to the staff as to how the activity could be improved.
4. Mrs. S. will learn to propel her wheelchair so that she can safely navigate throughout the building without falling. She will be supervised for walks to the bathroom or in the hall.
5. Mrs. S. will choose and successfully complete three leisure activities within a month using adaptive equipment or techniques recommended by the occupational therapist.
6. Mrs. S. will complete a list of things that she is unhappy with as well as a list of things she is grateful for and review them with her daughter at least once a week to encourage her to express her feelings appropriately.

Next Steps

The occupational therapist decided to see Mrs. S. once or twice a week for a month to achieve these goals. Mrs. S. agreed to pay for the therapy because she did not qualify for skilled services under Medicare regulations.

Direct Intervention

1. Instruction in safety for mobility within her room;
2. Adjustment of call signal button and chairs and removal of throw rugs and other barriers to safe mobility in the room;
3. Provision of long-handled reachers and instruction in use of them;
4. A session to assess safety issues during dressing and hygiene activities;
5. Suggestions for adaptive equipment for playing cards, reading, and plant care;
6. A daily calendar and structured time to read the paper or watch the news on television for current events;
7. A meeting with Mrs. S. and her family at the end of the month to review progress on goals and to make decisions about continuance of therapy or discharge.

The occupational therapist suggested referrals to physical therapy for a program to maintain or enhance mobility and physical conditioning, speech pathology to review issues related to dysphagia and dysarthria, and social work to help Mrs. S. and her family apply for Medicaid or other support, as financial concerns were becoming an issue. The therapist consulted the nursing and activities staff and provided written copies of suggestions for the staff to facilitate accomplishment of the therapy goals. Suggestions were also made to Mrs. S. and her family to explore a visit to a chronic pain specialist for the knee pain and to a urologist for follow-up on bladder control issues.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“Are the goals being met? Why or why not? Did the other consultants contribute to the interventions and what were the outcomes? How are the client, caregivers, and family responding? What barriers could be further addressed to address the problems and goals more effectively? Is additional support needed to ensure safety? Has the client reached maximum potential to achieve the goals based upon progress notes and consultation with all stakeholders? What progress can be documented? Do all stakeholders agree that further therapy would be beneficial in reaching particular goals?”

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Intervention Despite Age-Related Deterioration

What strategies did the therapist use to collaborate with patient, family, and nursing home staff? What else could be done to ensure that stakeholders maintain their contribution to Mrs. S.'s function long after the occupational therapy intervention is complete?

adults engage in many activities; others focus on one or two. For example, some older adults report activities that are related primarily to family, while others may be active in volunteer work, several hobbies, social relationships, and care of their personal needs.

The importance of habits must be emphasized. Evidence shows that when a familiar task is undertaken in a familiar environment, the effect of aging on performance is reduced (Rogers, Holm, & Stone, 1997). Where such habits can be followed closely, task performance is improved.

Most older adults accommodate to age-related changes well by modifying routines or finding and accepting assistance. This is especially true when the activity is one for which it is socially acceptable to receive help. Help with driving, cooking, or managing finances is often acceptable. Some older adults are determined to do for themselves, while others are accepting, even relieved, when they can rely on others to take care of them.

Driving

Older drivers have higher rates of fatal crashes, based on miles driven, than any other group except very young drivers, according to the Insurance Institute for Highway Safety (IIHS). The high death rate is due in large part to their greater physical frailty. They are less likely to survive after an injury than a younger person. By 2030, people age 65 and older are expected to represent 25% of the driving population and 25% of fatal crash involvements, IIHS says. According to the National Highway Traffic Safety Administration (NHTSA), there were 19.9 million licensed drivers age 70 and older in the United States in 2002 (latest data available), or 10% of all licensed drivers (Insurance Information Institute, 2004).

Model driving evaluation and rehabilitation programs for the older driver include measuring driver potential before on-road evaluation (visual, cognitive, auditory, motor, neuropsychological, and psychosocial factors; driver/vehicle fit; reaction time; and driver simulation); measuring and improving driver performance with on-road testing and intervention; proper documentation of

fitness to drive; environmental and ergonomic factors impacting drivers, passengers, and pedestrians; and communication with all of the stakeholders in making a decision about the safe performance of an older driver (College of Health Professionals, University of Florida, n.d.; Pellertino, 2006).

Self-Care

A significant issue for older adults has to do with level of independence in self-care (Hayase et al., 2004). If personal ability is compromised, the issue is availability and acceptance of assistance. Most older adults show decline in ADL performance over time (Hayase et al., 2004). Among the deficits that are commonly seen are complex actions such as cutting toenails. Heavy housework, such as mopping floors and washing windows, is difficult for many individuals and may be hired out or done by family members. In addition, most elders spend more time on self-care activities than they did when younger (Christiansen & Hammecker, 2001). Issues of time can be significant when self-care consumes such a significant proportion of the day that other desired activities cannot be pursued.

Substantial disability in self-care is most likely to be perceived when there is a sudden change due to illness or change in social circumstances rather than the gradual ones that affect most well elders. If the change is loss related, emotional reactions that typically accompany loss must be addressed. Changes perceived as positive, however, such as a move to a long-desired retirement location, can also cause unanticipated emotional difficulties.

Urinary Incontinence

Urinary incontinence affects more than 13 million Americans. Up to 35% of community-dwelling people over age 60 experience incontinence; two thirds of these are women (Neumann, 2002). Ability to bathe and urinary and bowel incontinence are issues that can influence life-altering decisions for elders. Those who are unable to

bathe or who are incontinent are most likely to be placed in institutional settings, which is an event that most elders wish to avoid. Interventions for urinary/ bowel incontinence include surgery, medications, and behavioral treatment. Occupational therapists provide behavioral interventions that may include regular scheduling of toileting, pelvic muscle reeducation (Kegel exercises), biofeedback, bladder training, urge inhibition, bowel management, and dietary and fluid modifications (Burgio et al., 2002; Neumann, 2002).

Work

Emerging patterns in work and retirement reflect increasing diversity in the older population (Sterns, Laier, & Dorsett, 2001). For example, some older adults are creating a trend to earlier retirement followed by a second career in a different area, a return to part-time work, or a move to volunteer work.

Physiological changes seen in normal aging do not typically interfere with work abilities (Sterns, Laier, & Dorsett, 2001). Elders require somewhat different kinds of in-service training to maintain or expand competency, requiring slightly more time than younger adults to learn new skills. They respond best to learning that is based on practical examples. If these special needs are accommodated, however, they are as capable of maintaining their skills as younger people.

Substantial evidence exists that voluntary retirement is not viewed as a negative event (Bambrick & Bonder, 2005). When retirement is involuntary, however, either as a result of a personal situation such as failing health or external events such as layoffs, individuals are likely to be dissatisfied with retirement.

Retirement often does not mean the cessation of productive activity (Bambrick & Bonder, 2005; Herzog & House, 1991). Herzog and House note that individuals who engage in volunteer work, child care, other service for family members, or other forms of unpaid service report that these have value both to them and to others. Bambrick and Bonder found that older adults describe several major themes in their perceptions of work, including (1) contribution to self-concept, (2) giving back to the community, and (3) staying engaged.

At present, work as undertaken by older adults is receiving considerable attention for several reasons. Some of these reasons relate to demographics and public policy (Bergstrom & Holmes, 2004), some relate to the preferences of older adults (Altschuler, 2004; Bambrick & Bonder, 2005), and others are related to the age-related changes that affect ability to work (Bosma et al., 2003).

With regard to demographic and policy issues, several factors emerge in current discussion of older workers (Bergstrom & Holmes, 2004). As previously noted, the population of older adults in the United States is

becoming a larger proportion of the population as a whole. This means fewer young adult workers, those individuals historically viewed as the productive members of society. The so-called dependency ratio is changing such that, within a decade or so, there will be only two adult workers for every adult over 65. This has implications for public programs, such as Social Security, that depend on worker contributions to support retirees (Bergstrom & Holmes, 2004). At the same time, historical discrimination against older workers is being addressed through policy initiatives like the Age Discrimination in Employment Act and the Americans with Disabilities Act. Changing demographics require fundamental reconsideration of policies designed to either encourage or discourage elders' choices about paid employment.

At the same time, many older adults are making choices that differ from those of previous generations. Although there is a trend toward earlier retirement compared with previous generations, there is also a trend toward continued paid employment, albeit in new work circumstances (Altschuler, 2004; Bambrick & Bonder, 2005). Elders describe multiple reasons for wanting to continue to work, including issues of independence, sense of self-worth, and a wish to continue to contribute to society.

Considerable evidence shows that elders remain capable of work far beyond the traditional retirement age of 65 (Sterns, Laier, & Dorsett, 2001). Due to changes in cognition and physical status, older adults may require modest modifications in training and in work tasks; given these accommodations, however, they can continue to be productive and valuable workers far into later life. Elders in the workplace benefit from training that is practical and from repetition of new information. With regard to the content of work tasks, there is some speculation that cognitively challenging work delays deterioration of cognitive function (Bosma et al., 2003) and that remaining at work can reduce incidence of depression (Tian et al., 2004). Decreases in physical capacity require adjustment in the physical demands of work tasks (Savinainen, Nygard, & Ilmarinen, 2004) (Fig. 37-1).

Leisure

Leisure is extremely important to older adults (Bundy, 2001). It provides a sense of identity for individuals who are no longer working. It appears to delay onset of some disabling conditions, and it is linked to life satisfaction. Furthermore, it offers opportunities for expression of important personal meanings (Bonder & Martin, 1998). For older adults, the line between leisure and work may be indistinct, with activities providing both a sense of usefulness to others and satisfaction of personal need for engagement and challenge (Bambrick & Bonder, 2005) (Fig. 37-2).

Figure 37-1 The gentleman pictured is still on the job, despite the physical demands of his work in delivering supplies around his organization.

Figure 37-2 Even elders with substantial impairments derive great satisfaction from meaningful leisure activities.

The general belief, consistent with activity theory, is that maintaining a high level of activity is positive (Rosenfeld, 1997). This theory, however, has been challenged by some who believe that an important component of later life is reflection and life review (Ekerdt, 1986; Rowles, 1991).

TASKS AND LIFE ROLES

Elders also have greater personal choice in determining their tasks and life roles than do younger individuals. Although some individuals must continue to work to support themselves, most have the option of retiring from paid employment. Those who have children typically have finished rearing them. Since living in certain school districts is no longer an issue, some elders opt to sell their home and move to an apartment or to new community.

Satisfaction of Emerging Personal Needs and Meanings

In recent years, researchers have made increasing attempts to understand the occupations of older adults (Bambrick & Bonder, 2005; Bonder & Martin, 1998; Bonder & Martin, 2000; Rudman, Cook, & Polatajko, 1997). In particular, researchers are interested in knowing what is important to elders and how their occupations contribute to quality of life (Johansson, 2003).

Physical health is not, in and of itself, sufficient to ensure good quality of life (Johansson, 2003). Occupational therapists theorize that individuals are most satisfied with their lives when they engage in a variety of occupations that balance self-care, work, and leisure

(Kielhofner, 1995). Research suggests that this is true for older adults as well as younger individuals (Rowe & Kahn, 1998).

Elimination or Alteration of Roles

Clearly, although elders often make choices about self-enhancement roles, far less choice is involved in the elimination of tasks associated with changes in social roles. Death of a spouse, siblings, or friends dramatically shifts occupational tasks. Many elders find that they must modify their roles to accommodate them. As an example, one woman who had made her living as a weaver found that she could no longer sit at a large floor loom. She chose to weave at a small table loom or use finger looms (Bonder, 2001a). The salient issue seems to be the ability to find outlets for expression of personal meaning (Bonder & Martin, 2000).

Additional Roles

Elders not only lose or choose to end previous roles; they also add roles. An elder who stops paid employment becomes a retiree and may become a volunteer. A parent whose children are grown may become a grandparent. A notable rite of passage in the United States is the receipt of the letter at age 50 that indicates one is eligible for membership in the AARP; individuals electing to join add this role, too.

New chosen roles can enhance life satisfaction. In some instances, even roles that are not chosen may be satisfying. For example, some elders become not only grandparents but surrogate parents for their grandchildren. As many

Table 37-1. Summary of Theories of Psychological Processes of Older Adults

Theorists	Constructs
Disengagement Theory (Cummings & Henry, 1961)	<ol style="list-style-type: none"> 1. Elderly withdraw from activity 2. Elderly disengage emotionally from people and events
Activity Theory (Havighurst, 1963; Longino & Kart, 1982)	<ol style="list-style-type: none"> 1. Elderly strive to maintain activity 1. High levels of activity correlate with well-being
Continuity Theory (Atchley, 1989)	<ol style="list-style-type: none"> 1. Elderly attempt to continue activities that were always important to them 2. Elderly perceive activities as continuous 3. Elderly adapt activity to compensate for change 4. Successful aging is characterized by degree of continuity achieved
Lifespan Theories (Erikson, 1963; Levinson, 1986; Neugarten, 1975)	<ol style="list-style-type: none"> 1. Old age is a continuation of the developmental process, representing a new development stage 2. Tasks specific to the stage can be identified 3. Successful aging results from accomplishing tasks
Person-Environment-Occupation (Christiansen & Baum, 1997)	<ol style="list-style-type: none"> 1. Successful occupational engagement results from an interaction of the person, the environment, and the occupation 2. Intervention can occur in any of these three elements to enhance performance

Based on Table 3-1 in Bonder, B. R. (2001). The psychosocial meaning of occupation. In B. R. Bonder & M. Wagner (Eds.), *Functional performance in older adults* (p. 46). Philadelphia: F.A. Davis Co. Reprinted with permission.

as 10% of elders are custodial grandparents (Fuller-Thompson, Minkler, & Driver, 1997). Although this may be perceived by some as a burden, many grandparents express great satisfaction with this role.

COMPETENCE AND SELF-ESTEEM: PSYCHOSOCIAL CHANGES

Psychosocial status may well be a more significant predictor of occupational function than any other factor. Highly motivated, enthusiastic individuals tend to fare well, often despite what appear to be substantial physical limitations. Practitioners must attend to situations in which the individual, following an injury or illness, becomes depressed, loses motivation, and becomes increasingly disabled.

Changes in psychosocial status must be separated into those that are psychological and those that are social. For a well older adult, the former relate to developmental tasks of later life. The latter relate to external factors, including major life changes such as retirement and the loss of social contacts through moves, retirement, or death of peers.

A number of theorists have attempted to identify the normal psychological processes that accompany aging. Among the theories are disengagement, activity, continu-

ity, and life span models. The principal characteristics of these theories are noted in Table 37-1. Although each theory has appeal, each also has limitations in explaining the psychological functioning of older individuals, and all remain to be carefully tested.

Social changes are also less than clear. It is well established that older individuals have significant losses of social contacts (Bye, Llewellyn, & Christi, 2001). It is less clear, however, whether or how individuals compensate for those losses. For example, loss of a spouse is devastating for most older individuals (Bye, Llewellyn, & Christi, 2001). Some individuals compensate for the loss within a year or so, while others never recover.

IMPEDIMENTS TO OCCUPATIONAL FUNCTION

We review two categories of barriers to occupational function: disease and environmental factors.

Impact of Disease

Almost all older adults eventually fall ill or have an injury that may call for secondary or tertiary preventive interventions, that is, minimizing consequences early in treatment or

enhancing rehabilitation once severe disability has occurred. The following special characteristics of older adults must be considered in planning intervention.

Differential Severity of Condition

Some conditions that are relatively innocuous in younger individuals can have severe consequences for older individuals (Rowe & Kahn, 1998). One example is influenza, which is unpleasant for younger adults but may be lethal for older ones. On the other hand, cancers that may be terminal in younger adults are often quite slow growing in older individuals, leading to much less severe outcomes.

Multiple Health Problems

Otherwise well older adults are likely to have two or three chronic health problems (Administration on Aging, 2004), each of which may require a different intervention. A common example is a client who has both rheumatoid arthritis and osteoporosis. Although moderately strenuous weight-bearing exercise may be the treatment of choice to prevent bone loss, such activity may exacerbate the arthritis.

Duration of Recuperation

Older adults generally recuperate more slowly than younger ones. Even if the eventual outcome is every bit as good, it is likely to take the older individual longer to arrive at that point. Treatment often ends too soon for older individuals.

Consequences of Dysfunction

Most elders prefer to live independently or “age in place” (Rowe & Kahn, 1998). It is their wish to remain in the living situation to which they have grown accustomed. Illness and dysfunction, however, can lead to a decision to institutionalize. Functional abilities are central to such decisions. In particular, bathing and toileting abilities influence family decisions. For this reason, occupational therapists often find that elders want to emphasize these abilities in treatment.

Environmental Factors

As with all clients, environmental factors, both physical and social, can have a profound influence on function. Issues described in Chapters 10 and 11 of this text should be carefully considered during interaction with elderly clients, since changes to the personal, social, cultural, and environmental context can greatly facilitate personal abilities.

FACILITATORS OF OCCUPATIONAL FUNCTION

Clinicians consider each patient’s age as they plan assessment and treatment to optimize occupational function.

Evaluation

Careful evaluation is vital to successful intervention focused on supporting functional performance of older adults. Perhaps most attention has been given to assessment of self-care (Wilkins, Law, & Letts, 2001). In assessing older adults, however, it is important to be cognizant of the goals of the individual (Canadian Association of Occupational Therapists, 2002). Assessment should begin with identification of the individual’s goals and proceed to determination of factors that support or impede those goals. The Practice Framework (AOTA, 2002) recommends completing an occupational profile and an analysis of occupational performance. The two combined provide information about what the individual needs and wants to do and what factors limit ability to accomplish those tasks.

Several instruments may be helpful in determining those goals. The *Canadian Occupational Performance Measure* (Law et al., 2005) involves interview of the client and joint identification of goals for therapy. These goals then become the measures of outcome. Other instruments that may be helpful include the *Role Change Assessment* (Jackoway, Rogers, & Snow, 1987) and *Interest Checklist* (Matsut-suyu, 1963).

Legislation, particularly the Omnibus Budget Reconciliation Act (OBRA) (Glantz & Richman, 1991), requires that people in nursing homes have an environmental assessment, but such assessment should be done in community settings as well. A number of good environmental assessment instruments are available (Mann, 2001; Tiedeksaar, 2001) (see Chapter 11).

Instruments are also being developed to assess driving ability (Pellerito, 2006) because transportation is an important concern in accomplishing occupations. In addition, it is important to evaluate risk for falls (Nandy, 2004) because falls are common among older adults, have a high risk of significant injury, and can, therefore, significantly affect occupation. It is important to evaluate both the physical and the social environment to understand fully the individual’s situation.

Therapists must be aware that some assessment is mandated by third-party payers. For example, the U.S. government has implemented a minimum data set (MDS) (Health Care Financing Administration, 1999) for residents of nursing homes, and the Outcomes Assessment Information (OASIS) for home health. Furthermore, accreditation bodies, such as the Joint Commission on

Accreditation of Healthcare Organizations (1999), require that a patient's age be considered in both assessment and treatment planning.

Intervention

An important role for occupational therapists working with older adults is prevention or remediation of functional disability (AOTA, 2002). Intervention may include prevention, screening, environmental modifications, modification or substitution of activities, educational interventions, and acceptance of individual needs and wishes by health care providers.

Prevention

The wellness movement (Gallup, 1999) is based on the principle of maximizing both health and performance. Activities such as stress management, exercise to increase physical fitness, maintenance of adequate nutrition, safe driving habits, avoidance of alcohol and drugs, cessation of smoking, and activities to increase safety are associated with this model (Bonder, 2001b). In prevention programs, occupational therapists work with other health care providers to maximize the individual's physical and functional well-being. The occupational therapist may emphasize activities that encourage socialization and physical fitness, modification of the environment to reduce the possibility of accidents, and identification of roles and activities that are satisfying to the individual. Such interventions have demonstrated benefit (Clark et al., 1997).

One particularly important issue with regard to prevention is falls. Older adults are particularly prone to falls (Lach, 2005; Tideiksaar, 2002). As many as one third of elders fall in a given year, and of these, as many as half sustain serious injuries such as hip fracture. These injuries are associated with high mortality rates, making falls a serious concern for older adults. In addition, because they are aware of the potential for falls, many older adults have considerable fear of falling (Lach, 2005). While fear of falling is particularly prominent among individuals who have a previous history of falling, it is also common among elders who have not fallen. Some older adults significantly curtail their activities because of this fear; thus, their accomplishment of desired occupations suffers even in the absence of a physical injury.

Falls are multifactorial in nature. Among the contributing factors are: changes in sensation necessary to avoid falls (Tideiksaar, 2002), changes in musculoskeletal and vestibular function that compromise balance and gait (Nitz & Choy, 2004; Waddington & Adams, 2004), and environmental hazards such as wet or uneven

surfaces (Hantula, Bragger, & Rajala, 2001). Risk factors shared both by falls and fear of falling include stroke, Parkinson's disease, comorbidity, and White race (Friedman et al., 2002).

Similarly, recent research on fall prevention suggests that the most effective strategies are multifactorial (Chang et al., 2004). Recommended interventions fall into three main categories: education (Deery, Day, & Fildes, 2000), environmental modification such as improved lighting and removal of objects posing trip hazards (Boyce, 2003; Tideiksaar, 2001), and interventions to modify client factors and performance skills. These last interventions include such approaches as balance training (Nitz & Choy, 2004; Waddington & Adams, 2004) and t'ai chi (Verhagen et al., 2004).

Outcomes of these strategies suggest that modest reductions in risk for falls can be achieved (Kempton et al., 2000; Vassallo et al., 2004). Some evidence has shown that environmental modifications are less successful than modifications in individual capacities and knowledge, although the data are not sufficiently compelling to eliminate the possibility that environmental modifications can be helpful (Gill, 1999).

Screening

During the course of prevention activities, occupational therapists should be alert to potential problems (Wilkins, Law, & Letts, 2001). If individuals who are nutritionally compromised or who have recently had a life-changing loss receive early intervention, disability may be minimized or avoided. For example, if a client becomes unable to drive because of increasing visual impairment, the therapist may acquaint him or her with community transit services or help make contact with friends and relatives who can provide occasional transportation. Such an intervention helps reduce the likelihood of social isolation, which can lead to depression and perhaps to significant disability.

Environmental Modifications

If it is not feasible to increase the individual's performance ability, another highly effective intervention is to reduce some demands through alteration of the environment (Procedures for Practice 37-2).

Technological Aids to Function

Numerous technological assists can maximize function (Procedures for Practice 37-3). Some are simple, such as an alarm on the doorknob to warn family members that a person is wandering away or automatic off switches

PROCEDURES FOR PRACTICE 37-2

Environmental Modifications for Elderly Individuals

Cognitive Problems

- Reduce clutter.
- Label drawers and cabinets by their contents; for individuals who have dementia or other serious cognitive deficits, pictures may be easier to understand than words.
- Use color, texture, and lighting changes to provide location cues, such as changes from carpet to tile signaling the move from dining area to hallway.
- Use timers as reminders for specific functions.
- Put safety off switches on stoves and furnaces.

Visual Problems

- Use high-tone colors and low-gloss finishes to improve visual acuity and depth perception (Tideiksaar, 2001).
- Incorporate devices to increase magnification or enlarge print, contrasting colors, and dependence on other sensory systems such as touch.
- Maintain a consistent environment to allow the visually impaired individual to function more effectively.
- Write with felt-tipped pens and in bold print to help improve visibility (Mann, 2001).
- Access optometrists, ophthalmologists, and staff at sight centers or the Society for the Blind for helpful input.
- Provide high-intensity, low-glare light; avoid fluorescent lights; and put glare-reducing screens over televisions and windows (Tideiksaar, 2001).
- Teach compensatory techniques to individuals who have reduced peripheral vision or who have only peripheral vision (Lewis, 2003).

Hearing and Communication Problems

- Refer for a thorough evaluation from a speech pathologist, audiologist, or otolaryngologist.
- Speak slowly and clearly and use a deep voice with someone who has high-frequency loss; do not shout.
- Make sure the individual can see you when you speak (Hooper, 2001).

- Write messages if necessary.
- Select activities for which verbal interaction may not be essential, such as bowling, swimming, checkers, and walks.
- Check that hearing aids are fitted and used properly and that batteries are fresh; remember that these aids do not restore normal hearing and may not help everyone with hearing impairment.
- Use visual cues, such as flashing lights, to get the client's attention.

Neuromuscular, Motor, or Mobility Problems

- Make sure the environment is free of hazards such as slippery floors, poorly marked stairs, and architectural barriers.
- Adjust the height of chairs, beds, dressers, clothes, and toilet seats, and provide a bath chair if needed; ensure that grab bars are within easy reach.
- Provide task-oriented treatment in the individual's environment; numerous repetitions enhance learning, and simulated activities may not be easily transferred to real situations.
- In institutional settings, keep in mind OBRA regulations that mandate reduced use of restraints. Careful evaluation of seating can eliminate the need for restraints; for example, a chair that is higher in front than in back can make it more difficult to rise, and well-fitted chairs can enhance balance.

Self-Care: Toileting and Continence Problems

- Make sure that the bathroom is physically accessible. Add grab bars and non-skid mats.
- Mark the bathroom clearly. Use large, clear words, pictures, and color coding if necessary.
- Reduce liquid intake prior to bedtime.
- Institute regular reminders to use the bathroom.
- Use behavior modification techniques to assist elders to notice full bladders.

on stoves to reduce fire hazard. Others, such as the computer-operated Smart House, are highly sophisticated and expensive.

There are limits to the application of technology with older clients. Some clients may resist learning to use the new technologies. Devices can break down and may be expensive to repair. Acquiring the devices may be expensive and not covered by insurance. It is difficult to keep up with advances, and sometimes, a new and better device appears on the market as soon as a client has

purchased an expensive piece of equipment. Many older adults, however, enjoy technological devices, quickly learn to use them, and with them gain considerable independence (Mann, 2001).

Modification and Substitution of Activity

Activity analysis, a cornerstone of occupational therapy, can be particularly helpful in assisting older clients. The

**PROCEDURES FOR PRACTICE 37-3****Assistive Technology for Problems Associated with Aging**

- Telephones with amplifiers, large-print numbers, one-touch dialing, and memory features; cordless, cellular, or digital phones; external speakers
- Screen magnification, print enhancements, and voice synthesizers for computer screen reading
- Assistive listening devices, telecommunication devices (TDDs), or computer software/hardware to facilitate communication via Internet (e.g., chat rooms and instant messaging), closed captioning for television; devices to convert auditory output to flashing lights for smoke detectors, telephones, and doorbells
- Life call systems that provide a link with emergency services
- Advances in technology for mobility, such as wheelchair seating systems, power carts that are easy to disassemble, lightweight wheelchairs, wheeled walkers with brakes and built-in seating systems, and adaptive controls for cars

process involves matching present skills, interests, and motivation with activities that are stimulating, challenging, enjoyable, goal directed, and purposeful. Some specific suggestions are presented in Procedures for Practice 37-4.

In conclusion, intervention with older adults requires understanding of the normal developmental processes that affect performance as well as the special life circumstances of older adults. To be most effective, intervention must address all spheres of function. The special factors that alter intervention with older adults must be taken into account. With older adults, the goal of good quality of life as measured by satisfying activities is in reach in many situations. Thoughtful intervention by occupational therapists can ensure it.

SUMMARY REVIEW QUESTIONS

1. In a well elderly individual, what are the most typical changes in sensation? How can they affect function?
2. How do normal neuromuscular changes that accompany aging affect mobility? How can these changes ultimately affect occupational function?

**PROCEDURES FOR PRACTICE 37-4****Promoting Activity Choice for Intervention with Elders**

- Link older adults with activities that express important personal meanings, especially connectedness with others, spirituality, service to others, and self-expression (Bonder & Martin, 2000).
- Recognize the vast individual variability in selection of activities that express personal meanings. One individual may choose to express spirituality through attendance at church, another through meditation.
- Find out what specific self-care activities are perceived as vital to elders who are concerned about remaining in their homes.
- Remember that older adults persist for longer periods with activities that are purposeful (Nelson, 1988).
- Employ reminiscence as a means to establish and maintain connections with others.
- Use activity inventories to stimulate an older client to think about what he or she values.
- Adapt the activity or help the client identify an activity that meets similar needs when preferred activities become too difficult for a client. To do so, ascertain what component of the activity is meaningful. For example, if he or she likes to cook because it is a way to socialize, substituting an activity that is not social will not be satisfying.

3. What are some key differences in the cognitive complaints of adults with age-associated memory impairment versus Alzheimer's disease? Describe ways the therapeutic response to these complaints may differ.
4. In general, what effect does retirement have on an older individual who has planned for the event?
5. What is the first step an occupational therapist should take in assessing the status of an older individual?
6. What factors are important in selecting substitute activities for an older adult?
7. In deciding about technological interventions, what factors must be considered to ensure acceptance of the device?
8. What factors complicate intervention with an older adult who falls ill or is injured?

Evidence Table 37-1 Best Evidence for Occupational Therapy Practice for Older Adults

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Reactivating occupational therapy (OT)	A technique used to improve engagement in activity cognitively.	44 participants, with slight to moderate dementia, each randomly assigned to one of two treatment groups (age 65–95 years).	2 hours per week (in addition to traditional OT).	Randomized, control study. IA1b	Yes. After 12 and 24 weeks, subjects who received reactivating O.T. plus functional rehabilitation had significantly better scores in cognitive performance, psychosocial functioning, and subjective well-being compared to those receiving functional rehabilitation only.	$p < 0.01$	Bach et al., 1995
3R Program	Reminiscence, Reality orientation, and Remotivation used in small-group therapy sessions.	30 participants; 15 in the control group and 15 in the treatment group.	8 weeks, 1 session per week.	Quasi-experimental study. IIB2b	Yes. Improvement in mental state noted.	$p < 0.001$	Koh et al., 1994
Leisure activities after a stroke	Leisure activities.	40 participants, 20 in control group and 20 in treatment group; mean age = 69.6 years.	5 weekly visits.	Randomized, control study. IB1a	No. None found.		Jongbloed & Morgan, 1991
Occupational therapy for community-residing elders	Studied preventive occupational therapy intervention.	361 culturally diverse older adults living independently in the community (age 60 years and older).	1 hour per week for 9 months.	Randomized controlled study (3 groups: OT, activity, and no intervention). IA1a	Yes. OT intervention produced superior outcomes on health, functional status, pain, and physical and social functioning.	$p < 0.05$ or better (depending on outcome variable).	Clark et al., 1997

Evidence Table 37-1 Best Evidence for Occupational Therapy Practice for Older Adults(*continued*)

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Follow-up of health promotion for independent-living elders	Reevaluation of participants in health promotion OT after 6 months (see Clark et al., 1997).	285 of original 361 participants.	No treatment; follow-up assessment only		Yes. Outcomes were sustained on many measures over the 6-month period.	$p < 0.05$ or better (depending on outcome variable)	Clark et al., 2001
OT interventions	Meta-analysis of various OT interventions.	Review of 15 studies about OT with older adults.		Meta-analysis	Yes. OT helps with physical outcomes and daily living and psychosocial outcomes.	$p < 0.001$; effect size of 0.51.	Carlson et al., 1996

SECTION VI: Treatment to Promote Occupational Function for Selected Diagnostic Categories

CHAPTER 38

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Define stroke, or cerebrovascular accident, and briefly describe the causes, incidence, and impairments and disabilities that can result from stroke.
2. Describe the continuum of care for individuals recovering from stroke, including the interdisciplinary team, the various settings for care, and the phases of recovery and intervention.
3. Describe methods for evaluating occupational performance and component abilities and capacities of patients recovering from stroke.
4. Suggest goals and methods for treatment to improve the occupational performance and component abilities and capacities of patients recovering from stroke.
5. Analyze the effectiveness of occupational therapy intervention in improving a patient's quality of life and adjustment to life with stroke.

Stroke

Anne M. Woodson

Glossary

Aphasia—Language disorder caused by brain damage that affects production and/or comprehension of written or spoken language.

Apraxia—Impairment of motor planning or organized, controlled movement not explained by motor or sensory impairment.

Backward chaining—Process of breaking a task into steps and guiding or assisting learner through all but the last step, which learner performs independently. Preceding steps of task are added until learner can perform entire sequence independently.

Hemiparesis—Weakness or partial paralysis on one side of the body caused by brain damage.

Hemiplegia—Paralysis on one side of the body caused by brain damage.

Hemorrhage—Bleeding resulting from the rupture of a blood vessel.

Homonymous hemianopsia—Visual field deficit caused by brain damage in which patient cannot perceive half of visual field of each eye.

Ischemia—Loss of blood flow through a vessel resulting in an insufficient supply of blood and oxygen to surrounding tissues, as when a blood clot blocks a cerebral artery.

Learned non-use—Phenomenon observed in patients with hemiparesis in which patient avoids functional use of involved arm after failed attempts to use it and successful attempts to use uninvolved arm.

Postural adaptation—Ability of body to maintain balance automatically and remain upright during alterations in position and challenges to stability.

Shoulder subluxation—Incomplete dislocation of humerus out of glenohumeral joint caused by weakness, stretch, or abnormal tone in the scapulohumeral and/or scapular muscles.

Unilateral neglect—Disturbance in the ability to notice, orient, or respond to stimuli in space on side of body opposite site of brain damage.

Stroke, or cerebrovascular accident (CVA), describes a variety of disorders characterized by the sudden onset of neurological deficits caused by vascular injury to the brain. Vascular damage in the brain disrupts blood flow, limits oxygen supply to surrounding cells, and leads to brain tissue death or infarction. The mechanism, location, and extent of the lesion determine the symptoms and prognosis for the patient. This chapter focuses on patients with stroke, but non-vascular brain trauma or disease, such as gunshot wounds or tumors, may manifest many of the same neurological deficits and may be treated similarly.

CAUSATION

Strokes are usually classified by the mechanism and location of the vascular damage. The two broad causes are **ischemia** and **hemorrhage**. Ischemic strokes result from a blockage of a cerebral vessel and can further be categorized as caused by thrombosis or embolism. Thrombosis is the stenosis or occlusion of a vessel, usually as a result of atherosclerosis. This occlusion is typically a gradual process, often with preceding warning signs, such as transient ischemic attack (TIA). An embolism is dislodged platelets, cholesterol, or other material that travels in the bloodstream and blocks a vessel. Ischemic strokes are the most common type, representing roughly 80% of strokes (Brandstater, 2005).

Hemorrhagic strokes result from a rupture of a cerebral blood vessel. In such strokes, blood is released outside of the vascular space, cutting off pathways and leading to pressure injuries to brain tissue. Hemorrhages, which are either intracerebral (bleeding into the brain itself) or sub-arachnoid (bleeding into an area surrounding the brain), may be caused by hypertension, arteriovenous malformation, or aneurysm (Bartels, 2004). Hemorrhagic strokes are less common (an estimated 20% of strokes), but they result in a higher mortality rate than ischemic strokes (American Heart Association, 2005).

Location of Involvement

Most lesions are either anterior circulation strokes, which present signs and symptoms of hemispheric dysfunction, or posterior circulation strokes, which display signs and symptoms of brainstem involvement (Aminoff, Greenberg, & Simon, 2005). Another distinction related to location of CVA is whether the lesion results from large-vessel or small-vessel disease. Thrombosis occurs most often in the large cerebral blood vessels. Small-vessel, or lacunar, strokes are very small infarctions that occur only where small arterioles branch off the larger vessels in deeper portions of the brain, such as the basal ganglia, internal capsule, thalamus, and pons. Lacunar strokes can produce distinctive syndromes and have a good prognosis for recovery (Brandstater, 2005).

CASE

EXAMPLE # 1

Mrs. H.: Right Cerebrovascular Accident

Occupational Therapy Process

Clinical Reasoning Process

	Objectives	Examples of Therapist's Internal Dialogue
<p>Patient Information</p> <p>Mrs. H. is an 82-year-old widow who lived alone independent in ADL and IADL except for community transportation. She was found unresponsive at home by a neighbor and diagnosed with a large right middle cerebral artery infarction.</p> <p>During her acute hospital stay, an occupational therapist evaluated Mrs. H. and reported inconsistent levels of awareness, no spontaneous movement on the left side, and signs of left hemianopsia and spatial neglect. Treatment consisted of involving the patient in simple self-care tasks and initiating a bed positioning and mobility program in conjunction with nursing and physical therapy to prevent secondary complications. Ten days post stroke, Mrs. H. was able to sit in a wheelchair for 1-hour periods, follow one-step commands consistently, and perform simple grooming and bed mobility tasks with minimal assistance. She was transferred to an inpatient rehabilitation unit for more intensive treatment. At the time of discharge from acute care, Mrs. H. was incontinent of bowel and bladder and had a small area of skin breakdown over her coccyx. The social worker reported that Mrs. H. had led a sedentary life and enjoyed going to church, visiting with neighbors and family, reading her Bible, and watching television. Staff reported her verbal skills, comprehension, and memory to be good, although Mrs. H. expressed frustration at her continued hospitalization and stated that she expected a full recovery and return home. Mrs. H.'s family consisted of four adult grandchildren and their families, who were unable to change their work or living situations to care full time for Mrs. H. The family was supportive and hopeful that Mrs. H. could return home with a hired care provider, although they were willing to consider skilled nursing home placement if Mrs. H. did not gain sufficient functioning to return home.</p>	Understand the patient's diagnosis or condition	"The large size of Mrs. H.'s lesion, persistent altered levels of consciousness, initial severe ADL dependence and motor deficits, visuospatial deficits, and incontinence all predict poor functional outcomes and lengthy recovery period. In her favor, Mrs. H. was able to live alone at home and has no significant prior medical history."
	Know the person	"Mrs. H. seems to have limited knowledge and understanding of the nature of her stroke and resulting impairments. She appears to be someone with limited experience living in a dependent role. Because she had not been a physically active person, she may fatigue easily during an intense rehabilitation program. It would not be difficult for her, however, to resume valued roles and activities from a wheelchair level, especially with supportive friends and family. The fact that her thinking skills appear intact will help Mrs. H. achieve her rehabilitation goals, but her visual-perceptual impairments will hinder learning new techniques."
<p>Reason for Referral to Occupational Therapy</p> <p>Mrs. H. was referred to occupational therapy to increase self-care independence, increase awareness of left visual spatial field, recommend proper management of the left arm, and assist in determination of optimum discharge plans. She will also be seen daily by physical therapy and periodically by speech-language pathology, social work, psychology, and therapeutic recreation.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	"I will coordinate my services closely with other disciplines to avoid patient fatigue and develop consistent strategies. I will involve family in therapy early because it seems likely that Mrs. H. will need moderate to maximum skilled care upon discharge."

Assessment Process and Results

The rehabilitation team completed the *Functional Independence Measure (FIM)* (Keith et al., 1987) for Mrs. H. as part of the standard care process for the unit. Mrs. H. scored a 28 (out of a possible 91) on the FIM motor score, and 30 (out of a possible 35) on the cognitive score. In areas assessed by OT, Mrs. H. required minimal (25%) assistance with eating, grooming, and upper body dressing; maximum (75%) assistance with bed bathing and toilet transfers; and total (more than 75%) assistance for lower body dressing, toileting, and tub transfers. During interview/observation of leisure skills, Mrs. H. described difficulty reading (“I think I need new glasses”) and watching TV (“The picture isn’t very good”). Mrs. H. was observed consistently keeping her head turned to the right and having difficulty finding or concentrating on people or objects in her left visual field.

OT assessment of component abilities and capacities revealed impaired sensation in the left arm; inconsistent minimal movement in left pectorals, internal rotators, and biceps only; and mild shoulder pain with movement above shoulder level. In addition, a screen of visual field function found significant loss of left peripheral field perception.

The speech-language pathologist reported swallowing difficulties and recommended a pureed diet with no thin liquids. Physical therapy described Mrs. H. as requiring maximum (75%) assistance to perform a scooting transfer and unable to sit unsupported, stand, or propel a wheelchair.

Consider evaluation approach and methods

Interpret observations

“From the PT assessment, I learned of Mrs. H.’s postural control deficits. It was important to observe her performance in self-care rather than rely on self-report because she seems to have limited insight into her disabilities. Although observation of ADL gave me information about her visual field and inattention problems, I will consider more in-depth testing of her visual function, perhaps portions of the *Brain Injury Vision Assessment Battery for Adults* (Warren, 1996), because of her desire to resume reading.”

“I can observe that Mrs. H.’s limited ability in lower extremity dressing, bathing, and transfers are due to her poor sitting balance and lack of mobility. Her difficulties with upper extremity dressing, grooming, and feeding are a result of decreased attention to left visual space and left side of body. Her left side somatosensory and motor deficits and her lack of awareness of her visual problems add to her left inattention.”

Occupational Therapy Problem List

- Loss of independence in basic ADL
- Loss of independence in IADL and leisure activities
- At risk for injury or complications in left arm because of lack of voluntary movement, decreased sensation, and visual-spatial neglect
- Limited insight into impairments and disabilities resulting from stroke and the predicted course of recovery

Synthesize results

“Mrs. H.’s stroke has severely reduced her ability to live independently in her home, although returning home is her discharge goal. Her degree of hemiparesis, postural instability, and neglect, along with her lack of awareness, increases her risk for secondary complications.”

Occupational Therapy Goal List

Patient will be able to do the following:

- Perform feeding, grooming, and upper body dressing with supervision and minimal cueing
- Perform lower body dressing, toilet transfers, and bathing on a tub bench with moderate (50%) assistance
- Independently operate television by remote control and tape recorder for books on tape
- Maintain sitting balance on the side of bed for at least 2 minutes while engaged in upper body activity
- Properly position left arm during change of position in bed and while seated in wheelchair
- Independently perform stretching and range-of-motion activities for left hand, wrist, forearm, and elbow; perform stretching and range-of-motion activities for shoulder with moderate assistance

Develop intervention hypotheses

Select an intervention approach

“I do not think Mrs. H. will be able to return to independent living, but improving basic capacities (balance, visual attention) would allow her to succeed in simple meaningful activities. Education will assist with continuity of care in a new setting and allow the patient and family to feel they can contribute to the recovery process.”

“Occupational therapy intervention will include restoration, compensation, and prevention approaches.”

Occupational Therapy Goal List (cont'd)

Patient's family will be able to do the following:

- Demonstrate proper techniques for positioning
- Assist with self-care
- Assist with left arm mobility
- Encourage attention to left visual field

Consider what will occur in therapy, how often, and for how long

"I predict that Mrs. H. will progress slowly in therapy but will benefit from multidisciplinary treatment. She will need at least 2 weeks of inpatient rehabilitation. She will be seen daily in OT, twice a day for shorter periods (30 minutes) to allow rest between sessions."

Intervention

The treatment program during Mrs. H.'s 2-week inpatient rehabilitation stay consisted of (1) an activity program emphasizing basic and instrumental ADL training to address sitting balance, transitional movements, management of left upper extremity, and attention to and scanning of the left visual field and (2) patient and family education regarding the consequences and course of recovery of stroke, safety awareness and prevention of secondary impairments, and compensatory techniques and adaptations to promote functional independence.

At discharge, Mrs. H. was able to feed herself, perform simple grooming activities, and use her television and tape recorder with setup and supervision. Status in all other ADL remained unchanged. Sitting balance remained poor, and left spatial neglect remained pronounced. Mrs. H. required maximum assistance with protection and mobilization of her left arm.

Mrs. H.'s family attended family training sessions prior to discharge and was provided with written instructions of material covered in training.

Assess the patient's comprehension

Understand what she is doing

Compare actual to expected performance

Know the person

Appreciate the context

"Mrs. H. had difficulty learning new techniques for familiar activities, so she required repeated practice and reinforcement from nursing and other disciplines. Because Mrs. H. could not recognize or monitor her visual or balance impairments, interventions to improve these capacities had to rely more on external rather than internal adjustments. Mrs. H. was always pleasant and cooperative and continued to feel that soon she would get better and go home. It was disappointing that she did not gain more independence, but I feel the family understands the impact of Mrs. H.'s stroke and the probability of a lengthy recovery period."

Next Steps

Mrs. H. was transferred to a skilled nursing facility, where she will continue occupational and physical therapy. Copies of all therapy documentation were forwarded to the center and information was shared through phone calls.

During a conference prior to discharge, the family was informed of possible future settings for continuing care for Mrs. H, and provided with a list of home health agencies, outpatient services, and provider services.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

"I felt it was important to talk directly to the therapists at the skilled nursing facility to discuss Mrs. H.'s unique problems. It has been less than a month since the onset of her stroke, which is too soon to determine the extent of her recovery. I have emphasized to the patient and family that transfer from the rehabilitation unit does not mean her recovery is over, but it is merely moving to a different stage. I have tried to give the patient and family as much information as possible to help them recognize signs of progress or regression so that they can be advocates to ensure that Mrs. H. receives the proper type of therapy at the proper time."

CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE

Role of Family and Caregiver in Continuing Therapeutic Goals

One of the problems interfering with Mrs. H.'s progress in inpatient rehabilitation was her left visual field deficit and unilateral neglect. How would this problem affect Mrs. H.'s awareness of and involvement in her new environment at a skilled nursing facility? How would this problem affect her performance of self-care tasks and valued leisure activities? How would the therapist explain this problem to the patient and family? What instruction could the therapist give family members so that they could help Mrs. H. learn to compensate for her visual-perceptual deficits? What adaptations could they make in Mrs. H.'s environment?

CASE

EXAMPLE # 2

Mr. G.: Left Cerebrovascular Accident

Occupational Therapy Process

Clinical Reasoning Process

	Objectives	Examples of Internal Dialogue
<p>Patient Information Mr. G. is a 38-year-old man with a history of hypertension who had abrupt onset of right-sided weakness and loss of speech. He was hospitalized quickly and diagnosed with a left subarachnoid hemorrhage. He spent 9 days in acute care and 2 weeks on an inpatient rehabilitation unit before being discharged home to live with his wife and two children aged 10 and 12. During his hospitalization, Mr. G. made rapid progress and regained most of his speech and movement on the right side. Upon discharge, Mr. G. could perform self-care tasks, simple meal preparation, and household walking using a straight cane with supervision and increased amount of time. He had mild apraxia resulting in delays initiating and sequencing multistep tasks. He had decreased control of his right arm, particularly when he tried to raise it above shoulder level or attempted fine motor activities.</p> <p>Before his stroke, Mr. G. worked in the parts department of an automobile dealership. His job included inventory, ordering, stocking, and pickup and delivery of parts. His wife was a teacher who was home for the summer but planned to return to work when school started in 2 months.</p>	<p>Understand the patient's diagnosis or condition</p> <p>Know the person</p>	<p>“Mr. G.’s rapid recovery and young age predict good functional recovery. He should continue to gain independence in basic self-care, but persisting problems with higher level right arm and leg function, with higher level communication skills, and with skilled motor planning may interfere with his participation in desired life roles.”</p> <p>“Mr. G. was quite successful in achieving inpatient rehabilitation goals and will probably expect similar rapid progress after he returns home. He and his wife will be anxious for him to gain higher levels of function within 2 months. The early months after discharge home can be stressful and frustrating as patients encounter difficulty resuming previous roles.”</p>
<p>Reason for Referral to Occupational Therapy Mr. G. was referred to outpatient occupational therapy to continue progress in ADL and IADL independence and to assist with resuming community roles. He was also referred for outpatient physical therapy to work on improving balance and upgrading gait and for speech therapy to improve word retrieval and higher level reading and math skills.</p>	<p>Appreciate the context</p> <p>Develop provisional hypotheses</p>	<p>“Home is the best place for Mr. G. to practice and refine his ADL/IADL skills. As he gains confidence at home and competence in performance skills, he will look more to resuming community roles, especially his worker/provider role.”</p>
<p>Assessment Process and Results Mr. G.’s goals for occupational therapy were to function safely alone at home after his wife returned to work, to regain normal function of his right dominant arm, and to return to work as soon as possible.</p> <p>Initial outpatient assessments included the <i>Stroke Impact Scale</i> (Duncan et al., 1999), which allowed Mr. G. to rate how various impairments and disabilities caused by his stroke affected his quality of life.</p>	<p>Consider evaluation approach and methods</p> <p>Interpret observations</p>	<p>“I like using the <i>Stroke Impact Scale</i> and <i>Functional Test for the Hemiplegic/Hemiparetic Upper Extremity</i> because they are specific to stroke and help patients focus on functional results and appreciate that their problems are typical. These assessments are both useful for tracking progress over a long period of time.”</p> <p>“Mr. G is at a stage where he is beginning to experience and realize the effects of his stroke on his</p>

Assessment Process and Results (cont'd)

Responses to this scale and further interview revealed that Mr. G. is concerned about the continuing difficulty in using his right arm; worries about being a burden on his family and returning to work; feels foolish and inadequate because of frequent mistakes in speech, reading, writing, and math; admits that he is very slow with his daily care routine and household tasks and depends on his wife for help more than he would like; and feels unable to participate in most previous leisure or social activities.

A home assessment was completed to observe Mr. G. perform his morning bathing/dressing/grooming tasks and to assess safety risks. He took almost 2 hours to complete these tasks, needed occasional physical assistance for balance, needed occasional verbal cueing for sequencing, and had difficulty with fine motor tasks such as buttoning.

The *Functional Test for the Hemiplegic/Paretic Upper Extremity* (Wilson, Baker, & Craddock, 1984a, 1984b) was administered to determine level of functional use of his right arm (see Fig. 38-3).

unique life roles. He shows good insight into his problems, and that will help him achieve or adapt his goals. His ADL deficits are due to a combination of dynamic balance problems, delays in initiation, and decreased coordination of his right arm. He is able to use his right arm effectively as a stabilizing assist and for simple grasp and release, but he has difficulty with activities involving moving the arm above shoulder level or right-hand fine motor prehension or manipulation.”

Occupational Therapy Problem List

- Requires supervision and extended time to complete bathing, grooming, and dressing
- Requires supervision and/or increased time to perform home IADL tasks (writing checks, preparing meals)
- Unable to perform tasks required for job, including using computer, lifting boxes up to 50 pounds, and driving
- Unable to resume leisure activities, including bowling and coaching son's baseball team
- Difficulty using right arm for activities above shoulder level
- Unable to use right hand for fine motor prehension or manipulation tasks
- Depressed, anxious over loss of independence and role functioning and financial uncertainties

Synthesize results

“Mr. G. has shown good functional recovery in a short period of time and is working hard to readapt to his home environment. However, his deficits in higher level occupational and component skills hinder his role competence.”

Occupational Therapy Goal List

- Perform morning self-care independently in 45 minutes or less
- Assume partial meal preparation and laundry tasks to help wife
- Use right arm to comb hair and to place and retrieve objects on shelf at eye level
- Use right hand to tie shoelaces, manipulate coins, sign name, and perform simple computer functions
- Participate in gross motor recreational activities with children (swimming, table tennis)
- Perform job simulation activities for 2 hours without rest break
- Complete pre-driving evaluation
- Be able to use community transportation independently

Develop intervention hypotheses

“I think Mr. G. will gain independence in basic ADL and limited IADL. I think he will make substantial progress in resuming valued roles, but this may take a long time, and he may need to accept modified roles.”

Select an intervention approach

“Occupational therapy intervention will primarily be restorative, with compensation/adaptation intervention used as needed.”

Consider what will occur in therapy, how often, and for how long

“Because Mr. G. has a time goal (his wife's return to work), I will see him 3 times a week for 1 month, and then 2 times a week for a month.”

Intervention

Treatment consisted of the following: (1) Task-specific training in ADL, IADL, and job activities. Activities were adapted, graded, and expanded as Mr. G. gained competency. (2) Repetitive task-oriented program to improve motor planning, postural adaptation, and right arm strength and control. This program was designed to be carried over to home. (3) Education concerning safety issues, home and activity adaptations, social supports, and available community resources.

His wife and children attended therapy sessions at least once a week and provided valuable suggestions and encouragement for carryover of therapy in the home.

All goals were achieved at the end of 2 months. He scored significant improvements on both the *Functional Test for the Hemiplegic/Paretic Upper Extremity* and the *Stroke Impact Scale*. Mr. G was able to demonstrate independence with written home programs addressing component skills and was able to verbalize appropriate safety precautions.

Assess the patient's comprehension

Understand what he is doing

Compare actual to expected performance

Know the person

Appreciate the context

“Mr. G. was highly motivated for therapy and was relieved to see incremental improvements. He had problems that seemed to respond best to familiar, meaningful, repetitive treatment activities. Treatment was designed to provide structure to substitute for his loss of employment, to allow him to resume alternative roles at home, and to allow him to explore the feasibility of returning to his previous job.”

Next Steps

Mr. G. was scheduled for follow-up visits with his neurologist in the outpatient stroke clinic every 3 months for a year post stroke, which allowed OT a chance to contact him and monitor his progress. He was referred for behind-the-wheel driving assessment and training. He initiated application procedures for his state's vocational rehabilitation financial aid and training services. He and his wife were given the names of counseling resources to help them deal with the stresses of his continued recovery.

Anticipate present and future patient concerns

Analyze patient's comprehension

Decide if the patient should continue or discontinue therapy and/or return in the future

“I anticipate that Mr. G. will continue to gain competence in component skills and occupational functioning but that his rate of recovery will slow down. I am glad I will have a chance to check with him periodically to alter his home program if necessary and to determine if he will benefit from additional therapy. Depending on the results of vocational screening, he may decide to pursue different employment that might require specific job training. Both he and his wife seem to understand that depression is a common complication of stroke.”

**CLINICAL REASONING IN OCCUPATIONAL THERAPY PRACTICE****Use of ADL and IADL to Improve Component Impairments: Occupation-As-Means**

Although he showed rapid recovery, Mr. G. was unable to resume occupational roles after returning home because of residual impairments. How would training in meal preparation and laundry activities help to lessen Mr. G.'s particular impairments? How could these activities be graded to increase active shoulder range of motion? Improve hand dexterity? Upgrade balance requirements? What compensatory strategies could Mr. G. use to improve initiation and sequencing of kitchen and laundry tasks? What safety techniques should he employ?

**INCIDENCE**

Stroke is the third leading cause of death in the United States and a leading cause of chronic disability among adults. Of the estimated 700,000 persons who have first or recurrent CVAs in the United States each year, approximately two thirds survive, bringing the number of stroke

survivors in the U.S. population at any one time to over two and a half million (American Heart Association, 2005). Stroke is the most common diagnostic category among patients seen by occupational therapists (Rijken & Dekker, 1998). The projected aging of the U.S. population is expected to raise the incidence of stroke because about two thirds of all strokes occur in those over age 65 (Aminoff, Greenberg, & Simon, 2005).

MEDICAL MANAGEMENT

Acute stroke care focuses on determining the cause and site of the stroke, preventing progression of the lesion, reducing cerebral edema, preventing secondary medical complications, and treating acute neurological symptoms (Bartels, 2004). Advances in the use of technology and pharmaceuticals have transformed acute stroke care from mainly supportive to possible prevention and intervention. Improved techniques of diagnosis, including computed tomography (CT) and magnetic resonance imaging (MRI), can distinguish ischemic from hemorrhagic lesions and define their location, size, and vascular territory (Caplan, 2002).

In acute ischemic stroke, treatment concerns include restoration of blood flow and limitation of neuronal damage. Anti-platelet and anti-coagulation drugs, such as aspirin and heparin, are frequently used to improve flow through occluded vessels and prevent further clotting or thrombosis. Newer pharmacological treatments include thrombolytic drugs, such as tissue plasminogen activator (t-PA), that can open occluded cerebral vessels and immediately restore circulation (Bartels, 2004). Their use is limited, however, by the associated increased risk of hemorrhage and the fact that they must be administered within 3–6 hours after stroke onset. As the effectiveness of various medical treatments has not been established, only a small percentage of patients with ischemic stroke are treated with thrombolytic drugs (Caplan, 2002). With hemorrhagic stroke, acute treatment includes control of intracranial pressure, prevention of rebleeding, maintenance of cerebral perfusion, and control of vasospasm (Bartels, 2004).

RECOVERY FROM STROKE

The degree and time course of recovery from stroke vary with the nature and severity of the initial injury (Dobkin, 2005). Early initial improvement or spontaneous recovery occurs because pathologic processes in the brain resolve and neurotransmission resumes near and remote from an infarct or hemorrhage (Dobkin, 2005). Later, ongoing improvement occurs with structural and functional reorganization within the brain, or neuroplasticity. Neuroplasticity includes greater excitability and recruitment of intact neurons in both hemispheres of the brain as a response to stimulation, participation, training, and experience (Dobkin, 2005). Langton Hewer (1990) described a model of stroke recovery that includes both intrinsic and adaptive recovery. Intrinsic recovery refers to the remediation of neurological impairments, such as return of movement to a paralyzed limb. Adaptive recovery entails regaining the ability to perform meaningful activities, tasks, and roles without full restoration of neurological function, such as using the unaffected hand for dressing or walking with a cane or walker.

Most patients gain some degree of both intrinsic (neurological) and adaptive (functional) recovery (Langton Hewer, 1990). Rehabilitation, including occupational therapy, is designed to promote maximum possible functional recovery from stroke.

Neurological Impairments and Recovery

Each survivor of a CVA has a unique combination of deficits determined by the location and severity of the lesion. Definition 38-1 lists the most commonly encountered neurological impairments following stroke and describes the possible effect of each on occupational functioning. The most typical manifestation of CVA is **hemiparesis** or **hemiplegia**, ranging from mild weakness to complete paralysis on the side of the body opposite the site of the CVA. As much as 88% of patients with acute stroke have hemiparesis (Foulkes et al., 1988), although the rate of physical impairment usually decreases after the first 3–6 months post stroke (Dobkin, 2005).

Certain impairments are associated with lesions in a particular hemisphere. For example, left CVA may cause right hemiparesis, aphasia or other communication deficits, and/or apraxia or motor planning deficits. Right CVA may result in left hemiparesis, visual field deficits or spatial neglect, poor insight and judgment, and/or impulsive behavior (Brodie, Holm, & Tomlin, 1994).

Many patients do not regain full movement or function of the upper extremity. Studies found that 69% of patients admitted to a rehabilitation unit following CVA had initial mild to severe upper extremity dysfunction, but only 14% experienced complete motor recovery, and 30% regained partial motor recovery in the arm (Nakayama et al., 1994). Historically, motor recovery in the patient with hemiparesis is described as progressing from proximal to distal movement and from mass, patterned, undifferentiated movement to selective, coordinated movement (Brunnstrom, 1970; Fugl-Meyer et al., 1975). Therapists now rarely see such a distinct progression of motor recovery in patients, perhaps because improved medical treatments limit brain damage or because of arbitrarily shortened time frames for rehabilitation services (see Definition 38-1).

Functional Recovery

Much attention is given to the functional outcomes of patients surviving stroke. Although residual neurological deficits can lead to permanent impairments, disabilities, and handicaps, impairments alone do not predict levels of disability or occupational functioning (Kelly-Hayes et al., 1998). Important aspects of functional recovery include the amount of assistance required to carryout daily living tasks and whether a stroke survivor can resume function at home. Studies indicate that independence in

DEFINITION 38-1
de·fin·i·tion
Neurological Impairments Following Stroke

Hemiplegia, hemiparesis	Impaired postural adaptation, bilateral integration Impaired mobility Decreased independence in any or all ADL, IADL
Hemianopsia, other visual deficits	Decreased awareness of environment; decreased ability to adapt to environment Impaired ability to read, write, navigate during mobility, recognize people and places, drive; can affect all ADL, IADL
Aphasia	Impaired speech and comprehension of verbal or written language; inability to communicate, read, or comprehend signs or directions Decreased social, community involvement; isolation
Dysarthria	Slurred speech, difficulty with oral motor functions such as eating, altered facial expressions
Somatosensory deficits	Increased risk of injury to insensitive areas Impairment of coordinated, dexterous movement
Incontinence	Loss of independence in toileting Increased risk of skin breakdown Decreased social, community involvement
Dysphagia	At risk for aspiration Impaired ability to eat or drink by mouth
Apraxia	Decreased independence in any motor activity (ADL, speech, mobility), decreased ability to learn new tasks or skills
Cognitive deficits	Decreased independence in ADL, IADL; decreased ability to learn new techniques; decreased social interactions
Depression	Decreased motivation, participation in activity; decreased social interaction

activities of daily living (ADL) improves with time after an acute stroke. A large prospective community-based study (Jorgensen et al., 1995) using the *Barthel Index* of ADL scores (Mahoney & Barthel, 1965) found that, after completing inpatient rehabilitation, 64% of patients with acute stroke were discharged to their homes and 15% were discharged to nursing homes. After completing rehabilitation, 28% of stroke survivors were considered moderately to severely disabled in self-care, 26% were mildly disabled in self-care, and 46% were independent in self-care.

Few studies have addressed the recovery of instrumental activities of daily living (IADL), such as home management, vocational, leisure, or community skills. Most persons surviving stroke report decreased levels of activity, socialization, and overall quality of life, with only an estimated 25% returning to the level of everyday participation of community-matched persons who have not had a stroke (Lai et al., 2002).

Factors Influencing Recovery

Research in stroke outcomes has sought to identify characteristics and indicators that predict survival rate, degree of disability, and functional status. No simple predictors have been identified from numerous prospective studies. Patients with similar impairments after stroke may achieve wide ranges in outcomes: individuals with mild neurological impairments may end up with serious disabilities or handicaps, while other individuals with severe residual stroke impairments achieve satisfactory functional recovery (Kelly-Hayes et al., 1998).

The type, size, and site of the brain lesion, of course, influence the extent and course of recovery. Advanced age and the presence and severity of co-existing disease, such as diabetes, heart disease, and peripheral vascular disease, can impede optimal functional recovery. The effect of age may partly be related to more frequent co-impairments, such as arthritis or dementia, in the elderly. Many elderly

patients with poor outcomes following a stroke had reduced function prior to the stroke (Brandstater, 2005).

Other factors associated with poor functional outcomes include severe initial motor deficits, poor sitting balance, dependence in basic ADL, prior stroke, persistent bowel and urinary incontinence, severe visuospatial deficits, severe cognitive impairments, depression, severe aphasia, altered level of consciousness, and poor social supports (e.g., living alone). Factors that may predict good quality of life after stroke include family support, independence in basic ADL, and access to continued services (Brandstater, 2005).

Time Frame for Recovery

It has traditionally been reported that recovery of function following stroke occurs most rapidly during the first 1–3 months, but slower improvement can continue for up to a year (Wade, 1992). Policy makers tend to regard stroke as an acute disorder following a circumscribed recovery course rather than as a chronic, changing condition. Plateaus in recovery often reflect the insensitivity of measurement scales to incremental improvements rather than a patient's reduced potential for learning new tasks or gaining skill (Dobkin, 2005). Multiple studies have shown that patients more than 1 year post stroke can exhibit substantial motor and functional improvement after participation in novel rehabilitation protocols (Page, Gater, & Bach-y-Rita, 2004). Individual stroke survivors who have successfully resumed life roles or taken on new ones report the process of recovery as continuing years after onset of stroke, with gains reported both in component skills and occupational performance (Buscherhof, 1998; Matola, 2001).

SPECTRUM OF CARE

Since the brain damage resulting from stroke has the potential to affect any aspect of an individual's health and functioning, a wide array of disciplines are involved in caring for survivors of stroke. A patient recovering from stroke may receive care in multiple settings as he or she progresses from onset through a rehabilitation program to a return to the community. Coordination of services and ongoing communication among patients, families, and care providers at each step of rehabilitation is mandatory for optimum outcomes.

Interdisciplinary Team

Ideally, members of the stroke rehabilitation team include the patient, the patient's family, the primary physician (internal medicine, family medicine, or geriatrics), a neurologist or physical medicine specialist (physiatrist), reha-

bilitation nurse, occupational therapist, physical therapist, social worker, speech-language pathologist, clinical psychologist, therapeutic recreation specialist, and dietitian. Team members vary with the patient's needs and available resources. Frequent communication in the form of clear documentation, team meetings, and individual exchanges among members is vital for effective and efficient teamwork.

Settings for Care

Occupational therapists treat patients recovering from stroke in a variety of settings, including acute-care hospitals, skilled nursing facilities, inpatient rehabilitation centers, outpatient clinics, and home care settings. A study of 1991 Medicare claims for rehabilitation services found that 73% of patients who survived stroke received services in one or more of these settings, with 17% treated in inpatient rehabilitation programs, 23% admitted to nursing facilities, and 40% receiving either home health or outpatient services (Gresham et al., 1995). To facilitate a patient's transition from one setting of care to another, occupational therapists should be familiar with facilities and available services in the patient's area and communicate pertinent information to the next setting, particularly the patient's goals of resuming life roles.

ASSESSMENT

Numerous evaluations exist to identify stroke impairments and disability. To help in the selection and ordering of assessment tools, therapists are guided by models of practice and evidence-based practice guidelines. Occupational function is the focus of occupational therapy; thus, assessment of a patient post stroke begins with determination of roles, tasks, and activities important to that individual. From this context, the occupational therapist assesses the individual's competence in performing these valued roles, tasks, and activities. Where disabilities are discovered, further evaluation identifies specific impairments in abilities and capacities and residual abilities that can lead to restoration of function.

In response to growing demands for standards of quality health care, the U.S. Department of Health and Human Services' Agency for Health Care Policy and Research (now the Agency for Healthcare Research and Quality) published the *Post-stroke Rehabilitation Clinical Practice Guideline* (Gresham et al., 1995). Concerning assessment, this guideline recommends that practitioners "use well-validated standardized measures" throughout acute care and rehabilitation to achieve consistency of treatment decisions, facilitate team communication, and monitor progress for each survivor (Gresham et al., 1995, p. 7). Often, multiple

assessment instruments must be used because of the wide variation in individual stroke manifestations and the patient's changing needs over the course of recovery. The guideline recommends specific assessments based on the instrument's validity, reliability, sensitivity to change, and practicality.

Therapists should be familiar with commonly used standardized stroke deficit scales because they are frequently used as an interdisciplinary summary of baseline function and as indicators of recovery or treatment outcomes. The *National Institute of Health Stroke Scale* (Brott et al., 1989) is a brief, well-validated tool that can be administered by physicians, nurses, or therapists. Items scored include consciousness, vision, extraocular movements, facial palsy, limb strength, ataxia, sensation, speech, and language. The *American Heart Association Stroke Outcome Classification* (Kelly-Hayes et al., 1998) was devised to summarize the neurological impairments, disabilities, and handicaps that occur post stroke. This classification formula records the number of neurological domains affected (motor, sensory, visual, language, cognitive, affective), the severity of these impairments, and the functional (ADL) performance rating resulting from these impairments. Such a classification system can be used to assess recovery, determine response to various treatments, and track long-term effects of stroke on survivors.

Assessment of Occupational Performance

The patient's ability to perform the self-care, recreational, and vocational tasks that he or she hopes to continue is evaluated by observation rather than report because there can be a difference between what a patient can do and actually does. Evaluation to determine a patient's level of occupational functioning is administered early to predict answers to the following questions (Wade, 1992): (1) Where will the patient live, and what physical adaptations will be necessary? (2) How much and what type of assistance will the patient need? (3) What roles will the patient be able to fulfill, and how will he or she spend his or her time?

A patient's ADL performance in a structured clinical setting may not indicate performance at home. For example, patients who can put on and remove clothing during therapy sessions may not be able to find and retrieve their clothes in a cluttered closet, select clothing appropriate for the weather, or initiate the dressing routine without prompting (Campbell et al., 1991). Conversely, a patient may be unable to master simple meal preparation in the unfamiliar environment of a clinic kitchen but may readapt easily to this task upon return home. A home evaluation can help determine what resources and means a patient has to achieve independence in tasks as well as assessing safety and accessibility (see Chapter 11).

Self-Care

Methods for assessing self-care, or basic ADL, and examples of evaluation tools are discussed in Chapter 4. Measures of disability in ADL recommended by the *Post-Stroke Rehabilitation Clinical Practice Guideline* (Gresham et al., 1995) are the *Barthel Index* (Mahoney & Barthel, 1965) and the *Functional Independence Measure* (Keith et al., 1987). These interdisciplinary measures are well known and widely used in stroke research. Their use can strengthen the team approach to stroke, with occupational therapists typically completing the self-care portions of these assessments and practitioners of other disciplines completing portions pertaining to bowel and bladder control, mobility, communication, cognition, and social interaction. These functional scales tend to have ceiling effects and are limited in their ability to measure higher levels of function or quality of life (Lai et al., 2002).

Instrumental Activities of Daily Living

A patient's goals and probable discharge situation may direct a therapist to evaluate more complex areas of occupational performance. Measures of IADL recommended by the *Post-Stroke Rehabilitation Clinical Practice Guideline* include the *Frenchay Activities Index* (Holbrook & Skilbeck, 1983) and the *Philadelphia Geriatric Center Instrumental Activities of Daily Living Scale* (Lawton, 1988). The *Frenchay Activities Index* is a self-report tool developed specifically for patients with stroke that compares how frequently a patient engaged in activities, such as washing clothes, going on social outings, and gardening, prior to a stroke with frequency of participation in the same activities afterward. The stated purposes of this evaluation are to record changes in patterns of activity after stroke and to reflect quality of life rather than to measure performance in survival skills. The *IADL Scale*, on the other hand, is an observed measure that ranks quality of performance of activities such as using a telephone, managing medications, and handling finances. The *Stroke Impact Scale* (Duncan et al., 1999) was developed to be a more comprehensive measure of outcomes for stroke survivors (Lai et al., 2002). The scale is a self-report interviewer-administered measure with questions pertaining to higher-level functions of affected limbs, memory and thinking, mood and emotions, communication skills, home and community mobility, typical daily activities, and participation in meaningful life roles. Items included in this scale were derived from feedback of stroke patients and their caregivers who identified the persistent consequences of stroke that interfered the most with quality of life.

When appropriate, potential for driving and return to work may be evaluated by an occupational therapist or other specialist trained in these areas. A patient's ability to resume driving and/or vocational tasks is discussed later in this chapter; see also Chapters 31 and 33.

Assessment of Component Abilities and Capacities

Observation of a patient's ADL performance suggests to the therapist probable deficits in components of independent functioning, which can be measured directly by administration of selected tests. Areas to be evaluated include postural adaptation, specific components of upper extremity function, and motor learning ability.

Postural Adaptation

Postural adaptation, or postural control, refers to the individual's ongoing ability to remain upright against gravity for stability and during changes in body position (Bobath, 1990; Warren, 1990). The recognition and treatment of deficits in postural adaptation constitute an important aspect of therapy for stroke patients because so many daily living tasks (e.g., putting on socks, getting in and out of a bathtub, housework, and participating in sports) depend on this skill. Evaluation and treatment limited to a patient securely supported in bed or in a wheelchair fail to address most usual daily tasks that require dealing with gravity. A person with hemiplegia typically has decreased trunk control, poor bilateral integration, and impaired automatic postural control. As a result, the patient must devote considerably more effort to remaining upright, with decreased ability to focus on purposeful tasks (Warren, 1991). When engaging in a challenging activity, the hemiplegic patient often resorts to a developmentally lower level compensatory strategy to help maintain stability, such as using upper extremities to help with standing balance (Warren, 1990).

Postural adaptation capacities such as balance can best be observed during the performance of meaningful functional activities, although the *Berg Balance Scale* (Berg et al., 1989) has been listed as a recommended tool in the *Post-Stroke Rehabilitation Clinical Practice Guideline*. Determining status of a patient's trunk control after stroke is an important starting point for assessing component capacities or skills because poor trunk control can lead to dysfunctional limb control, increased risk of falls, contracture and deformity, diminished sitting and standing endurance, decreased visual feedback and swallowing effectiveness secondary to head and neck malalignment, and impaired ability to interact with the environment (Gillen, 2004a). A patient's posture and balance, both static and dynamic, can be observed and noted while the patient is seated and standing and during self-care tasks such as dressing, transfers, and bathing. Definition 38-2 compares functional seated posture with the dysfunctional positioning typically observed in patients recovering from stroke.

Upper Extremity Function

Occupational therapists are the clinicians most often involved with the evaluation and treatment of motor

deficits in the hemiplegic or hemiparetic upper extremity. Evaluation of the involved upper extremity should address sensation; the mechanical and physiological deterrents to movement; the presence and degree of active or voluntary movement; the quality of this movement, including strength, endurance, and coordination; and the extent of function resulting from movement.

Somatosensory Assessment

During evaluations of sensory deficits in the stroke patient, it is important to remember that sensation is a component of function and not a focus for treatment except as it relates to the ability to perform usual daily living tasks. When somatosensory disturbances are present, they usually accompany motor impairment in the same anatomic distribution (Brandstater, 2005).

Most tests of sensation require attention, recognition, and response to multiple stimuli; therefore, sensory testing is difficult in patients with aphasia, confusion, and other cognitive deficits. It is often necessary to determine the patient's level of comprehension and communication, including yes/no reliability. An expressively aphasic patient can nod, gesture, point to written or pictured cues, or select a stimulus object from an array of objects. When testing with standard procedures is not possible, information may still be gained from observing a patient's reactions to the testing. The presence of gross protective sensation (flinching when pricked with a sharp pin) can be documented even if discriminatory perception cannot be determined.

Patients who have had mild CVAs and who have intact primary sensory awareness may need to be tested for more subtle discriminatory problems using the two-point discrimination test (Callahan, 1995) or the *Moberg Pick-up Test* (Dellon, 1981). Such testing is indicated when motor return is good but hand dexterity remains impaired. Chapter 7 provides details of sensory assessment.

Mechanical and Physiological Components

Factors that can interfere with movement and function of the hemiplegic upper extremity include limitations in passive range of motion, joint malalignment, abnormal muscle tone, and pain. Interview and medical records can help determine whether these conditions resulted from the stroke or were present prior to onset. Passive movement restrictions in the joints and soft tissues of the extremity may result from an individual's anatomy and lifestyle or from pre-morbid conditions such as arthritis or injury. Limitations may result more directly from the stroke, with sudden and prolonged immobilization of joints due to weakness or spasticity in muscles. Persistent stereotyped positioning of joints without counteracting movement results in the shortening and eventual contracture of muscles, tendons, and ligaments. In the shoulder, adhesions, tendinitis, and bursitis are common

DEFINITION 38-2
de·fin·i·tion
Common Impairments in Sitting Posture Seen After Stroke

Body Part	Normal Sitting Posture Ready for Function	Abnormal Sitting Posture Typical of Stroke
Head, neck	Neutral	Forward Flexed to weak side Rotated away from weak side
Shoulders	Symmetrical height Aligned over pelvis	Uneven height Involved shoulder retracted
Spine, trunk	Straight from posterior view Appropriate lateral curves Lateral trunk muscle lengths equal bilaterally	Curved from posterior view Thoracic kyphosis Shortened lateral trunk muscles on one side, elongation on opposite side
Arms	Not used to maintain static upright posture Relaxed	Use of stronger arm to maintain upright posture Increased or decreased muscle tone in involved arm
Pelvis	Symmetrical weight bearing through both ischial tuberosities Neutral to slight anterior pelvic tilt Neutral rotation	Asymmetrical weight bearing Posterior pelvic tilt One hip retracted forward
Legs	Hips at 90° flexion Knees aligned with hips; hips in neutral adduction or abduction and internal or external rotation Feet under knees Feet flat on floor, able to bear weight	Hips in more extension Hips adducted so that knees touch or involved hip externally rotated so that knees wide apart Feet in front of knees Feet not flat on floor, unable to bear weight

complications of hemiparesis, and all can result in limited range of motion (Andersen, 1985). Edema secondary to reduced circulation and loss of muscle action can further limit passive joint motion, particularly in the hand. Goniometric measurement of passive range of motion is usually not indicated unless treatment is specifically aimed at increasing passive motion, such as when trying to eliminate an elbow flexion contracture. More useful in assessing patients with stroke is a comparison of the involved to the uninvolved arm to determine probable baseline joint motion.

Shoulder subluxation, or malalignment of the glenohumeral joint, occurs in 30–50% of stroke patients. This condition is probably caused by the weight of the arm pulling down the humerus when the supraspinatus and deltoid muscles are weak and by weakness of scapular muscles that allows the glenoid cavity to rotate downward (Brandstater, 2005). Shoulder subluxation can be identi-

fied by palpation: the patient's arm hangs freely with trunk stabilized while the examiner palpates the subacromial space for the separation between the acromion and the head of the humerus. The distance separating the two is measured in finger widths, that is, the number of fingers that can be inserted in the space (Bohannon & Andrews, 1990).

The role of subluxation in the painful shoulder is controversial; other processes that may cause pain in the hemiplegic shoulder include spasticity and/or contracture, impingement, soft tissue trauma, rotator cuff tears, glenohumeral capsulitis, bicipital tendonitis, complex regional pain syndrome, and traction neuropathy (Walsh, 2001). Most patients with shoulder pain will have varying combinations of these disorders (Brandstater, 2005; Walsh, 2001).

Abnormal muscle tone is a common component of movement deficits in hemiplegia but is also associated

with range-of-motion limitations and pain. Definitions of states of increased and decreased muscle tone and methods for evaluating muscle tone are found in Chapter 6. See Chapter 5 for descriptions of pain evaluation.

Voluntary Movement

Determining the amount and quality of voluntary movement a patient can produce is one of the first steps in assessing movement potential (Warren, 1991). The patterns of motion available are different for each stroke patient. Movement can change dramatically or subtly with time; hence, it requires careful reassessment throughout recovery. Factors to consider when evaluating motor control of the involved upper extremity include:

- Can the patient perform reflexive but not voluntary movement? Example: Patient demonstrates active elbow extension in the involved arm when balance is disturbed (equilibrium reaction) or flexes the hemiparetic elbow while yawning (associated reaction) but cannot perform these movements on request.
- Do proximal segments (neck, trunk, shoulder, hip) stabilize as needed to provide firm support for movement of the distal parts? Example: A patient cannot keep his balance when attempting arm movement and can raise his hemiparetic arm only with pronounced lateral bending of the trunk and excessive elevation of the shoulder girdle.
- Can voluntary movement be performed unassisted against gravity, or is assistance required in the form of positioning, support, or facilitation? Example: A patient can bring her hand to her mouth only by flexing her elbow in a horizontal plane with gravity eliminated.
- Can voluntary movement be performed in an isolated fashion or only in a synergistic pattern? Example: A patient can reach for an object on a table only with a pattern of shoulder abduction, elbow flexion, and trunk flexion, rather than with the more efficient pattern of shoulder flexion and elbow extension.
- Can reciprocal movement (the ability to perform agonist/antagonist motion in succession in an individual joint) be performed with practical speed and precision? Examples: A patient cannot produce a smooth pattern of elbow extension-flexion-extension needed to grasp a glass, take a drink, and set it back on the table but can perform both movements separately. A patient cannot perform the rapid alternating movements necessary to brush teeth.

One of the major movement difficulties following stroke is attaining the capacity and ability to isolate and control single muscle actions and combine them in a pattern appropriate for the task at hand. In motor patterns typical in hemiplegia, movement initiated in one joint results in automatic contraction of other muscles linked in synergy with that movement. This results in limited,

stereotyped movement patterns rather than adaptive, selective motions. Typical stereotyped patterns are described as flexor or extensor synergy patterns according to the motion at the elbow (Brunnstrom, 1970) (see Chapter 25). There is considerable variation in synergistic patterning, and other causes of abnormal stereotyped patterns include compensatory movements, unnecessary movement, muscle tension resulting from exertion or stress, and movement in response to gravity (e.g., pronation).

Several methods for evaluating voluntary movement post stroke are described in Chapters 6 and 22 to 25. Valid and reliable evaluation tools recommended by the *Post-Stroke Rehabilitation Clinical Practice Guidelines* include the *Fugl-Meyer Assessment of Motor Function* (Fugl-Meyer et al., 1975) (Chapter 25) and the *Motor Assessment Scale* (Carr et al., 1985) (Chapters 6 and 23).

Strength and Endurance

Muscle weakness ranging from slightly less than normal strength to total inability to activate muscles has been recognized as a limiting factor in the rehabilitation of patients with hemiplegia (Andrews & Bohannon, 2000). The measurement of muscle strength to monitor recovery after stroke has been controversial because of the debate regarding the influence of muscle weakness versus spasticity (Teixeira-Salmela et al., 1999) and the theory that applied resistance increases spasticity (Bobath, 1990). Clinical studies, however, suggest that strengthening of hemiplegic upper extremity musculature is appropriate for many patients (Kluding & Billinger, 2005). The motor assessment evaluations mentioned in this chapter and techniques described in Chapter 5 are recommended to establish baseline levels of muscle strength.

Reduced endurance, seen as a decrease in the ability to sustain movement or activity for practical amounts of time, is an important limiting factor in the motor performance of stroke patients because it affects the patient's ability to participate fully in rehabilitation (deGroot, Phillips, & Eskes, 2003) (Research Note 38-1). Decreased endurance can be the result of physical and/or mental fatigue caused by the exertion required to move weakened limbs or the result of comorbid cardiac or respiratory conditions (see Chapter 5).

Functional Performance

Assessing functional use of a hemiparetic arm post stroke is problematic because, although occupational performance evaluations identify deficits in ADL and IADL, they do not accurately reflect a patient's ability to use the affected arm for tasks. As observed in a population-based study, recovery of function in more than half of patients with significant upper extremity paresis was achieved only with compensatory use of the unaffected arm (Nakayama et al., 1994). Similarly, physical component skill evaluations may predict a patient's potential

RESEARCH NOTE 38-1

Fatigue After Stroke: Ingles, J. L., Eskes, G. A., & Phillips, S. J. (1999). Fatigue after stroke. *Archives of Physical Medicine and Rehabilitation*, 80, 173–178.

Abstract

The objective was to determine the frequency and outcome of fatigue, its effect on functioning, and its relationship to depression in patients 3 to 13 months post stroke. Participants included 88 individuals from a pool of consecutive patients previously admitted to an acute stroke service who were willing and able to complete the self-report questionnaires and 56 elderly control subjects living independently in the community. The main outcome measures were the *Fatigue Impact Scale*, a self-report measure of the presence and severity of fatigue and its effect on cognitive, physical, and psychosocial functions, and the *Geriatric Depression Scale*. Results showed that the frequency of self-reported fatigue was greater in the stroke group (68%) than in the control group (36%; $p < 0.001$) and was not related to time post stroke, stroke severity, or lesion location. Among the stroke group, 40% reported that fatigue was either their worst or one of their worst symptoms. Patients attributed more functional limitations to fatigue than did control subjects with fatigue. Although fatigue was accompanied by depressed mood in a substantial number of subjects in the stroke group (29%), an even greater number (39%) reported fatigue without feelings of depression. The authors concluded that, although fatigue was independent of depression, the effect of fatigue on functional abilities was strongly influenced by depression.

Implications for Practice

- Fatigue is expected to be a problem soon after stroke but is not always considered a deterrent to functional capacity or occupational therapy treatment several months post stroke. Therapists should recognize the long-term effect of fatigue symptoms when planning therapy in community or home programs.
- Training in energy conservation and work simplification techniques, including pacing and balancing of rest with activity, is appropriate for patients with stroke.
- The use of objective measures of functional and physical performance and standardized measures of fatigue and depression can help patients and families understand the effect of fatigue on function and recommend treatments to lessen that effect.

for functional use of a hemiparetic arm but are not measures of occupational performance. Many tests are described in the literature as useful for evaluating function of the involved upper extremity. Okkema and Culler (1998) reviewed 13 evaluations that include functional

or task-oriented items and concluded that few of these tests are actually functional; that is, few use relevant real-life activities. Most of these tests can be categorized as task-oriented evaluations, with portions or simulations of familiar activities.

One difficulty in measuring function after stroke results from the normal differences in performance ability between dominant and non-dominant arms (Bornstein, 1986). Eating with utensils, combing hair, and writing, for example, are normally performed by the dominant arm; testing the ability of a hemiparetic non-dominant arm to perform these tasks is not relevant or useful to a patient. The arm has a wide range of functions, and any single test assesses only a portion of the actual possible functions (Wade, 1989). Therapists must choose tests that seem best suited for the individual patient.

One functional test developed specifically for use with stroke patients is the *Action Research Arm Test* (Lyle, 1981). This test is divided into four categories (grasp, grip, pinch, and gross movement) and has 19 items that are graded on a 4-point scale. This test can be quickly administered, was found to have high validity and reliability, and correlates well with the *Fugl-Meyer Assessment of Motor Function* (DeWeerd & Harrison, 1985). However, the test requires specific handmade and difficult to obtain materials, and items tested are simulations rather than true occupational tasks.

The *Frenchay Arm Test* was developed as a battery of functional tasks used to study recovery after stroke (DeSouza, Langton Hower, & Miller, 1980). The most recent abbreviated version includes five tasks (Heller et al., 1987) requiring use of the affected arm (Fig. 38-1). The test takes little time to administer, and materials are easy to assemble. Validity and reliability were established, but this test has relatively low sensitivity for patients on the low and high ends of the performance scale (Okkema & Culler, 1998).

A standardized test developed by occupational therapists specifically to evaluate patients' ability to use the hemiplegic upper extremity for purposeful tasks is the *Functional Test for the Hemiplegic/Paretic Upper Extremity* (Wilson, Baker, & Craddock, 1984a, 1984b). This test consists of 17 tasks divided into seven functional levels that range from absence of voluntary movement to selective and coordinated movement (Figs. 38-2 and 38-3). The tasks follow a pattern of increasing difficulty and complexity and reflect Brunnstrom's hierarchy of motor recovery in hemiplegia. This test was found to have inter-rater reliability and validity, and scores showed a strong correlation to scores on the *Fugl-Meyer Assessment of Motor Function* (Filiatrault et al., 1991). The *Functional Test for the Hemiplegic/Paretic Upper Extremity* is dominance neutral in that most items are activities normally performed by either arm or bilaterally. Disadvantages of this test are that it does not provide specific information about why a patient has failed a task (Wilson, Baker, & Craddock, 1984a) and it uses pass/fail

Figure 38-1 Frenchay Arm Test tasks. **A.** Stabilizing a ruler while drawing a line. **B.** Drinking from a handleless cup. **C.** Removing and replacing a clothespin.

scoring rather than an ordinal scale, making it difficult to use for documenting partial progress.

Motor Learning Ability

Motor learning ability refers to a patient's ability to learn and organize movement for adaptation to the environment (Warren, 1991). The motor learning model of rehabilitation states that regaining the ability to perform purposeful tasks entails setting a recognizable goal, practicing, and receiving feedback (Carr & Shepherd, 1987). In this context, therapists should assess factors that can affect a patient's ability to learn or relearn, including visual function, speech and language disorders, motor planning ability, cognitive disorders, and psychosocial adjustments. Although discussed as separate categories, these factors operate as parts of an integrated system. It is often difficult to discern or separate, for example, cog-

nitive functioning from visual-perceptual or speech-language skills. Does a patient fail to respond to a request to brush his teeth because he can't locate the toothbrush in his visual field, because he has forgotten how to sequence this task, because he cannot understand the verbal request, or because he is not motivated to perform grooming tasks? These classifications are meant to assist the therapist in recognizing the components of learning impairments that follow stroke.

Visual Function

The visual system is a complex of almost all parts of the central and peripheral nervous system; therefore, any type or degree of brain damage is expected to have some effect on the function of the visual system (Warren, 1999). Chapter 8 describes assessments of vision and visual perception.

Figure 38-2 Functional Test for the Hemiplegic/Paretic Upper Extremity, sample tasks. **A.** Holding a pouch with a 1-pound weight. **B.** Stabilizing a jar while removing lid. **C.** Stabilizing a package while wrapping. **D.** Hooking and zipping a zipper. **E.** Putting in light bulb.

The most common visual disturbance associated with stroke is **homonymous hemianopsia**. Hemianopsia is a visual field defect affecting half of the visual field. Homonymous means the deficit involves both eyes. A patient with left homonymous hemianopsia has decreased or absent vision in the nasal field of the right eye and the temporal field of the left eye. Deficits in visual attention in stroke patients are hemi-inattention and hemineglect, or **unilateral neglect**. Unilateral neglect is a failure to notice,

orient, or respond to stimuli on one side of visual space (Heilman & Valenstein, 1979). Patients can have hemianopsia without neglect or hemi-inattention without a visual field deficit, but neglect, the most severe form of decreased visual attention, usually indicates a visual field deficit in addition to hemi-inattention (Warren, 1999). Neglect is almost always associated with right parietal lobe damage (Shinsha & Ishigami, 1999) and is highly predictive of poor functional recovery (Cherney et al., 2001).

FUNCTIONAL TEST FOR THE HEMIPLEGIC/PARETIC UPPER EXTREMITY

Patient Name E.G. (L CUA)

LEVEL	TASK	DATE: 6-17-06		DATE: 7-13-06		DATE: 8-12-06

Because visual deficits are disabling to the degree that they prevent completion of necessary ADL, observation of the patient's functional performance provides the most valuable information concerning the visual system (Warren, 1993, 1999). Patients with significant field deficits or unilateral neglect may display behaviors such as not noticing food only on the left side of the tray, shaving only the right side of the face, or bumping into walls or furniture on the left while walking.

Speech and Language

Disturbances in the ability to communicate or to comprehend verbal or written information can significantly affect the ability to resume or relearn usual activities. **Aphasia** is an acquired language disorder that can cause impairment in listening, speaking, reading, writing, arithmetic, or using appropriate gestures (Cherney, 1995). Stroke is the leading cause of aphasia, with damage to the left cerebral hemisphere the usual origin. A simplified clinical classification of aphasia recognizes fluent and non-fluent aphasias based on the patient's ability to produce speech (Goodglass, 1993). In the fluent aphasias, patients can easily produce spontaneous speech, but auditory comprehension and understanding of language is limited. The most common type of fluent aphasia is Wernicke's aphasia, or receptive aphasia, characterized by the smooth articulation of speech but marked by incorrect word or sound substitutions and the inability to name objects, repeat phrases, or follow commands. Reading and writing impairments are also common to this disorder (Sarno, 1994). Non-fluent aphasia is speech output that is difficult to produce and is characterized by slow, awkward articulation with limited vocabulary and grammar usage in the presence of relatively well-preserved auditory comprehension. An example is Broca's aphasia or expressive aphasia, in which the patient can follow commands but cannot name objects, repeat phrases, or convey ideas. Patients with non-fluent aphasia may be able to sing familiar songs or speak in other automatic ways, such as praying or swearing. Patients with non-fluent aphasia may also have agraphia, or the inability to express themselves in writing (Sarno, 1994).

Dysarthria is a speech disorder characterized by slurred speech, poor articulation, drooling, or decreased facial expression caused by weakness or incoordination of facial and oral musculature. Oral apraxia is another communication problem in which the patient has difficulty initiating and sequencing the movements necessary to produce speech. In these disorders, the patient can understand and express symbolic language (Sarno, 1994).

The speech-language pathologist evaluates functions and dysfunctions of speech and speech musculature. The occupational therapist needs to confer with the speech-language pathologist to learn the results of a patient's communication evaluation, support the patient's lan-

guage goals, and request suggestions for the most effective communication strategies (Sarno, 1994).

Motor Planning

Motor planning deficits, or **apraxia**, are deficits of skilled, organized, purposeful movement sequences that cannot be explained by motor or sensory impairments. These deficits are best identified during performance of daily living tasks. Clinical manifestations of motor planning difficulties include the following (Warren, 1991):

- Failure to orient the head or body correctly to a task, such as a patient attempting a toilet transfer who tries to sit on the toilet before correctly positioning the body in front of it.
- Failure to orient the hand properly to objects and/or poor tool use, such as a patient who has to be reminded of the correct way to hold a pen when writing with the uninvolved hand.
- Difficulty initiating or carrying out a sequence of movements, such as a patient with nearly normal motor performance who cannot put on a shirt without step-by-step verbal and physical cueing.
- Movements characterized by hesitations and perseveration, such as a patient who, after brushing his teeth, is handed a razor and asked to shave. After a delay, the patient brings the razor to his mouth and tries to brush his teeth with it.
- Movements that can be performed only in context or in the presence of a familiar object or situation, such as a patient who does not follow a command to move hand to mouth unless given something to eat or drink.

These deficits are most pronounced during learning sessions, such as when training in wheelchair propulsion or one-handed buttoning, and in activities with multiple steps, such as making a sandwich.

Cognition

Disorders in higher brain functions, including problems with attention, orientation, concentration, memory, reasoning, judgment, or problem solving, are common after stroke (Gresham et al., 1995). Patients with cognitive dysfunction may not achieve rehabilitation goals due to difficulty learning new techniques for performing tasks and decreased safety awareness. Cognitive impairment can be assessed during evaluation and treatment of occupational performance by focusing on the adaptive abilities of planning, judgment, problem solving, and initiation. Chapter 9 describes specific assessment techniques. Mental status screening tests recommended by the *Post-Stroke Rehabilitation Clinical Practice Guideline* are the *Mini-Mental State Examination* (Folstein, Folstein, & McHugh, 1975) and the *Neurobehavioral Cognitive Status Examination* (Kiernan et al., 1987). Therapists must be

careful to differentiate between cognitive deficits and communication difficulties common to stroke (Gresham et al., 1995).

Psychosocial Aspects

Adjustment to disability is a critical component of rehabilitation, although effective measures of adjustment have not been described (Morris, 1998). Most patients have natural emotional reactions to their stroke, including denial, anxiety, anger, and depression (Gresham et al., 1995). Depression is the most frequently reported reaction, affecting 25–40% of patients within the first year after a stroke (Eriksson et al., 2004). Depression tends to develop over time and is more likely to be seen as rehabilitation proceeds than during the acute period post stroke (Gresham et al., 1995). Depression in stroke is both a physiological result of biochemical changes in the brain and a reaction to the personal losses of patients who realize, with time, that they will not fully recover (Eriksson et al., 2004).

Denial, an adaptive emotional mechanism employed to cope with depression or anxiety, is seen when the survivor of a stroke is unable or unwilling to acknowledge the short- and long-term consequences of stroke (Remer-Osborn, 1998). It presents a challenge for the rehabilitation team because the patient may deny the need for treatment, set unreasonable personal goals, and fail to accommodate to the condition in the expectation of complete recovery (Versluys, 1995).

Emotional lability is an emotional response, such as laughing or crying, that is disproportionate to the emotional stimulus (Remer-Osborn, 1998). A patient may cry whenever seeing a family member or when asked about a valued activity.

Emotional reactions, compounded by cognitive, perceptual, and language impairments, may lead to behavioral outcomes including frustration, anger, impatience, irritability, overdependence, insensitivity to others, and rigid thinking (Versluys, 1995). These responses can further result in impaired personal interactions, inability to perform social and leisure activities or roles, and eventual isolation. Patients 3 months or more post stroke have reported decreased socialization and quality of life despite improved physical functioning (Lai et al., 2002). Evaluation of the patient's and family's adjustments to the stroke, to rehabilitation, and to the prospect of living with the aftermath of the stroke can be done through interview and observation and by sharing information with other members of the rehabilitation team.

TREATMENT

A careful interpretation of evaluation results helps determine a patient's assets and deficits in areas of occupa-

tional functioning. Possible goals for patients recovering from stroke include the following:

- The patient will gain competence in valued and necessary basic ADL and IADL in order to perform at the highest level of independence possible in the desired post-discharge setting.
- The patient will improve postural control in order to perform daily living tasks requiring balance and changes in body position.
- The patient will gain increased somatosensory perception and/or will employ compensatory strategies in order to perform ADL safely.
- The patient and/or caregiver will demonstrate appropriate management techniques for the hemiparetic upper extremity to prevent pain and other secondary mechanical or physiological movement restrictions.
- The patient will gain the necessary strength, endurance, and control of movement of the involved upper extremity in order to use the involved upper extremity spontaneously during the performance of ADL.
- The patient will gain visual function or will employ compensatory strategies in order to resume previously performed ADL safely.
- The patient will improve motor planning ability in order to relearn old methods or learn new methods of performing ADL.
- The patient and/or caregiver will demonstrate appropriate strategies for improving or compensating for cognitive deficits during the performance of ADL.
- The patient and/or caregiver will be able to verbalize the reality and impact of emotional reactions to stroke and identify coping strategies or resources to help adjust to living with a stroke.
- The caregiver will demonstrate appropriate methods and problem-solving strategies for assisting the patient with ADL and with home activities to improve component skills.
- The patient will gain competence in tasks and activities necessary to resume valued roles or to assume new meaningful roles in the community.

Safety of the patient is a concern during and after treatment (Safety Note 38-1). In this chapter, the description of occupational therapy for stroke patients is divided into three stages: the acute phase, the rehabilitation phase, and reentry to the community. For most patients, progression of recovery and provision of services are not this clear cut. For a variety of reasons, many patients do not have access to the full spectrum of services with smooth continuity of care. Any treatment described, therefore, may apply to any or all other stages for a particular patient and should be viewed as part of a continuum of care adapted to meet changing needs over time (Sabari, 1998). Specific recommendations from the *Post-Stroke Rehabilitation Clinical Prac-*

SAFETY NOTE 38-1

Precautions with Stroke Patients

- In the acute period after stroke, ascertain the patient's medical status and stability daily before treatment. Know the symptoms of progressing or recurrent stroke.
- Determine whether cardiac or respiratory precautions apply for a particular patient and monitor accordingly, watching for signs of cardiac distress and blood pressure changes, including dizziness, breathing difficulties, chest pain, excessive fatigue, and altered heart rate or rhythm.
- Guard against falls by providing appropriate supervision and assistance during transfers and other transitional movements.
- To avoid shoulder injury or pain, never pull or lift a patient by or under the weak arm during transfers or other transitional movements.
- Use appropriate precautions in the presence of insensitive skin, particularly if a patient also has visual field deficits and/or unilateral neglect.
- Ascertain a patient's ability to swallow and follow recommended management techniques during feeding.
- Provide appropriate supervision for patients who demonstrate impulsive behavior and/or poor safety awareness.
- Teach the patient, family members, and other health care workers about safety concerns for an individual patient.

tice Guideline are included and indicated by **colored print**. These recommendations are backed by research evidence and/or expert opinion.

Acute Phase

Stroke rehabilitation begins “as soon as the diagnosis of stroke is established and life-threatening problems are under control” (Gresham et al., 1995, p. 53). Length of stay in acute hospital beds is typically just long enough for necessary diagnostic tests, for initiation of appropriate medical treatment, and for making decisions and arrangements for the next phase of rehabilitation. Patients who have just had a stroke may need to be seen bedside because of precautions, monitoring, and varying levels of consciousness. During this phase, the patient must adjust to the sudden, unexpected shift from usual life roles to the role of patient.

Early Mobilization and Return to Self-Care

The patient with acute stroke should be mobilized as soon after admission as is medically feasible. The pa-

tient should be encouraged to perform self-care as soon as medically feasible and, if necessary, should be offered compensatory training to overcome disabilities.

The early introduction of basic ADL, such as rolling in bed, sitting on the side of the bed, transferring to a wheelchair or commode, self-feeding, grooming, and dressing, helps the patient reestablish some control over the environment and begin to improve occupational functioning and component abilities and capacities (Gresham et al., 1995). Even at this early stage, the occupational therapist's assessment of a patient can help determine the most appropriate setting for rehabilitation and discharge. **Discharge planning should begin at the time of admission. Goals are to determine the need for rehabilitation, arrange the best possible living environment, and ensure continuity of care after discharge.** The occupational therapist in an acute-care setting should take an active role in rehabilitation triage, basing recommendations on the patient's identified deficits and abilities (Radomski, 1995).

Lowering Risk for Secondary Complications

As part of the stroke care team, the occupational therapist should practice methods to prevent or lessen complications resulting from stroke.

Skin Care

It is estimated that up to 21% of patients with stroke develop pressure sores (Langhorne et al., 2000). Those who are comatose, malnourished, obese, or incontinent or who have severe paralysis or muscle spasticity are at greatest risk. The occupational therapist helps patients maintain skin integrity by doing the following:

- Using proper transfer and mobility techniques to avoid undue skin friction
- Recommending appropriate positioning for bed and sitting and participating in scheduled position changes as needed
- Assisting with wheelchair and seating selection and adaptation
- Teaching patient and caregiver precautions to avoid injury to insensitive skin and involved side of body
- Watching for signs of skin pressure or breakdown on a patient (bruising, redness, blisters, abrasions, ulceration), especially over bony areas, and alerting nursing or medical staff as appropriate

Maintaining Soft Tissue Length

Contractures, or shortening of skin, tendons, ligaments, muscles, and/or joint capsules, may result from the immobilization following stroke. Risk factors include muscle paralysis, spasticity, and imbalance between agonist and antagonist muscle groups. Contractures restrict movement, may be painful, and may limit functional recovery

(Gresham et al., 1995). The appropriate management is therefore a preventive program of proper positioning and soft tissue and joint mobilization. Suggested bed positioning for patients with stroke, based on a literature review (Carr & Kenney, 1992), is summarized in Procedures for Practice 38-1. However, bed positioning, like any treatment, must be adapted to meet the individual needs of the patient. Care must be taken to protect the weak upper extremity during treatment because handling, positioning, and transferring can exert great stress on the vulnerable shoulder early after stroke (Walsh, 2001). Specific techniques for supporting the hemiparetic shoulder are discussed later in this chapter. Resting hand splints are often applied to prevent soft tissue shortening, but their use has not been found to significantly prevent or reverse contracture of wrist and finger flexor muscles (Lannin et al., 2003).

Controlled and frequent movement of body parts is the preferred method to prevent contractures. When a patient cannot use the involved side to engage in meaningful activities, therapists should initiate supervised active or active-assistive movement activities. When active movement is not possible, therapists should see that immobile body parts go through passive range of motion at least once daily. If performing passive range of motion on the involved arm, ensure proper scapulohumeral rhythm by relaxing and mobilizing the scapula before elevation of the arm and by manually assisting upward rotation of the scapula (Bobath, 1990). The humerus should be externally rotated during abduction to prevent impingement of the supraspinatus between the greater tubercle of the humerus and the acromion process. Whenever possible, a patient should attend closely to passive movement as a first step in relearning motion (Carr & Shepherd, 1987). A study using positron emission tomography (PET) on early post-stroke patients who had no active movement showed that passive elbow movements elicited some of the same brain activation patterns as active movement in more recovered patients (Nelles et al., 1999).

Fall Prevention

For patients hospitalized with stroke, falls are the most common cause of injury (Gresham et al., 1995). Factors that increase the risk of falls include advanced age, confusion, impulsive behavior, mobility deficits, poor balance or coordination, visual impairments, and communication deficits that interfere with a patient's ability to request assistance in a timely manner. Treatment that helps to prevent falls includes detecting and removing environmental hazards, optimizing motor control, recommending appropriate adaptive devices, and teaching safety measures to the patient and family.

Patient and Family Education

Early in recovery, support for patients who have had strokes and their families may best be provided in the form

PROCEDURES FOR PRACTICE 38-1

Recommended Bed Positioning for Patients With Hemiplegia

Supine Positioning

- Head and neck slightly flexed
- Trunk straight and aligned
- Involved upper extremity supported behind scapula and humerus with a small pillow or towel, shoulder protracted and slightly flexed and abducted with external rotation, elbow extended or slightly flexed, forearm neutral or supinated, wrist neutral with hand open
- Involved lower limb with hip forward on pillow, nothing against soles of feet

Lying on the Unaffected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted with arm forward on pillows, elbow extended or slightly flexed, forearm and wrist neutral, and hand open
- Involved lower extremity with hip and knee forward, flexed, and supported on pillows

Lying on the Affected Side

- Head and neck neutral and symmetrical
- Trunk aligned
- Involved upper extremity protracted forward and externally rotated with elbow extended or slightly flexed, forearm supinated, wrist neutral, and hand open
- Involved lower extremity with knee flexed
- Uninvolved lower extremity with knee flexed and supported on pillows

Information from Carr & Kenney (1992).

of education to promote a realistic understanding of the consequences of stroke and the purposes and methods of various treatments (Gresham et al., 1995). All aspects of occupational therapy assessment and treatment for survivors of stroke should be considered opportunities for education: to engage cooperation and participation in the identification of meaningful treatment goals, to highlight residual abilities as well as disabilities, and to promote carryover of treatment gains. As the period after stroke is stressful, emotional, and tiring for both the patient and family, education sessions provided during the acute phase should be brief, simple, and reinforced as needed with repetition or appropriate learning aids (see Chapter 14).

Rehabilitation Phase

Part of discharge planning during the acute phase of stroke is screening for rehabilitation services. Rehabilitation choices depend on a patient's condition, the social support

system, and the resources available in a community. To qualify for further treatment in a rehabilitation program, a patient must be medically stable, have at least one functional disability, have sufficient endurance to sit supported for at least an hour, and be able to learn and to participate actively in therapy (Gresham et al., 1995). Patients who meet these criteria are referred for inpatient rehabilitation programs, for multidisciplinary rehabilitation services at a skilled nursing facility, or for treatment by one or more disciplines in home care or in an outpatient clinic. Patients who do not meet these criteria should continue to receive appropriate medical or support services at home, in a skilled nursing facility, or in a chronic care facility; they may be reassessed later for rehabilitation services.

During this phase of recovery, the patient and family are focused on getting better and are usually more concerned with recovering lost function than on adapting to a life of chronic disability (Sabari, 1998). Successful occupational therapy intervention coordinates a patient's striving for restoration of function with the potential for compensation and alternative occupational roles.

Treatment to Improve Performance of Occupational Tasks

The occupational therapist's primary goal in stroke rehabilitation is to improve independence in daily living tasks and hence the patient's quality of life. **Patients with persistent, non-remediable functional deficits should be taught compensatory methods for performing important tasks and activities, using the affected limb when possible and, when not, the unaffected limb.** Many consider that early ADL training focusing on compensatory techniques results in faster success and is therefore more cost effective and more satisfying to the patient, who again feels competent (Nakayama et al., 1994). Others contend that, when ADL training focuses entirely on one-handed techniques, the patient fails to relearn bilateral movements and, instead, develops unilateral habits (Bobath, 1990; Roberts et al., 2005). Skilled occupational therapy intervention combines both compensatory and remedial treatment strategies and attempts to reduce both disabilities and impairments by engaging the patient in meaningful activities. Putting on a front-buttoning shirt, for example, besides helping a patient gain independence in the task of dressing, addresses the following component abilities, capacities, and conditions:

- Joint and soft tissue integrity (self-stretching or relaxation techniques for involved arm in preparation for dressing, positioning of arm on a surface to prevent stretching of weak shoulder structures)
- Voluntary movement and function of involved upper extremity (abducting shoulder to put on a sleeve, extending elbow to push the hand through the sleeve, pinching one side of the shirt to stabilize while buttoning)

- Somatosensory perception (the texture of the shirt, the position of the affected arm)
- Postural adaptations (anterior pelvic tilt, trunk rotation, weight shifting)
- Visual-perceptual skills (finding the shirt in the visual field, distinguishing top from bottom, finding the sleeve opening)
- Cognitive skills and emotional reactions (sequencing, attention span, frustration tolerance, motivation)

ADL training with stroke patients begins with simple tasks and gradually increases in difficulty as a patient gains competency (Gresham et al., 1995). Several studies discerned a hierarchy of achievement of self-care skills. Results of one study showed that bathing, dressing, and climbing stairs were the activities for which stroke survivors most often required assistance, with 32% of patients needing help with bathing, 25.5% needing help with dressing, and 32% requiring assistance with stairs 12 months post stroke (Carod-Artal et al., 2002). Aspects of dressing that are particularly difficult for stroke patients are putting a sock and shoe on the affected foot, lacing shoes, and pulling up trousers or pants (Walker & Lincoln, 1990). A study that investigated the relationship between dressing abilities and cognitive, perceptual, and physical deficits found that, in general, lower extremity dressing correlates more with motor performance and upper extremity dressing correlates more with cognitive or perceptual performance (Walker & Lincoln, 1991). **Adaptive devices should be used only if other methods of performing the task are not available or cannot be learned. The device should have proven reliability and safety, and the patient and/or caregiver should be thoroughly trained in its proper use.**

As the patient progresses, occupational performance tasks other than basic self-care may have to be addressed. IADL tasks such as homemaking, home management, and community mobility involve greater interaction with the physical and social environment and require higher level problem-solving and social skills than basic ADL tasks (Carod-Artal et al., 2002). Avocational interests, including adapted methods of continuing familiar hobbies, are an important area of treatment. Many stroke survivors are faced with increases in leisure time because of inability to go back to work; however, a reduction in social and leisure participation has been found to be a common occurrence after stroke (Lai et al., 2002). Chapter 30 discusses specific techniques for regaining independence in ADL/IADL for those with loss of the use of one side of the body.

Treatment to Improve Component Abilities and Capacities

Performance component goals are based on the impairments associated with an individual's stroke and are directly linked to occupational performance goals. The goals

and modalities used to address these component deficits must be purposeful and meaningful from the patient's point of view (Trombly, 1995). Thus, a floor game may be used to improve sitting balance needed to don socks, or resistive grasp activities may be taught to strengthen muscles needed to squeeze a tube of toothpaste. Treatments for stroke deficits are described individually in the following sections, but most patients in rehabilitation programs have multiple interacting problems necessitating efficient, integrated treatment plans that address several deficit areas at once (Warren, 1991).

Postural Adaptation

The ability to make automatic postural adjustments, including trunk control and the maintenance of balance, is a prerequisite for successful performance of occupational tasks. Part of the occupational therapist's role in training a patient in ADL independence post stroke is in teaching the patient the safest, most effective and efficient "ready" position for engaging in activities (see Definition 38-2) and strategies for adapting to changes in body position. Various techniques can be used to accomplish these goals as long as the therapist has a clear understanding of each patient's particular strengths and weaknesses regarding stability and mobility. Treatment to improve postural control for the performance of daily living activities is aimed at reestablishing the prerequisites for mature postural adaptation, including the following abilities (Warren, 1990):

1. To produce full range of movement in the trunk and extremities.
2. To differentiate body parts from one another, such as rotating the shoulders independently of the hips.
3. To stop and hold movement at midrange to stabilize against gravity.
4. To increase and decrease postural tone in body segments automatically and appropriately to support movement and/or stability.
5. To move both sides of the body symmetrically.

The incorporation of transitional movement patterns (i.e., strategies to change body positions, such as from supine to side-lying or seated to standing) and the use of strategically placed activities allow patients to practice effective postural adjustment while focusing on the task at hand (Warren, 1990).

A particularly challenging impairment of postural control is pusher behavior. Pusher behavior is clinically defined to describe hemiplegic patients who actively push away from their non-paralyzed side with their stronger limbs and resist attempts to make them more upright (Davies, 2000). It is observed in approximately 5% of stroke patients, usually in the most involved patients, and negatively affects functional recovery (Pedersen et al., 1996). A pilot study by Perennou et al. (2002) concluded that pusher behavior does not result from disrupted pro-

cessing of vestibular information but from a higher order disruption in the processing of somesthetic information from the left side of the body, possibly an extinction or neglect phenomenon. Because patients with pusher behavior resist hands-on attempts to correct their alignment, therapists should select treatment that manipulates the environment (reaching for objects to encourage weight shift to the strong side) and provides external cues ("bring your right shoulder toward the wall") (Gillen, 2004a) (see Definition 38-2).

Upper Extremity Function

Bilateral use of the upper extremities is crucial to efficient and effective occupational performance. Patients recovering from stroke usually place a high priority on regaining function in the involved arm. The occupational therapist must determine which deficits most affect a patient's upper extremity performance and plan realistic multilevel, task-oriented treatment to restore function or promote adaptation to the loss of function.

SOMATOSENSORY DEFICITS

Treatment for sensory dysfunction of stroke patients has not been systematically developed, although therapists attempt remediation as well as compensation for these deficits (Trombly, 1989). Remedial treatment entails a sequence of presentation of a tactile stimulus, response by the patient, exact feedback, and practice (Weinberg et al., 1979). Compensatory treatment entails substituting intact senses for those lost or dysfunctional. Therapists must determine the appropriateness of either type of treatment for individual patients. For example, sensory retraining is unrealistic for patients with minimal voluntary movement, visual field neglect, or poor cognitive skills.

Yekutieli and Guttman (1993) conducted a controlled trial in which 20 hemiplegic patients 2 or more years post stroke received systematic sensory training for the hemiplegic hand for 6 weeks. Their sensory reeducation program included exploring with each patient the nature and extent of sensory loss, selecting sensory tasks of interest to the patient that promoted learning, and encouraging constant use of vision and the uninvolved hand to teach tactics of perception. At the end of the training period, the treatment group showed significant gains in all sensory tests, whereas the control group showed no changes.

Treatment to restore tactile awareness and teach compensation for sensory loss is discussed in Chapter 27. One method of providing repetitive stimulation is to encourage the patient to use the involved hand in ADL as soon as possible. The use of different textures (e.g., foam, terry cloth, Velcro) on weight-bearing surfaces or on the holding surfaces of commonly used utensils, such as cups, forks, and pens, can increase sensory input to the affected hand (Eggers, 1984).

MECHANICAL AND PHYSIOLOGICAL COMPONENTS OF MOVEMENT

Techniques for maintaining soft tissue length and avoiding pain in the involved upper extremity initiated during the acute phase of stroke recovery should be continued and adapted in response to changes in the patient's movement or muscle tone. As the patient in a rehabilitation program gains in mobility, measures should be taken to protect weak upper extremity structures from stretching or injury due to the effects of gravity and improper movement. Procedures for Practice 38-2 summarizes handling techniques for an affected upper extremity.

Treatment of problems related to the hemiplegic shoulder centers on prevention and management of symptoms and underlying causes. The use of a sling as a prevention or treatment for subluxation of the hemiplegic shoulder is not supported by empirical research (Gresham et al., 1995; Turner-Stokes & Jackson, 2002). Reasons for using slings are to reduce the subluxation of the glenohumeral joint, provide support for the arm, protect against trauma, and prevent or reduce pain. Carr and Shepherd (1987) found that radiographs of hemiplegic shoulders in slings revealed no significant reduction of subluxation. Bobath (1990) maintained that flexor spasticity in the upper extremity is reinforced with the use of a sling. Pain control is a valid reason for use of a positioning device; however, the relation between subluxation and shoulder pain is unclear. Several studies have found no association between shoulder pain and subluxation after stroke (Bohannon & Andrews, 1990; Turner-Stokes & Jackson, 2002), including one that found a low correlation between shoulder pain after

stroke and subluxation, age, and arm motor function but a high correlation between shoulder pain and limited passive shoulder external rotation (Zorowitz et al., 1996). These studies support a general recommendation that the hemiplegic arm should be appropriately supported but that shoulder supports should not be issued uniformly to all patients with shoulder subluxation. If considering a sling, therapists should address the following questions (Andersen, 1985; Ridgway & Byrne, 1999). A positive response to the following questions might indicate a sling:

- Does pain or edema increase when the arm hangs down?
- Is the patient's balance during standing, walking, or transfers improved by the use of a sling?
- Is the patient unable to attend to and protect the arm during movement?
- Can the patient or caretaker independently put on and take off a sling correctly?

A positive response to the following questions might contraindicate a sling:

- Would the sling prevent or hinder active movement or function in the arm?
- Would a sufficiently supportive sling impair circulation or cause excessive pressure on the neck?
- Would the sling put the patient at risk for contracture as a result of immobilization?
- Would a sling decrease sensory input and promote unilateral disregard?

Alternative positioning methods and devices for shoulder support include taping of the shoulder and scapula (Ridgway & Byrne, 1999), wheelchair lapboards and armrest troughs, use of a table while seated or standing, putting the hand in a pocket or under a belt, and using an over-the-shoulder bag while standing (Gillen, 2004b) (Fig. 38-4). Functional electrical stimulation has been used to prevent or improve shoulder subluxation, decrease pain, and improve range of motion. Studies evaluating the effectiveness of this treatment showed benefits during treatment but reduction of gains after treatment was discontinued (Walsh, 2001). Any patient with shoulder pain that persists and consistently interferes with function or progress in therapy should be referred to specialists best qualified to diagnose and treat specific shoulder problems.

Along with protection, patients learning to manage their involved arm should know techniques of active, active-assistive, or passive movement designed to maintain range of motion, stretch tight tissues, or relax hypertonicity. The combination of positioning for comfort and muscle imbalances brought on by spasticity and weakness can lead to the development of stereotyped non-functional positioning for the hemiplegic upper extremity with

PROCEDURES FOR PRACTICE 38-2

Proper Handling of the Hemiparetic Upper Extremity

- Teach the patient as early as possible to be responsible for the positioning of the arm during transfers, bed mobility, and other activities involving change of position.
- Use gait belts or draw sheets, rather than the affected arm, to assist the patient in moving his or her body.
- Avoid shoulder range of motion beyond 90° of flexion and abduction unless there is upward rotation of the scapula and external rotation of the humerus (Gresham et al., 1995).
- Avoid overhead pulley exercises, as they appear to increase the frequency of pain in the shoulder because neither scapular nor humeral rotation occurs, and the force may be excessive (Kumar et al., 1990).

Figure 38-4 Alternative methods for supporting the hemiplegic arm while standing. **A.** Hand in pocket. **B.** Use of shoulder bag.

shoulder retraction, adduction, and internal rotation; elbow flexion; forearm pronation; and wrist and finger flexion. Therapists should emphasize frequent changes of position to prevent contractures and pain.

Even in the absence of motor recovery, normal movement is an important model for movement reeducation (Van Dyck, 1999). Passive and assisted active movement can be incorporated into activities, with the patient experiencing and concentrating on movement in a functional context. Methods of teaching self-managed range of motion entail bilateral activities such as having the patient clasp his or her hands while leaning forward to reach for the floor or pushing both hands forward with arms supported on a table (Eggers, 1984). Advantages of these activities are that they can easily be given a functional context, such as picking up objects off the floor or dusting a table, and the patient can monitor his or her own pain threshold and is therefore not apprehensive about move-

ment of the arm (Andersen, 1985). Nelson et al. (1996), in a study of persons with hemiplegia, found that using a simple dice game to achieve bilaterally assisted forearm supination brought better results (more range of motion, more repetitions) than use of a rote exercise routine (Evidence Table 38-1). Self-management of range of motion should be closely supervised and may not be appropriate for patients who have decreased awareness of the involved side, who move too quickly, who do not respect pain, or who lack a mobile scapula.

Hand edema is a frequent complication of hemiplegia. Edema control techniques include elevation of the hand, retrograde massage, and use of pressure gloves. Patients with minimal voluntary movement should avoid allowing the hand and arm to hang down for long periods. Prolonged hand edema can lead to limited passive movement, pain, and soft tissue contractures. Edema combined with severe pain, hypersensitivity, and vasomotor distur-

bances of the hand are signs of shoulder-hand syndrome or reflex sympathetic dystrophy (RSD) and should be addressed vigorously to prevent further loss of functional potential (Turner-Stokes & Jackson, 2002) (see Chapter 42).

VOLUNTARY MOVEMENT AND FUNCTION

Chapters 21 to 26 describe various treatment approaches to promote motor abilities and capacities in the patient recovering from stroke. Therapists usually employ a variety of techniques in response to the complex multiple factors that interfere with upper extremity use in an individual patient. **Patients who have functional deficits and at least some voluntary control over movements of the involved arm or leg should be encouraged to use the limb in functional tasks and offered exercise and functional training directed at improving strength and motor control, relearning sensorimotor relationships, and improving functional performance.**

Success in restoring voluntary movement in the hemiplegic upper extremity has been limited, perhaps because investigation of factors enhancing or impeding motor skills and processes following stroke is limited (Winstein et al., 2004). Spasticity, for example, has traditionally been described as a major barrier to normal movement and function in the patient with hemiplegia (Bobath, 1990). However, clinical studies (Fellows & Thilmann, 1994; Sommerfeld et al., 2004) suggest that poor motor control with weakness is more likely to contribute to motor impairments and activity limitations than hypertonicity. Voluntary movement deficits in the patient with hemiplegia include problems of muscle force production and control, of abnormal muscle activation and inhibition patterns, and of synergistic organization. In analyzing reaching performance, Wu et al. (1998) found that persons with stroke produced movements that were less efficient, less direct, less smooth, and slower than movements pro-

duced by neurologically intact subjects. In short, the patient finds it difficult or impossible to use available movement in an adaptive way.

The American Heart Association has recommended that exercise programs for survivors of stroke include aerobic activities, strength training, flexibility exercise, and coordination and balance training (Gordon et al., 2004). Strength, endurance, and coordination can be graded in functional tasks to increase the motor performance of the involved upper extremity. Carefully selected resistive activities have been shown to improve performance as measured by motor function tests (Kluding & Billinger, 2005). More studies are needed to determine the effectiveness of specific clinical strengthening methods in improving occupational performance of stroke patients. As decreased physical and mental endurance can limit participation and performance in therapy, treatment should be carefully graded to compensate for and improve reduced endurance. Length of treatment sessions, energy requirements, and need for rest periods should be monitored to meet patients' needs.

Coordinated movement is the product of successful control of the strength, range, speed, direction, and timing of movement. As almost all purposeful activity requires coordination, encouraging use of the affected extremities in self-care tasks or leisure activities is an appropriate way to improve coordination. Treatment should progress from unilateral activities, in which the patient can concentrate fully on control of the hemiparetic arm, to bilateral simultaneous activities, in which both arms perform the same movement together (such as lifting and carrying a box and catching and throwing a large ball), to bilateral alternating activities, in which the two arms perform different movements at the same time (such as sorting and assembling nuts and bolts). Grading fine motor activities entails progressing from gross to precise manipulation

Figure 38-5 Constraint-induced movement therapy. **A.** Applying and removing jar lids. **B.** Eating a meal with involved upper extremity while non-involved hand is restrained.

tasks and attempting more difficult patterns of grasp and pinch. Because hand and arm control for patients with hemiplegia becomes more difficult as the arm moves away from the body, the placement of activities should be varied. Writing is a highly coordinated task that is frequently a goal for stroke patients who need at least to be able to sign documents. Training in writing may be necessary if a patient plans to use the hemiparetic hand or the uninjured non-dominant hand.

TASK-SPECIFIC AND TASK-ORIENTED INTERVENTIONS

In light of the range and complexity of possible motor impairments and the myriad of treatment strategies available, the occupational therapist should design treatment to fit the patient's level and interests and to guide and extend combinations of muscle action into meaningful tasks (Carr & Shepherd, 1987). There is growing evidence that intervention strategies providing context-relevant, meaningful engagement in activities are more beneficial for skill acquisition than rote exercise or passive modalities (Winstein et al., 2004). Task-specific training is aimed at improving component skills of selected tasks, such as using hand muscles to practice gripping a fork. An example of task-oriented training is a patient simulating a useful or familiar activity such as using a spoon to transfer dried beans from one container to another. Occupational engagement, such as a patient using a hemiparetic arm to eat a meal at home, involves the greatest degree of patient self-choice, motivation, and meaning (American Occupational Therapy Association, 2002), although therapists must judge adaptations necessary to allow patients to succeed. Trombly and Wu (1999) found that providing a meaningful object within a functional context during treatment (e.g., reaching for food on a plate) leads to improved performance over exercise or reaching for a neutral target. Similarly, Fasoli et al. (2002) found that, during functional reaching tasks, internally focused instructions (e.g., "straighten your elbow") resulted in slower, less forceful reach than externally focused instructions (e.g., "think about the size, shape, and weight of the object") in samples of adults with and without CVA.

Therapists should review the wide range of possible functions of the upper extremity to select activities patients can succeed in. In normal function, the hand performs as a prehensile tool, and the arm places the hand in a wide variety of different and precise positions (Savinelli et al., 1978). Bard, Hirschberg, and Tolleson (1964) proposed a classification of function of the upper extremity, including (1) non-manipulatory activities, (2) prehension and manipulation, and (3) skilled individual finger movements, such as typing. Non-manipulatory activities, such as weighting down a checkbook while writing, can be incorporated into functional activities by pa-

tients who have limited movement or no voluntary hand movement.

CONSTRAINT-INDUCED MOVEMENT THERAPY

It is important to promote functional use of the involved upper extremity early and consistently because patients tend to have difficulty translating limited upper extremity movement into functional use. They often report that their arm is "dead" or "useless" despite sufficient arm movement for simple activities. Movement may return spontaneously, but it appears that function or purposeful use of the arm is enhanced with therapeutic intervention and practice (Blanton & Wolf, 1999). Based on studies involving both animal and human subjects, Taub et al. (1993) described a phenomenon of **learned non-use**: the person with hemiparesis notices negative consequences of efforts to use the affected limb that are reinforced by successful compensatory use of the unaffected limb (Blanton & Wolf, 1999). The intervention termed forced use, or constraint-induced movement therapy (CIMT), was developed to counteract the effects of learned non-use (Fig. 38-5). In a comparative clinical study, Taub et al. (1993) restrained the unaffected upper extremity of chronic stroke patients (at least 1 year post onset) in a sling during waking hours for 2 weeks. This group also participated in sessions of intensive practice of functional tasks with the impaired arm. A comparison group was given activities designed to encourage use of the impaired arm but without practice and without restraint of the unimpaired arm. The restraint subjects showed greater improvement on measurements of motor function than the control group and showed carryover of this function to life tasks and maintenance of gains during a 2-year follow-up period. Dromerick, Edwards, and Hahn (2000) found that CIMT could be implemented during acute rehabilitation (1–2 weeks after stroke) with resulting improvement in involved arm function at the end of 14 days of treatment. This study suggests that preventing or minimizing learned non-use with early intervention is preferable to extinguishing learned behaviors.

Although CIMT is described as providing "the most promising evidence that motor recovery can be facilitated (after stroke)" (Duncan, 1997, p. 3), it is difficult to implement in standard clinical practice. CIMT emphasizes massed practice by combining daily 6-hour training sessions for the paretic arm with restraint of the uninjured arm in a sling or mitt during 90% of waking hours for a duration of 2–6 weeks (Page et al., 2004). Patients included in CIMT studies had to meet minimal voluntary movement requirements including the ability to initiate 20° or more of wrist extension and 10° or more of finger extension. As a result, benefits from this treatment are limited to those with less severe motor involvement, or approximately 20–25% of patients with chronic stroke (Blanton & Wolf, 1999). Other problems limiting the

application of CIMT techniques include poor compliance with patient restraint schedules, concerns over safety and limitations on independence caused by the restrictive device, lack of facility resources to provide intensive training sessions, and concerns about reimbursement (Page et al., 2004).

Recent research involving CIMT has deviated from the original research protocol by varying target populations, altering inclusion criteria, and modifying intensity and duration of treatment (Roberts et al., 2005). Ploughman and Corbett (2004) studied the effects of restraining patients' uninvolved arm without extensive shaping therapy. Roberts et al. (2005) monitored patient performance and satisfaction after 2 weeks of CIMT in the home environment incorporating meaningful daily activities chosen by the patient. Page et al. (2004) describes a modified CIMT for outpatients that combines involving the affected arm in functional tasks during structured 30-minute sessions 3 times a week with restraint of the unaffected arm every weekday for 5 hours. All studies reported improved motor function using standardized measurements, supporting the observation that techniques that induce a patient to use an affected limb should be considered therapeutically effective (Taub, Uswatte, & Pidikiti, 1999).

Motor Learning Ability

As occupational therapists mainly teach skills, they must address the learning process to help patients improve occupational performance. Learning to dress, for example, entails performing the task effectively and efficiently in a variety of circumstances or contexts (Carr & Shepherd, 1987). Therapists can best assist patients with stroke by helping them develop their own problem-solving techniques and strategies to deal with their environment.

VISUAL DYSFUNCTION

Chapter 28 describes treatment for patients with visual deficits. In general, therapists can employ either of two basic approaches for patients with visual problems following stroke, determined by the extent of visual impairment and a patient's intact capabilities (Warren, 1999). With an active approach, the goal of therapy is to improve a patient's visual perceptual processing, either by improving component skills, such as visual scanning ability, or by training in compensatory skills, such as turning the head to the left. With a passive approach, treatment emphasis is on altering the patient's environment to improve occupational performance, such as positioning all food in the right visual field before a meal.

There is limited research to support the effectiveness of visual training procedures used with patients following stroke (Ma & Trombly, 2002). Results of one study (Weinberg et al., 1977), however, suggest that visual-

perceptual deficits following stroke must be confronted and patients must be taught to recognize their deficits for treatment to be effective. Sharing results of objective evaluations with the patient and family, giving feedback on the effects of visual deficits on functional performance, and teaching patients to recognize and correct errors in performance have been suggested as techniques for increasing a patient's awareness of his or her deficits (Warren, 1993).

Studies of the effects of visual training skills on unilateral neglect (Cherney, Halper, & Papachronis, 2003) and visual-perceptual deficits (Edmans, Webster, & Lincoln, 2000) indicate that treatment involving forced awareness of neglected space, task-specific practice, and use of consistent strategies to accomplish functional activities improve cognitive-perceptual abilities after stroke. To ensure transfer of training, Toglia (1991) recommended a multicontext approach of practicing strategies in multiple environments with varied tasks and component demands. Therapists, for example, can provide a stronger learning event by reinforcing a visual searching task (finding all the forks in a dishwasher bin) with touching and moving the targets (picking up the forks and putting them in the correct space in a drawer). Training must be specific to the individual's deficits and goals for occupational functioning. A patient with hemianopsia and unilateral visual neglect who is unsafe with wheelchair propulsion and is not interested in reading or writing as a leisure activity will benefit more from specific environmental scanning activities in a wheelchair (obstacle courses, grocery shopping) than from paper and pencil or computer activities.

SPEECH AND LANGUAGE DISORDERS

Occupational therapists should work closely with speech-language pathologists to contribute to a patient's improvement in speech and language functioning. Therapists can promote proper posture as an assist to respiration and eye contact important to speech. Therapy sessions also provide a social context supportive of communication (Sarno, 1994). Whenever possible, therapists should incorporate speech and language goals into their treatment sessions, such as requiring verbal responses (counting repetitions of an activity or naming objects used) or addressing functional reading and writing tasks (reading signs and recipes, writing checks). Occupational therapists can assist in selecting and adapting a non-verbal form of communication for a patient, such as writing, drawing, use of a communication board, and gestures. Suggestions for working with patients with aphasia and their families include the following (American Heart Association, 1994):

- Avoid unnecessary noise: turn off television, find a quiet space.

- Do not speak to the patient or request speech when he or she is engaged in a physical activity.
- Allow enough time for the patient to respond; do not rush or force communication; do not switch topics quickly.
- Never assume that the person with aphasia can't understand what's being said; never allow others to ignore the person with aphasia.
- Speak slowly and clearly using simple, concise language; do not speak loudly unless hearing is impaired; do not talk down as if to a child.
- Use demonstration, visual cues, and gestures as needed to help with comprehension.

MOTOR PLANNING DEFICITS

Motor planning deficits, or apraxia, are serious learning disorders and among the most difficult to rehabilitate. The emphasis of treatment is on teaching compensatory skills rather than on remediation due to the complexity of these impairments (Warren, 1991), with goals of competent performance of desired habitual or novel activities (Gresham et al., 1995). Suggestions for treatment include manually guided movement, repetitive graded use of objects and contexts to evoke more automatic responses, explaining clearly the components of a task, **backward chaining**, and practicing activities as closely as possible to the patient's usual context or routine (Gresham et al., 1995). Language can facilitate movement planning; it assists in the sequencing of actions required for a task, helps focus concentration and identify mistakes, and reduces perseveration (Warren, 1991). Therapists can have patients verbalize step by step what they have done and are going to do, for example, "I have taken the cap off the toothpaste. Now I will pick up my toothbrush and put toothpaste on it."

COGNITIVE DEFICITS

Treatment to optimize cognitive abilities is discussed in Chapter 29. As in other areas of dysfunction, treatment for cognitive problems after stroke can include retraining of specific component skills, teaching compensation techniques or substitution of intact abilities, and/or adaptation of the environment (Gresham et al., 1995). Examples include using prompts or cues to shape desired behavior; providing feedback on performance with suggestions and strategies for improvement; providing visual aids, such as memory logs, checklists, maps, or diagrams for deficits of memory, sequencing, or organization; and simplifying the environment and grading tasks for patients with attention deficits. Caregivers must be educated regarding recommended adaptations, safety precautions, and the need for supervision.

PSYCHOSOCIAL ADJUSTMENT

Patients and families usually need assistance in making healthy emotional adjustments after stroke. It may be unreasonable to expect compliance to treatment instructions when patients and their families are coping poorly with the losses associated with stroke (Evans et al., 1992). Patients typically employ hope and determination to cope with hospitalization, the hard work of rehabilitation, and changes in body image but many cling to the belief that they will be "normal" again (Sabari, 1998). Therapists should reinforce the efforts of the rehabilitation team and encourage patients and families to talk about their reactions to stroke and their comprehension of its progression and prognosis. In light of the shortening time frames for rehabilitation, therapists should make sure patients and families understand that recovery from stroke does not end with discharge from a hospital or rehabilitation program. Therapists should also help patients and families to realize that the ultimate goal of rehabilitation is not complete recovery from physical and intellectual impairments but the ability to resume valued life roles.

Therapists should recognize the signs and symptoms of depression and inform appropriate team members if treatment has not been initiated. For the patient with emotional lability, both patient and family need to be reassured that lability is a symptom of the stroke and that control will improve with time (Carr & Shepherd, 1987). The therapist can instruct the patient in techniques such as deep breathing or redirecting attention to help him modify his behavior (Carr & Shepherd, 1987). Group activities, social interactions, and community outings are important methods for allowing a patient to practice roles from before the stroke and to realize that the patient role is a temporary transition to getting on with life despite residual impairments.

Transition to the Community

"For many stroke survivors and their families, the real work of recovery begins after formal rehabilitation. One of the most important tasks of a rehabilitation program is to help those involved to prepare for this stage of recovery." (Gresham et al., 1995, p. 143)

Discharge Planning

Discharge planning takes place throughout the rehabilitation phase. Successful planning allows the patient and family to feel comfortable with the decisions made for discharge, feel capable of maintaining gains and continuing progress without the intense level of support provided by rehabilitation specialists, and feel able to monitor for changes requiring adjustments or further intervention.

Occupational therapists assist in identifying the most appropriate discharge setting; training the patient, family, and caregiver in essential skills; and arranging for continuity of care with community services. Factors determining discharge setting include patient's and family's preferences, level of patient's disabilities, level of caregiver's support, and safety and accessibility of the home (Gresham et al., 1995). Often a patient with a fairly high level of physical functioning cannot return home because there is no caregiver or the residence is unsafe or inaccessible, whereas a more disabled patient can return home because a healthy spouse is willing to assume the role of caregiver and the residence is safe and accessible. Therapists perform a major role by participating with patients and families in home visits and safety assessments and recommending necessary home alterations or adaptive equipment.

Patient, Family, and Caregiver Education

Ideally, every treatment session is an opportunity to teach the patient, family, or caregiver techniques and problem-solving strategies for use after rehabilitation. Although learning styles vary, patients and their families are best served by a combination of demonstration, experiential sessions, and written instructions. Repetition is important, and caregivers should demonstrate, rather than simply verbalize, their ability to assist the patient safely and independently. At the time of discharge from a rehabilitation program, patients and their families are often overwhelmed with information from several disciplines that they must try to assimilate. After formal therapy sessions have ended, many patients and caregivers report good intentions of following home programs as prescribed but admit that the routine of daily activity leaves little time or energy for carrying out therapeutic recommendations at home. The most effective home programs therefore are those that incorporate treatment for component limitations into self-care and leisure routines (Van Dyck, 1999), for example: "Before bathing or dressing, briefly perform the following stretching movements to get the best posture and arm movement for these tasks." This is more likely to be complied with than: "Perform the following exercises, 10 repetitions each, at least twice a day." Home programs should, of course, be individualized and should remind the patient of skills already mastered, of skills the patient can reasonably expect to gain, and of possible problems common to stroke. Patients and families should be well informed of sources for information or assistance as new capabilities or problems evolve. Fall prevention is a necessary component of the home program and should encourage greater independence in mobility while identifying and reducing the risks of falls (Gresham et al., 1995).

Resuming Valued Roles and Tasks

Although most individuals who have had stroke improve in basic functional abilities such as walking and self-care, most have limitations in physical and social role functioning (Lai et al., 2002). Sabari (1998) refers to the third phase of stroke recovery as that of reestablishing social roles and suggests that this is the critical phase in defining one's quality of life. Occupational therapists should facilitate this adaptive process by helping patients set and achieve reasonable goals for task performance so as to assume adapted or new roles.

Work

For patients who expect to resume working, pre-vocational or vocational evaluation and appropriate work readiness training should be encouraged (see Chapter 33). A literature review (Teasell, McRae, & Finestone, 2000) examining return to work among working-age stroke patients found that between 17% and 51% of the patients were able to return to work. The wide variability seen in return to work is explained by differences in stroke severity and differences in defining work. A smaller percentage of patients were able to resume full-time competitive employment, and a greater percentage returned to part-time or home-based work. A majority of those returning to work acknowledged that their jobs required modifications (Teasell, McRae, & Finestone, 2000). Those able to return to work reported significantly higher levels of subjective life satisfaction (Vestling, Tufvesson, & Iwarsson, 2003). The factors generally found to predict likelihood of returning to work included independence in self-care, ability to walk, younger age, high educational and occupational levels, stable marital status, and preserved language and cognitive capacities (McMahon & Crown, 1998; Vestling, Tufvesson, & Iwarsson, 2003).

Leisure and Recreation

Throughout rehabilitation, **valued leisure activities should be identified, encouraged, and enabled.** Effective therapy incorporates leisure interests into treatment so that the patient recovering from stroke can begin to analyze the effects of impairments on valued activities and anticipate strategies for return to these activities. A study of 40 individuals discharged from rehabilitation programs post stroke found that individuals with a large variety of interests were more likely to resume at least one leisure activity than those with limited leisure interests (Jongbloed & Morgan, 1991). Other factors influencing leisure participation include family and social support, transportation or financial barriers, attitudes toward altered leisure performance, and amount of free time available (Jongbloed & Morgan, 1991). Many pa-

tients following stroke report decreased time and energy for leisure pursuits because of the increased demands of self-care. Many do not accept performance of a valued activity at a lower standard; for example, a patient with hemiparesis may give up golf rather than play at a reduced level of performance. Many patients, particularly those who were working at the time of their stroke, do not have established leisure roles or do not admit to any leisure interests. Methods to promote leisure and recreation after stroke include finding ways to overcome physical barriers in the home or community in order to adapt a valued activity; introduction of new leisure activities suitable for a patient's abilities; and education and advocacy regarding available community resources (Gresham et al., 1995).

Sexuality

Surveys of patients and their spouses show that typical effects of stroke on sexuality include decreased libido, impaired erectile functioning in men, decreased vaginal lubrication in women, and decreased frequency of sexual activity (Korpelaineu, Nieminen, & Myllyla, 1999). Causes may be physiological (decreased motor, sensory, or cognitive functioning; dependency in ADL; decreased endurance; incontinence; co-existing disease; or side effects of medications) or psychosocial (poor self-image, depression, role changes, impaired communication ability, fear of impotence, or fear of recurring stroke) (Farman & Friedman, 2004; Gresham et al., 1995; Korpelaineu, Nieminen, & Myllyla, 1999).

To assist with sexual expression, all therapists can impart the message that patients are permitted to have concerns and seek information about sexual problems after stroke. Therapists should reassure their clients that these problems are common and that sexual activity after stroke is not contraindicated (Farman & Friedman, 2004; Gresham et al., 1995). Other possible interventions include providing or referring to resources to increase the patient's knowledge, encouraging open communication between partners, suggesting adaptations such as changes in positioning or timing, and referring to a qualified specialist (Farman & Friedman, 2004; Gresham et al., 1995).

Driving

Nearly all adults in the United States drive (Warren, 1999), so the ability to resume driving is a high priority for most individuals with brain damage and is seen as a way to continue community independence and avoid isolation (Gresham et al., 1995). Improved survival rates and longevity after stroke increase the need for health professionals to make recommendations regarding a patient's ability to drive (Korner-Bitensky et al., 2000). Due to its

complexity and danger, driving after stroke is usually not addressed until a patient has returned home and gained a satisfactory level of independence with self-care and short-distance mobility. It has been reported that only 30% of those who drove before stroke are able to resume driving, and 87% of those who drove before stroke did not receive any form of driving evaluation (Fisk, Owsley, & Pulley, 1997). Although it is not known with certainty which deficits necessitate the use of adaptive driving aids or render a stroke survivor unfit to drive, perceptual and cognitive deficits are recognized as having a serious effect on driving safety (Korner-Bitensky et al., 2000). Hemiparesis alone does not appear to prevent a return to driving because vehicles or techniques can be adapted to compensate for most motor deficits seen post stroke. There are no standard evaluation procedures for determining the ability of cerebrally injured patients to return to driving, but consistent practices include: (1) a pre-driving evaluation battery to test for visual scanning, visual attention, higher level visual-cognitive skills, distractibility, mental slowness, problem solving, and ability to follow directions; (2) a driving simulator evaluation; and (3) a road test, both on a protected course and in traffic (Gal-ski, Ehle, & Williams, 1997; Korner-Bitensky et al., 1998). Studies have failed to establish the accuracy of various components of pre-driving assessment in predicting on-road driving performance, although road tests appear to have the highest correlation (Akinwuntan et al., 2002).

Few studies have substantiated the effectiveness of rehabilitation to improve driving-related deficits (Klavora et al., 1995). Current practices include in-car driver retraining, driving simulator training, and attempts to remediate underlying impairments. Klavora et al. found significant improvement in behind-the-wheel driving assessments in post-stroke subjects who trained with Dynavision, which is an apparatus "designed to train visual scanning, peripheral visual awareness, visual attention, and visual-motor reaction time across a broad, active visual field" (Klavora et al., 1995, p. 535). Therapists must remember that the decision to allow a person who has had a stroke to resume driving rests with the state licensing bureau (Gresham et al., 1995) (see Chapter 31).

Community Support and Resources

Methods to reintegrate the patient into the community (e.g., transportation options, dealing with architectural barriers, assistance from family or friends, access to senior citizen centers) should be addressed throughout rehabilitation because failure to resume pre-morbid community activities has been significantly correlated with isolation and depression in stroke patients (Logan, Dyas, & Gladman, 2004). Successful reintegration into the community, according to individuals who have had strokes, can take years rather than months (Buscherhof, 1998; Matola,

2001), continuing after a patient has regular contact with rehabilitation specialists. **Acute-care hospitals and rehabilitation facilities should maintain up-to-date inventories of community resources; provide this information to stroke survivors, their families, and their caregivers; and offer assistance in obtaining needed services.** In general, supports for patients and their families include educational, instrumental, and emotional supports (Gresham et al., 1995). Educational resources are available through organizations (Resources 38-1) that offer direct audiotaped, videotaped, printed, and/or online information specific to stroke. Instrumental supports are physical assistance programs such as personal provider services, Meals on Wheels, and volunteer groups who can build wheelchair ramps. Emotional support can come from family, friends, mental health professionals, and other survivors of stroke.

Support for long-term caregivers is especially important because caregivers appear to be at substantial risk for burnout, depression, isolation, and general health problems (Gresham et al., 1995; Han & Haley, 1999). Therapists can encourage and suggest sources for respite care, support groups, or counseling. Many communities, unfortunately, are limited in resources for the patient and family. Therapists can be advocates and consultants for the development of community programs; this can range from referring patients and families to others in the community living with stroke, to organizing a stroke club, to identifying opportunities for volunteer jobs for patients.

Post-Discharge Monitoring

Because of the varying rates of recovery and adjustment after stroke and the trends toward earlier discharges from acute centers and rehabilitation programs, occupational therapists should facilitate provision of services along a smooth continuum. **The stroke survivor's progress should be evaluated within 1 month after return to a community residence and at regular intervals during at least the first year, consistent with the person's condition and the preferences of the stroke survivor and family.** The 12 months after stroke is considered a high-risk time crucial to the redevelopment of satisfactory life roles (Gresham et al., 1995; Sardin, Cifu, & Noll, 1994).

Managed health care programs tend to focus resources on the most acute patients and on those showing the greatest response to therapy. As patients become more chronic and/or fail to progress in therapy (commonly termed recovery plateau), they are frequently terminated from rehabilitation services (Page, Gater, & Bach-y-Rita, 2004). Studies have shown, however, that patients with chronic CVA (greater than 1 year post stroke) can exhibit substantial motor and functional improvement with novel rehabilitation protocols requiring repetitive, task-specific practice (Page, Gater, & Bach-y-Rita, 2004; Page et al., 2004). Rather than indicating a permanent diminished capacity for improvement, plateaus may represent patient adaptations to an unvaried treatment regimen (Page, Gater, & Bach-y-Rita, 2004).

Radomski (1995) recommends greater emphasis on outpatient programming to enhance quality of life and health care effectiveness. Occupational performance and component abilities should be assessed during follow-up visits to determine whether a patient is maintaining the functional level achieved during rehabilitation or is progressing or regressing from this level. A period at home often provides patients the opportunity to experience and acknowledge their strengths and weaknesses and focuses their interest on improving specific skills needed to reintegrate into the home and community. Long-term survivors of stroke report the value of timely interventions over an extended period as they slowly regained confidence in a new self and resumed meaningful life roles (Buscherhof, 1998; Matola, 2001).

EFFECTIVENESS OF TREATMENT

In compiling the *Post-Stroke Rehabilitation Clinical Practice Guideline*, a panel of experts and consultants concluded after an extensive review of the literature that “few well-controlled clinical studies document benefits from rehabilitation” (Gresham et al., 1995, p. 11). Difficulties in determining effectiveness of treatment for the stroke pop-

ulation include differentiating benefits of rehabilitation from spontaneous neurological recovery after stroke (Gresham et al., 1995); the heterogeneous nature of the population of stroke survivors with their diverse causes and impairments; and the ethical and practical problems inherent in assigning patients to control groups.

Recent emphasis on evidence-based practice has resulted in greater efforts to use empirical research findings to guide treatment decisions.

Studies analyzing the effects of stroke rehabilitation in general suggest that patients benefit from early intervention, that favorable ADL and neuromuscular outcomes are associated with higher intensities of rehabilitation, and that improvements in impairments do not automatically lead to improvements in ADL (Kwakkel et al., 1997; Ottenbacher & Jannell, 1993). Although treatment effects for rehabilitation were small, they were significantly practical in that small improvements in independent functioning can make the difference between discharge to home and institutionalization.

Duncan (1997) reviewed clinical trials and summarized evidence for interventions to improve motor control after stroke. The trials compared various therapeutic approaches, such as traditional biomechanical and rehabilitative therapy versus neurodevelopmental or proprioceptive neuromuscular facilitation treatment. Based on this review of research, remediation programs appear to improve motor control in patients with some initial voluntary movement. There were no statistically significant differences among treatment groups receiving various types of sensorimotor treatment as measured for motor or functional outcomes and no evidence that reduction of motor impairment carries over to functional performance.

Steultjens et al. (2003) conducted a systematic review of available literature to determine whether OT interventions improve outcome for stroke patients. Their meta-analysis of 32 studies looked at the effects of six specific OT intervention categories on primary outcome measures of basic ADL (BADL) and IADL and on secondary process measures of arm and hand function, muscle tone, and cognitive functions. The reviewers established small but significant effect sizes favoring OT effectiveness on BADL and IADL. They concluded that evidence establishing efficacy of training of cognitive functions, of advice and instruction regarding assistive devices, and of providing splints is lacking. No study was available to determine effectiveness of family or caregiver training.

Trombly and Ma (2002) reviewed 36 studies for level of evidence to support OT treatment for the restoration of roles, tasks, and activities and for the remediation of psychosocial, cognitive-perceptual, and sensorimotor impairments. Acknowledging the limitations of this small body

of research and the lack of replication, the authors summarize evidence for OT practice for stroke patients as follows (see Evidence Table 38-1 for best evidence):

- To improve performance of BADL and IADL and role participation, provide opportunities for practice of client-chosen activities in a familiar context and provide necessary adaptations and training in the use of the adaptations.
- To improve cognitive abilities and capacities, use homemaking or other occupational tasks and activities rather than paper-and-pencil tasks.
- To improve function in those patients with unilateral neglect, provide training that involves moving into neglected space for goal accomplishment.
- To improve visual-perceptual abilities, use functional (task-specific) training and consistent strategies of compensation.
- To increase participation and endurance, use goal-directed and meaningful activities, such as games.
- To increase voluntary movement and coordination, practice with goal-directed and meaningful objects, preferably using bilateral simultaneous movement, rather than rote exercise.
- To improve motor performance, teach the patient to imagine functional use of the affected limb.
- To promote voluntary movement after discharge, provide a written and illustrated home program of movement exercises and activities.

The authors also concluded that two treatments, splinting to reduce spasticity and exercise to recruit motor units in the prime mover to improve movement were not supported by evidence. The effects of OT on reducing depression after stroke has not been studied enough to warrant recommendation (Trombly & Ma, 2002; Ma & Trombly, 2002).

In conclusion, more research is needed to determine evidence-based OT interventions for stroke patients. Limitations in determining OT effectiveness include the variability of treatment approaches among OT practitioners and settings (Steultjens et al., 2003) and the team approach to patient treatment, which makes it difficult to isolate OT effects from those of other disciplines (Trombly & Ma, 2002). Current studies additionally provide no information regarding the effectiveness of OT programs in reducing the need for and relative costs of health care services for stroke patients (Landi & Bernabei, 2003). Future research must focus on verifying findings of existing studies, determining which treatments are effective for desired outcomes, which patients will most benefit from these services, and what are the appropriate times, settings, and intensities of treatment.

Evidence Table 38-1 Best Evidence for Occupational Therapy Practice Regarding Stroke

Intervention	Description of Intervention Tested	Participants	Dosage	Type of Best Evidence and Level of Evidence	Benefit	Statistical Probability and Effect Size of Outcome	Reference
Task-specific practice of client-chosen BADL or IADL	Practice of specific tasks in a familiar context	323 acute stroke survivors (147 with left cerebrovascular accident [LCVA], 156 with right cerebrovascular accident [RCVA]). Mean age = 72.5 years.	Ranged from 1 to 15 visits over a period of 6 weeks to 5 months.	Meta-analysis of 2 studies.	Yes. The treated groups improved in BADL as measured by <i>Barbel Index</i> , and improved in IADL as measured by <i>Nottingham EADL Scale</i> .	Mean weighted effect size was $r = 0.16$, equivalent to a 16% success rate over control treatment.	Trombly & Ma, 2002
Use of cueing strategies to improve scanning function in unilateral neglect	Practice of scanning tasks with visual or motor cues.	13 acute stroke survivors (0 with LCVA, 13 with RCVA). Mean age = 57.5 years.	21 trials/day for 4 consecutive days.	Randomized controlled study. IC1b	Yes. Bias Index of Line Bisection improved in all cue conditions compared with controls (strongest effect with motor cueing).	Mean effect size was $r = 0.87$.	Lin et al., 1996

continued

Practice of goal-directed tasks to increase voluntary active range of motion	Experimental group: use of exercise apparatus and game to increase forearm supination. Control: use of same apparatus without game.	30 acute stroke survivors (11 with LCVA, 15 with RCVA, 4 with other). Mean age = 68.4 years.	2 sets of 10 trials for each condition; different days.	Randomized controlled study, IC2c	Yes. Mean gain of 13.4° more supination (handle rotation) in experimental group.	$r = 0.42$	Nelson et al., 1996
Use of goal-directed present activity to enhance quality of movement	Practice of reaching with object present or to accomplish functional goal versus reaching without object or without functional goal.	28 chronic stroke survivors (17 with LCVA, 9 with RCVA, 2 with other). Mean age = 63.4 years.	10 trials/condition within 1 day.	Meta-analysis of 2 studies.	Yes. Better organization of reaching movement for functional goal as described by kinematic variables for speed, smoothness, strategy used, and force.	Combined effect size: $r = 0.62$.	Ma & Trombly, 2002
Use of written and illustrated home exercise program to improve coordinated movement	Experimental group: home therapy by individualized written and illustrated program of upper extremity exercises. Control Group: no treatment.	22 acute stroke survivors (13 with LCVA, 9 with RCVA). Mean age = 58 years.	3–4 visits for an average of 9 weeks; patients practiced home program 2–3 times a day.	Comparison of 2 treatment groups without randomization. IIC2b	Yes. Experimental group showed improved performance in Upper Extremity Reaching Subtest of <i>Southern Motor Group's Motor Assessment</i> and in <i>Timed 10-Hole Peg Test</i> .	$r = 0.30$ (for reaching subtest); $r = 0.50$ (for <i>Timed 10-Hole Peg Test</i>).	Turton & Fraser, 1990

SUMMARY REVIEW QUESTIONS

1. Name the two main categories of stroke and the subtypes and causes of each.
2. Name six neurological deficits that can result from stroke and describe how each may interfere with dressing.
3. What is the difference between neurological recovery and functional recovery after stroke? How might occupational therapy facilitate both types of recovery in a patient?
4. Name five settings where occupational therapists work with patients recovering from stroke and describe characteristics of a patient who might be treated in each setting.
5. Define postural adaptation and name three ways impairments in this area affect occupational performance. Describe treatment methods to improve postural control.
6. What mechanical and physiological components of movement should be evaluated in the hemiplegic upper extremity? What methods can be used to prevent development of a painful shoulder?
7. What variables should be considered during evaluation for voluntary movement in the hemiplegic upper extremity?
8. What factors can affect a stroke patient's ability to learn and organize movement? Describe how deficits in each of these areas affect self-care.
9. Select a treatment activity for a patient recovering from stroke and describe how this activity can both increase ADL independence (reduce disability) and improve component abilities and capacities (reduce impairment).
10. Describe methods to assist a post-stroke patient resume self-enhancement and self-advancement roles after discharge from rehabilitation services.

CHAPTER 39

Traumatic Brain Injury

Mary Vining Radomski

LEARNING OBJECTIVES

After studying this chapter, the reader will be able to do the following:

1. Describe the similarities and differences in the typical course of recovery for persons with severe, moderate, and mild traumatic brain injury.
2. Select appropriate assessment tools and strategies for persons with traumatic brain injury during acute medical management and inpatient and post-acute rehabilitation.
3. Apply information from related chapters of this text to the treatment of motor, cognitive, behavioral, and emotional aspects of traumatic brain injury.
4. Analyze how needs of family members change during recovery and adaptation and determine how to meet their needs in occupational therapy.
5. Anticipate possible roles for occupational therapists in addressing long-term needs of survivors of traumatic brain injury.

Glossary

Agitation—Subtype of delirium that is unique to survivors of TBI in altered states of consciousness in which there are excesses in behavior that include some combination of aggression, disinhibition, restlessness, and confusion.

Anterograde amnesia—Inability or impaired ability to remember events beginning with the onset of a condition (Lezak, 1995).

Diffuse axonal injury—Axonal damage (torn axons, shearing of axon clusters, and reactive swelling of strained and damaged axons) resulting from acceleration or deceleration and contracting waveform movements of the brain matter and accompanying fast rotational propulsion of the brain in the skull (Lezak, 1995).

Hematoma—Masses of blood confined to an organ or space that is caused by a broken blood vessel (Scott & Dow, 1995).

Mild brain injury—Trauma-induced physiological disruption

of brain function as manifested by at least one of the following: any period of loss of consciousness, any loss of memory for events immediately before or after the accident, any alteration in mental state at the time of the accident, focal neurological deficit that may or may not be transient (American Congress of Rehabilitation Medicine, 1995a).

Post-traumatic amnesia—Inability to remember day to day events after brain injury. The time elapsed from injury to recovery of continuous memory is one indicator of severity of brain damage.

Traumatic brain injury (TBI)—Insult to the brain, not degenerative or congenital, that is caused by an external physical force. This insult may produce a diminished or altered state of consciousness and resultant impairment of cognitive, behavioral, emotional, or physical functioning (Brain Injury Association, 2000).

People who have had a **traumatic brain injury (TBI)** often undergo changes in their ability to carry out valued roles, tasks, and activities. In fact, moderate to severe brain injury affects virtually every area of life for the survivor and his or her family (Pagulayan et al., 2006). These individuals are often young adults at the time of injury, thus, changes in capacities and abilities may affect their occupational functioning for months, years, or decades. The complex interaction of factors associated with impairment and context require a multidisciplinary approach to treatment. Therefore, occupational therapists who work with patients with TBI must appreciate the contributions and expertise of other team members as they offer the patient all that is unique to occupational therapy.

To enable the reader to appreciate the effect of TBI on society, this chapter begins with a discussion of its incidence and causes. Next, mechanisms of injury are explained. A review of the typical clinical course of recovery from severe TBI emphasizes how occupational therapy contributes to remediation of impairments and adaptation to deficits throughout the continuum of care. The unique needs of persons with **mild brain injury** are also highlighted, but it is hoped that readers can determine appropriate evaluation and treatment approaches for persons with moderate TBI based on descriptions of the two extremes of severity of injury. Since brain injury rehabilitation requires an integration of many aspects of occupational therapy evaluation and treatment, the reader will frequently be referred to other chapters of this text.

INCIDENCE, PREVALENCE, AND CAUSATION

The Brain Injury Association (BIA) (2000) defines traumatic brain injury (TBI) as an insult to the brain, not degenerative or congenital, that is caused by an external physical force. This insult may produce a diminished or altered state of consciousness and hence impairment of cognitive, behavioral, emotional, or physical functioning. Rates of TBI-related hospitalization have declined by approximately 50% since 1980 because of successes in prevention and a shift in treatment of relatively mild cases from inpatient to outpatient settings (Thurman et al., 1999). The BIA, however, estimates that 5.3 million Americans are living with disabilities resulting from TBI. Each year, approximately 1.4 million people in the United States sustain a TBI, and an estimated 80,000–90,000 each year have onset of disabilities resulting from TBI (Langlois, Rutland-Brown, & Thomas, 2004). Beyond the sheer numbers of persons with TBI, demographic characteristics of this population have many implications for society and rehabilitation. After children ages 0–4 years, adolescents and young adults have the highest incidence of TBI in the United States (1995–2001 data), followed by people over age 75 years (Langlois, Rutland-Brown, & Thomas, 2004). Adults aged 75 years and older have the highest rate of TBI-related hospitalization and death (Langlois, Rutland-Brown, & Thomas, 2004). Regardless of age, men have more TBIs than women (Langlois, Rutland-Brown, &

Thomas, 2004). Age of onset appears to be related to cause of TBI (Elovic & Antoinette, 1996).

Falls are the leading cause of TBI, but motor vehicle accidents result in the greatest numbers of TBI-related hospitalizations (Langlois, Rutland-Brown, & Thomas, 2004). Motor vehicle accidents that result in TBI cause the highest rates of hospitalization and death and are the leading cause of TBI for persons aged 15–19 years (Langlois, Rutland-Brown, & Thomas, 2004). Falls result in the greatest number of TBI-related ED visits and are the leading cause of TBI among the elderly (Langlois, Rutland-Brown, & Thomas, 2004). Interpersonal violence ranks third, although in some urban areas, the percentage of TBIs caused by violence may exceed that caused by falls or motor vehicle accidents (Elovic & Antoinette, 1996; Harrison-Felix et al., 1996). Alcohol use is a contributing factor to accidents resulting in TBI, with estimates that approximately 50% of people who sustain TBI were intoxicated at the time of injury (Agency for Health Care Policy and Research, 1999). Pre-injury alcohol use has implications for outcome, treatment, and long-term adjustment to TBI. Patients who were intoxicated when injured reportedly have a longer hospitalization, longer duration of **agitation**, and lower cognitive status at discharge than those who were not intoxicated (Kelly et al., 1997; Sparadeo & Gill, 1989). Furthermore, a history of TBI increases a person's risk of TBI. The BIA estimates that after one TBI, the risk of a second is three times normal, and after a second TBI, the risk of a third injury is eight times normal.

Finally, it is important to appreciate the incidence of TBI based on severity. TBI is characterized as mild, moderate, or severe (Definition 39-1). Most people who sustain a

TBI have a relatively mild injury (at least 75% of all TBIs in the United States [National Center for Injury Prevention and Control, 2003]), although trauma centers appear to have a much higher proportion of patients with severe injuries (Harrison-Felix et al., 1996).

MECHANISMS OF INJURY AND CLINICAL IMPLICATIONS

A TBI is usually caused by a dynamic loading or impact to the head from direct blows or from sudden movements produced by blows to other body parts. This loading can result in any combination of compression, expansion, acceleration, deceleration, and rotation of the brain inside the skull (Bakay & Glasauer, 1980). The type of damage is directly related to the nature and severity of the injury (Katz, 1992).

Diffuse Versus Focal Injuries

Brain injuries may be diffuse, focal, or both. Motor vehicle accidents and falls produce acceleration, deceleration, and rotation of the brain inside the skull. The brainstem is more stable than the cerebrum, which rotates around the brainstem during impact. The rotation places a stretch or shear force on the long axons that transmit information throughout the brain and brainstem (Leech & Shuman, 1982). These injuries, termed **diffuse axonal injuries**, are likely to result in coma because of the damage to the axons in the midbrain reticular activating system (Duff, 2001).

Coma caused by diffuse axonal injuries may quickly reverse if the axonal damage was mild or may continue as a vegetative state if axons were ruptured. Recovery from coma progresses to a period of confusion with impaired attention and **anterograde amnesia**. When confusion clears, any cognitive impairments become more evident. Impairments may include diminished mental processing speed and efficiency and difficulty with divided-attention tasks, which require the patient to respond simultaneously to two sources of information. There is a reduced capacity for higher level cognitive functions, including abstract reasoning, planning, and problem solving. Typical behavioral outcomes range from impulsivity, irritability, and exaggerated pre-morbid traits to apathy and poor initiative (Katz, 1992). Diffuse injuries often include damage to the brainstem and cerebellar pathways, resulting in ataxia, diplopia, and dysarthria (Trexler & Zappala, 1988).

Focal lesions include contusions, lacerations of the brain, and intracranial hematomas (Duff, 2001). Although focal lesions can occur anywhere beneath the impact, they

DEFINITION 39-1

Defining Severity of TBI

Severe—Loss of consciousness longer than 6 hours; initial *Glasgow Coma Scale* score of 8 or less (O'Dell & Riggs, 1996).

Moderate—Initial *Glasgow Coma Scale* score of 9 to 12 (Hall & Johnston, 1994); **post-traumatic amnesia** of 1 to 24 hours (Bond, 1990).

Mild—Trauma-induced physiological disruption of brain function as manifested by at least one of the following: any period of loss of consciousness, any loss of memory for events immediately before or after the accident, any alteration in mental state at the time of the accident, focal neurological deficit that may or may not be transient (American Congress of Rehabilitation Medicine, 1995a), and initial *Glasgow Coma Scale* score of 13 to 15 (Hall & Johnston, 1994).

are usually seen at the anterior poles and inferior surfaces of the frontal and temporal lobes. They occur when the brain hits the skull and scrapes over the irregular bony structures at these locations (Katz, 1992). The occipital and parietal lobes, which have smooth surfaces, are less likely to incur damage. The folds of the dural membranes, especially the falx cerebri and the tentorium, can also cause damage to the brainstem, the medial aspect of the occipital lobe, and the superior surface of the cerebellum (Bakay & Glasauer, 1980).

Focal lesions to the prefrontal and anterior temporal areas interrupt connections to subcortical limbic structures and affect modulation of memory, emotion, and drive (Katz, 1992). Damage to the orbitofrontal areas results in impulsivity that is greater than with diffuse damage, but there are no motor impairments of the extremities or of speech (Trexler & Zappala, 1988). Damage to the frontolateral cortex results in hemiparesis, impulsivity, and attentional impairments. There is decreased accuracy and decreased mental flexibility, which affects the quality of performance (Trexler & Zappala, 1988).

Cranial Nerve Damage Associated with TBI

Cranial nerves can be torn, stretched, or contused. The olfactory nerve (I) is often abraded or torn when the frontal lobes scrape across the orbital surface of the skull (Leech & Shuman, 1982). The optic nerve (II) may be damaged directly, or vision can be compromised by injury to the eye, the optic tracts, or the visual cortex (Brandstater et al., 1991). Cranial nerves III, IV, and VI, which control eye movements, are all vulnerable to injury (Brandstater et al., 1991; Leech & Shuman, 1982). The oculomotor nerve (III) is stretched when edema, bleeding, or a tumor expands the contents of the skull, causing the uncus of the temporal lobe to herniate into the foramen magnum and compress the brainstem (Leech & Shuman, 1982). The abducens nerve (VI) is very long and consequently vulnerable to injury. The facial and vestibulocochlear nerves (VII and VIII, respectively) may be damaged if the temporal bone is fractured at the base of the skull (Brandstater et al., 1991; Leech & Shuman, 1982). Cranial nerves V and IX to XII are rarely damaged (Leech & Shuman, 1982).

Fractures Associated with TBI

The skull may fracture from the force of the blow in the area of or at a distance from the actual impact site. The patient with a brain injury from a motor vehicle accident or a fall may have other systemic trauma, such as fractures of the extremities, shoulder girdle, pelvis, or face; cervical fractures with possible spinal cord injury; abdominal trauma; and pneumothorax or other chest cavity trauma.

Secondary Effects of TBI

Secondary effects of the TBI can occur immediately or develop within hours or days (Jennett & Teasdale, 1981). Trauma can abolish or disrupt autoregulation of cerebral blood flow, the blood–brain barrier, and vasomotor functions, resulting in disordered cerebral energy metabolism, intracranial hypotension, cerebral vasospasm, and increases in intracranial pressure (ICP) and cerebral edema (Duff, 2001; Jennett & Teasdale, 1981). Other secondary effects of brain trauma include intracranial hemorrhage, ischemic brain damage, uncal herniation resulting in brainstem compression, general systemic reactions to the neural impairment, electrolyte abnormalities, altered respiratory regulation, intracranial infection, and abnormal autonomic nervous system responses (Lillehei & Hoff, 1985). Usually by the time the patient is stabilized and occupational therapy is ordered, the secondary effects of brain trauma are present, influencing the patient’s ability to respond to therapy.

FOUR PHASES OF LIFE FOR THE SURVIVOR OF TBI

Based on their review of the literature, authors of the Agency for Health Care Policy and Research evidence report on the effectiveness of rehabilitation for persons with TBI described four phases of life for the adult survivor of moderate to severe TBI: pre-injury, medical treatment, rehabilitation, and survivorship (Fig. 39-1) (Chestnut et al., 1999). While management of TBI is typically a multidisciplinary enterprise, the following description of each phase is based on a typical recovery from severe TBI with emphasis on occupational therapy evaluation and treatment. Note how the role of occupational therapy changes with each phase, increasingly and uniquely focusing on occupational functioning the further the patient progresses in recovery.

Pre-Injury Phase

“In Chris’s first 17 years she became used to being called ‘outstanding.’ She usually was one of the top students in every honors class. . . . Chris is a fairly good organist and gymnast too. In her first 17 years, outstanding was normal. Outstanding was easy.” (Rain, 2000, p. 6)

Occupational therapists always appreciate the person as distinct from his or her condition, impairment, or disability. People who sustain a TBI bring their personal, social, and cultural backgrounds to recovery (see Chapter

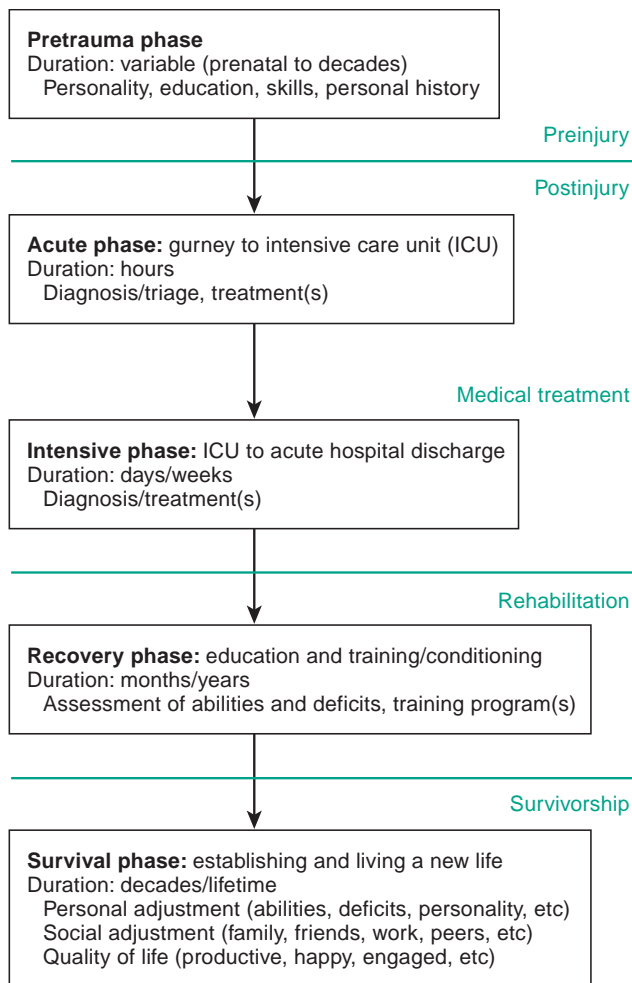

Figure 39-1 Four phases of life of the TBI survivor. (Reprinted with permission from Chestnut, R. M., Carney, N., Maynard, H., Mann, N. C., Patterson, P., & Helfand, M. [1999]. Summary report: Evidence for the effectiveness of rehabilitation for persons with traumatic brain injury. *Journal of Head Trauma Rehabilitation*, 14, 176–188.)

10). Chestnut et al. (1999) suggested that, while standard treatments are appropriate for the acute medical treatment phase of TBI, consideration of individual differences becomes increasingly important as patients progress through recovery and adaptation.

Rosenthal and Bond (1990) summarized the importance of understanding pre-morbid factors that may affect the patient's recovery. They reported that researchers have noted a high frequency of pre-injury learning disabilities and behavior disorders in persons with TBI. They suggested finding out about the patient's pre-morbid cognitive strengths and weaknesses through school records or family interviews and investigating any pre-existing neurological conditions, such as previous TBI, epilepsy, dementia, or stroke. Eames, Haffey, and Cope (1990) further recommended asking family members how the patient

previously reacted to frustration so as to recognize and avoid stress-provoking situations.

Medical Treatment of TBI

“As I gradually regain consciousness in the hospital, I imagine I am having a nightmare. . . . As I open my eyes and stare around the room at the monitors and plugs and dripping IV bottles, I hope this nightmare will end quickly.” (Rain, 2000, p. 6)

The primary goals of this phase of recovery center on survival, achieving medical stability, and preventing or minimizing the secondary effects of TBI.

Emergency Medical Treatment

Paramedics are typically the first medical specialists to respond to the needs of a person with severe TBI. Once they have ensured an adequate airway and stabilized blood pressure, they usually immobilize the patient on a rigid backboard with the neck in a rigid cervical spine collar (Marion, 1996). As most secondary brain injury occurs during the first few hours of TBI, vital signs are checked frequently en route to the trauma center, and any deterioration is addressed immediately (Marion, 1996).

Once in the emergency department, the medical team continues to ensure protection of the airway and adequacy of breathing and blood pressure (Marion, 1996). The medical team performs a general assessment of injuries and neurological status, often using the *Glasgow Coma Scale (GCS)* (Teasdale & Jennett, 1974). The GCS provides an objective assessment of moderate to severe TBI using a 15-point system to test motor, eye-opening, and verbal capabilities (Table 39-1) (Teasdale & Jennett, 1974), although in some cases, alcohol or other drug intoxication or sedation prevents an accurate neurological assessment in the emergency department (Marion, 1996).

Computed tomography (CT) of the head is usually obtained within 30 minutes after the patient arrives in the emergency department; it is the most reliable test for determining the presence of intracranial hematomas (Marion, 1996). **Hematoma**, a mass of blood confined to an organ or space and caused by a broken blood vessel (Scott & Dow, 1995) must be evacuated as soon as possible to optimize chances for survival and recovery (Marion, 1996).

Intensive Medical Management

After appropriate evaluation and treatment for life-threatening injuries, the patient is taken to the intensive care unit (ICU). Medical treatment aims to optimize cerebral perfusion and brain tissue oxygenation, minimize brain swelling, and maintain all other physiological variables within the normal range (Marion, 1996). The length of stay in the ICU

Table 39-1. Glasgow Coma Scale

Eye opening (<i>E</i>)	Spontaneous	4
	To speech	3
	To pain	2
	Nil	1
Best motor response (<i>M</i>)	Obeys	6
	Localizes	5
	Withdraws	4
	Abnormal flexion	3
	Extensor response	2
	Nil	1
Verbal response (<i>V</i>)	Oriented	5
	Confused conversation	4
	Inappropriate words	3
	Incomprehensible sounds	2
	Nil	1

Coma score = (*E* + *M* + *V*) = 3 to 15.

is primarily determined by the ability to manage the patient's brain swelling, which usually subsides within 4–5 days (Marion, 1996). A physiatrist is typically consulted on the day the patient is admitted to the ICU, and he or she follows the patient throughout the hospital stay and often through reentry to the community. The physiatrist orders rehabilitation services for the coma patient that may begin in the ICU, including occupational therapy. Rehabilitation for patients with alterations in consciousness, as described in this overview, may also occur in medical, rehabilitation, or subacute units or in long-term care facilities.

Patients with Severe Alterations in Consciousness

A person with TBI may exhibit any of a number of altered states of consciousness, depending on the severity of the injury (Talbot & Whitaker, 1994). Various terms are used to describe the continuum from complete consciousness to complete absence of consciousness (Definition 39-2). Patients with severe TBI begin in coma, which is a time-limited state (Duff, 2001). Some patients gradually or abruptly recover consciousness directly from coma, while others shift over 2–4 weeks into the vegetative state (Duff, 2001). Vegetative patients may still recover consciousness, but they do so gradually, spending long periods in a minimally conscious state in which there is verifiable evidence of conscious processing (Phipps et al., 1997). Giacino and Kalmar (1997) suggested that the distinction between vegetative state and minimally conscious state is important in terms of diagnosis and prognosis. Patients diagnosed with minimally conscious state at admission to rehabilitation attained significantly more favorable outcomes 1–12 months after injury than did those in the vegetative state. The ability to sustain visual pursuit eye movement seems to be one of the first signs

DEFINITION 39-2

Definitions of Severe Alterations of Consciousness (American Congress of Rehabilitation Medicine, 1995b)

Coma

Coma denotes unarousability with absence of sleep-wake cycles on electroencephalogram (EEG) and loss of capacity for environmental interaction. Neurobehavioral criteria for this diagnosis include:

1. Patient's eyes do not open either spontaneously or to external stimulation.
2. Patient does not follow commands.
3. Patient does not mouth or speak recognizable words.
4. The patient does not demonstrate intentional movement (may show reflexive movement such as posturing, withdrawal from pain, or involuntary smiling).
5. Patient cannot sustain visual pursuits through a 45° arc in any direction when the eyes are held open manually.
6. These criteria cannot be attributed to use of paralytic agents.

Vegetative State

Vegetative state indicates complete loss of ability to interact with the environment despite the capacity for spontaneous or stimulus-induced arousal. This state always follows an initial period of coma after TBI and is further characterized by behavioral responses that consist of reflexive reactions only. Sleep-wake cycles may be present on EEG. Neurobehavioral criteria for this diagnosis include:

- Patient opens his or her eyes spontaneously or after stimulation.
- Criteria 2 to 6 under coma are met.

Minimally Responsive State

Minimally responsive state describes patients who are no longer comatose or vegetative but who are severely disabled. Patients in this state have the capacity for environmental interaction evidenced through observation or testing. Meaningful responses are inconsistent and depend on external stimulation. Patients in this category are sometimes referred to as slow to recover (Ansell, 1993). The neurobehavioral criterion for this diagnosis includes:

- Patient demonstrates a meaningful behavioral response after a specific command, question, or environmental prompt.

of the transition out of vegetative state (Giacino & Kalmar, 1997) and is an early indicator of possible readiness for rehabilitation (Ansell, 1993).

Assessment

Diagnosis of specific alterations in consciousness and prognostic decisions must be reserved for physicians and other

professionals with experience in neurological assessment of patients with impaired consciousness (American Congress of Rehabilitation Medicine, 1995b). The rehabilitation team, however, including occupational therapists, uses a number of objective assessments to monitor changes in function and response to pharmacological, environmental, and behavioral interventions and for early detection of neuromedical complications (O'Dell & Riggs, 1996).

RANCHO LOS AMIGOS LEVELS OF COGNITIVE FUNCTIONING SCALE

The *Rancho Los Amigos Levels of Cognitive Function Scale* uses behavioral observations to categorize a patient's level of cognitive function (Table 39-2) (Hagen, Malkmus, & Durham, 1979; Hagen, 1998). It helps clinicians to communicate about a patient's level of cognitive function among themselves and with families and to develop appropriate rehabilitation strategies. The first three levels of the *Rancho Los Amigos Levels of Cognitive Functioning Scale* describe the response to stimulation and the environment of patients emerging from coma.

BEHAVIOR-BASED ASSESSMENT INSTRUMENTS

In addition to the GCS, the instruments described in Table 39-3 are all brief assessments that occupational therapists and other rehabilitation team members can use at bedside to evaluate patients with severe alterations in consciousness.

USE OF SINGLE-SUBJECT EXPERIMENTAL METHODOLOGY

As many scales do not adequately operationalize or define stimuli and target behaviors, DiPasquale and

Whyte (1996) proposed that clinicians use single-subject experimental methodology as a means of answering individualized questions about responsiveness. They described how these methods were used to determine whether or not a patient with a brain injury was able to follow a verbal command to squeeze her hand. The protocol began with the therapist performing passive range of motion to the patient's right hand, placing the patient's hand in hers, and then waiting 1 minute. There were three conditions: correct command ("Squeeze my hand"); incorrect command ("Tie your shoes"); and observation period (equal duration but no command given). Six trials were performed in random order in which the command was given and then the therapist waited for 5 seconds to observe the patient's response. If the patient did not respond in 5 seconds, the command was given again. If again, there was no response in 5 seconds, the trial was recorded as no response. The results of assessment using this approach cast doubts on family reports of volitional hand squeezing and helped inform team/family planning. They describe a similar methodology to assess vision in minimally responsive patients (Whyte & DiPasquale, 1995) (see Chapter 8).

Prognosis and Outcome

Early prediction of outcome presumably helps direct expensive medical treatment or rehabilitation to patients who have the best chance for survival with fewer residual impairments and enables the family to make informed, realistic decisions on immediate and long-term care (Davis &

Table 39-2. Rancho Los Amigos Levels of Cognitive Functioning

Level	Description
I	No response: unresponsive to stimuli
II	Generalized response: non-specific, inconsistent, and non-purposeful reaction to stimuli
III	Localized response: response directly related to type of stimulus but still inconsistent or delayed
IV	Confused, agitated: response heightened, severely confused, may be aggressive
V	Confused-inappropriate: some response to simple commands, but confusion with more complex commands; high level of distractibility
VI	Confused-appropriate: response more goal directed but cues necessary
VII	Automatic-appropriate: response robotlike, judgment and problem solving lacking
VIII	Purposeful-appropriate (<i>with standby assistance</i>): response adequate to familiar tasks, subtle impairments require standby assistance with acknowledging other people's needs and perspectives, modifying plans
IX	<i>Purposeful-appropriate (with standby assistance on request): responds effectively to familiar situations but generally needs cues to anticipate problems and adjust performance; low frustration tolerance possible</i>
X	<i>Purposeful and appropriate (modified independent): responds adequately to multiple tasks but may need more time or periodic breaks; independently employs cognitive compensatory strategies and adjusts tasks as needed</i>

Rancho levels I to VIII are widely used in brain injury rehabilitation. The addition of levels IX and X in 1998 (revisions italicized) describe higher level cognitive, behavioral, and emotional barriers to optimal functioning (Hagen, Malkmus, & Durham, 1979; Hagen, 1998).

Table 39-3. Behavior-Based Assessment Tools for Altered States of Consciousness

<i>Coma/Near Coma Scale</i> ^a (Rappaport et al., 1992)	Measures small clinical changes in patients with severe TBI and non-traumatic brain injuries who function at levels characteristic of near-vegetative or vegetative states; consists of 8 parameters, each with a specified number of stimuli and trials. Based on the numerical scoring system, patient falls into 1 of 5 categories: no coma, near coma, moderate coma, marked coma, extreme coma.
